components can be far more tolerant of excessive dissipation than in actual circuits. One must, therefore, account for the dissipation of one's components before assuming that a design that performs flawlessly in simulation is complete. Having manually determined that a temperature increase will occur, no difficulty exists in causing SPICE to simulate at the higher temperature. Some applications include a menu entry for temperature, whereas others require syntax such as "temp 100." Although some manufacturers supply models with temperatures in Kelvin degrees, many SPICE applications require Celsius degrees and produce anomalous results when given Kelvin degrees. Likewise, many active device models do not include voltage breakdown. A 60 V transistor with 200 V on its collector may simulate flawlessly. High SWR that may destroy real transistors may not be noticed in SPICE unless voltages and currents are examined.

Habituation to real-world circuits usually does not encourage observation of currents. However, in SPICE, observation of voltages and currents is equally practical. It is helpful to cultivate the habit of observing currents in RF circuits. For example, in RF circuits it is not uncommon for ground planes to resonate with bypass capacitors. The tell-tale sign in real circuits is that a capacitor with good ESR exhibits far more voltage drop than its capacitive reactance and the available power-supply voltage would seem to permit. Q of the resonant tank formed by plane and bypass is the culprit. With strays correctly modeled, the resonance will also occur in SPICE, but the current in the bypass will be directly observable.

As well as simulating common components, SPICE also facilitates simulation of functions incorporating LaPlace transforms. Some applications offer explicit LaPlace blocks, ideal components with infinite input impedances and infinitesimal output impedances, into which can be inserted numerical expressions of the form "6347/(s+355)." In other applications, the LaPlace functions are less obvious. In some, dependent voltage and current sources may be endowed with values including the LaPlacian, using such syntax as "LaPlace = 5473/(s + 23495)." In addition to their use as ideal components, LaPlacian sources, when embedded in circuitry yielding the appropriate nonidealities, often provide effective replacement models when component models are not available.

3. ACCOMMODATING SPICE AND MODEL ANOMALIES

Like any tool, SPICE is not perfect. One annoying problem is that sometimes a circuit portion that has been totally disabled will generate simulation artifacts. If one sees in simulation what appears to be low-level interference or crosstalk from a source that has been reduced to zero volts, it is good not to be surprised. This problem looks just like RF leakage, but it is not. Saving a version of the circuit and eliminating the offending source therein usually causes the problem to disappear, thus proving the problem to be an artifact.

Another perplexing problem can develop because of the default resolutions of SPICE applications. For instance, the leakage currents of some MOSFETS are in the femtoamps. If one's application defaults to 1 nanoamp resolution, it is understandable that measurements on the picoamp and femtoamp regions will appear to wander aimlessly as SPICE dithers between minimal levels at maximum resolution. If one needs to work in extreme areas, it is wise to examine the defaults of the SPICE application.

Most problems encountered using SPICE do not originate in the SPICE application; models and subcircuits are the most abundant source of errors. At this time, most engineers obtain their models over the Internet. For SPICE models, macromodels, and subcircuits, as for other information, the Internet offers an abundant wellspring of undifferentiated truth and error. The Internet abounds with SPICE models, some totally erroneous. The best are usually offered by device manufacturers, but even some of these are rife with errors.

Although some engineers feel that SPICE models are sacred and should be preserved inviolate, such a stance denies one the ability to correct obvious errors. It is not uncommon, even with manufacturer-supplied models, to encounter errors. As many component characteristics are also supplied in datasheets, it is wise to compare datasheet values with SPICE models. If something seems wrong with a transistor's parameters, examination of the datasheet may resolve the problem. For example, a BJT model that exhibited an unusually high Vbe (base-emitter voltage) had given for its parameter "N = 2.4." The Vbe was noticeably higher than indicated by the datasheet. Similar transistors of the same family by the same manufacturer had "N = 1.4." The 2.4 was a typographical error. Some manufacturers' datasheets have decimal point errors that misrepresent parameters by two orders of magnitude. Usually, such a gross error is made manifest by the data explicitly or implicitly provided on the datasheet.

For this reason and others, it is wise not to "fly blind" with SPICE. The definitions of SPICE itself and the parameters of its models are freely available on the Internet. The descriptions given are succinct. The SPICE user will be amply rewarded by the insight gained from the minimal investment required to understand SPICE and its parameters.

Another kind of understanding is helpful for getting the most from SPICE. One should try to understand the physics of the situation. For example, a manufacturer's subcircuit for a 45 GHz SiGe transistor seems to behave in a manner that violates Kirchoff's law when a reversal of emitter current exists. When the emitter current of the transistor is plotted, it is reported in the forward direction, but not in the reverse direction. Current in a resistor uniquely in series with the emitter is plotted as bidirectional. The subcircuit comprises a transistor and some diode models embedded in parasitics representing the device package. In numbering the nodes to which the subcircuit elements are connected, an error was made. Diode model terminals, obviously part of the chip, were mistakenly numbered by the device manufacturer

to be connected to external package connections. It is obvious that a few bits of metal embedded in epoxy cannot function as a diode. Examination of the subcircuit file reveals this obvious error, and simple renumbering of the diode terminals moves it electrically to the inside of the package strays and onto the chip, where it belongs.

The correction of model and subcircuit errors requires editing of same. There are other uses for editing. For example, one may copy and edit a BJT model into several related BJTs, one set perhaps representing the minimum and maximum betas of the parent device. One may similarly scale model resistances and currents to obtain sets of related devices with different current densities. Such scaling is very applicable to the mismatches encountered in differential pairs of transistors of a given type.

Models of transistors with transition frequencies approaching 1 GHz and above are often given with the model of the transistor itself in a convenient, ready-to-use form, and the package parasitics given in a separate not so easy-to-use table, tempting one to use only what is convenient. It is wise to resist that temptation. If a schematic is drawn including the BJT model alone, biased with a current, having its base and collectors connected together, the simulation usually yields a well-behaved diode drop of voltage at the collector and base. If, however, the subcircuit representing the packaged transistor is similarly treated, a violent oscillation, perhaps of 10 to 20 GHz, will likely result. A 100 Ohm resistor in series with the base will likely restore peace. Such transistors and their packages are often designed to operate properly with certain impedances on their terminals. Omission of the package from the simulation can produce erroneous expectations. If you must enter into your library numerous instances of similar transistors made by the same manufacturer and packaged in the same package, it may prove efficient to copy and rename the subcircuit of the first and replace the semiconductor models therein with the easy-to-use models pertaining to the latter subcircuit. Some datasheets are so inconvenient as to require one to construct a subcircuit from the data given. If this is needed, one may simply draw a small schematic diagram of the package with the semiconductor contained therein. The parts and nodes must then be named and numbered. The syntax for the subcircuit may be copied from a known, working, similar device, edited to substitute the names and numbers of the small schematic and the models contained therein.

SPIRAL ANTENNAS

THOMAS P. CENCICH
DEJAN S. FILIPOVIC
University of Colorado at
Boulder
Boulder, Colorado

1. INTRODUCTION

Found in many natural phenomena (galaxies, DNA, tornado, spiderweb, ramhorns, seashells, the face of a sunflower, human fingerprints, etc.), the spiral form has intrigued mathematicians and physicists from ancient times to the modern era. Radar developments after World War II, particularly the need for broadband (from L to Ku bands) circularly polarized antennas for electronic warfare, influenced antenna engineers to look into radiating structures of the spiral shape. Although the obvious needs existed at the time, the first spiral antenna was realized by a curiosity of Edwin Turner [1]. In 1954 he wound a long wire dipole into a spiral form and connected its terminals to a two-wire feedline. The largest antenna bandwidths at that time were on the order of one octave, but the results obtained with the first spiral experiment were so encouraging that an immediate research effort was launched. Half a century down the road with hundreds of papers and patents published and awarded, and thousands of antennas already in the use, the spiral shape is still being heavily investigated by many researchers throughout the world.

Spiral antennas are inherently circularly polarized radiators with relatively constant input impedance and

radiation patterns maintained over wide frequency ranges. Bandwidth is determined by the fine precision of the feeding region (high frequencies) and overall spiral aperture size (low frequencies). Often the balun feed limits antenna performance, although very wideband feeds have been devised. Spirals can be designed in various planar or conical shapes, and the most common configurations include the equiangular [2–4] and Archimedian spirals [5]. The finite features of equiangular aperture prohibit its frequency-independent [6] operation for wavelengths greater than the antenna aperture circumference and lower than the diameter of its feeding region. Spirals operate in a so-called three-way (3W): as a fast wave, leaky wave, and traveling-wave antenna. Basically, the *traveling-wave* form of the excited currents on the spiral arms allows for its broadband performance. This wave is *fast* because of the mutual coupling between neighboring arms, and *leaks* energy while propagating on the line to produce radiation.

Spirals can be designed with different numbers of arms, but typically two or four arms are used. The number of arms and their excitation phase/amplitude difference determines both near- and the far-field antenna performance, which is frequently described using spiral modes. Until relatively recently it was considered that the number of broadband spiral modes that can be excited using an N -arm spiral is $N-1$ [7, pp. 108–109]. However, a broadband dual-mode operation of a two-arm slot spiral was demonstrated for the first time by the authors [8]. Two-arm spirals are most frequently used to operate in the first (mode 1, sum or Σ) mode, which is obtained when the arms are excited 180° out of phase. Leaking (radiation) occurs throughout the propagation path of the current traveling wave, with the most efficient radiation from the ring one wavelength in circumference. When operating in this mode the spiral directs its radiation toward broadside.

Spiral antennas can be classified (with respect to the type of transmission line supporting the excited traveling wave) in two major groups: (1) printed or wire spirals and (2) slot spirals. Although the first published records of spiral research were on slot spirals [1,3,4], the majority of publications and patenting have occurred for printed geometries [5,7,9]. The main reason is that the multiarm designs are much easier with printed spirals. Additionally, once the multioctave broadband matching techniques were developed, vertical feeds were realized and many aperture designs became feasible. Other spiral designs have also been introduced, including the spiral-mode microstrip (SMM) antennas, realized from microstrip lines wound into a spiral shape [10].

In this article, various aspects of spiral antenna engineering are discussed. Basic theory of spiral operation, characteristic geometries and shapes, and multiarm and multimode configurations, as well as theoretical and practical aspects needed for successful design and understanding of spiral antennas, are reviewed. Special attention is given to understanding the modal performance of multiarm spiral antennas and its importance to overall antenna characteristics, analysis theory, mode-forming networks, and related topics. Dual-polarized spiral designs, including inside/out-fed spirals and modulated armwidth (MAW) spirals, are also described.

2. HISTORICAL HIGHLIGHTS

The following is a brief timeline of developments in spiral antenna technology:

Year	Development	Researcher [Ref.]
1954	Two-arm spiral antenna	Turner [1]
1955	Two-arm complementary equiangular spiral	Rumsey [2]
1959	Two-arm slot spiral	Dyson [3,4]
1959	Infinite balun	Dyson [3,4]
1959	Two-arm conical spiral	Dyson [3,4]
1959	Impedances of complementary structures	Deschamps [17]
1960	Mode 2 spiral	Donnellan [13]
1960	Four-arm dual-mode spiral	Shelton [34]
1961	Explanation of spiral radiation regions	Wheeler [35]
1967	Sum-difference feed network (patent)	Shelton and Chadwick [36]
1966	Spiral mode impedances	Bruce [37]
1971	Multiple-polarization spiral (patent)	Kuo and Liu [38]
1977	Helix-loaded spiral (patent)	Grieser [39]
1979	Broadband center-fed antenna (patent)	Lamberty and Andrews [40]
1986	Modulated armwidth spiral (patent)	Ingerson [14]
1983	Spiral mode-matching transformer (patent)	Ohara et al. [41]
1986	Direction-finding antenna interface (patent)	Corzine and Mosko [7]

3. BASIC THEORY OF OPERATION

The radiating ring theory, also known as a *band theory* [5], is used to describe the theoretical principles behind operation of spiral antennas. The band theory will be demonstrated on the simplest and most commonly used spiral antenna: a two-arm, planar, wire spiral operating in the first mode (mode 1, sum or Σ). As depicted in Fig. 1, the spiral is fed from its center at ports A and A' , with ideally equal amplitudes and a 180° phase difference. When fed with an ideal balanced line, and assuming discontinuity-free aperture, the spiral will support propagation of the forward traveling wave. Mode 1 radiation will predominantly occur from a ring with approximately one guided wavelength (λ) circumference. When excited to operate in this mode, spiral currents at points B and B' , which belong to neighboring arms, will be directed the same way; specifically, they will have the same phase value. The same is the case with diametrically opposite points C and C' (see Fig. 1). The nonradiated traveling-wave currents will flow past this region, and if size of the spiral permits, radiate in the next properly phased section. This will occur at the three-guided-wavelength circumference (mode 3 for a two-arm spiral), or they will reach the end of the spiral arms, where they are either absorbed or reflected back toward

Figure 1. Mode 1 radiating region for a two-arm spiral. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the spiral center. Note that if the spiral is large enough in size, the in-phase current conditions will show up at odd guided-wavelength circumferences of the spiral and higher-order modes will radiate. This condition is often referred to as *overmoding*. If attenuation of the forward-traveling wave through radiation and dissipation in the lossy termination are insufficient, the currents will reflect back from the end of the spiral and the backward-traveling waves will be generated. Since the wrap direction currents now have the opposite sense, the corresponding radiation of this current wave will be cross-polarized. The majority of backward current wave power will also leak in the odd wavelength circumference regions. Any remaining power will arrive at the spiral input ports (if perfectly matched) and show up as increased input VSWR.

This similar radiation process occurs with other modes and different numbers of arms. For example, a four-arm spiral fed in mode 1 (total phase progression of 360° at the input ports, i.e., where the feed phase vector is $\{0^\circ, 90^\circ, 180^\circ, 270^\circ\}$) will radiate higher modes of orders 5, 9, $4m + 1$, $m = 1, 2, \dots$, and so on if the spiral large enough to support those modes. When fed with 720° phase progression between input ports (where the feed phase vector is

$\{0^\circ, 180^\circ, 0^\circ, 180^\circ\}$), the spiral will operate in the second mode (mode 2, difference or Δ), and overmoding will show up at radiating rings at 6, 10, $\dots 4m + 2$, $m = 1, 2, \dots$ guided wavelength circumferences. Mode 1 and 2 regions of a four-arm spiral are shown in Fig. 2. Undesired modes sometimes occurs as a result of imperfections in the feed circuitry, loose or improperly attached cables, material impurities, and other conditions capable of alternating the natural progression of the current traveling wave.

4. SPIRAL ANTENNA TYPES, CHARACTERISTICS, AND TECHNOLOGY

4.1. Archimedean and Equiangular Spirals

The most frequently used spiral shapes are that of Archimedean and equiangular spirals in planar or conical form. These shapes in planar form are depicted in Fig. 3. The Archimedean spiral has constant armwidth and constant separation between arms through the entire aperture. The defining equation for this antenna is $r = r_0 + a\Phi$, where r_0 is the starting radius, a is the growth rate, and Φ is the progressive growth angle. The equiangular spiral has progressively increased armwidth and separation between the arms as they open toward the outside. This shape can be entirely described by angles and is the basis for the frequency-independent principles [6]. The defining equation for an equiangular spiral is $r = r_0 e^{a\Phi}$, where r_0 is starting radius, a is the growth rate and Φ is the progressive growth angle. Another term frequently used to describe tightness of the equiangular spirals is the so-called expansion factor (EXP), defined as $EXP = e^{2\pi a}$. For an expansion factor of 2, the spiral radius as well as the armwidth and separation between the arms will double for each turn.

4.2. Spiral Modes

Spiral modes were first theoretically studied in early 1960s [11,12], when radiation conditions for orthogonal radiation modes of infinite arm spirals were derived. The

Figure 2. Four-arm spiral currents depicting mode 1 and mode 2 radiation. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 3. Two-arm Archimedean (left) and equiangular (right) spirals.

notion of spiral modes is associated with either the dominant (desired) or the higher-order (undesired) radiation conditions from a spiral aperture. Dominant modes are those for which the proper phase progressions at the feed are devised; for mode m an overall phase progression of $m \times 360^\circ$ is needed. They radiate a circularly polarized wave from the $m\lambda$ circumference rings and have a far-field phase (on a cone) progression with m cycles of 360° . Only mode 1, with both right circular polarization (RCP) and left circular polarization (LCP), has any boresight component. Other modes have an on-axis null. Higher-order modes are typically unwanted and they are formed due to existence of the nonradiated currents on the spiral aperture outside the nominal radiating ring. They can be suppressed by reducing the size of the spiral, so that its circumference is smaller than $m\lambda$, where m is the unwanted mode. Improving the efficiency of the radiation through the dominant radiating ring can reduce the negative effects of these modes, and this is recommended for spiral antenna designers. Radiated power of the higher-order modes is to blame for scalloping spiral patterns and significantly increased amplitude wobble on conical spiral pattern cuts (the parameter often termed as WoW [7,9]).

A NEC-generated numerical model of a 16-arm equiangular spiral is used to compute the radiation patterns for dominant modes supported by this antenna, and the radiation patterns are shown in Fig. 4. Each higher-order spiral mode peaks successively further from boresight.

Approximate beam peak angles and directivities for the first nine spiral modes are shown in Table 1. These values are typical, but there will be minor variations based on spiral design and frequency. To demonstrate the overmoding on a two-arm spiral antenna, a first higher-order mode, mode 3, was computed for several equiangular spirals with various growth rates. As seen in Fig. 5, tighter growth rates can be utilized to design antennas with high-cross-mode difference gains and thus improved patterns. The maximum value shown for mode 3 radiation is -18 dB below the mode 1 gain at 18 GHz, resulting in only a 2 dB azimuth ripple (WoW).

4.3. Number of Spiral Arms

The first spiral antennas were realized with two arms and operated in a single mode. Initially, they were fed by a balanced two-wire transmission line, and they were the best broadband antennas at that time (2–1 bandwidths were considered extremely wide). The interest in spirals with more than two arms was ignited by Paul Shelton in 1960. He proposed three- and four-arm spiral designs for multimode operation (see App. A in Ref. 7 for a copy of the original letter). Shelton recognized that for proper phase progression at the input ports an extra arm (reference) was needed; thus, to achieve two broadband modes, at least three arms were required. His finding heavily impacted funded research conducted in several labs that had

Figure 4. Radiation patterns of ideal modes from a 16-arm spiral. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Table 1. Directivity and Beam Peak Position for Spiral Modes in Free Space

	Mode								
	1	2	3	4	5	6	7	8	9
Beam peak (deg)	0	40	45	49	52	54	56	58	60
Directivity (dBic)	8.5	6.3	6.3	6.3	6.3	6.3	6.3	6.3	6.3

been trying to obtain two broadband modes from two-arm spiral antennas [13]. Since then, it has been generally accepted that an N -arm spiral can radiate $N-1$ broadband modes. Therefore, the minimum number of arms for a multimode spiral is 3. A unique feature of the three-arm spiral is that the first and second modes have the same impedance. However, four arms are generally used because of the more complex feed network, often called *beamformer* or *modeformer*, for a three-arm spiral (feed phase vectors are mode 1 {0, 120, 240°} and mode 2 {0, 240, 480°}). For dual-polarized spirals, such as the modulated armwidth (MAW) spiral [14], a minimum of five arms are required for multimode operation. Because of the beamformer simplicity, six or eight arms are generally used. Finally, single-arm spirals have also been investigated [15], and some narrowband applications were found where these antennas provide satisfactory performance. However, they do not have conventional spiral behavior and will not be discussed here.

4.4. Pattern Modal Decomposition

To investigate the composition of the modes in a radiation pattern of a spiral antenna, a technique referred to as a *pattern modal decomposition* is often used [16]. The radiating modes of an N -arm spiral can be obtained by producing a phase progression between adjacent arms at the feedpoints equal to $2\pi m/N$, where $m = 1, 2, \dots$ is the desired mode of operation. To compute the modal content of the

radiated field, the phase progression is applied to the arms of the spiral through complex voltage coefficients defined by

$$V_{k,m} = V_{0m} \cdot e^{[-j2\pi m(k-1)]/N} \tag{1}$$

where $k = 1, \dots, N$ denotes the arm, V_{0m} is a constant amplitude, and j equals $\sqrt{-1}$. Equation (1) has the restriction

$$\sum_{k=1}^N V_{k,m} = 0 \tag{2}$$

for each mode. A determination of the modal fields in terms of the measured pattern

$$E_m(\theta) \cong \frac{1}{N(\phi)} \cdot \sum_{k=1}^{N\phi} V_{k,m}^* \cdot E(\theta, \phi_k) \tag{3}$$

The modal decomposition, $E_m(\theta)$, are the coefficients to the discrete Fourier series representation of $E(\theta, \phi_k)$. $N\phi$ is the number of points per conic cut (at a constant θ value), in the far-field pattern data, and the highest number of ambiguity free modes that can be resolved is equal to $(N\phi/2 - 1) \cdot E(\theta, \phi_k)$ can be measured pattern data or calculated from electromagnetic models. To demonstrate the capabilities of this technique, the beamformed patterns of an eight-arm spiral are decomposed into modes as shown in Fig. 6. Both, left- and right-handed modes supported by this structure are measured and as seen, the power in cross-polarized modes (negative ones) is much smaller than that of the copolarized fields. Also clear from this figure is that the higher-order modes “turn on” at progressively higher frequencies. A single-arm measurement without beamformer can also be decomposed into basic spiral modes, thus providing significant amount of data (i.e., all possible spiral modes) from a single-port measurement.

Figure 5. Mode 3 content (relative to mode 1), of a 2.4-in.-diameter two-arm equiangular spiral with various growth rates. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 6. Power in each mode for a single arm of a 25-cm-diameter eight-arm spiral. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

4.5. Spiral Impedance

The input impedance to the ground for a self-complementary N -arm structure in free space is derived by Deschamps [17] and is given as

$$Z_m^{fs,comp} = \frac{\eta_0/4}{\sin\left(\frac{m \cdot \pi}{N}\right)} \tag{4}$$

where $\eta_0 = 120\pi \Omega$ is the impedance of the free space. The integer m denotes the eigenvalue or characteristic mode ($m = 1, 2, \dots, N-1$) where N is the number of arms on the structure. Modal impedances for self-complementary two-through eight-arm spirals are computed using (4), and results are shown in Table 2. As seen, only a three-arm spiral has the same modal impedances for modes 1 and 2. As discussed in the previous section, the complexity of the beamforming network for this antenna reduce its practical

application. In practice, these theoretical impedances are lowered because of the finite thickness of the metallic parts on an antenna as well as inevitable dielectric loading (used for mechanical support).

To impedance-match the spiral to a particular mode, the arm-to-gapwidth ratio (A/G) at the spiral feedpoints can be adjusted to match to the feed cable impedance (usually 50Ω). Since spirals radiate most efficiently as self-complementary structures, the noncomplementary feed region should be slowly transformed back to complementary before the first desired radiation region. As with most impedance transformers, this transition should be at least a quarter of a guided wavelength long at the lowest frequency of operation. A drawing of a tapered A/G feed region for an eight-arm spiral is shown in Fig. 7. For this antenna, to simultaneously match both modes 2 and 3 to $50\text{-}\Omega$ coax (coaxial cable), the predicted optimum A/G ratio is about 14 (see Fig. 8).

Table 2. Input Impedance (in Ω) of Free-Space Self-Complementary Spirals

Number of Arms	Spiral Mode						
	1	2	3	4	5	6	7
2	94.2	—	—	—	—	—	—
3	108.8	108.8	—	—	—	—	—
4	133.3	94.2	133.3	—	—	—	—
5	160.3	99.1	99.1	160.3	—	—	—
6	188.5	108.8	94.2	108.8	188.5	—	—
7	217.2	120.5	96.7	96.7	120.5	217.2	—
8	246.3	133.3	102.0	94.2	102.0	133.3	246.3

Figure 7. Impedance transformer for an eight-arm spiral. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Simultaneous matching of spiral mode impedances is a challenging problem, and several methods have been devised. These methods utilize a feedline structure that is highly decoupled at the beamformer input (all input ports are 50Ω, regardless of mode), and strongly coupled at the spiral interface (impedance is dependant on input excitation). In the feedline section, near the spiral, coupling is obtained similar to that between the arms in a spiral antenna. A six-arm spiral with a coaxial type coupled feedline [18] had maximum return loss of -13, -17, and -16 dB for the first three modes. Average return loss over the 4:1 bandwidth was -18, -22, and -24 dB for these same modes.

4.6. Spiral Feeding Methods

A number of different feeding techniques have been developed for spiral antennas. Some include not only balanced-to-unbalanced (balun) transitions but also impedance

Figure 8. Theoretical input impedance versus arm-to-gapwidth ratio for modes 1, 2, and 3 of an eight-arm spiral antenna on a 0.010-in.-thick 2.1 dielectric substrate. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

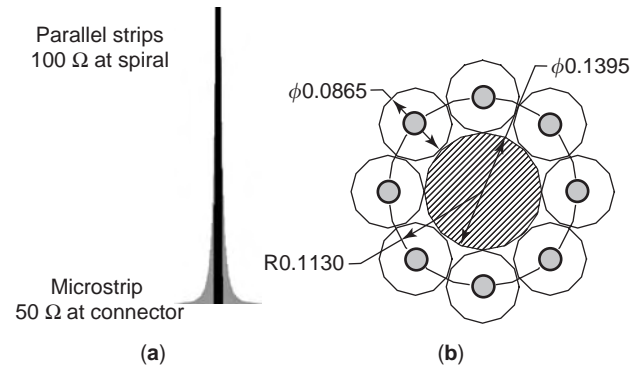

Figure 9. Microstrip tapered balun (a) and coaxial cluster feed (b). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

transformation. The tapered microstrip balun [19], Marchand balun [20], and 180° hybrids with coaxial feeds are commonly used for two-arm printed spirals. The tapered microstrip balun, shown in Fig. 9a, has the advantage that the spiral impedance can be matched by tapering the width of the strips. It can be designed for bandwidths several octaves wide. For more than two arms, coaxial feedlines are used; one realization is shown in Fig. 9b. The outer conductors of these coaxial cables are soldered together to form a compact coaxial cluster. To further reduce unwanted feed line radiation, absorber paint is sometimes used to coat the outer conductor of the coaxial feedline cables between the beamformer and spiral. The so-called infinite balun developed by Dyson [3] is the most commonly used feeding method for slot spirals. The outer conductor of the coaxial cables is soldered to the metallic portion of the spiral (in between the slot arms), and a transition to the slotline is provided in the center. A recently proposed dual Dyson balun for a four-arm slot spiral [21] is shown in Fig. 10. In this configuration the dummy cable (used with two-arm configurations to provide symmetry) is replaced by another feed cable, and proper mode 2 phasing is obtained using a simple power divider.

4.7. Spiral Start and End Radius Guidelines

In this section, recommendations for start and end radii of spiral apertures are provided. If the spiral start radius is too large, excessive energy will leak through the mode

Figure 10. Directivity–gain for various modes of a four-arm equiangular spiral.

1 radiation region. Spiral size permitting, this energy will radiate in higher order modes, thus significantly contaminating its far field. The guideline given in Eq. (5) is for the spirals with relatively small growth rates ($EXP < 2$):

$$R_{start} = \frac{\lambda_{high} m_{lowest}}{6\pi} \tag{5}$$

where λ_{high} is the guided wavelength of the highest frequency of operation and m_{lowest} is the mode order of the lowest desired mode of operation. Additionally, the feed region of the spiral can interact with the feeding cables and create currents that propagate on the outside of the cables. This can severely deteriorate the radiation patterns and also provide unwanted interference. Since multiarm spirals are commonly fed with some form of coaxial clusters, special care must be exercised when the minimum spiral radius is determined. The approximate upper frequency limits for quality mode 1 radiated patterns for various coaxial cable sizes are summarized in Table 3. The outer shields of these coax clusters are usually soldered together to reduce unwanted cluster radiation.

As discussed earlier, a spiral needs to be $m\lambda$ in circumference to support the radiation of mode m . Since the radiation region is actually a finite width ring, it will be severely truncated if the circumference is only $m\lambda$. A good rule to avoid unnecessary truncation of the radiating ring of tightly wound spiral ($EXP < 2$) is expressed in (6)

$$D \geq \frac{(m_{highest} + 0.5)\lambda_{lowest}}{2\pi} \tag{6}$$

where λ_{lowest} is the guided wavelength of the lowest frequency of operation and $m_{highest}$ is the mode order of the highest desired mode of operation. For higher spiral efficiency, the numerator of Eq. (6) should be increased to $(m_{highest} + 1)\lambda_{lowest}$. Loss (directivity minus gain) versus spiral circumference for a four-arm printed equiangular spiral over an absorptive cavity is shown in Fig. 11. At least 3 dB of this loss can be attributed to absorbing the back hemisphere pattern of the spiral.

4.8. Slot Spirals

The slot spiral antenna [1,3] can be considered as a complement to the more frequently used wire or printed spirals, thus their performance is quite similar. The basic transmission line used to support the forward traveling wave is slotline-wrapped in the spiral form. To maintain input impedance of a two-arm design close to $50\ \Omega$ and allow for “clean” slot mode excitation, a metal to slot ratio is typically larger than 1. The proper mode excitation of

Table 3. Maximum Mode 1 Frequency (GHz) for Coaxial Cable Feeding Arrangements

Number of Coaxial Lines	Coaxial Cable Diameter (in.)			
	0.141	0.085	0.047	0.034
2	7	12	>18	>18
4	6	10	18	>18
6	5	8	14	>18
8	4	6	12	16

Figure 11. Four-arm slot spiral with dual Dyson balun feed. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the slot spiral has been best obtained by utilizing a Dyson infinite balun [3], shown in Fig. 10. This feed provides almost perfect balance, and its bandwidth is restricted only by the spiral aperture and excitation of the higher-order coaxial cable and connector modes. The disadvantages of Dyson baluns include difficult fabrication, restriction on the spiral growth rate (thus somewhat lesser coupling in the active region), high-frequency losses, and increased scattering from the cables if the balun is placed outside the cavity. Other techniques for feeding slot spirals including the microstrip feed [22] and vertical balanced excitation, have been proposed, but significant improvements are still necessary (microstrip radiation and coupling into the slot outside the transition region, both negatively affecting the crosspol).

The design of the termination region is crucial for slot spirals. Because of the smaller attenuation through the active region (to be discussed later), the residual traveling wave on the slotline not only radiates in the higher-order modes but also undergoes strong reflections from the spiral arm ends and severely deteriorates the pattern and impedance performance at low- and midband frequencies. Excellent treatment of the slotline termination is provided in Ref. 23. A photo of the 15-cm slot spiral fed with Dyson balun and terminated with a 30 resistors per arm Klopfenstein taper [24] is shown in Fig. 12.

4.9. Beamforming

Beamformers, also known as *modeformers*, are used to provide proper phasing of the spiral arms to achieve the desired mode excitations. Phase excitations for the first two modes of four-arm RCP and LCP spirals are shown in Fig. 13. For a counterclockwise (CCW)-wound RCP spiral, phase excitation of successive spiral arms is given by $P = [-360m(n - 1)]/N$ (in degrees), where $m = 1, 2$ is the mode number, $n = 1, 2, 3, 4$ is the arm number, and $N = 4$ is the number of arms. Note that the theoretical phase distributions are identical for modes 2 RCP and LCP and that spiral’s wrap direction determines the polarization sense. The beamforming networks are typically stripline circuits built as a combination of 90° and 180° hybrids and phase

Figure 12. Two-arm slot spiral with coaxial Dyson balun feed.

shifters. An excellent treatment of spiral beamformers can be found in Ref. 7.

The modal decomposition of the mode 1 input of a 4×4 Butler matrix beamformer (shown as inset) is depicted in Fig. 14. Complex S_{N1} data are measured from the mode 1 input to each of the four outputs of the beamformer ($N = 1, 2, 3, 4$). These data are then decomposed into the four spiral modes. Both amplitude and phase imbalances contribute to the modal contamination. The top curve denotes the insertion loss for mode 1; while the remaining curves (modal isolation > 25 dB) represent the contamination level of each of undesired modes 2, 3, and 4. An ideal spiral integrated with this beamformer will have these modal pattern errors, assuming the spiral is large enough to support all the modes. Modal purity of other ports (modes 2–4) is determined in the same manner. Mode 4 will not radiate well from a four-arm spiral, but the beamformer modal contamination should be low so it will not excite direct radiation from the spiral feed structure.

4.10. Cavity Types

A planar spiral antenna radiates bidirectionally, with opposite polarization senses in the two hemispheres. For many applications unidirectional radiation is required.

The most commonly utilized approaches for eliminating the backward radiation of a planar spiral are use of either a reflective or absorber filled cavity. Absorptive cavities dissipate backward radiation using carbon filled materials in some form of honeycomb, syntactic foam or polyurethane foam, to mention just a few. A graded absorber is used to taper match the air to the heavily loaded carbon material. If the absorber is placed too close to the spiral element, additional attenuation of the forward traveling wave will occur (more than the 3 dB of expected cavity loss). To decrease the loss due to the absorptive cavity, a contact dielectric lens can be placed on the top of spiral [25]. The lens enhances direct coupling to free space and typical gain increases of 1–2 dB have been observed.

A reflective cavity or ground plane can also be used over limited bandwidths. Fields reflected off the metallic bottom undergo polarization reversal and constructively add in the far field if the bottom is a quarter-wavelength from the spiral. Overmoding will occur if the spiral size permits creation of higher-order mode active regions. Thus, an effective way for suppressing overmoding effects is to increase the number of spiral arms such that the active region of the lowest-order parasitic mode falls outside of the spiral aperture. For example, if we want to design a mode 1 spiral to operate in 2–20 GHz range with 5 cm aperture diameter and absorber free metallic backing, how many arms should we consider? Assuming ideal conditions on the spiral (zero width of the active region, no miniaturization and ideal arms termination), and knowing that the circumference of the active region for the first parasitic mode is $(N + 1)\lambda_{\text{high}}$, we can compute that the number of arms as $N \geq D\pi/\lambda_{\text{high}} - 1$; thus, at least $N = 10$ arms are needed. A more appropriate inequality for computing the number of arms for this type of spiral antenna is

$$N = \left\lfloor \frac{f_{\text{high}}}{f_{\text{low}}} (m + \Delta) \right\rfloor - m + 1 \quad (7)$$

where f_{high} and f_{low} are highest and lowest frequencies of operation, m is the desired mode of operation ($m = 1$ in the given example), $\lfloor x \rfloor$ is the integer part of x , and Δ is the safety factor depending on the width of the active region, depth of metallic backing, and established criteria for tolerable cross-modal difference (typical values for Δ are ~ 0.5 – 1). Note that multiarm designs have higher complexity and price associated primarily with the beamformer. Often the increase in antenna efficiency

Figure 13. Four-arm phase excitations.

Figure 14. Modal decomposition of mode 1 for a 4 × 4 Butler matrix beamformer. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

does not compensate for the excessive cost (remember that the beamformer must have the same bandwidth as the antenna; thus for a 12-arm spiral, maintaining 30° phase progression between neighboring ports over a decade bandwidth is very respectable task).

Effects of the metal backing are clearly depicted in Fig. 15, where modal content of metal backed and freestanding two-arm spirals are compared. As seen, the power radiated by the higher-order modes of the freestanding spiral is significantly lower. Note that the cross-modal difference of 10 dB typically causes WoW on the order of 6 dB on wide-angle conical cuts.

A metallic backing spaced further than $\lambda/4$ will begin to degrade the boresight gain. At a height of $\lambda/2$, the mode 1

pattern will have a null on boresight and still maintain mode 1 phase characteristics. Several designs utilizing tapered absorber filled and absorber free conical cavities can be found in Ref. 23.

4.11. Spiral Cross-Polarization

Cross-polarization is determined primarily by the effectiveness of radiation through the spiral region and the quality of the spiral termination. Feedline radiation can also generate cross-polarization, particularly with slot spirals when a microstrip feed is used. A drawing of the microstrip feed of a four-arm slot spiral is shown in Fig. 16. The microstrip line not only enhances cross-polarization

Figure 15. Modal contamination of cavity-backed and freestanding two-arm spiral. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

directly (by radiation), but the microstrip also couples into the slot spiral and creates an inward slotline wave (cross-polarization due to the direction of travel). In the case of coaxial clusters, a monopole type radiation with dominant vertically polarized field component (due to excited currents on the outside conductors on the cluster) creates the cross-polarization. A reflective cavity also contributes to the increased cross-polarization levels.

4.12. Attenuation through the Active Region

As discussed earlier, spirals are traveling/fast/leaky-wave antennas realized by wrapping a transmission line into a spiral shape. If a spiral is considered as a lossy transmission line, it should be designed to ensure large radiation loss for the traveling wave passing through the active region. Attenuation through the active region is usually directly correlated with the ability of a spiral antenna to efficiently radiate. The faster the wave on the spiral (i.e., the more the arms that couple), the greater is the attenuation through the active region. The radiation efficiency (and attenuation through the active region) increases when the spiral is on a thin, low-loss dielectric constant substrate. This efficiency also improves as the spiral is more tightly wound. In practice, one should allow at least one turn before the active region. Excellent discussion on this subject is given in Ref. 9.

4.13. Arm Termination Methods

When attenuation through the active region(s) is insufficient, the residual traveling wave will reach arm ends, encounter a discontinuity (open end for printed and short end for slot spirals), and reflect back. Simultaneous existence of two oppositely directed traveling waves on the spiral create conditions for standing wave, thus reducing bandwidth and increased cross-polarization. To mitigate these effects, a special care must be taken in the design of arm terminations. Various techniques for terminating the

spiral arms are devised in the past, including

- Distributed resistive loading in a form of matched taper such as exponential or Klopfenstein tapers (preferred method for slot spirals)
- Resistive termination to the spiral cavity
- $50\ \Omega$ termination in the form of a microstrip or strip-line transition (for outside ports)
- Absorber ring around spiral perimeter, either on the top (contact) or inside the cavity
- Helix loaded spiral (absorber loads the helix at low frequencies; see Fig. 17a)
- A thin (thus lossy) multiple turns wire at the spiral perimeter, sometimes painted with lossy material
- Absorber paint on the last turn (or a few turns)

The rule of thumb is that the termination section should be at least quarter of a guided wavelength long at the lowest frequency of the spiral.

4.14. Reduced-Size Spirals

A spiral is fast leaky wave antenna that performs at its best when the traveling-wave phase velocity is as high as possible. Thus slowing the wave on the spiral arms, though possible, must be exercised with extreme care. Among techniques for slowing the wave on the spiral arms are loading the spiral with higher contrast/thickness dielectric material, increasing the length of the spiral arms using modulations or a modified spiral shape, capacitive and inductive loading of the line, and so on. Although some techniques result in acceptable patterns and improved matching conditions, the antenna efficiency typically is reduced (for dielectric loading) and some pattern contamination occurs (for all methods). A good example of extended low-frequency performance is the helix-loaded spiral [7]. A 25-cm spiral demonstrated good patterns down to 250 MHz. A similar commercially available realization is shown in Fig. 17a. In Ref. 26 a 15-cm-diameter two-arm meanderline slot spiral, shown in Fig. 17b, had good performance down to 250 MHz. A very interesting property of an Archimedian spiral has been derived [27]. More specifically, if spiral miniaturization/loading technique can be characterized through an effective dielectric constant ϵ^{ef} , then the input impedance scales as $(\epsilon^{ef})^{-1/2}$, while the radiating region scales as $(\epsilon^{ef})^{-1/4}$. This result showed why the gain curves translate to the lower frequencies with much smaller miniaturization factor as in the case of resonant dipoles.

5. OTHER SPIRAL ANTENNA GEOMETRIES

Spiral antennas have been fabricated in a wide range of geometries not only for improved performance but also for the reasons of packaging, arraying, conformal and flush-mounting and so forth. For example, square spirals (see Fig. 18) allow closer packaging in an array environment and, due to longer circumference than round spirals, provide some inherent miniaturization factor ($MF=4/\pi$) for improved low frequency operation. Wiggly spirals

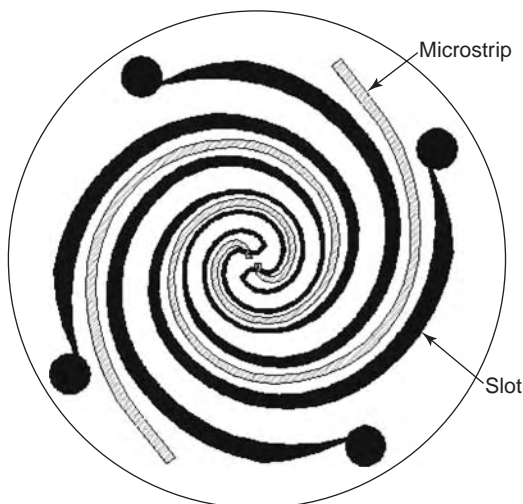

Figure 16. Sketch of a microstrip feed for a four-arm slot spiral antenna.

(b)

Figure 17. Helix-loaded spiral (courtesy of EDO) and meanderline slot spiral (b).

have modulations in the form of zigzag, sinusoid, or meanderline added to the spiral arms to make armlengths longer and also enhance low-frequency performance. These methods can improve low-frequency performance, but overmoding is still present at higher frequencies. The ambidextrous spiral, shown in Fig. 19, has phase centers spaced closer together, which reduces ambiguities for high-frequency interferometer applications. This antenna can be also designed in a four-aperture configuration for quadrant coverage applications. Spirals can be conformal and embedded into the leading edge of aircraft wings. Spirals have also been made on parabolic reflector surfaces.

(a)

(b)

Figure 18. Square (a) and hybrid (b) four-arm spiral designs.

5.1. Conical Spirals

To reduce the bidirectional radiation of a spiral, Dyson wrapped the spiral onto a cone [4]. This increases radiation toward the cone apex and reduces backward-traveling hemisphere radiation. Various photographs of the first conical spiral antennas can be found in Ref. 28. Printed and slot designs, including spirals with outer coaxial conductors playing the role of arms, have been realized, and they were fed with some form of Dyson balun. Dyson used his experimental brilliancy to determine that when the spiral currents reduce by 3 dB on the high-frequency end (at the top of the cone) and 15 dB (at the bottom of the cone), the radiation characteristics seldom change significantly. This finding was important for truncation of the spiral, thus simplifying fabrication while reducing the feed coaxial length, and the height of the cone. A computed front-to-back (F/B) ratios for various cone

Figure 19. Ambidextrous spiral (courtesy of BAE).

apex angles of a four-arm conical spiral are shown in Fig. 20. As the cone angle is decreased (the spiral gets taller), the backlobe is reduced and the directivity increases. Directivity also increases when the spiral is wrapped tighter since more turns cross the active region and coupling between them is enhanced.

Conical spirals designed to operate in the mode 2 have been utilized for surveillance applications [29]. It was shown that the cone apex angle and other parameters of the spiral can be adjusted to peak the beam at desired angles.

5.2. Simultaneous Inside/Outside-Fed Spiral

A spiral can be fed from either the inner ports or outer ports, or both simultaneously. Spiral polarization can be determined using the right-hand rule, so that a CCW wound spirals fed from the inside radiates RCP. The same spiral when fed from the outer ports radiates LCP. Simultaneous excitation can result in the broadband dual-polarized operation. Feeding from the outside has the additional advantage of ample room to provide impedance-matching networks. Stripline or microstrip transitions can be designed to match to $50\ \Omega$ and broadband match for multiple modes can be readily achieved. A major disadvantage of outside feeding is that the highest-order mode of excitation will radiate first, thus limiting the effective bandwidth of this type of antenna. To increase the bandwidth, more arms must be added, thus increasing cost (a more complicated and expensive beamforming network). A higher-order (for this structure sometimes also called “parasitic”) mode free dual-polarized bandwidth of inside/outside-fed spirals can be found using the expression

$$B \leq \frac{N + 2}{2(M_h + \pi\Delta)} \quad (8)$$

where B is the bandwidth ($f_{\text{high}}/f_{\text{low}}$), N is the minimum number of arms, M_h is the highest order mode used, and Δ is the width of the radiation band (typically $\Delta = 0.18$).

(a)

(b)

Figure 20. Conical spiral front-to-back ratio versus cone angle for various growth rates (a) and modes (b). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Computed bandwidths for multiple arms and multi-mode operation of inside/outside-fed spiral are shown in Table 4. As seen, with this spiral for octave bandwidth dual-mode and dual-polarization performance, at least eight arms are required (1.95:1 bandwidth). For a four-arm spiral, the dual-mode dual-polarization bandwidth is only about 17%. By relaxing the requirements for the gain and WoW, the bandwidth will increase.

When spiral is fed from outside, a continuous conductive ring is required to keep coaxial feed outside conductors at the same potential. This can be accomplished by using a mounting flange just outside the spiral cavity. Microstrip or stripline is used to transform the impedance from $50\ \Omega$ (at the outside port connectors) to match to the spiral arm ending width. This works well for small growth rates towards the spiral perimeter. A drawing of an outer microstrip transition is shown in Fig. 21.

5.3. Modulated Armwidth (MAW) Spiral

The MAW spiral was introduced by Ingerson [14]. It was the first center-fed spiral antenna with multioctave dual-polarized operation. The MAW spiral incorporates arm impedance modulations for creation of bandstop regions. A bandstop (often called *band-reflect*) region utilizes a series of quarter wavelength high/low-impedance sections, which

Table 4. Bandwidth of a Mode-free Dual Spiral (Inside/Outside-Fed)

N	Mode		
	1	2	3
3	1.6	—	—
4	1.9	1.2	—
6	2.5	1.5	1.1
8	3.1	1.9	1.4

provide a broadband method for reflecting the spiral’s traveling wave, thus in turn generating the backward oppositely polarized wave. These reflected currents generate modes similar to the outside-fed spiral described above, but without the overmoding limitations. The MAW spiral bandwidth has the same limits as for the regular spiral; thus the highest frequency is determined by the fineness of the central region, and the lowest limit is determined by the diameter of the spiral. Because of its ability to support both forward and backward waves in dominant active regions, multimode operation can be achieved by increasing the number of arms. For a MAW spiral to operate with m useful modes, the minimum number of arms is $N = 2m + 1$. Thus for a single-mode dual-polarized operation the MAW must have at least three arms.

The 4, 6, and 8-arm MAW spirals are shown in Fig. 22. The band-reflect region is set at the circumference of $N/2$ guided wavelengths, where N is the number of arms. A four-arm spiral will reflect the currents at the 2λ circumference, thus limiting this antenna to single-mode operation, but preserving the dual circularly polarized capability. So, how does the port phasing work for the MAW spiral? Assume a clockwise-wound four-arm printed MAW spiral. This antenna (center-fed) will produce LCP mode 1 radiation for feed phasing vector $\{0^\circ, 90^\circ, 180^\circ, 270^\circ\}$. Now, if we excite the feed ports with the vector $\{0^\circ, -90^\circ, -180^\circ, -270^\circ\}$, this corresponds to the mode -1 for the LCP spiral. This phase progression is identical to the phase vector $\{0^\circ, 270^\circ, 540^\circ, 810^\circ\}$, which creates $3 \times 360^\circ$ conical far-field progression and represents the mode 3 phase vector. Thus, the forward traveling wave will pass the mode 1 radiation region without radiation, arrive at its bandstop region, undergo reflection, and become a backward-traveling wave spiraling back toward spiral center. At the 1λ circumference, phasing is correct to radiate mode -1 and a RCP mode pattern is generated.

Figure 21. Outside feed of the spiral using microstrip transition.

Figure 22. MAW spirals with four (a), six (b), and eight (c) arms.

The band-reflect section is not required in the low frequency region. For example, an eight-arm 25-cm-diameter spiral will have good mode 2 radiation at 800 MHz; however, the mode 4 band-reject ring need not exist since the spiral will not radiate mode -2 (m_6). Since a reflection

from the end of the arm is desired, end loading should not be used for most MAW spirals. Also, the inner band-reject region does not need to exist until it is required for rejecting the highest frequency of the lowest mode. Making this inner portion a traditional spiral, with no modulations, leaves room for impedance matching. Modulation ratios (wide section/thin section) should be in the 4:1 to 15:1 range for a good band-reflect region.

MAW spirals with multidecade bandwidths have been demonstrated. The six-arm MAW can support dual polarization for two modes, and the eight-arm MAW can support three modes. Spiral pathlengths, and therefore losses, will be higher for the reflected modes. Measured data shows only minor gain degradations for a properly designed MAW spiral. Conical MAW spirals have also been realized, but they exhibited different patterns for the reflected modes. This is because the phasing between turns is different for the reflected modes. This also applies to the conical spiral when fed from the outside.

5.4. Spiral with Narrowband Dual Polarization

A spiral antenna can radiate dual polarization over narrow bandwidths without the aid of inside/outside feeding or modulations. The reverse polarization mode can be obtained by feeding the spiral with a negative mode (for a RCP spiral). If the spiral is not large enough to radiate the energy, currents will reflect off the spiral open ends and reradiate at the one wavelength circumference ring in the opposite polarization (LCP) since they are now traveling inward (clockwise) [30]. This can be accomplished by feeding from either the inner or outer ports. For single mode and dual polarization, bandwidths (f_{hi}/f_{low}) are approximately 1.3 for four arms, 2.7 for six arms, and 4.0 for eight-arm spirals. Using this method, 8 to 10 arms will be required for a dual-polarized and dual-mode spiral over an octave bandwidth, for typical gain and WoW requirements.

5.5. Reflector Feed Spirals

Since spirals have approximately constant beamwidths, they make ideal reflector feeds if broadband circular polarization is required. For planar absorptive cavity spirals, a reflector F/D of approximately 0.35 is optimal for mode 1. The spiral phase center is relatively stable across wide frequency ranges and is slightly in front of the spiral element, outside of the cavity, for this configuration. Figure 23 shows amplitude taper loss (ATL) and spillover loss (SPL) versus F/D , for both modes 1 and 2, using measured patterns of a four-arm spiral feeding a center-fed reflector. Maximum mode 1 aperture efficiency is at a 0.42 F/D . Mode 2 is most efficient at a 0.37 F/D . Simultaneous illumination is best at $F/D = 0.40$. Note the ATL + SPL curves are relatively flat and optimal F/D may be chosen on the basis of other factors such as maximum mode 1 gain or lower sidelobes. With a reflective cavity, the spiral directivity increases and the optimum F/D ratios increase to 0.45 for mode 1, 0.38 for mode 2, and 0.45 for simultaneous illumination of both modes.

Conical spirals have also been used as reflector feeds. The major advantage of conical spirals is improved efficiency (due to backlobe reduction). A disadvantage is that

Figure 23. Aperture losses for a center-fed reflector with a four-arm spiral feed. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the phase center moves with frequency resulting in a quadratic phase loss with frequency for a symmetric reflector. For this reason, the conical spiral can have optimal performance at only one frequency. Also, phase centers are not collocated for multiple modes at the same frequency. When used in an offset reflector, a conical feed will have beam squint versus frequency due to phase center movement. Even with these limitations, conical spirals can be efficient feeds over broad bandwidths. Illumination losses of less than 1.5 dB for 10–1 bandwidths using cone angles ($2\theta_0$) of 20 to 40° are demonstrated in Ref. 31.

6. NUMERICAL MODELING

The complexity of the spiral geometry and absence of appropriate computational tools (including methods for numerical electromagnetics) in the 1950s limited the study of spiral antennas to primarily experimental efforts. The first theoretical analysis of a spiral antenna was published in 1960 [32], where the spiral geometry was approximated by semicircles, and the vector potentials were computed by employing the appropriate Green function. Although this was a simplified model, the physical understanding of the spiral's operation, including the low- and high-frequency limits, were obtained from this analysis. The availability of faster computers and the introduction of rigorous analysis methods for solving integral equations (numerical methods) were critical for comprehensive theoretical investigation of spiral antennas. Nevertheless, while integral equation methods have traditionally been used for freestanding printed and wire spirals, and non-cavity-backed slot spirals partial-differential equation and volume modeling methods are more appropriate for the cavity-backed spirals and spirals on a finite substrate. The finite element-boundary integral method (FE-BI), developed especially for the cavity-backed Archimedian slot spirals [33], was introduced more recently. This method combines triangular and quadrilateral prismatic finite elements to obtain the best representation of the electric fields inside an extremely narrow slotline. This field modeling secures the convergence of the method for geometries that contain a number of small details, along with the

Figure 24. Measured versus computed (FE-BI) broadside gain of a two-arm slot spiral. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

inherent capability of a FEM for modeling of inhomogeneous materials inside the cavity [27]. An example depicting the capability of this technique is given in Fig. 24, where the computed gain of a cavity-backed slot spiral is compared with measurement. Excellent agreement between measurements and simulations over a wide dynamic range of >40 dB, predictions of the TM_{110} cavity resonance and antenna response after the resonance, fully validate this simulation tool. The slot spiral parameters were $d = 14.9$ cm, $D = 1.27$ cm, $w = 0.0762$ cm, $t = 0.0508$ cm, $\epsilon_r = 3.38$, and 60 resistors per arm Klopfenstein taper [23]. For more detailed discussion and reference list regarding spiral analysis, see Ref. 27.

Analysis of spiral antennas have also been performed using commercially available numerical tools, including MoM (method-of-moments) codes such as NEC, FEKO, Ansoft Designer, and IE3D, etc., as well as finite-element software tools such as HFSS and extended finite-difference time-domain XFDTD.

SQUIDS

ROBERT L. FAGALY
Tristan Technologies

Since the development of the Superconducting QUantum Interference Device (SQUID) in the late 1960s and its commercial introduction in 1970, SQUID-based instruments have proven to be the most sensitive measurement devices not only for magnetization measurements but also for several other electrical measurements. Their device noise (well below 1 mK), frequency response to dc, and low drift permit electromagnetic measurements at levels far below those of conventional techniques.

SQUID instruments consist of a SQUID amplifier or sensor and a detection circuit that transforms the signal of interest into a magnetic flux that is detected by the SQUID sensor. Associated control electronics transform this signal into a room temperature voltage that is available for additional signal processing if needed. The SQUID amplifier and the detection coils are superconducting devices. Thus some type of refrigerant (e.g., liquid helium or nitrogen) or refrigeration device is needed to maintain the SQUID (and detection coil) in the superconducting state. Additional signal-conditioning electronics may be needed to improve the signal-to-noise ratio.

1. THE JOSEPHSON EFFECT

SQUIDS combine two phenomena—flux quantization where the flux $\phi = \mathbf{B} \cdot \mathbf{A}$ penetrating a superconducting loop is quantized in steps of $1 \phi_0 = h/2e = 2.068 \times 10^{-15}$

Figure 1. *IV* curve of a Josephson tunnel junction.

I_C , and the Josephson effect [1] (electrons tunneling from one superconducting region to another separated by a resistive barrier). Currents smaller than a critical current I_C , can penetrate the barrier (usually called a weak link) with no voltage drop (Fig. 1).

A typical weak link might have a critical current of $10 \mu\text{A}$. If the loop has a diameter of 2 mm, this is equivalent to several flux quanta. In a superconductor loop interrupted by a weak link Josephson junction, magnetic flux threading through a superconducting loop sets up a current in the loop. As long as the current is below the critical current, the complete loop behaves as if it was superconducting. Any changes in the magnetic flux threading through the loop induce a shielding current that generates a small magnetic field to oppose the change in magnetic flux. The weak link can be a region in which the current flowing is greater than the current needed to drive the superconductor normal I_C . Details on the Josephson effect and the theory of SQUIDS can be found in Refs. 2, 3, and 4.

2. SQUID OPERATION

SQUIDS are operated as either RF (radiofrequency) or dc SQUIDS. The prefix RF or dc refers to whether the Josephson junction(s) is biased with an alternating current (RF) or a dc current.

2.1. The RF SQUID

For the RF SQUID [5], flux is normally (inductively) coupled into a SQUID loop containing a single Josephson junction via an input coil (which connects the SQUID to the experiment) and an RF coil that is part of a high- Q resonant circuit to read out current changes due to induced flux in the SQUID loop (Fig. 2).

This tuned circuit is driven by a constant current RF oscillator that is weakly coupled to the SQUID loop. The detected RF output is found to be the periodic function (Fig. 3).

One way to measure the change in input coil current is to simply count the number of periods it produces in the detected RF output. A more common mode of operation is a feedback scheme (Fig. 2), which locks in on either a peak or a valley in the triangle pattern output from the RF peak detector. A feedback flux is applied to the SQUID through the RF coil that just cancels the change in flux from the input coil.

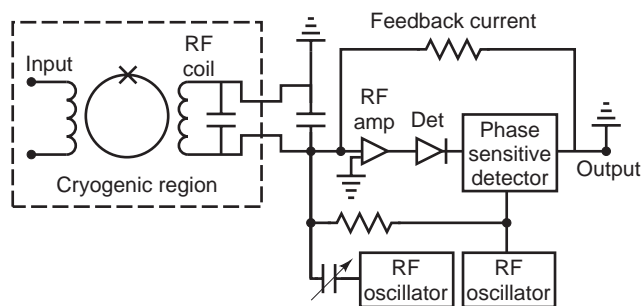

Figure 2. Block diagram of SQUID input and electronics for locked-loop operation.

2.2. The dc SQUID

The dc SQUID (Fig. 4) differs from the RF SQUID in the manner of biasing the Josephson junction (dc rather than ac) and the number of junctions (two rather than one).

The dc SQUID is biased with a dc current approximately equal to twice I_C and develops a dc voltage across the junctions. A change in the flux penetrating the SQUID loop enhances the current through one Josephson junction and reduces the current through the other, driving one junction normally and the other superconducting. This asymmetry, which is periodic in ϕ_0 , provides a feedback current that nulls the flux penetrating the SQUID loop. Although total flux within the SQUID loop is in multiples of ϕ_0 , by measuring the voltage drop across the feedback resistor, resolutions of external flux changes at the 10^{-6} level can be achieved. The linearity of flux-locked loop SQUID systems are typically better than 1 ppm. Like the RF SQUID, this feedback current (presented as a voltage at the output) is a direct measure of changes in flux applied to the SQUID.

2.2.1. Control Electronics. The system output voltage is the voltage drop across the feedback resistor in a negative feedback loop controlled by the SQUID electronics. The feedback signal is generated in response to changes in the output signal of the SQUID sensor. The output of the SQUID sensor is periodic in the field coupled into the SQUID loop. Negative feedback (similar to a phase-locked loop technique) maintains the system operating point at a particular (and arbitrary) flux quantum. When operated in this mode, the system is in a flux-locked loop.

Figure 3. Triangle pattern showing detected output voltage as a function of flux in the SQUID.

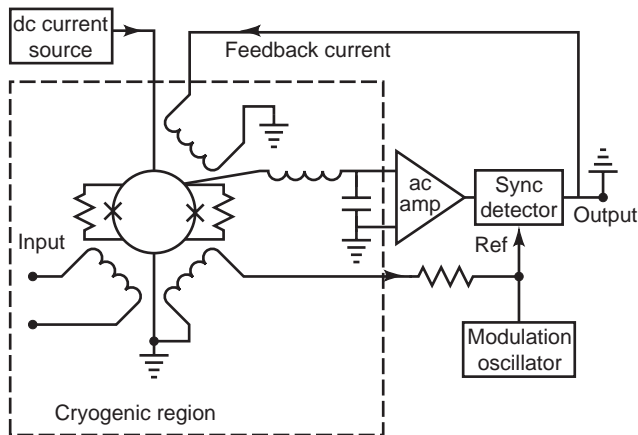

Figure 4. Block diagram of a typical dc SQUID.

One important factor of SQUID design is such that the feedback electronics be able to follow changes in the shielding currents. If the shielding current changes so fast that the flux in the SQUID loop changes by more than $\phi_0/2$, it is possible that the feedback electronics will lag behind the rapidly changing flux. When the electronics finally “catch up,” they can lock on an operating point (Fig. 3) different from the original. In this case, the SQUID has “lost lock” because the SQUID has exceeded the maximum slew rate of the electronics. This places an upper limit on the bandwidth of the system. The typical bandwidth of commercially available SQUID systems is dc to 50 + kHz. Custom electronics have been built extending bandwidths above 5 MHz. Typical slew rates for SQUIDs are in the range of 10^5 – $10^6 \phi_0/s$.

Even though one may not need or want to observe rapidly changing signals, situations may arise when ambient noise (e.g., 60 Hz) may determine the slew rate requirements of the system. To recover a signal from such interference, the system must be able to track all signals present at the input, including the noise. When system response is sped up to handle very fast signals, sensitivity to RF interference and spurious transients is also increased. Because the ability to remain locked while subjected to strong electrical transients is greatest when the maximum slew rate is limited (slow), whereas ability to track rapidly varying signals is greatest when the maximum slew rate is greatest (fast), it is desirable to be able to match the maximum slew-rate capability to the measuring situation. As a matter of convenience, many commercial SQUID systems offer user-selectable slew rates along with high-pass and low-pass filters for noise reduction.

2.3. Sensitivity

Because of the varying input impedances of SQUID sensors, the sensitivity of SQUID devices is best discussed in terms of the energy sensitivity:

$$E_N = L_i I_N^2 = \frac{\phi_N^2}{L_i} \tag{1}$$

where L_i is the input inductance of the device, I_N is the current noise, and ϕ_N is the flux sensitivity. E_N is often expressed in terms of Planck's constant $h = 6.6 \times 10^{-34}$ J/Hz.

The major limiting factor in the noise of an RF SQUID is the bias frequency f_0 used to excite the tank circuit and that RF SQUID noise is proportional to $1/\sqrt{f_0}$ [6]. As f_0 increases, the complexity of the electronics also tends to increase.

The minimum noise energy for a dc SQUID is given by [7]

$$E_N = k_B T \sqrt{L_{\text{loop}} C} \quad (2)$$

where k_B is Boltzmann's constant, L_1 is the inductance of the SQUID loop, and C is the capacitance of the junction. Substituting appropriate numbers indicates that the minimum noise energy E_N for a dc SQUID is on the order of $h/2$. Devices with sensitivities of $\sim h$ have been constructed. These extremely low noise levels are achieved by limiting dynamic range and avoiding feedback. The need for practical (useful) devices requires that feedback be used and that the SQUID have a reasonable dynamic range. Commercially available RF SQUIDS have noise levels of 10^{-29} J/Hz; commercial dc SQUIDS are typically $\sim 10^{-31}$ J/Hz.

In addition to the frequency independent (white) component of system noise, a low-frequency contribution exists that increases as the frequency decreases. The onset of this $1/f$ noise can be dependent on the ambient magnetic field when the SQUID sensor is cooled. When cooled in the earth's magnetic field, the point at which the $1/f$ noise equals the white (frequency independent) noise is typically ~ 1 Hz. Cooling the SQUID sensor in low ambient magnetic fields (less than $1 \mu\text{T}$) may improve the $1/f$ performance by as much as an order of magnitude. A large contribution to this noise in some dc SQUIDS can arise from the presence of the dc current bias. By chopping the dc bias in combination with the conventional flux modulation techniques, it is possible to reduce this added $1/f$ noise. This ac bias reversal approach [8] separates the original signal waveform from the noise associated with the dc bias and can reduce $1/f$ noise at very low frequencies.

The major difference between RF and dc SQUIDS is that the dc SQUID offers lower noise. From a historical viewpoint, although the dc SQUID was the first type of SQUID magnetometer made, the early development was with RF SQUIDS because of the difficulty in fabricating two nearly identical Josephson junctions in a single device. With modern thin film fabrication techniques and improvements in control electronics design, the dc SQUID offers clear advantages over the RF SQUID for many applications.

2.4. Limitations on SQUID Technology

It is important to bear in mind several fundamental limitations in designing SQUID-based measurement systems and data reduction algorithms.

1. A fundamental limitation of SQUIDS is that they are sensitive to *relative* (field or current) changes only. This is a consequence of the fact that the output voltage of a SQUID is a periodic function (Fig. 3) of the flux penetrating the SQUID loop. The SQUID is "flux locked" on an arbitrary maximum (or minimum) on the $V - \Phi$ curve, and the SQUID output is sensitive to flux changes relative to this lock point.
2. A second limitation exists on the system bandwidth. Although the SQUID has an intrinsic bandwidth of several gigahertz, when operated with standard flux-locked loop electronics using ac flux modulation, the maximum bandwidth is typically 50 kHz to 100 kHz. Another limitation is the presence of $1/f$ noise. High Temperature Superconducting (HTS) SQUIDS [and early commercial Low Temperature Superconducting (LTS) dc SQUIDS] exhibit excess $1/f$ noise due to critical current fluctuations of the Josephson junctions. This noise can be reduced by reversing the dc bias voltage (ac bias). This limits the maximum bandwidths less than half the bias reversal frequency. If the bias reversal frequency is too high, noise can be induced due to voltage spikes in the transformer coupled preamplifier input circuit. Because of this, the maximum bandwidth of present day HTS SQUIDS is ~ 30 kHz. If megahertz bandwidths are required, the ac bias is not used; however, there will be excess noise below 1 kHz.
3. Finally, SQUID magnetometers are vector magnetometers. For a pure magnetometer operating in the earth's magnetic field, a 180° rotation will sweep out a total field change of $\sim 100 \mu\text{T}$. If the magnetometer has a sensitivity of $10 \text{ fT}/\sqrt{\text{Hz}}$, tracking the total field change requires a dynamic range of $100 \mu\text{T}/10 \text{ fT} = 200 \text{ dB}$, well beyond the capabilities of current electronics. In addition, the rotational speed must not cause the current flowing through the SQUID sensor to exceed its slew rate limitations. An ideal gradiometer is insensitive to a uniform field and would not suffer this dynamic range limitation.

3. INPUT CIRCUITS

Whether an RF or dc SQUID, a SQUID system can be considered as a black box that acts like a current- (or flux-) to-voltage amplifier with extremely high gain. In addition, it offers extremely low noise, high dynamic range ($> 140 \text{ dB}$), excellent linearity ($> 1 : 10^7$), and a wide bandwidth that can extend down to dc.

Today, SQUIDS are fabricated as planar devices. In this configuration, the superconducting loop, Josephson junctions, and coils (input, feedback, and modulation) are patterned on the same device. Multilayer deposition techniques are used (primarily in LTS devices), and coils are normally in the form of a square washer. The planar configuration leads to quite small devices, occupying only a few cubic millimeters compared with $5 + \text{cm}^3$ ($1.2 \text{ cm diam.} \times 5 \text{ cm}$) for older toroidal RF SQUIDS [9]. Another advantage of the planar device is that it is

possible to have the detection coils as part of the SQUID sensor, eliminating the need for separate (three-dimensional) detection coils. Such an integrated sensor has the potential to reduce the complexity of multichannel systems significantly.

Although it is possible to couple magnetic flux directly into the SQUID loop, environmental noise considerations (see Fig. 9) make this difficult, if not impossible, in an unshielded environment. In addition, the area of a typical SQUID loop is small ($< 0.1 \text{ mm}^2$), and its resulting sensitivity to external flux changes ($\Delta\Phi = A \cdot \Delta B$) is also small. Although a larger loop diameter would increase the SQUID's sensitivity to external flux, it would also make it much more susceptible to environmental noise. For this reason, external flux is normally inductively coupled to the SQUID loop by a flux transformer.

Conceptually, the easiest input circuit to consider for detecting changes in magnetic fields is that of a SQUID sensor connected to a simple superconducting coil (Fig. 5).

Because the total flux in a superconducting loop is conserved, any change in external field through the signal coil will induce a current in the flux transformer that must satisfy

$$\Delta\Phi = NA\Delta B = (L_{\text{coil}} + L_i)\Delta I \quad (3)$$

where ΔB is the change in applied field; N , A , and L_{coil} are the number of turns, area, and inductance of the detection coil; L_i is the inductance of the SQUID input coil; and ΔI is the change in current in the superconducting circuit. If the lead inductance is not negligible, it must be added to L_{coil} and L_i .

To calculate the sensitivity and noise level of a simple detection coil system, the inductance of the detection coil must be known. The inductance of a flat, tightly wound, circular multiturn loop of superconducting wire is given by [10].

$$4 \times 10^{-3} N^2 \pi r \left[\ln \left(\frac{8r}{\rho} \right) - 2 \right] \frac{\mu\text{H}}{\text{cm turn}^2} \quad (4)$$

where r is the radius of the detection coil and ρ is the radius of the (superconducting) wire. Knowing the coil inductance L_{coil} , we can rewrite Eq. (3) as

$$\Delta B = (L_{\text{coil}} + L_i)\Delta I/NA \quad (5)$$

Because the SQUID system has an output proportional to the input current, maximum sensitivity is obtained by using the input circuit that provides the maximum current

Figure 5. Schematic diagram of typical SQUID input circuit.

into the SQUID and satisfies all other constraints of the experimental apparatus. For a pure magnetometer, the maximum sensitivity will occur when the impedance of the detection coil matches that of the SQUID sensor ($L_{\text{coil}} = L_i$).

3.1. Detection Coils

Several factors affect the design of the detection coils [11]. These include the desired sensitivity of the system, the size and location of the magnetic field source, and the need to match the inductance of the detection coil to that of the SQUID. The ability to separate field patterns caused by sources at different locations and strengths requires a good signal-to-noise ratio. At the same time, one has to find the coil configuration that gives the best spatial resolution. Unfortunately, these two tasks are not independent. For example, increasing the signal coil diameter improves field sensitivity but sacrifices spatial resolution. In practice, system design is restricted by several constraints: the impedance and noise of the SQUID sensors, the size of the dewar, and the number of channels, along with the distribution and strength of noise sources.

It is extremely important for dc response that the detection coil(s) be superconducting. Resistance in the detection circuit has two effects: (1) attenuating the signal and (2) adding Nyquist noise. Resistive attenuation is important only below a frequency f_0 , such that the resistive impedance is equal to the sum of the inductive impedances in the circuit (e.g., $f_0 \approx R/L_t$, where L_t is the total inductive impedance of the circuit). Resistive noise is important only if it becomes comparable with other noise sources or the signal ($< 10^{-30} \text{ J/Hz}$ for biomagnetism, $< 10^{-26} \text{ J/Hz}$ for geophysics). For a SQUID with $E_N \approx 10^{-30} \text{ J/Hz}$, the total resistance of the circuit, including any joints, must be less than $1.4 \times 10^{-13} \Omega$ [12]. Thus it is very important that all solder joints, press-fits, or connections have as low a joint resistance as possible.

Figure 6 displays a variety of detection coils. The magnetometer [Fig. 6(a)] responds to the changes in the field penetrating the coil. More complicated coil configurations provide the advantage of discriminating against unwanted background fields from distant sources while retaining sensitivity to nearby sources.

Because of the present inability to make flexible wire or make true superconducting joints in HTS materials, three-dimensional HTS coil structures [e.g., Figs. 6(b,d-f)] are not possible. Present day HTS magnetometers are fabricated as planar devices and are available only as pure magnetometers [Fig. 6(a)] and planar gradiometers [Fig. 6(c)]. As a result, commercially available HTS devices are currently in the form of magnetic-sensing rather than current-sensing devices.

3.2. Gradiometers

Magnetometers are extremely sensitive to the outside environment. This may be acceptable if one is measuring ambient fields. If what is to be measured is close to the detection coil and weak, outside interference may prevent measurements at SQUID sensitivities. If the measurement is of a magnetic source close to the detection coil, a

Figure 6. (a) Magnetometer, (b) first derivative gradiometer, (c) planar gradiometer, (d) second derivative gradiometer, (e) first derivative asymmetric gradiometer, and (f) second derivative asymmetric gradiometer. Courtesy of S. J. Williamson.

gradiometer coil may be preferred. The field of a magnetic dipole is inversely proportional to the cube of the distance between the dipole and the sensor. It follows that the field from a distant source is relatively uniform in direction and magnitude at the sensor. If we connect in series two identical and exactly parallel loops wound in opposite senses, separated by a distance b (the base-line), we obtain a coil [Fig. 6(b)] that will reject uniform fields.

Because the response of a single coil to a magnetic dipole goes as $1/r^3$, an object that is much closer to one coil than the other will couple better to the closer coil than the more distant. Sources that are relatively distant will couple equally into both coils. For objects that are closer than $0.3 b$, the gradiometer acts as a pure magnetometer, while rejecting more than 99% of the influence of objects more than $300 b$ distant (Fig. 7). In essence, the gradiometer acts as a compensated magnetometer. It is possible to use two gradiometers connected in series opposition [Fig. 6(d)] to further minimize the response of the system to distant sources. This can be extended to higher orders by connecting in series opposition two second-order gradiometers, and so on. Doing so, however, reduces the sensitivity of the instrument to the signal of interest and may not significantly improve the signal-to-noise ratio.

Rejection of distant noise sources depends on having a precise match (or balance as it is sometimes referred to) between the number of area-turns in the coils. A symmetric gradiometer [Fig. 6(b) requires that $N_s A_s = N_c A_c$,

Figure 7. Response of gradient coils relative to magnetometer response ($1/r^3$ suppressed).

where N is the number of turns and A is the area of the signal and compensation coils, respectively. An asymmetric design [Fig. 6(e,f)] has the advantage that the inductance (L_s) of the signal coil(s) is much greater than the compensation coils (L_c); greater sensitivity is achieved than with a symmetric design. Another advantage is that the signal coil diameter is reduced, leading to potentially higher spatial resolution. The optimum conditions for the number of turns in an asymmetric signal coil is given by [13]:

$$(L_s + L_c + L_i + L_l) - N_s \frac{\partial}{\partial N_s} (L_s + L_c + L_i + L_l) = 0 \quad (6)$$

If the gradiometer is perfectly made (balanced), it will reject uniform fields. However, if one coil has a larger effective diameter than the other, the response will not be that of a perfect gradiometer, but that of a gradiometer in series with a magnetometer. Mathematically, the balance, β can be defined as $V_t \propto \mathbf{G} + \beta \cdot \mathbf{H}$, where V_t is the system response, \mathbf{G} is the coil's response to a gradient field, and \mathbf{H} is the applied uniform fields. Typically, coil forms that wind gradiometers can be machined (grooved) to achieve balances β that range from 0.01 to 0.001. Planar devices, through photolithography, can achieve lower levels—a factor of 10 or better. Superconducting trim tabs placed within the detection coils can improve β to the parts per million level. High degrees of balance can allow a SQUID gradiometer to operate in relatively large (millitesla) ambient fields while maintaining sensitivities in the tens of femtotesla.

For multichannel systems (such as are used in biomagnetism), it is not possible to use externally adjustable trim tabs—each tab tends to interfere with the others. Electronic balancing [14] can provide balance ratios at the parts per million level. In this situation, portions of (additional) magnetometer reference channel response are summed electronically with the gradiometers' input to balance out its effective magnetometer response. Eight-element tensor arrays as reference channels can further improve external noise rejection. The major advantage of electronic balancing is significant improvement in immunity to low-frequency environment noise.

4. REFRIGERATION

The superconducting nature of SQUIDs require them to operate well below their superconducting transition temperature (9.3 K for Nb and 93 K for $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$). The thermal environment for the SQUID sensor and detection coil has typically been liquid helium or liquid nitrogen contained in a vacuum-insulated vessel known as a dewar (Fig. 8). The cryogen hold time depends on the boil-off rate (heat load) and the inner vessel volume.

The major heat load on dewars is the result of thermal conduction down the neck tube and a magnetometer probe along with black body radiation. The space between the inner and outer walls is evacuated to prevent thermal conduction between room temperature and the cryogen chamber. Within the vacuum space, a thermal shield (anchored to the neck tube) acts to reduce heat transfer by thermal (black body) radiation. The thermal shield either can be vapor cooled—using the enthalpy of the evaporating helium or nitrogen gas—or have the shield thermally connected to a liquid nitrogen reservoir. Dewars with removable sections use liquid-nitrogen-cooled shields.

If the experiment involves measurements interior to the dewar, then a metallic dewar is preferable. Metallic dewars offer significant shielding from environmental noise at frequencies above 10 Hz to 100 Hz. If the system is to measure magnetic fields exterior to the dewar, the dewar must be magnetically transparent, and metallic construction is not appropriate. Dewars for external field measurements are normally constructed of nonmetallic, low-susceptibility materials to minimize their magnetic interactions with the SQUID sensors and detection coils.

Figure 8. Typical design of a fiberglass dewar used for biomagnetic measurements.

Materials used are typically glass-fiber epoxy composites such as G-10. In an effort to get the detection coil(s) as close as possible to the object being measured, a “tailed” design is often used. This decreases the forces on the bottom of the dewar and allows the use of thinner end pieces (closer tail spacing). Dewars for biomagnetic measurements often have curved tails to get closer to the head.

The major advantage of high-temperature superconductivity is the simplified cryogenics and reduced spacing between cryogenic regions and room temperature. The thermal load (due to conduction and black body radiation) is less, and the heat capacity of what needs to be cooled is larger (implying smaller temperature variations for a given heat load). Because the latent heat/unit volume of liquid nitrogen is 60 times larger than liquid helium, hold times become months rather than days for an equivalently sized dewar.

4.1. Closed Cycle Refrigeration

As an alternative to liquid cryogens, closed cycle refrigeration would be desirable for several reasons. These include reduction of operating costs, use in remote locations, operation in nonvertical orientations, avoiding interruptions in cryogen deliveries, safety, and the convenience of not having to transfer every few days. Although one mechanically cooled SQUID system has been built [15], the inherent vibration and magnetic signature of present day closed cycle refrigerators prevent them from widespread use. The development of pulse tube refrigerators [16] offers promise for magnetometer operation without cryogens.

4.2. Environmental Noise

The greatest obstacle to SQUID measurements is external noise sources. If the object being measured is within the cryostat (such as is typical in most laboratory experiments), metallic shielding can minimize external noise (e.g., act as a low-pass eddy current shield). Superconducting shields essentially eliminate all external field variations. This assumes that any electrical inputs to the experimental region have been appropriately filtered. Powerline or microprocessor clock frequencies can severely degrade performance.

When measuring external fields, the SQUID magnetometer must operate in an environment—the magnetic field of the earth—that can be ten orders of magnitude greater than its sensitivity (Fig. 9). The magnetic field at the surface of the earth is generated by several sources. A background field of $\sim 50 \mu\text{T}$ exists with a daily variation of $\pm 0.1 \mu\text{T}$. In addition, there is a contribution (below 1 Hz) from the interaction of the solar wind with the magnetosphere. The remaining contributions to external magnetic fields are primarily man-made. These can be caused by structural steel and other localized magnetic materials such as furniture and instruments that distort the earth’s field and result in field gradients; moving vehicles that generate transient fields; electric motors; elevators; radio, television, and microwave transmitters; and the ever-present powerline electromagnetic field and its harmonics.

Figure 9. Rms field noise spectra in various environments as a function of frequency. Courtesy of S. J. Williamson.

4.3. Noise Reduction

One method to attenuate external noise sources is with an eddy current shield that generates fields that act to cancel the externally applied fields within the conducting material. The shielding effect is determined by skin depth λ . For a sinusoidal varying wave

$$\lambda = \sqrt{\rho / \pi \mu_0 f} \quad (7)$$

where f is the frequency of the applied field, ρ is the electrical resistivity, and μ_0 is the magnetic permeability of free space. In situations where the wall thickness $t \ll \lambda$, external fields are attenuated by

$$\frac{H_i}{H_e} = \frac{1}{1 + (2\pi f L / R)^2} \quad (8)$$

where L is the inductance of the enclosure and R is the resistance along the path of current flow. Unfortunately, induced currents in the shield generate noise. For a

cylindrical shape,

$$B_{\text{rms}} = \sqrt{\frac{64\pi k_B T t}{h d \rho}} \quad (9)$$

where h is the length and d is the diameter of the can. The cutoff frequency is given by $f_{-3\text{dB}} \approx \rho / 4\pi d t$. Because of noise considerations, eddy current shields that are to be placed near the detection coils should be made from relatively poor conductors such as BeCu.

4.4. Shielded Rooms

Another approach is to use eddy current shielding to shield the entire measurement system. An eddy current room constructed with 2 cm high purity aluminum walls can achieve shielding > 40 dB at 60 Hz with improved performance at higher frequencies. The equivalent field noise is less than $200 \text{ fT} / \sqrt{\text{Hz}}$ at frequencies above 1 Hz.

The need for shielding at lower frequencies has led to the use of magnetically shielded rooms (MSR). In the situation where $t \gg \lambda$, the attenuation goes as $(r/\lambda)e^{t/\lambda}$. Using pure eddy current shielding would require wall thicknesses that could exceed 1 m or more (below 1 Hz). For a ferromagnetic material, the permeability of the material $[\mu = \mu_0(1 + \chi)]$ replaces μ_0 in Eq. (8). The shielding is due to the fact that flux prefers the path with the highest permeability. Because magnetically “soft” materials (e.g., mu-metal[®]) can have permeabilities that exceed 10^4 , the external magnetic flux is routed around the walls, avoiding the interior. Multiple shields can act to further shield the interior of an MSR. For the six-layer Berlin MSR (Fig. 9), shielding factors exceeded 10^4 at frequencies above 0.01 Hz with noise levels below $3 \text{ fT} / \sqrt{\text{Hz}}$.

5. APPLICATIONS

Many applications (Fig. 10) configure the SQUID as a magnetometer. SQUIDS can also be configured to measure a wide variety of electromagnetic properties (Fig. 11).

The state of the art in materials processing limits the variety of superconducting input circuits that can be used with HTS SQUIDS. As already mentioned, there is no existing method for making superconducting connections to SQUIDS with HTS wire. As a result, commercially available HTS devices are currently in the form of magnetic sensing [Fig. 6(b)] rather than current sensing devices [Fig. 6(a,c-f)].

5.1. Laboratory Applications [4,8,17]

Table 1 shows typical capabilities of commercially available SQUID-based instruments. The number in the parenthesis refers to the corresponding Fig. 11.

5.1.1. Current. One common use of a SQUID is as an ammeter [Fig. 11(a)]. The input can be connected to an experiment at liquid helium temperatures or to room temperature. If the signal is to be inductively coupled to a detection coil that is connected to the SQUID input,

Figure 10. Field sensitivities and bandwidths typical of various applications. The lines indicate the sensitivity of commercially available SQUIDS.

then the circuit must be superconducting if dc response is desired.

If the measurement is of a current that passes through the detection coil, a toroidal geometry for the detection coil has the advantage of extremely good coupling to the source while rejecting contributions due to external sources. Because the measurement is inductive, there is no loading of the current-generating elements.

5.1.2. Voltage. Typically most applications use superconducting circuits. There are, however, several applications where resistive circuits are used. One example is

the detection of extremely small voltages or resistances (Fig. 12).

When a voltage V_I is applied across the input terminals, a current is generated in the SQUID input coil. In this situation, the feedback current (I_F) that would normally be applied to the SQUID loop is fed back via RF through r_s until the voltage drop across r_s is equal to V_I and there is no net current through the SQUID. V_O measures the voltage drop across RF and r_s with $V_I = V_O r_s / (R_F + r_s)$. The voltage gain of the system is determined by the ratio of R_F / r_s . Typical values for R_F and r_s are 3 and $30 \mu\Omega$, respectively, giving a voltage gain of

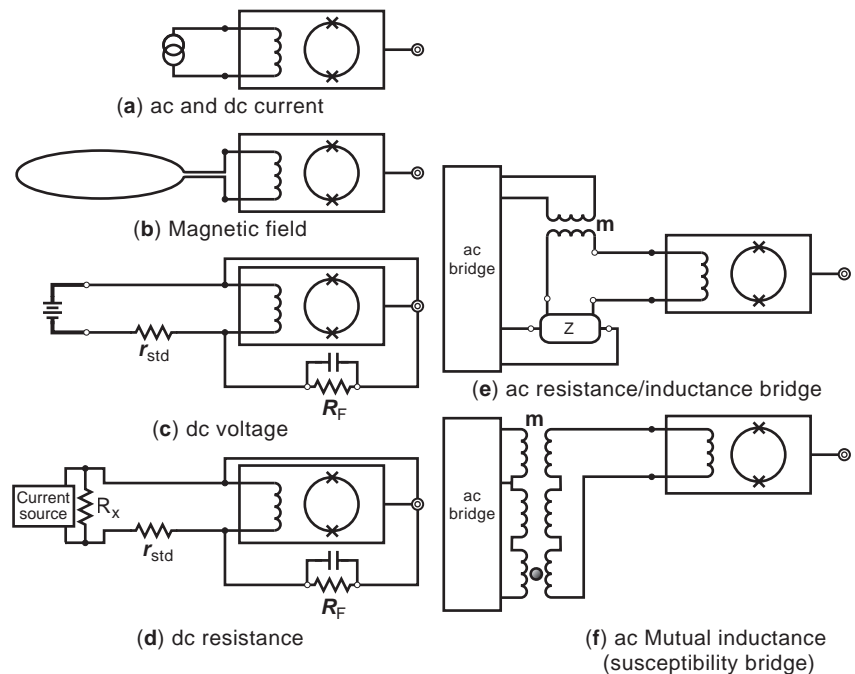

Figure 11. (a) ac and dc current, (b) magnetic field, (c) dc voltage, (d) dc resistance, (e) ac resistance/inductance bridge, and (f) ac mutual inductance (susceptibility bridge).

Table 1. Typical Capabilities of SQUID-based Instruments

Measurement	Sensitivity
Current [Fig. 11(a)]	10^{-12} A/ $\sqrt{\text{Hz}}$
Magnetic fields [Fig. 11(b)]	10^{-15} T/ $\sqrt{\text{Hz}}$
dc voltage [Fig. 11(c)]	10^{-14} V
dc resistance [Fig. 11(d)]	10^{-12} Ω
Mutual/self inductance [Fig. 11(e)]	10^{-10} H
Magnetic moment [Fig. 11(f)]	10^{-10} emu

10^8 . The standard resistor r_s is typically at 4.2 K. The voltage source, however, may be at a completely different temperature.

The input noise of a SQUID picovoltmeter ($\sim 10^{-14}$ V) is a function of the source resistance and temperature ($R \propto T_s$), the inherent voltage noise (due to r_s), and the inherent current noise of the SQUID. Measurement of the Johnson noise in a resistor ($\langle V^2 \rangle = 4k_B TR \Delta f$ where Δf is the bandwidth of the measurement) can determine absolute temperature. Commercially available LTS SQUIDS have equivalent device temperatures

With the addition of an appropriate current source [Fig. 11(d)], it is possible to measure resistance. Resolutions of $10^{-11} \Omega$ can be achieved for $R_x < 10^{-2} \Omega$. Other applications of picovoltmeters include measurements of thermopower, thermal electromotive forces (emfs) (thermocouples), and infrared bolometers.

5.1.3. Ac Susceptibility [4]. The SQUID can also be the null detector in an ac bridge circuit (Fig. 13) to measure both resistive and reactive components of a complex impedance. The unknown impedance Z is excited by a current generated by an oscillator voltage, which is attenuated by a precision ratio transformer λ . The difference between the voltage developed across the unknown impedance Z and that developed in the secondary of a nulling mutual inductor m is applied to the input of the SQUID circuit. The primary current in m is proportional to the oscillator voltage and defined by the setting of the ratio transformer α . An additional reactive current is supplied by a second ratio transformer β , which causes the

Figure 13. Block diagram of ac bridge.

primary current to be passed through a capacitor rather than a resistor, thus generating a 90° phase shift in the voltage applied to m . The amplified off-balance signal, which appears at the output of the SQUID control electronics, can be displayed by means of a lock-in amplifier tuned to the oscillator frequency.

As mentioned earlier, the sensitivity is limited inherently by Johnson noise in the resistive components of the unknown (including the potential connections) and by the device noise of the SQUID sensor. Assuming $I_N \approx 1$ pA/ $\sqrt{\text{Hz}}$, such a system is capable of measuring R between 10^{-10} to 0.5Ω and L (self and mutual) between 10^{-12} and 10^{-3} H. Using a current comparator as the bridge excitation V , a 0.1 ppm resistance bridge can be constructed.

5.1.4. SQUID Magnetometer/Susceptometers [16]. Instead of using a secondary ac excitation coil [Fig. 11(f)], a dc field can magnetize samples. Typically the field is fixed, and the sample is moved into the detection coil's region of sensitivity. The change in detected magnetization is directly proportional to the magnetic moment of the sample. Because of the superconducting nature of SQUID input circuits, true dc response is possible.

Commonly referred to as SQUID magnetometers, these systems are properly SQUID susceptometers. They have a homogeneous superconducting magnet to create a very uniform field over the entire sample measuring region and the superconducting pick-up loops. The magnet induces a moment allowing a measurement of magnetic susceptibility. The superconducting detection loop array is rigidly mounted in the center of the magnet [17]. This array is configured as a gradient coil to reject external noise sources. The detection coil geometry determines what mathematical algorithm calculates the net magnetization. Oppositely paired Helmholtz, first and second derivatives, have all been successfully used. Coupling two axial channels of differing gradient order can significantly improve noise rejection.

Sensitivities of 10^{-8} emu have been achieved, even at applied fields of 9 T. Placement of secondary excitation

Figure 12. Block diagram of SQUID picovolt measuring system. Negative feedback is applied to the cryogenic input circuit through the voltage divider formed by R_F and r_s .

coils can allow ac susceptibility measurements to be made in the presence of a significant dc bias field. Variable temperature capability (1.7 K to 800 K) is achieved by placing a reentrant cryostat within the detection coils.

5.1.5. Other Laboratory Applications. NMR signals [18] can be measured by placing a sample (e.g., protons or ^{19}F) in the center of SQUID detection coils and either sweeping the external field or applying an RF excitation to the sample. The same experimental concept can measure electron paramagnetic resonance (EPR) signals. SQUIDs have been used for more esoteric applications including temperature measurements with resolution near 10 K to 12 K. SQUIDs have also measured position for gravity wave detectors with sub-Ångstrom resolution and tests of Einstein's General Theory of Relativity. Because SQUID magnetometers are vector devices, they can detect rotations better than 10^{-3} arc-seconds in the earth's magnetic field. SQUIDs have been used in searches for dark matter such as Weak Interacting Massive Particles (WIMPs) along with attempts at detecting magnetic monopoles and free quarks.

5.2. Geophysical Applications [19,20]

SQUID magnetometers measure the earth's magnetic field (Fig. 9) at frequencies ranging between 1 kHz and 10^{-4} Hz. A technique known as magnetotellurics [21] can determine the electrical conductivity distribution of the earth's crust by measuring the earth's electric and magnetic field. Because the earth is a good electrical conductor compared with the air, the electrical field generated in the ionosphere (as a result of solar wind) is reflected at the earth's surface, with components of both the electric and magnetic field decaying as they penetrate into the earth. The decay length or skin depth $\delta = 500\sqrt{\rho\tau}$, where ρ is the electrical resistivity of the earth and τ is the period of the electromagnetic wave.

In magnetotellurics, the electric field (as a function of frequency) is related to the magnetic field via an impedance tensor where $\mathbf{E}(\omega) = \mathbb{Z}\mathbf{H}(\omega)$. The impedance tensor \mathbb{Z} contains four complex elements Z_{xx} , Z_{xy} , Z_{yx} , and Z_{yy} and is related to the resistivity by $\rho_{ij} = 0.2|Z_{ij}(\omega)|^2\tau$ where \mathbb{Z} has units of mV/km-nT.

Magnetic anomaly detection uses the five unique spatial components of $\nabla\mathbf{B}$ to locate a magnetic dipole uniquely. This has potential uses in mineralogical surveys and detection of unexploded ordnance.

5.3. Nondestructive Test and Evaluation [22,23]

Magnetic-sensing techniques such as eddy current testing have been used for many years to detect flaws in structures. A major limitation on their sensitivity is the skin depth [Eq. (7)] of metallic materials. Because SQUID sensors have true dc response and superior sensitivity, they can see "deeper" into metallic structures. dc response also means that they can detect remnant magnetization—without the need for externally applied magnetic fields. Their flat frequency response and zero phase distortion allows for a wide range of applications. One potential application of SQUIDs is in detection of stress or corrosion in reinforcing rods used in bridges, aircraft runways, or

buildings. Table 2 shows some of the measurement techniques that can be used with SQUID sensors.

SQUID magnetometers have made noncontact measurements of timing circuits [24]—one instrument has better than $10\ \mu\text{m}$ resolution [25]. Such instruments with megahertz bandwidths could be used for circuit board and integrated circuit (IC) mapping.

5.4. Medical Applications of SQUIDs [23,26–29]

Bioelectric signals as a diagnostic tool is well known in medicine [e.g., the electrocardiogram (ECG) for the heart and the electroencephalogram (EEG) for the brain]. The electrical activity that produces the surface electrical activity that is measured by EEG and ECG also produces magnetic fields. The analogous magnetic measurements are known as the magnetocardiogram (MCG) and the magnetoencephalogram (MEG). Other physiological processes also generate electrical activity with analogous magnetic fields (Fig. 14).

Magnetic fields from active electrical sources in the body can be measured passively and external to the body by placing the magnetometer in close proximity to the body's surface. It has been shown that a population of neurons in the brain can be modeled as a current dipole that generates

a well-defined magnetic field profile. Mapping of these field profiles can infer the location of the equivalent active dipole site region to within millimeters. Using evoked response techniques, the location of signal pathways and information processing centers in the brain can be mapped at different delay times (latencies) after the stimulus.

There are also magnetic measurements for which there are no electrical analogs. These are measurements of static magnetic fields produced by ferromagnetic materials ingested into the body and measurements of the magnetic susceptibility of materials in the body. In particular, information on the quantity and depth of diamagnetic or paramagnetic materials (such as iron stored in the liver) can be obtained by using magnetizing and detection coils of differing sizes in the same instrument and measuring the induced field as a function of distance. This technique is already being used to monitor patients suffering from iron overload diseases such as thalassemia and hemochromatosis.

The development of the SQUID has allowed the development of noninvasive clinical measurements of biomagnetic fields. Gradiometers can allow measurements to be made in unshielded environments at sensitivities below $20 \text{ fT}/\sqrt{\text{Hz}}$. Typically, however, neuromagnetic measurements are made in room-sized MSRs that will allow measurements of the magnetic field of the brain over the entire surface of the head (>150 positions simultaneously). Table 3 gives some of the areas in which SQUID magnetometers are currently being used in medical research.

STABILITY OF NONLINEAR SYSTEMS

GUANRONG CHEN
City University of Hong Kong
Kowloon, Hong Kong, China

1. INTRODUCTION

A *nonlinear system* refers to a set of nonlinear equations (algebraic, difference, differential, integral, functional, or abstract operator equations, or a combination of some of these) used to describe a physical device or process that otherwise cannot be clearly defined by a set of linear equations of any kind. *Dynamical system* is used as a synonym for mathematical or physical system when the describing equations represent evolution of a solution with time and, sometimes, with control inputs and/or other varying parameters as well.

The theory of nonlinear dynamical systems, or *nonlinear control systems* if control inputs are involved, has been greatly advanced since the nineteenth century. Today, nonlinear control systems are used to describe a great variety of scientific and engineering phenomena ranging from social, life, and physical sciences to engineering and technology. This theory has been applied to a broad spectrum of problems in physics, chemistry, mathematics, biology, medicine, economics, and various engineering disciplines.

Stability theory plays a central role in system engineering, especially in the field of control systems and automation, with regard to both dynamics and control. Stability of a dynamical system, with or without control and disturbance inputs, is a fundamental requirement for its practical value, particularly in most real-world applications. Roughly speaking, stability means that the system outputs and its internal signals are bounded within admissible limits (the so-called bounded-input/bounded-output stability) or, sometimes more strictly, the system outputs tend to an equilibrium state of interest (the so-called asymptotic stability). Conceptually, there are different kinds of stabilities, among which three basic notions are the main concerns in nonlinear dynamics and control systems: the stability of a system with respect to its equilibria, the orbital stability of a system output trajectory, and the structural stability of a system itself.

The basic concept of stability emerged from the study of an equilibrium state of a mechanical system, dated back to as early as 1644, when E. Torricelli studied the equilibrium of a rigid body under the natural force of gravity. The classical stability theorem of G. Lagrange, formulated in 1788, is perhaps the best known result about stability of conservative mechanical systems, which states that if the potential energy of a conservative system, currently at the position of an isolated equilibrium and perhaps subject to some simple constraints, has a minimum, then this equi-

librium position of the system is stable [23]. The evolution of the fundamental concepts of system and trajectory stabilities then went through a long history, with many fruitful advances and developments, until the celebrated Ph.D. thesis of A. M. Lyapunov, *The General Problem of Motion Stability*, finished in 1892 [21]. This monograph is so fundamental that its ideas and techniques are virtually leading all kinds of basic research and applications regarding stabilities of dynamical systems today. In fact, not only dynamical behavior analysis in modern physics but also controllers design in engineering systems depend on the principles of Lyapunov's stability theory. This article is devoted to a brief description of the basic stability theory, criteria, and methodologies of Lyapunov, as well as a few related important stability concepts, for nonlinear dynamical systems.

2. NONLINEAR SYSTEM PRELIMINARIES

2.1. Nonlinear Control Systems

A continuous-time nonlinear control system is generally described by a differential equation of the form

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t; \mathbf{u}), \quad t \in [t_0, \infty) \quad (1)$$

where $\mathbf{x} = \mathbf{x}(t)$ is the *state* of the system belonging to a (usually bounded) region $\Omega_{\mathbf{x}} \subset \mathbf{R}^n$, \mathbf{u} is the *control* input vector belonging to another (usually bounded) region $\Omega_{\mathbf{u}} \subset \mathbf{R}^m$ (often, $m \leq n$), and \mathbf{f} is a Lipschitz or continuously differentiable nonlinear function, so that the system has a unique solution for each admissible control input and suitable initial condition $\mathbf{x}(t_0) = \mathbf{x}_0 \in \Omega_{\mathbf{x}}$. To indicate the time evolution and the dependence on the initial state \mathbf{x}_0 , the *trajectory* (or *orbit*) of a system state $\mathbf{x}(t)$ is sometimes denoted as $\varphi_t(\mathbf{x}_0)$.

In control system (1), the initial time used is $t_0 \geq 0$, unless otherwise indicated. The entire space \mathbf{R}^n , to which the system states belong, is called the *state space*. Associated with the control system (1), there usually is an *observation* or *measurement* equation

$$\mathbf{y} = \mathbf{g}(\mathbf{x}, t; \mathbf{u}) \quad (2)$$

where $\mathbf{y} = \mathbf{y}(t) \in \mathbf{R}^\ell$ is the *output* of the system, $1 \leq \ell \leq n$, and \mathbf{g} is a continuous or smooth nonlinear function. When both $n, \ell > 1$, the system is called a *multiinput/multioutput* (MIMO) system; while if $n = \ell = 1$, it is called a *single-input/single-output* (SISO) system. MISO and SIMO systems are similarly defined.

In the discrete-time setting, a nonlinear control system is described by a difference equation of the form

$$\begin{cases} \mathbf{x}_{k+1} = \mathbf{f}(\mathbf{x}_k, k; \mathbf{u}_k) \\ \mathbf{y}_k = \mathbf{g}(\mathbf{x}_k, k; \mathbf{u}_k), \end{cases} \quad k = 0, 1, \dots \quad (3)$$

where all notations are similarly defined. This article usually discusses only the control system (1), or the first equation of (3). In this case, the system state \mathbf{x} is also considered as the system output for simplicity.

A special case of system (1), with or without control, is said to be *autonomous* if the time variable t does not appear separately (independently) from the state vector in the system function \mathbf{f} . For example, with a state feedback control $\mathbf{u}(t) = \mathbf{h}(\mathbf{x}(t))$, this often is the situation. In this case, the system is usually written as

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbf{R}^n \tag{4}$$

Otherwise, as (1) stands, the system is said to be *nonautonomous*. The same terminology may be applied in the same way to discrete-time systems, although they may have different characteristics.

An *equilibrium*, or *fixed point*, of system (4), if it exists, is a solution, \mathbf{x}^* , of the algebraic equation

$$\mathbf{f}(\mathbf{x}^*) = 0 \tag{5}$$

It then follows from (4) and (5) that $\dot{\mathbf{x}}^* = 0$, which means that an equilibrium of a system must be a constant state. For the discrete-time case, an equilibrium of system

$$\mathbf{x}_{k+1} = \mathbf{f}(\mathbf{x}_k), \quad k = 0, 1, \dots \tag{6}$$

is a solution, if it exists, of equation

$$\mathbf{x}^* = \mathbf{f}(\mathbf{x}^*) \tag{7}$$

An equilibrium is *stable* if some nearby trajectories of the system states, starting from various initial states, approach it; it is *unstable* if some nearby trajectories move away from it. The concept of system stability with respect to an equilibrium will be precisely introduced in Section 3.

A control system is *deterministic* if there is a unique consequence to every change of the system parameters or initial states. It is *random* or *stochastic*, if there is more than one possible consequence for a change in its parameters or initial states according to some probability distribution [6]. This article deals only with deterministic systems.

2.2. Hyperbolic Equilibria and Their Manifolds

Consider the autonomous system (4). The Jacobian of this system is defined by

$$J(\mathbf{x}) = \frac{\partial \mathbf{f}}{\partial \mathbf{x}} \tag{8}$$

Clearly, this is a matrix-valued function of time. If the Jacobian is evaluated at a constant state, say, \mathbf{x}^* or \mathbf{x}_0 , then it becomes a constant matrix determined by \mathbf{f} and \mathbf{x}^* or \mathbf{x}_0 .

An equilibrium \mathbf{x}^* of system (4) is said to be *hyperbolic* if all eigenvalues of the system Jacobian, evaluated at this equilibrium, have nonzero real parts.

For a p -periodic solution of system (4), $\tilde{\mathbf{x}}(t)$, with a fundamental period $p > 0$, let $J(\tilde{\mathbf{x}}(t))$ be its Jacobian evaluated

at $\tilde{\mathbf{x}}(t)$. Then this Jacobian is also p -periodic:

$$J(\tilde{\mathbf{x}}(t+p)) = J(\tilde{\mathbf{x}}(t)) \quad \text{for all } t \in [t_0, \infty)$$

In this case, there always exist a p -periodic nonsingular matrix $M(t)$ and a constant matrix Q such that the fundamental solution matrix associated with the Jacobian $J(\tilde{\mathbf{x}}(t))$ is given by [4]

$$\Phi(t) = M(t)e^{tQ}$$

Here, the fundamental matrix $\Phi(t)$ consists of, as its columns, n linearly independent solution vectors of the linear equation $\dot{\mathbf{x}} = J(\tilde{\mathbf{x}}(t))\mathbf{x}$, with $\mathbf{x}(t_0) = \mathbf{x}_0$.

In the preceding, the eigenvalues of the constant matrix e^{pQ} are called the *Floquet multipliers* of the Jacobian. The p -periodic solution $\tilde{\mathbf{x}}(t)$ is called a *hyperbolic periodic orbit* of the system if all its corresponding Floquet multipliers have nonzero real parts.

Next, let \mathcal{D} be a neighborhood of an equilibrium, \mathbf{x}^* , of the autonomous system (4). A *local stable* and *local unstable manifold* of \mathbf{x}^* is defined by

$$W_{\text{loc}}^s(\mathbf{x}^*) = \{\mathbf{x} \in \mathcal{D} \mid \varphi_t(\mathbf{x}) \in \mathcal{D} \ \forall t \geq t_0 \text{ and } \varphi_t(\mathbf{x}) \rightarrow \mathbf{x}^* \text{ as } t \rightarrow \infty\} \tag{9}$$

and

$$W_{\text{loc}}^u(\mathbf{x}^*) = \{\mathbf{x} \in \mathcal{D} \mid \varphi_t(\mathbf{x}) \in \mathcal{D} \ \forall t \leq t_0 \text{ and } \varphi_t(\mathbf{x}) \rightarrow \mathbf{x}^* \text{ as } t \rightarrow -\infty\} \tag{10}$$

respectively. Furthermore, a *stable* and *unstable manifold* of \mathbf{x}^* is defined by

$$W^s(\mathbf{x}^*) = \{\mathbf{x} \in \mathcal{D} \mid \varphi_t(\mathbf{x}) \cap W_{\text{loc}}^s(\mathbf{x}^*) \neq \phi\} \tag{11}$$

and

$$W^u(\mathbf{x}^*) = \{\mathbf{x} \in \mathcal{D} \mid \varphi_t(\mathbf{x}) \cap W_{\text{loc}}^u(\mathbf{x}^*) \neq \phi\} \tag{12}$$

respectively, where ϕ denotes the empty set. For example, the autonomous system

$$\begin{cases} \dot{x} = y \\ \dot{y} = x(1 - x^2) \end{cases}$$

has a hyperbolic equilibrium $(x^*, y^*) = (0, 0)$. The local stable and unstable manifolds of this equilibrium are illustrated by Fig. 1a, and the corresponding stable and unstable manifolds are visualized by Fig. 1b.

A hyperbolic equilibrium only has stable and/or unstable manifolds since its associated Jacobian has only stable and/or unstable eigenvalues. The dynamics of an autonomous system in a neighborhood of a hyperbolic equilibrium is quite simple—it has either stable (convergent) or unstable (divergent) properties. Therefore, complex dynamical behaviors such as chaos are seldom associated with isolated hyperbolic equilibria or isolated hyperbolic

Figure 1. Stable and unstable manifolds.

periodic orbits [7,11,15] (see Theorem 16, below); they generally are confined within the *center manifold*, $W^c(x^*)$, where $\dim(W^s) + \dim(W^c) + \dim(W^u) = n$.

2.3. Open-Loop and Closed-Loop Systems

Let S be an MIMO system, which can be linear or nonlinear, continuous-time or discrete-time, deterministic or stochastic, or any well-defined input–output map. Let U and Y be the sets (sometimes, spaces) of the admissible input and corresponding output signals, respectively, both defined on the time domain $\mathcal{D} = [a, b]$, $-\infty \leq a < b \leq \infty$ (for control systems, usually $a = t_0 = 0$ and $b = \infty$). This simple relation is described by an open-loop map

$$S : \mathbf{u} \rightarrow \mathbf{y} \text{ or } \mathbf{y}(t) = S(\mathbf{u}(t)) \tag{13}$$

and its block diagram is shown in Fig. 2. Actually, every control system described by a differential or difference equation can be viewed as a map in this form. But, in such a situation, the map S can be implicitly defined only via the equation and initial conditions.

In the control system (1) or (3), if the control inputs are functions of the state vectors, $\mathbf{u} = \mathbf{h}(\mathbf{x}; t)$, then the control system can be implemented via a closed-loop configuration. A typical closed-loop system is shown in Fig. 3, where usually S_1 is the plant (described by \mathbf{f}) and S_2 is the controller (described by \mathbf{h}); yet they can be reversed.

2.4. Norms of Functions and Operators

This article deals only with finite-dimensional systems. For an n -dimensional vector-valued functions, $\mathbf{x}(t) = [x_1(t) \dots x_n(t)]^T$ where superscript “T” denotes transpose, let $\|\cdot\|$ and $\|\cdot\|_p$ denote its *Euclidean norm* and *L_p norm*, defined respectively by the “length”

$$\|\mathbf{x}(t)\| = \sqrt{x_1^2(t) + \dots + x_n^2(t)}$$

and

$$\|\mathbf{x}\|_p = \left(\int_a^b \|\mathbf{x}(t)\|^p dt \right)^{1/p}, \quad 1 \leq p < \infty$$

$$\|\mathbf{x}\|_\infty = \text{ess sup}_{\substack{a \leq t \leq b \\ 1 \leq i \leq n}} |x_i(t)|$$

Here, a few remarks are in order:

1. The term “ess sup” means “essential supremum” (i.e., the supremum except perhaps over a set of

Figure 2. The block diagram of an open-loop system.

measure zero). For a piecewise continuous function $f(t)$, actually

$$\text{ess sup}_{a \leq t \leq b} |f(t)| = \sup_{a \leq t \leq b} |f(t)|$$

2. The main difference between the “sup” and the “max” is that $\max |f(t)|$ is attainable but $\sup |f(t)|$ may not. For example, $\max_{0 \leq t < \infty} |\sin(t)| = 1$ but $\sup_{0 \leq t < \infty} |1 - e^{-t}| = 1$.
3. The difference between the Euclidean norm and the L_p norms is that the former is a function of time but the latter are all constants.
4. For a finite-dimensional vector $\mathbf{x}(t)$, with $n < \infty$, all the L_p norms are equivalent in the sense that for any $p, q \in [1, \infty]$, there exist two positive constants α and β such that

$$\alpha \|\mathbf{x}\|_p \leq \|\mathbf{x}\|_q \leq \beta \|\mathbf{x}\|_p$$

For the input–output map in Eq. (13), the so-called operator norm of the map S is defined to be the maximum gain from all possible inputs over the domain of the map to their corresponding outputs. More precisely, the *operator norm* of the map S in (13) is defined by

$$\|S\| = \sup_{\substack{\mathbf{u}_1, \mathbf{u}_2 \in U \\ \mathbf{u}_1 \neq \mathbf{u}_2}} \frac{\|\mathbf{y}_1 - \mathbf{y}_2\|_Y}{\|\mathbf{u}_1 - \mathbf{u}_2\|_U} \tag{14}$$

where $\mathbf{y}_i = S(\mathbf{u}_i) \in Y$, $i = 1, 2$, and $\|\cdot\|_U$ and $\|\cdot\|_Y$ are the norms of the functions defined on the input–output sets (or spaces) U and Y , respectively.

3. LYAPUNOV, ORBITAL, AND STRUCTURAL STABILITIES

Three different types of stabilities, namely, the Lyapunov stability of a system with respect to its equilibria, the orbital stability of a system output trajectory, and the structural stability of a system itself, are of fundamental importance in the studies of nonlinear dynamics and control systems.

Figure 3. A typical closed-loop control system.

Roughly speaking, the Lyapunov stability of a system with respect to its equilibrium of interest is about the behavior of the system outputs toward the equilibrium state—wandering nearby and around the equilibrium (stability in the sense of Lyapunov) or gradually approaches it (asymptotic stability); the orbital stability of a system output is the resistance of the trajectory to small perturbations; the structural stability of a system is the resistance of the system structure against small perturbations [3,13,16,17,19,20,23,25,26,29,35]. These three basic types of stabilities are introduced in this section, for dynamical systems without explicitly involving control inputs.

Consider the general nonautonomous system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbf{R}^n \tag{15}$$

where the control input $\mathbf{u}(t) = \mathbf{h}(\mathbf{x}(t), t)$, if it exists [see system (1)], has been combined into the system function \mathbf{f} for simplicity of discussion. Without loss of generality, assume that the origin $\mathbf{x} = 0$ is the system equilibrium of interest. Lyapunov stability theory concerns various stabilities of the system orbits with respect to this equilibrium. When another equilibrium is discussed, the new equilibrium is first shifted to zero by a change of variables, and then the transformed system is studied in the same way.

3.1. Stability in the Sense of Lyapunov

System (15) is said to be *stable in the sense of Lyapunov* with respect to the equilibrium $\mathbf{x}^* = 0$, if for any $\varepsilon > 0$ and any initial time $t_0 \geq 0$, there exists a constant, $\delta = \delta(\varepsilon, t_0) > 0$, such that

$$\|\mathbf{x}(t_0)\| < \delta \Rightarrow \|\mathbf{x}(t)\| < \varepsilon \quad \text{for all } t \geq t_0 \tag{16}$$

This stability is illustrated by Fig. 4.

It should be emphasized that the constant δ generally depends on both ε and t_0 . It is particularly important to point out that, unlike autonomous systems, one cannot simply fix the initial time $t_0 = 0$ for a nonautonomous system in a general discussion of its stability. For example, consider the following linear time-varying system with a discontinuous coefficient:

$$\dot{x}(t) = \frac{1}{1-t}x(t), \quad x(t_0) = x_0$$

Figure 4. Geometric meaning of stability in the sense of Lyapunov.

It has an explicit solution

$$x(t) = x_0 \frac{1-t_0}{1-t}, \quad 0 \leq t_0 \leq t < \infty$$

which is stable in the sense of Lyapunov about the equilibrium $x^* = 0$ over the entire time domain $[0, \infty)$ if and only if $t_0 = 1$. This shows that the initial time, t_0 , does play an important role in the stability of a nonautonomous system.

The above-defined stability, in the sense of Lyapunov, is said to be *uniform* with respect to the initial time, if the existing constant $\delta = \delta(\varepsilon)$ is indeed independent of t_0 over the entire time interval $[0, \infty)$. According to the discussion above, uniform stability is defined only for nonautonomous systems since it is not needed for autonomous systems (for which it is always uniform with respect to the initial time).

3.2. Asymptotic and Exponential Stabilities

System (15) is said to be *asymptotically stable* about its equilibrium $\mathbf{x}^* = 0$, if it is stable in the sense of Lyapunov and, furthermore, there exists a constant, $\delta = \delta(t_0) > 0$, such that

$$\|\mathbf{x}(t_0)\| < \delta \Rightarrow \|\mathbf{x}(t)\| \rightarrow 0 \quad \text{as } t \rightarrow \infty \tag{17}$$

This stability is visualized by Fig. 5.

The asymptotic stability is said to be *uniform* if the existing constant δ is independent of t_0 over $[0, \infty)$, and is said to be *global* if the convergence, $\|\mathbf{x}\| \rightarrow 0$, is independent of the initial state $\mathbf{x}(t_0)$ over the entire spatial domain on which the system is defined (e.g., when $\delta = \infty$). If, furthermore

$$\|\mathbf{x}(t_0)\| < \delta \Rightarrow \|\mathbf{x}(t)\| \leq ce^{-\sigma t} \tag{18}$$

for two positive constants c and σ , then the equilibrium is said to be *exponentially stable*. The exponential stability is visualized by Fig. 6.

Clearly, exponential stability implies asymptotic stability, and asymptotic stability implies the stability in the sense of Lyapunov, but the reverse need not be true. For illustration, if a system has output trajectory $x_1(t) = x_0 \sin(t)$, then it is stable in the sense of Lyapunov about 0, but is not asymptotically stable; a system with output

Figure 5. Geometric meaning of the asymptotic stability.

Figure 6. Geometric meaning of the exponential stability.

trajectory $x_2(t) = x_0(1+t-t_0)^{-1}$ is asymptotically stable (so also is stable in the sense of Lyapunov) if $t_0 < 1$ but is not exponentially stable about 0; however, a system with $x_3(t) = x_0e^{-t}$ is exponentially stable (hence, is both asymptotically stable and stable in the sense of Lyapunov).

3.3. Orbital Stability

The orbital stability differs from the Lyapunov stabilities in that it concerns with the stability of a system output (or state) trajectory under small external perturbations.

Let $\varphi_t(\mathbf{x}_0)$ be a p -periodic solution, $p > 0$, of the autonomous system

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbf{R}^n \quad (19)$$

and let Γ represent the closed orbit of $\varphi_t(\mathbf{x}_0)$ in the state space, namely,

$$\Gamma = \{\mathbf{y} \mid \mathbf{y} = \varphi_t(\mathbf{x}_0), \quad 0 \leq t < p\}$$

If, for any $\varepsilon > 0$, there exists a constant $\delta = \delta(\varepsilon) > 0$ such that for any \mathbf{x}_0 satisfying

$$d(\mathbf{x}_0, \Gamma) := \inf_{\mathbf{y} \in \Gamma} \|\mathbf{x}_0 - \mathbf{y}\| < \delta$$

the solution of the system, $\varphi_t(\mathbf{x}_0)$, satisfies

$$d(\varphi_t(\mathbf{x}_0), \Gamma) < \varepsilon, \quad \text{for all } t \geq t_0$$

then this p -periodic solution trajectory, $\varphi_t(\mathbf{x}_0)$, is said to be *orbitally stable*.

Orbital stability is visualized by Fig. 7. For a simple example, a stable periodic solution, particularly a stable equilibrium of a system is orbitally stable. This is because all nearby trajectories approach it and, as such, it becomes a nearby orbit after a small perturbation and so will move back to its original position (or stay nearby). On the contrary, unstable and semistable (saddle-type of) periodic orbits are orbitally unstable.

Figure 7. Geometric meaning of the orbital stability.

A more precise concept of orbital stability is given in the sense of Zhukovskij [37].

A solution $\varphi_t(\mathbf{x}_0)$ of system (19) is said to be stable in the sense of Zhukovskij, if for any $\varepsilon > 0$, there exists a $\delta = \delta(\varepsilon) > 0$ such that for any $\mathbf{y}_0 \in B_\delta(\mathbf{x}_0)$, a ball of radius δ centered at \mathbf{x}_0 , there exist two functions, $\tau_1 = \tau_1(t)$ and $\tau_2 = \tau_2(t)$, satisfying

$$\|\mathbf{x}_{\tau_1}(\mathbf{x}_0) - \mathbf{x}_{\tau_2}(\mathbf{x}_0)\| < \varepsilon$$

for all $t \geq t_0$, where τ_1 and τ_2 are homeomorphisms (i.e., a continuous map whose inverse exists and is also continuous) from $[0, \infty)$ to $[0, \infty)$ with $\tau_1(0) = \tau_2(0) = 0$.

Furthermore, a Zhukovskij stable solution $\varphi_t(\mathbf{x}_0)$ of system (19) is said to be asymptotically stable in the sense of Zhukovskij, if for any $\varepsilon > 0$, there exists a $\delta = \delta(\varepsilon) > 0$ such that for any $\mathbf{y}_0 \in B_\delta(\mathbf{x}_0)$, a ball of radius δ centered at \mathbf{x}_0 , there exist two functions, $\tau_1 = \tau_1(t)$ and $\tau_2 = \tau_2(t)$, satisfying

$$\|\mathbf{x}_{\tau_1}(\mathbf{x}_0) - \mathbf{x}_{\tau_2}(\mathbf{x}_0)\| \rightarrow 0$$

as $t \rightarrow \infty$, where τ_1 and τ_2 are homeomorphisms from $[0, \infty)$ to $[0, \infty)$ with $\tau_1(0) = \tau_2(0) = 0$.

It can be verified that (asymptotic) Zhukovskij stability implies (asymptotic) Lyapunov stability about an equilibrium. However, the converse may not be true. Moreover, these two types of stabilities are equivalent if the orbit $\varphi_t(\mathbf{x}_0)$ is an equilibrium of the system.

3.4. Structural Stability

Two systems are said to be *topologically orbitally equivalent*, if there exists a homeomorphism that transforms the family of trajectories of the first system to that of the second while preserving their motion directions. Roughly, this means that the geometrical pictures of the orbit families of the two systems are similar (no one has extra knots, sharp corners, bifurcating branches, etc.). For instance, systems $\dot{x} = x$ and $\dot{x} = 2x$ are topologically orbitally equivalent, but are not so between $\dot{x} = x$ and $\dot{x} = \sqrt{x}$. These three system trajectories are shown in Fig. 8.

Return to the autonomous system (19). If the dynamics of the system in the state space changes radically, for example by the appearance of a new equilibrium or a new periodic orbit, due to small external perturbations, then the system is considered to be structurally unstable.

Figure 8. Trajectories of three systems for comparison: (a) $\dot{x} = x$; (b) $\dot{x} = 2x$; (c) $\dot{x} = \sqrt{x}$.

To be more precise, consider the following set of functions:

$$\mathcal{S} = \left\{ \mathbf{g}(\mathbf{x}) \mid \|\mathbf{g}(\mathbf{x})\| < \infty, \left\| \frac{\partial \mathbf{g}(\mathbf{x})}{\partial \mathbf{x}} \right\| < \infty \text{ for all } \mathbf{x} \in \mathbf{R}^n \right\}$$

If, for any $g \in \mathcal{S}$, there exists an $\varepsilon > 0$ such that the orbits of the two systems

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) \text{ and } \dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \varepsilon \mathbf{g}(\mathbf{x})$$

are topologically orbitally equivalent, then the autonomous system (19), namely, the first (unperturbed) system above, is said to be *structurally stable*.

For example, $\dot{x} = x$ is structurally stable but $\dot{x} = x^2$ is not, in a neighborhood of the origin. This is because when the second system is slightly perturbed, to become, say, $\dot{x} = x^2 + \varepsilon$, where $\varepsilon > 0$, then the resulting system has two equilibria, $x_1^* = \sqrt{\varepsilon}$ and $x_2^* = -\sqrt{\varepsilon}$, which has more numbers of equilibria than the original system that possesses only one, $x^* = 0$.

4. VARIOUS STABILITY THEOREMS

Consider the general nonautonomous system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbf{R}^n \tag{20}$$

where $\mathbf{f}: \mathcal{D} \times [0, \infty) \rightarrow \mathbf{R}^n$ is continuously differentiable in a neighborhood of the origin, $\mathcal{D} \subseteq \mathbf{R}^n$, with a given initial state $\mathbf{x}_0 \in \mathcal{D}$. Again, without loss of generality, assume that $\mathbf{x}^* = 0$ is a system equilibrium of interest.

4.1. Lyapunov Stability Theorems

First, for the autonomous system (19), an important special case of (20), with a continuously differentiable $\mathbf{f}: \mathcal{D} \rightarrow \mathbf{R}^n$, the following criterion of stability, called the *first (or indirect) method of Lyapunov*, is very convenient to use.

Theorem 1 (First Method of Lyapunov: For Continuous-Time Autonomous Systems). Let $J = [\partial \mathbf{f} / \partial \mathbf{x}]_{\mathbf{x} = \mathbf{x}^* = 0}$ be the system Jacobian evaluated at the zero equilibrium of system (19). If all the eigenvalues of J have a negative real part, then the system is asymptotically stable about $\mathbf{x}^* = 0$.

First, note that this and the following Lyapunov theorems apply to linear systems as well, for linear systems are merely a special case of nonlinear systems. When $\mathbf{f}(\mathbf{x}) = A\mathbf{x}$, the linear time-invariant system $\dot{\mathbf{x}} = A\mathbf{x}$ has the only equilibrium $\mathbf{x}^* = 0$. If A has all eigenvalues with negative real parts, Theorem 1 implies that the system is asymptotically stable about its equilibrium since the system Jacobian is simply $J = A$. This is consistent with the familiar linear stability results.

Note also that the region of asymptotic stability given by Theorem 1 is local, which can be quite large for some nonlinear systems but may be very small for some others. However, there is no general criterion for determining the

boundaries of such local stability regions when this and the following Lyapunov methods are applied.

Moreover, it is important to note that this theorem cannot be applied to a *general* nonautonomous system, since for general nonautonomous systems this theorem is neither necessary nor sufficient [36]. A simple counterexample is the following linear time-varying system [17,34]:

$$\dot{\mathbf{x}}(t) = \begin{bmatrix} -1 + 1.5 \cos^2(t) & 1 - 1.5 \sin(t) \cos(t) \\ -1 - 1.5 \sin(t) \cos(t) & -1 + 1.5 \sin^2(t) \end{bmatrix} \mathbf{x}(t)$$

This system has eigenvalues $\lambda_{1,2} = -0.25 \pm j0.25\sqrt{7}$, both having negative real parts and being independent of the time variable t . If this theorem is used to judge the system, the conclusion would be that the system is asymptotically stable about its equilibrium 0. However, the solution of this system is

$$\mathbf{x}(t) = \begin{bmatrix} e^{0.5t} \cos(t) & e^{-t} \sin(t) \\ -e^{0.5t} \sin(t) & e^{-t} \cos(t) \end{bmatrix} \begin{bmatrix} x_1(t_0) \\ x_2(t_0) \end{bmatrix}$$

which is unstable, for any initial conditions with a bounded and nonzero value of $x_1(t_0)$, no matter how small this initial value is. This example shows that by using the Lyapunov first method *alone* to determine the stability of a general time-varying system, the conclusion can be wrong.

This type of counterexamples can be easily found [35]. On the one hand, this demonstrates the necessity of other general criteria for asymptotic stability of nonautonomous systems. On the other hand, however, a word of caution is that this types of counterexamples do not completely rule out the possibility of applying the first method of Lyapunov to *some* special nonautonomous systems in case studies. The reason is that there is no theorem saying that “the Lyapunov first method cannot be applied to *all* nonautonomous systems.” Because of the complexity of nonlinear dynamical systems, they often have to be studied class by class, or even case by case. It has been widely experienced that the first method of Lyapunov does work for some, perhaps not too many, *specific* nonautonomous systems in case studies (e.g., in the study of some chaotic systems [7]; see also Theorem 18, below). The point is that one has to be very careful when this method is applied to a particular nonautonomous system; the stability conclusion must be verified by some other means at the same time.

Here, it is emphasized that a rigorous approach for asymptotic stability analysis of general nonautonomous systems is provided by the second method of Lyapunov, for which the following set of class \mathcal{K} functions are useful:

$$\mathcal{K} = \{g(t) : g(t_0) = 0, g(t) > 0 \text{ if } t > t_0,$$

$$g(t) \text{ is continuous and nondecreasing on } [t_0, \infty)\}$$

Theorem 2 (Second Method of Lyapunov: For Continuous-Time Nonautonomous Systems). The system (20) is globally (over the entire domain \mathcal{D}), uniformly (with respect to the initial time over the entire time interval $[t_0, \infty)$), and asymptotically stable about its zero equilibrium, if there

exist a scalar-valued function, $V(\mathbf{x}, t)$, defined on $\mathcal{D} \times [t_0, \infty)$, and three functions $\alpha(\cdot), \beta(\cdot), \gamma(\cdot) \in \mathcal{K}$, such that

- (a) $V(0, t_0) = 0$.
- (b) $V(\mathbf{x}, t) > 0$ for all $\mathbf{x} \neq 0$ in \mathcal{D} and all $t \geq t_0$.
- (c) $\alpha(\|\mathbf{x}\|) \leq V(\mathbf{x}, t) \leq \beta(\|\mathbf{x}\|)$ for all $t \geq t_0$.
- (d) $\dot{V}(\mathbf{x}, t) \leq -\gamma(\|\mathbf{x}\|) < 0$ for all $t \geq t_0$.

In Theorem 2, the function V is called a *Lyapunov function*. The method of constructing a Lyapunov function for stability determination is called the *second* (or *direct*) *method of Lyapunov*.

The geometric meaning of a Lyapunov function used for determining the system stability about the zero equilibrium may be illustrated by Fig. 9. In this figure, assuming that a Lyapunov function, $V(\mathbf{x})$, has been found, which has a bowl shape as shown based on conditions (a) and (b). Then, condition (d) is

$$\dot{V}(\mathbf{x}) = \left[\frac{\partial V}{\partial \mathbf{x}} \right] \dot{\mathbf{x}} < 0 \tag{21}$$

where $[\partial V / \partial \mathbf{x}]$ is the gradient of V along the trajectory \mathbf{x} . It is known, from calculus, that if the inner product of this gradient and the tangent vector $\dot{\mathbf{x}}$ is constantly negative, as guaranteed by condition (21), then the angle between these two vectors is larger than 90° , so that the surface of $V(\mathbf{x})$ is monotonically decreasing to zero (this is visualized in Fig. 9). Consequently, the system trajectory \mathbf{x} , the projection on the domain as shown in the figure, converges to zero as time evolves.

As an example, consider the following nonautonomous system

$$\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{g}(\mathbf{x}, t)$$

where A is a stable constant matrix and \mathbf{g} is a nonlinear function satisfying $\mathbf{g}(0, t) = 0$ and $\|\mathbf{g}(\mathbf{x}, t)\| \leq c\|\mathbf{x}\|$ for a constant $c > 0$ for all $t \in [t_0, \infty)$. Since A is stable, the following *Lyapunov equation*

$$PA + A^T P + I = 0$$

Figure 9. Geometric meaning of the Lyapunov function.

has a unique positive definite and symmetric matrix solution, P . Using the Lyapunov function $V(\mathbf{x}, t) = \mathbf{x}^T P \mathbf{x}$, it can be easily verified that

$$\begin{aligned} \dot{V}(\mathbf{x}, t) &= \mathbf{x}^T [PA + A^T P] \mathbf{x} + 2\mathbf{x}^T P \mathbf{g}(\mathbf{x}, t) \\ &\leq -\mathbf{x}^T \mathbf{x} + 2\lambda_{\max}(P)c\|\mathbf{x}\|^2 \end{aligned}$$

where $\lambda_{\max}(P)$ is the largest eigenvalue of P . Therefore, if the constant $c < 1/(2\lambda_{\max}(P))$ and if the class \mathcal{K} functions

$$\begin{aligned} \alpha(\zeta) &= \lambda_{\min}(P)\zeta^2, & \beta(\zeta) &= \lambda_{\max}(P)\zeta^2, \\ \gamma(\zeta) &= [1 - 2c\lambda_{\max}(P)]\zeta^2 \end{aligned}$$

are used, then conditions (c) and (d) of Theorem 2 are satisfied. As a result, the above system is globally, uniformly, and asymptotically stable about its zero equilibrium. This example shows that the linear part of a weakly nonlinear nonautonomous system can indeed dominate the stability.

Note that in Theorem 2, the uniform stability is guaranteed by the class \mathcal{K} functions α, β, γ stated in conditions (c) and (d), which is necessary since the solution of a nonautonomous system may sensitively depend on the initial time, as seen from the numerical example discussed in Section 3.1. For autonomous systems, these class \mathcal{K} functions [hence, condition (c)] are not needed. In this case, Theorem 2 reduces to the following simple form.

Theorem 3 (Second Method of Lyapunov: For Continuous-Time Autonomous Systems). The autonomous system (19) is globally (over the entire domain \mathcal{D}) and asymptotically stable about its zero equilibrium, if there exists a scalar-valued function $V(\mathbf{x})$, defined on \mathcal{D} , such that

- (a) $V(0) = 0$.
- (b) $V(\mathbf{x}) > 0$ for all $\mathbf{x} \neq 0$ in \mathcal{D} .
- (c) $\dot{V}(\mathbf{x}) < 0$ for all $\mathbf{x} \neq 0$ in \mathcal{D} .

Note that if condition (c) in Theorem 3 is replaced by (d) $\dot{V}(\mathbf{x}) \leq 0$ for all $\mathbf{x} \in \mathcal{D}$, then the resulting stability is only in the sense of Lyapunov but may not be asymptotic. For example, consider a simple model of an undamped pendulum of length ℓ described by

$$\begin{cases} \dot{x} = -\frac{g}{\ell} \sin(y) \\ \dot{y} = x \end{cases}$$

where $x = \dot{\theta}$ is the angular variable defined on $-\pi < \theta < \pi$, with the vertical axis as its reference, and g is the gravity constant. Since the system Jacobian at the zero equilibrium has one pair of purely imaginary eigenvalues, $\lambda_{1,2} = \pm \sqrt{-g/\ell}$, Theorem 1 is not applicable. However, if one uses the Lyapunov function

$$V = \frac{g}{\ell} (1 - \cos(y)) + \frac{1}{2} x^2$$

then it can be easily verified that $\dot{V} = 0$ over the entire domain. Thus, the conclusion is that the undamped

pendulum is stable in the sense of Lyapunov but may not be asymptotically, consistent with the physics of the undamped pendulum.

Theorem 4 (Krasovkii Theorem: For Continuous-Time Autonomous Systems). For the autonomous system (19), let $J(\mathbf{x}) = [\partial \mathbf{f} / \partial \mathbf{x}]$ be its Jacobian evaluated at $\mathbf{x}(t)$. A sufficient condition for the system to be asymptotically stable about its zero equilibrium is that there exist two real positive definite and symmetric constant matrices, P and Q , such that the matrix

$$J^T(\mathbf{x})P + PJ(\mathbf{x}) + Q$$

is seminegative definite for all $\mathbf{x} \neq 0$ in a neighborhood \mathcal{D} of the origin. For this case, a Lyapunov function is given by

$$V(\mathbf{x}) = \mathbf{f}^T(\mathbf{x})P\mathbf{f}(\mathbf{x})$$

Furthermore, if $\mathcal{D} = \mathbf{R}^n$ and $V(\mathbf{x}) \rightarrow \infty$ as $\|\mathbf{x}\| \rightarrow \infty$, then this asymptotic stability is also global.

Similar stability criteria can be established for discrete-time systems [10]. Two main results are summarized as follows.

Theorem 5 (First Method of Lyapunov: For Discrete-Time “Autonomous” Systems). Let $\mathbf{x}^* = 0$ be an equilibrium of the discrete-time “autonomous” system

$$\mathbf{x}_{k+1} = \mathbf{f}(\mathbf{x}_k) \tag{22}$$

where $\mathbf{f}: \mathcal{D} \rightarrow \mathbf{R}^n$ is continuously differentiable in a neighborhood of the origin, $\mathcal{D} \subseteq \mathbf{R}^n$, and let $J = [\partial \mathbf{f} / \partial \mathbf{x}_k]_{\mathbf{x}_k = \mathbf{x}^* = 0}$ be the Jacobian of the system evaluated at this equilibrium. If all the eigenvalues of J are strictly less than one in absolute value, then the system is asymptotically stable about its zero equilibrium.

Theorem 6 (Second Method of Lyapunov: For Discrete-Time “Nonautonomous” Systems). Let $\mathbf{x}^* = 0$ be an equilibrium of the “nonautonomous” system

$$\mathbf{x}_{k+1} = \mathbf{f}_k(\mathbf{x}_k) \tag{23}$$

where $\mathbf{f}_k: \mathcal{D} \rightarrow \mathbf{R}^n$ is continuously differentiable in a neighborhood of the origin, $\mathcal{D} \subseteq \mathbf{R}^n$. Then, system (22) is globally (over the entire domain \mathcal{D}) and asymptotically stable about its zero equilibrium, if there exists a scalar-valued function, $V(\mathbf{x}_k, k)$, defined on \mathcal{D} and continuous in \mathbf{x}_k , such that

- (a) $V(0, k) = 0$ for all $k \geq k_0$.
- (b) $V(\mathbf{x}_k, k) > 0$ for all $\mathbf{x}_k \neq 0$ in \mathcal{D} and for all $k \geq k_0$.
- (c) $\Delta V(\mathbf{x}_k, k) := V(\mathbf{x}_k, k) - V(\mathbf{x}_{k-1}, k-1) < 0$ for all $\mathbf{x}_k \neq 0$ in \mathcal{D} and all $k \geq k_0 + 1$.
- (d) $0 < W(\|\mathbf{x}_k\|) < V(\mathbf{x}_k, k)$ for all $k \geq k_0 + 1$, where $W(\tau)$ is a positive continuous function defined on \mathcal{D} , satisfying $W(\|\mathbf{x}_{k_0}\|) = 0$ and $\lim_{\tau \rightarrow \infty} W(\tau) = \infty$ monotonically.

As a special case, for discrete-time “autonomous” systems, Theorem 6 reduces to the following simple form.

Theorem 7 (Second Method of Lyapunov: For Discrete-Time “Autonomous” Systems). Let $\mathbf{x}^* = 0$ be an equilibrium for the “autonomous” system (22). Then the system is globally (over the entire domain \mathcal{D}) and asymptotically stable about this zero equilibrium if there exists a scalar-valued function, $V(\mathbf{x}_k)$, defined on \mathcal{D} and continuous in \mathbf{x}_k , such that

- (a) $V(0) = 0$.
- (b) $V(\mathbf{x}_k) > 0$ for all $\mathbf{x}_k \neq 0$ in \mathcal{D} .
- (c) $\Delta V(\mathbf{x}_k) := V(\mathbf{x}_k) - V(\mathbf{x}_{k-1}) < 0$ for all $\mathbf{x}_k \neq 0$ in \mathcal{D} .
- (d) $V(\mathbf{x}) \rightarrow \infty$ as $\|\mathbf{x}\| \rightarrow \infty$.

To this end, it is important to emphasize that all the Lyapunov theorems stated above only offer *sufficient* conditions for asymptotic stability. On the other hand, usually more than one Lyapunov function may be constructed for the same system. For a given system, one choice of a Lyapunov function may yield a less conservative result (e.g., with a larger stability region) than other choices. However, no conclusion regarding stability may be drawn if, for technical reasons, a satisfactory Lyapunov function cannot be found. Nevertheless, there is a necessary condition in theory about the existence of a Lyapunov function [15], as follows.

Theorem 8 (Massera Inverse Theorem). Suppose that the autonomous system (19) is asymptotically stable about its equilibrium \mathbf{x}^* and \mathbf{f} is continuously differentiable with respect to \mathbf{x} for all $t \in [t_0, \infty)$. Then a Lyapunov function exists for this system.

4.2. Some Instability Theorems

Once again, consider a general autonomous system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbf{R}^n \tag{24}$$

with an equilibrium $\mathbf{x}^* = 0$. To disprove the stability, the following instability theorems may be used.

Theorem 9 (A Linear Instability Theorem). In system (24), let $J = [\partial \mathbf{f} / \partial \mathbf{x}]_{\mathbf{x} = \mathbf{x}^* = 0}$ be the system Jacobian evaluated at $\mathbf{x}^* = 0$. If at least one of the eigenvalues of J has a positive real part, then $\mathbf{x}^* = 0$ is unstable.

For discrete-time systems, there is a similar result. A *discrete-time “autonomous” system*

$$\mathbf{x}_{k+1} = \mathbf{f}(\mathbf{x}_k), \quad k = 0, 1, 2, \dots,$$

is unstable about its equilibrium $\mathbf{x}^* = 0$ if at least one of the eigenvalues of the system Jacobian is larger than 1 in absolute value.

The following two negative theorems can be easily extended to nonautonomous systems in an obvious way.

Theorem 10 (A General Instability Theorem). For system (24), let $V(\mathbf{x})$ be a positive and continuously differentiable function defined on a neighborhood \mathcal{D} of the origin, satisfying $V(0)=0$. Assume that in any subset, containing the origin, of \mathcal{D} , there is an $\hat{\mathbf{x}}$ such that $V(\hat{\mathbf{x}})>0$. If, moreover

$$\frac{d}{dt} V(\mathbf{x}) > 0 \quad \text{for all } \mathbf{x} \neq 0 \text{ in } \mathcal{D}$$

then the system is unstable about the equilibrium $\mathbf{x}^* = 0$.

One example is the system

$$\begin{cases} \dot{x} = y + x(x^2 + y^4) \\ \dot{y} = -x + y(x^2 + y^4) \end{cases}$$

which has equilibrium $(x^*, y^*) = (0, 0)$. The system Jacobian at the equilibrium has a pair of imaginary eigenvalues, $\lambda_{1,2} = \pm \sqrt{-1}$, so Theorem 1 is not applicable. On the contrary, the Lyapunov function

$$V = \frac{1}{2} (x^2 + y^2)$$

leads to $\dot{V} = (x^2 + y^2)(x^2 + y^4) > 0$ for all $(x, y) \neq (0, 0)$. Therefore, the conclusion is that this system is unstable about its zero equilibrium.

Theorem 11 (Chetaev Instability Theorem). For system (24), let $V(\mathbf{x})$ be a positive and continuously differentiable function defined on \mathcal{D} , and let Ω be a subset, containing the origin, of \mathcal{D} , (i.e., $0 \in \mathcal{D} \cap \Omega$). If (a) $V(\mathbf{x}) > 0$ and $\dot{V}(\mathbf{x}) > 0$ for all $\mathbf{x} \neq 0$ in \mathcal{D} and (b) $V(\mathbf{x}) = 0$ for all \mathbf{x} on the boundary of Ω , then the system is unstable about the equilibrium $\mathbf{x}^* = 0$.

This instability theorem is illustrated by Fig. 10, which graphically shows that if the theorem conditions are satisfied, then there is a gap within any neighborhood of the origin, so that a system trajectory can escape from the neighborhood of the origin along a path in this gap [23].

As an example, consider the system

$$\begin{cases} \dot{x} = x^2 + 2y^5 \\ \dot{y} = xy^2 \end{cases}$$

Figure 10. Illustration of the Chetaev theorem.

with the Lyapunov function

$$V = x^2 - y^4$$

which is positive inside the region defined by

$$x = y^2 \quad \text{and} \quad x = -y^2$$

Let \mathcal{D} be the right half-plane and Ω be the shaded area shown in Fig. 11. Clearly, $V=0$ on the boundary of Ω , and $V>0$ and $\dot{V}=2x^3 > 0$ for all $(x, y) \in \mathcal{D}$. According to the Chetaev theorem, this system is unstable about its zero equilibrium.

4.3. LaSalle Invariance Principle

Consider again the autonomous system (24) with an equilibrium $\mathbf{x}^* = 0$. Let $V(\mathbf{x})$ be a Lyapunov function defined on a neighborhood \mathcal{D} of the origin. Let also $\varphi_t(\mathbf{x}_0)$ be a bounded solution orbit of the system, with the initial state \mathbf{x}_0 and all its limit states being confined in \mathcal{D} . Moreover, let

$$E = \{\mathbf{x} \in \mathcal{D} \mid \dot{V}(\mathbf{x}) = 0\} \tag{25}$$

and $M \subset E$ be the largest invariant subset of E in the sense that if the initial state $\mathbf{x}_0 \in M$, then the entire orbit $\varphi_t(\mathbf{x}_0) \subset M$ for all $t \geq t_0$.

Theorem 12 (LaSalle Invariance Principle). Under the assumptions above, for any initial state $\mathbf{x}_0 \in \mathcal{D}$, the solution orbit satisfies $\varphi_t(\mathbf{x}_0) \rightarrow M$ as $t \rightarrow \infty$.

This invariance principle is consistent with the Lyapunov theorems when they are applicable to a problem [11,19]. Sometimes, when $\dot{V}=0$ over a subset of the domain of V , a Lyapunov theorem is not easy to directly apply, but the above LaSalle invariance principle may be convenient to use. For instance, consider the system

$$\begin{cases} \dot{x} = -x + \frac{1}{3}x^3 + y \\ \dot{y} = -x \end{cases}$$

The Lyapunov function $V = x^2 + y^2$ yields

$$\dot{V} = \frac{1}{2} x^2 \left(\frac{1}{3} x^2 - 1 \right)$$

Figure 11. The defining region of a Lyapunov function.

which is negative for $x^2 < 3$ but is zero for $x = 0$ and $x^2 = 3$, regardless of variable y . Thus, Lyapunov theorems do not seem to be applicable, at least not directly. However, observe that the set E defined above has only three straight lines: $x = -\sqrt{3}$, $x = 0$, and $x = \sqrt{3}$, and that all trajectories that intersect the line $x = 0$ will remain on the line only if $y = 0$. This means that the largest invariant subset M containing the points with $x = 0$ is the only point $(0, 0)$. It then follows from the LaSalle invariance principle that starting from any initial state located in a neighborhood of the origin bounded within the two stripes $x = \pm \sqrt{3}$, say, located inside the disk

$$\mathcal{D} = \{(x, y) \mid x^2 + y^2 < 3\}$$

the solution orbit will always be attracted to the point $(0, 0)$. This means that the system is (locally) asymptotically stable about its zero equilibrium.

4.4. Comparison Principle and Vector Lyapunov Functions

For large-scale and interconnected nonlinear (control) systems, or systems described by differential inequalities rather than differential equations, the stability criteria above may not be directly applicable. In such cases, the comparison principle and vector Lyapunov function methods turn out to be advantageous [18,24,32].

To introduce the comparison principle, consider the general nonautonomous system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \tag{26}$$

where $\mathbf{f}(\mathbf{0}, t) = 0$ is continuous on a neighborhood \mathcal{D} of the origin, $t_0 \leq t < \infty$.

In this case, since \mathbf{f} is only continuous (but not necessarily satisfying the Lipschitz condition), this differential equation may have more than one solution [12]. Let $\mathbf{x}_{\max}(t)$ and $\mathbf{x}_{\min}(t)$ be its maximum and minimum solutions, respectively, in the sense that

$$\mathbf{x}_{\min}(t) \leq \mathbf{x}(t) \leq \mathbf{x}_{\max}(t) \quad \text{componentwise, for all } t \in [t_0, \infty)$$

where $\mathbf{x}(t)$ is any solution of the equation, and $\mathbf{x}_{\min}(t_0) = \mathbf{x}(t_0) = \mathbf{x}_{\max}(t_0) = \mathbf{x}_0$.

Theorem 13 (The Comparison Principle). Let $\mathbf{y}(t)$ be a solution of the following differential inequality:

$$\dot{\mathbf{y}}(t) \leq \mathbf{f}(\mathbf{y}, t) \quad \text{with } \mathbf{y}(t_0) \leq \mathbf{x}_0 \quad \text{componentwise}$$

If $\mathbf{x}_{\max}(t)$ is the maximum solution of system (26), then

$$\mathbf{y}(t) \leq \mathbf{x}_{\max}(t) \quad \text{componentwise for all } t \in [t_0, \infty)$$

The next theorem is established based on this comparison principle. First, recall that a vector-valued function, $\mathbf{g}(\mathbf{x}, t) = [g_1(\mathbf{x}, t) \cdots g_n(\mathbf{x}, t)]^T$ is said to be *quasimonotonic*, if

$$\begin{aligned} x_i = \tilde{x}_i \quad \text{and} \quad x_j \geq \tilde{x}_j \quad (j \neq i) \\ \Rightarrow g_i(\mathbf{x}, t) \geq g_i(\tilde{\mathbf{x}}, t), \quad i = 1, \dots, n \end{aligned}$$

Theorem 14 (Vector Lyapunov Function Theorem). Let $\mathbf{v}(\mathbf{x}, t)$ be a vector Lyapunov function associated with the

nonautonomous system (26), $\mathbf{v}(\mathbf{x}, t) = [V_1(\mathbf{x}, t) \cdots V_n(\mathbf{x}, t)]^T$ in which each V_i is a continuous Lyapunov function for the system, $i = 1, \dots, n$, satisfying $\|\mathbf{v}(\mathbf{x}, t)\| > 0$ for $\mathbf{x} \neq 0$. Assume that

$$\dot{\mathbf{v}}(\mathbf{x}, t) \leq \mathbf{g}(\mathbf{v}(\mathbf{x}, t), t) \quad \text{componentwise}$$

for a continuous and quasimonotonic function \mathbf{g} defined on \mathcal{D} . Then

- (a) If the system

$$\dot{\mathbf{y}}(t) = \mathbf{g}(\mathbf{y}, t)$$

is stable in the sense of Lyapunov (or asymptotically stable) about its zero equilibrium $\mathbf{y}^* = 0$, then so is the nonautonomous system (26).

- (b) If, moreover, $\|\mathbf{v}(\mathbf{x}, t)\|$ is monotonically decreasing with respect to t and the preceding stability (or asymptotic stability) is uniform, then so is the nonautonomous system (26).
- (c) If, furthermore, $\|\mathbf{v}(\mathbf{x}, t)\| \geq c \|\mathbf{x}\|^\sigma$ for two positive constants c and σ , and the preceding stability (or asymptotic stability) is exponential, then so is the nonautonomous system (26).

A simple and frequently used comparison function is

$$\mathbf{g}(\mathbf{y}, t) = A\mathbf{y} + \mathbf{h}(\mathbf{y}, t), \quad \lim_{\|\mathbf{y}\| \rightarrow 0} \frac{\|\mathbf{h}(\mathbf{y}, t)\|}{\|\mathbf{y}\|} = 0$$

where A is a stable M matrix (Metzler matrix). Here, $A = [a_{ij}]$ is an M matrix if

$$a_{ii} < 0 \quad \text{and} \quad a_{ij} \geq 0 \quad (i \neq j), \quad i, j = 1, \dots, n$$

4.5. Orbital and Structural Stability Theorems

Theorem 15 (Orbital Stability Theorem). Let $\tilde{\mathbf{x}}(t)$ be a p -periodic solution of an autonomous system. Suppose that the system has Floquet multipliers λ_i , with $\lambda_1 = 0$ and $|\lambda_i| < 1$ for $i = 2, \dots, n$. Then this periodic solution $\tilde{\mathbf{x}}(t)$ is orbitally stable.

Theorem 16 (Peixoto Structural Stability Theorem). Consider a two-dimensional autonomous system. Suppose that \mathbf{f} is twice differentiable on a compact and connected subset \mathcal{D} bounded by a simple closed curve Γ , with an outward normal vector $\tilde{\mathbf{n}}$. Assume that $\mathbf{f} \cdot \tilde{\mathbf{n}} \neq 0$ on Γ . Then the system is structurally stable on \mathcal{D} if and only if

- (a) All equilibria are hyperbolic.
- (b) All periodic orbits are hyperbolic.
- (c) If x and y are hyperbolic saddles (probably $x = y$), then $W^s(x)$ and $W^u(y)$ are transversal.

5. LINEAR STABILITY OF NONLINEAR SYSTEMS

The first method of Lyapunov provides a linear stability analysis for nonlinear autonomous systems. In this section, the following general nonautonomous system is

considered:

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbf{R}^n \tag{27}$$

which is assumed to have an equilibrium $\mathbf{x}^* = 0$.

5.1. Linear Stability of Nonautonomous Systems

In system (27), Taylor-expanding the function \mathbf{f} about $\mathbf{x}^* = 0$ gives

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t) = J(t)\mathbf{x} + \mathbf{g}(\mathbf{x}, t) \tag{28}$$

where $J(t) = [\partial \mathbf{f} / \partial \mathbf{x}]_{\mathbf{x}=0}$ is the Jacobian and $\mathbf{g}(\mathbf{x}, t)$ is the residual of the expansion, which is assumed to satisfy

$$\|\mathbf{g}(\mathbf{x}, t)\| \leq a \|\mathbf{x}\|^2 \quad \text{for all } t \in [t_0, \infty)$$

where $a > 0$ is a constant. It is known from the theory of elementary ordinary differential equations [12] that the solution of equation (28) is given by

$$\mathbf{x}(t) = \Phi(t, t_0)\mathbf{x}_0 + \int_{t_0}^t \Phi(t, \tau)\mathbf{g}(\mathbf{x}(\tau), \tau)d\tau \tag{29}$$

where $\Phi(t, \tau)$ is the fundamental matrix associated with matrix $J(t)$.

Theorem 17 (A General Linear Stability Theorem). For the nonlinear nonautonomous system (28), if there are two positive constants c and σ such that

$$\|\Phi(t, \tau)\| \leq ce^{-\sigma(t-\tau)} \quad \text{for all } t_0 \leq \tau \leq t < \infty$$

and if

$$\lim_{\|\mathbf{x}\| \rightarrow 0} \frac{\|\mathbf{g}(\mathbf{x}, t)\|}{\|\mathbf{x}\|} = 0$$

uniformly with respect to $t \in [t_0, \infty)$, then there are two positive constants, γ and δ , such that

$$\|\mathbf{x}(t)\| \leq c\|\mathbf{x}_0\|e^{-\gamma(t-t_0)}$$

for all $\|\mathbf{x}_0\| \leq \delta$ and all $t \in [t_0, \infty)$.

This result implies that under the theorem conditions, the system is locally, uniformly, and exponentially stable about its equilibrium $\mathbf{x}^* = 0$.

In particular, if the system matrix $J(t) = J$ is a stable constant matrix, then the following simple criterion is convenient to use.

Theorem 18 (A Special Linear Stability Theorem). Suppose that in system (28), the matrix $J(t) = J$ is a stable constant matrix (all its eigenvalues have a negative real part), and $\mathbf{g}(0, t) = 0$. Let P be a positive definite and symmetric matrix solution of the Lyapunov equation

$$PJ + J^T P + Q = 0$$

where Q is a positive definite and symmetric constant matrix. If

$$\|\mathbf{g}(\mathbf{x}, t)\| \leq a\|\mathbf{x}\|$$

for a constant $a < \frac{1}{2}\lambda_{\max}(P)$ uniformly on $[t_0, \infty)$, where $\lambda_{\max}(P)$ is the maximum eigenvalue of P , then system (28) is globally, uniformly, and asymptotically stable about its equilibrium $\mathbf{x}^* = 0$.

This actually is the example for illustration of Theorem 2 discussed in Section 4.1.

Again consider system (27) with equilibrium $\mathbf{x}^* = 0$.

Theorem 19 (The Lyapunov Converse Theorem). Suppose that \mathbf{f} is continuously differentiable in a neighborhood of the origin, and its Jacobian $\mathbf{J}(t)$ is bounded and Lipschitz in the neighborhood, uniformly in t . Then, the system is exponentially stable about its equilibrium if and only if its linearized system $\dot{\mathbf{x}} = \mathbf{J}(t)\mathbf{x}$ is exponentially stable about the origin.

5.2. Linear Stability of Nonlinear Systems with Periodic Linearity

Consider a nonlinear nonautonomous system of the form

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t) = J(t)\mathbf{x} + \mathbf{g}(\mathbf{x}, t), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbf{R}^n \tag{30}$$

where $\mathbf{g}(0, t) = 0$ and $J(t)$ is a p -periodic matrix ($p > 0$):

$$J(t + p) = J(t) \quad \text{for all } t \in [t_0, \infty)$$

Theorem 20 (Floquet Theorem). In system (30), assume that $\mathbf{g}(\mathbf{x}, t)$ and $\partial \mathbf{g}(\mathbf{x}, t) / \partial \mathbf{x}$ are both continuous in a bounded region \mathcal{D} containing the origin. Assume, moreover, that

$$\lim_{\|\mathbf{x}\| \rightarrow 0} \frac{\|\mathbf{g}(\mathbf{x}, t)\|}{\|\mathbf{x}\|} = 0$$

uniformly on $[t_0, \infty)$. If the system Floquet multipliers satisfy

$$|\lambda_i| < 1, \quad i = 1, \dots, n, \quad \text{for all } t \in [t_0, \infty) \tag{31}$$

then system (30) is globally, uniformly, and asymptotically stable about its equilibrium $\mathbf{x}^* = 0$.

Note that if $\mathbf{g}(\mathbf{x}, t) = 0$ in system (28) or (30), all the linear stability results presented above still hold and are consistent with the familiar results from the linear systems theory.

6. TOTAL STABILITY: STABILITY UNDER PERSISTENT PERTURBANCES

Consider a nonautonomous system of the form

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t) + \mathbf{h}(\mathbf{x}, t), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \in \mathbf{R}^n \tag{32}$$

where \mathbf{f} is continuously differentiable, with $\mathbf{f}(0, t) = 0$, and \mathbf{h} is a *persistent perturbation* in the sense that for any $\varepsilon > 0$, there are two positive constants, δ_1 and δ_2 , such that if $\|\mathbf{h}(\tilde{\mathbf{x}}, t)\| < \delta_1$ for all $t \in [t_0, \infty)$ and if $\|\tilde{\mathbf{x}}(t_0)\| < \delta_2$, then $\|\tilde{\mathbf{x}}(t)\| < \varepsilon$.

The equilibrium $\mathbf{x}^* = 0$ of the unperturbed system [system (32) with $\mathbf{h} = 0$ therein] is said to be *totally stable*, if the persistently perturbed system (32) remains to be stable in the sense of Lyapunov.

As the next theorem states, all uniformly and asymptotically stable systems with persistent perturbations are totally stable, namely, a stable orbit starting from a neighborhood of another orbit will stay nearby [13,15].

Theorem 21 (Malkin Theorem). If the unperturbed system (32), that is, with $\mathbf{h} = 0$ therein, is uniformly and asymptotically stable about its equilibrium $\mathbf{x}^* = 0$, then it is totally stable, namely, the persistently perturbed system (32) remains to be stable in the sense of Lyapunov.

Next, consider an autonomous system with persistent perturbations:

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \mathbf{h}(\mathbf{x}, t), \quad \mathbf{x} \in \mathbf{R}^n \tag{33}$$

Theorem 22 (Perturbed Orbital Stability Theorem). If $\varphi_t(\mathbf{x}_0)$ is an orbitally stable solution of the unperturbed autonomous system (33) (with $\mathbf{h} = 0$ therein), then it is totally stable, that is, the perturbed system remains to be orbitally stable under persistent perturbations.

7. ABSOLUTE STABILITY AND FREQUENCY-DOMAIN CRITERIA

Consider a feedback system in the Lur’e form

$$\begin{cases} \dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{h}(\mathbf{y}) \\ \mathbf{y} = \mathbf{C}\mathbf{x} \end{cases} \tag{34}$$

where A, B, C are constant matrices, in which A is non-singular but B and C are not necessarily square (yet, probably, $B = C = I$), and \mathbf{h} is a vector-valued nonlinear function. By taking the Laplace transform with zero initial conditions, and denoting the transform by $\hat{\mathbf{x}} = \mathcal{L}\{\mathbf{x}\}$, the state vector is obtained as

$$\hat{\mathbf{x}} = [sI - A]^{-1}B\mathcal{L}\{\mathbf{h}(\mathbf{y})\} \tag{35}$$

so that the output is given by

$$\hat{\mathbf{y}} = CG(s)\mathcal{L}\{\mathbf{h}(\mathbf{y})\} \tag{36}$$

with the system transfer matrix

$$G(s) = [sI - A]^{-1}B \tag{37}$$

This can be implemented via the block diagram shown in Fig. 12, where, for notational convenience, both time- and frequency-domain symbols are mixed.

The Lur’e system shown in Fig. 12 is a closed-loop configuration, where the feedback loop is usually considered as a “controller.” Thus, this system is sometimes written in the following equivalent form:

$$\begin{cases} \dot{\mathbf{x}} + \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \\ \mathbf{y} = \mathbf{C}\mathbf{x} \\ \mathbf{u} = \mathbf{h}(\mathbf{y}) \end{cases} \tag{38}$$

7.1. SISO Lur’e Systems

First, single-input/single-output Lur’e systems are discussed, where $u = h(y)$ and $y = \mathbf{c}^T\mathbf{x}$ are both scalar-valued functions:

$$\begin{cases} \dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{b}u \\ y = \mathbf{c}^T\mathbf{x} \\ u = h(y) \end{cases} \tag{39}$$

Assume that $h(0) = 0$, so that $\mathbf{x}^* = 0$ is an equilibrium of the system.

7.1.1. The Sector Condition. The Lur’e system (39) is said to satisfy the *local (global) sector condition* on the nonlinear function $h(\cdot)$, if there exist two constants, $\alpha < \beta$, such that

- 1. Local sector condition:

$$\begin{aligned} \alpha y^2(t) \leq y(t)h(y(t)) \leq \beta y^2(t) \quad \text{for all} \\ a \leq y(t) \leq b \quad \text{and } t \in [t_0, \infty) \end{aligned} \tag{40}$$

- 2. Global sector condition:

$$\begin{aligned} \alpha y^2(t) \leq y(t)h(y(t)) \leq \beta y^2(t) \quad \text{for all} \\ -\infty < y(t) < \infty \quad \text{and } t \in [t_0, \infty) \end{aligned} \tag{41}$$

Here, $[\alpha, \beta]$ is called the *sector* for the nonlinear function $h(\cdot)$. Moreover, the system (39) is said to be (globally) *absolutely stable within the sector* $[\alpha, \beta]$ if the system is (globally) asymptotically stable about its equilibrium $\mathbf{x}^* = 0$ for any nonlinear function $h(\cdot)$ satisfying the

Figure 12. Configuration of the Lur’e system.

Figure 13. Local and global sector conditions.

(global) sector condition. These local and global sector conditions are visualized by Figs. 13a and 13b, respectively.

7.1.2. The Popov Criterion.

Theorem 23 (Popov Criterion). Suppose that the SISO Lur’e system (39) satisfied the following conditions:

- (a) A is stable and $\{A, \mathbf{b}\}$ is controllable.
- (b) The system satisfies the global sector condition with $\alpha = 0$ therein.
- (c) For any $\varepsilon > 0$, there is a constant $\gamma > 0$ such that

$$\text{Re}\{(1 + j\gamma\omega)G(j\omega)\} + \frac{1}{\beta} \geq \varepsilon \quad \text{for all } \omega \geq 0 \quad (42)$$

where $G(s)$ is the transfer function defined by (37), and $\text{Re}\{\cdot\}$ denotes the real part of a complex number (or function). Then, the system is globally asymptotically stable about its equilibrium $\mathbf{x}^* = 0$ within the sector.

The Popov criterion has the following geometric meaning. Separate the complex function $G(s)$ into its real and imaginary parts, namely

$$G(j\omega) = G_r(\omega) + jG_i(\omega)$$

and rewrite condition (C) as

$$\frac{1}{\beta} > -G_r(\omega) + \gamma\omega G_i(\omega) \quad \text{for all } \omega \geq 0$$

Then the graphical situation of the Popov criterion shown in Fig. 14 implies the global asymptotic stability of the system about its zero equilibrium.

7.1.3. The Circle Criterion. The Popov criterion has a natural connection to the linear Nyquist criterion

Figure 14. Geometric meaning of the Popov criterion.

[17,26,27,29]. A more direct generalization of the Nyquist criterion to nonlinear systems is the following.

Theorem 24 (Circle Criterion). Suppose that the SISO Lur’e system (39) satisfies the following conditions:

- (a) A has no purely imaginary eigenvalues, and has κ eigenvalues with positive real parts.
- (b) The system satisfies the global sector condition.
- (c) One of the following situation holds:
 - (1) $0 < \alpha < \beta$ —the Nyquist plot of $G(j\omega)$ encircles the disk $D[-(1/\alpha), -(1/\beta)]$ counterclockwise κ times but does not enter it.
 - (2) $0 = \alpha < \beta$ —the Nyquist plot of $G(j\omega)$ stays within the open half-plane $\text{Re}\{s\} > -(1/\beta)$.
 - (3) $\alpha < 0 < \beta$ —the Nyquist plot of $G(j\omega)$ stays within the open disk $D[-(1/\beta), -(1/\alpha)]$.
 - (4) $\alpha < \beta < 0$ —the Nyquist plot of $-G(j\omega)$ encircles the disk $D[(1/\alpha), (1/\beta)]$ counterclockwise κ times but does not enter it.

Then, the system is globally asymptotically stable about its equilibrium $\mathbf{x}^* = 0$.

Here, the disk $D[-(1/\alpha), -(1/\beta)]$, for the case of $0 < \alpha < \beta$, is shown in Fig. 15.

7.2. MIMO Lur’e systems

Consider a multiinput/multioutput Lur’e system, as shown in Fig. 12, described by

$$\begin{cases} \mathbf{x}(s) = G(s)\mathbf{u}(s) \\ \mathbf{u}(t) = -\mathbf{h}(\mathbf{y}(t)) \end{cases} \quad (43)$$

with $G(s)$ as defined in (37). If this system satisfies the following Popov inequality

$$\int_{t_0}^{t_1} \mathbf{y}^T(\tau)\mathbf{x}(\tau)d\tau \geq -\gamma \quad \text{for all } t_1 \geq t_0 \quad (44)$$

for a constant $\gamma \geq 0$ independent of t , then it is said to be hyperstable.

The linear part of this MIMO system is described by the transfer matrix $G(s)$, which is said to be positive real if

1. There are no poles of $G(s)$ located inside the open half-plane $\text{Re}\{s\} > 0$.
2. Poles of $G(s)$ on the imaginary axis are simple, and the residues form a semipositive definite matrix.

Figure 15. The disk $D[-(1/\alpha), -(1/\beta)]$.

3. The matrix $[G(j\omega) + G^T(j\omega)]$ is a semipositive definite matrix for all real values of ω that are not poles of $G(s)$.

Theorem 25 (Hyperstability Theorem). The MIMO Lur’e system (43) is hyperstable if and only if its transfer matrix $G(s)$ is positive real.

7.3. Describing Function Method

Return to the SISO Lur’e system (39) and consider its periodic output $y(t)$. Assume that the nonlinear function $h(\cdot)$ therein is a time-invariant odd function, and satisfies the property that for $y(t) = \alpha \sin(\omega t)$, with real constants ω and $\alpha \neq 0$, only the first-order harmonic of $-h(y)$ in its Fourier series expansion is significant. Under this setup, the specially defined function

$$\Psi(\alpha) = -\frac{2\omega}{\alpha\pi} \int_0^{\pi/\omega} h(\alpha \sin(\omega t)) \sin(\omega t) dt \quad (45)$$

is called the *describing function* of the nonlinearity $-h(\cdot)$, or of the system [1,26,27].

Theorem 26 (First-Order Harmonic Balance Approximation). Under the conditions stated above, if the first-order harmonic balance equations

$$G_r(j\omega)\Psi(\alpha) = 1 \quad \text{and} \quad G_i(j\omega) = 0$$

have solutions ω and $\alpha \neq 0$, then

$$y^{(1)}(t) = \frac{j\alpha}{2} e^{-j\omega t} - \frac{j\alpha}{2} e^{j\omega t}$$

is the first-order approximation of a possible periodic orbit of the output of system (39); but if the preceding harmonic balance equations have no solution, then the system is unlikely to have any periodic output.

When solving the equation $G_r(j\omega)\Psi(\alpha) = 1$ graphically, one can sketch two curves in the complex plane: $G_r(j\omega)$ and $-1/\Psi(\alpha)$ by increasing gradually ω and α , respectively, to find their crossing points:

1. If the two curves are (almost) tangent, as illustrated by Fig. 16a, then a conclusion drawn from the describing function method will not be satisfactory in general.
2. If the two curves are (almost) transversal, as illustrated by Fig. 16b, then a conclusion drawn from the describing function analysis will generally be reliable.

Theorem 27 (Graphical Stability Criterion for a Periodic Orbit). Each intersection point of the two curves above, $G_r(j\omega)$ and $-1/\Psi(\alpha)$, corresponds to a periodic orbit, $y^{(1)}(t)$, of the output of system (39). If the points, near the intersection and on one side of the curve $-1/\Psi(\alpha)$ where $-\alpha$ is increasing, are not encircled by the curve $G_r(j\omega)$, then the corresponding periodic output is stable; otherwise, it is unstable.

8. BIBO STABILITY

A relatively simple, and also relatively weak, notion of stability is discussed in this section. This is the *bounded-input/bounded-output (BIBO) stability*, which refers to the property of a system that any bounded input to the system produces a bounded output throughout the system [8,9,17].

It can be verified that the linear system $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}$ is BIBO stable if the matrix \mathbf{A} is asymptotically stable.

Here, the focus is on the input-output map (13), with its configuration shown in Fig. 2.

The system S is said to be *BIBO stable* from the input set U to the output set Y , if for each admissible input $\mathbf{u} \in U$ and the corresponding output $\mathbf{y} \in Y$, there exist two non-negative constants, b_i and b_o , such that

$$\|\mathbf{u}\|_U \leq b_i \Rightarrow \|\mathbf{y}\|_Y \leq b_o \quad (46)$$

Since all norms are equivalent for a finite-dimensional vector, it is generally insignificant to distinguish under what kind of norms for the input and output signals the BIBO stability is defined and achieved. Moreover, it is important to note that in the definition above, even if b_i is small and b_o is large, the system is still considered to be BIBO-stable. Therefore, this stability may not be very practical for some systems in certain applications.

Figure 16. Graphical depiction of describing function analysis.

8.1. Small-Gain Theorem

A convenient criterion for verifying the BIBO stability of a closed-loop control system is the small-gain theorem [8,9,17], which applies to almost all kinds of systems (linear and nonlinear, continuous-time and discrete-time, time-delayed, of any dimensions), as long as the mathematical setup is appropriately formulated to meet the theorem conditions. The main disadvantage of this criterion is its overconservativity.

Return to the typical closed-loop system shown in Fig. 3, where the inputs, outputs, and internal signals are related via the following equations:

$$\begin{cases} S_1(e_1) = e_2 - u_2 \\ S_2(e_2) = u_1 - e_1 \end{cases} \quad (47)$$

It is important to note that the individual BIBO stability of S_1 and S_2 is not sufficient for the BIBO stability of the connected closed-loop system. For instance, in the discrete-time setting of Fig. 3, suppose that $S_1 \equiv 1$ and $S_2 \equiv -1$, with $u_1(k) \equiv 1$ for all $k = 0, 1, \dots$. Then S_1 and S_2 are BIBO-stable individually, but it can be easily verified that $y_1(k) = k \rightarrow \infty$ as the discrete-time variable k evolves. Therefore, a stronger condition describing the interaction of S_1 and S_2 is necessary.

Theorem 28 (Small-Gain Theorem). If there exist four constants, L_1, L_2, M_1, M_2 , with $L_1L_2 < 1$, such that

$$\begin{cases} \|S_1(e_1)\| \leq M_1 + L_1\|e_1\| \\ \|S_2(e_2)\| \leq M_2 + L_2\|e_2\| \end{cases} \quad (48)$$

then

$$\begin{cases} \|e_1\| \leq (1 - L_1L_2)^{-1}(\|u_1\| + L_2\|u_2\| + M_2 + L_2M_1) \\ \|e_2\| \leq (1 - L_1L_2)^{-1}(\|u_2\| + L_1\|u_1\| + M_1 + L_1M_2) \end{cases} \quad (49)$$

where the norms $\|\cdot\|$ are defined over the spaces that the signals belong. Consequently, (48) and (49) together imply that if the system inputs (u_1 and u_2) are bounded then the corresponding outputs [$S_1(e_1)$ and $S_2(e_2)$] are bounded.

Note that the four constants, L_1, L_2, M_1, M_2 , can be somewhat arbitrary (e.g., either L_1 or L_2 can be large) provided that $L_1L_2 < 1$, which is the key condition for the theorem to hold [and is used to obtain $(1 - L_1L_2)^{-1}$ in the bounds (49)].

In the special case where the input-output spaces U and Y are both the L_2 space, a similar criterion based on the system passivity property can be obtained [9,17]. In this case, an inner product between any two vectors in the space is defined by

$$\langle \xi, \eta \rangle = \int_{t_0}^{\infty} \xi^T(\tau)\eta(\tau) d\tau$$

Theorem 29 (Passivity Stability Theorem). If there exist four constants, L_1, L_2, M_1, M_2 , with $L_1 + L_2 > 0$, such that

$$\begin{cases} \langle e_1, S_1(e_1) \rangle \geq L_1\|e_1\|_2^2 + M_1 \\ \langle e_2, S_2(e_2) \rangle \geq L_2\|e_2\|_2^2 + M_2 \end{cases} \quad (50)$$

then the closed-loop system (47) is BIBO-stable.

As mentioned, the main disadvantage of this criterion is its overconservativity in providing the sufficient conditions for the BIBO stability. One resolution is to transform the system into the Lur'e structure, and then apply the circle or Popov criterion under the sector condition (if it can be satisfied), which can usually lead to less conservative stability conditions.

8.2. Contraction Mapping Theorem

The small-gain theorem discussed above, by nature, is a kind of contraction mapping theorem. The contraction mapping theorem can be used to determine the BIBO stability property of a system described by a map in various forms, provided that the system (or the map) is appropriately formulated. The following is a typical (global) contraction mapping theorem.

Theorem 30 (Contraction Mapping Theorem). If the operator norm of the input-output map S , defined on \mathbf{R}^n , satisfies $\|S\| < 1$, then the system mapping

$$\mathbf{y}(t) = S(\mathbf{y}(t)) + \mathbf{c}$$

has a unique solution for any constant vector $\mathbf{c} \in \mathbf{R}^n$. This solution satisfies

$$\|\mathbf{y}\| \leq (1 - \|S\|)^{-1}\|\mathbf{c}\|$$

In particular, the solution of the equation

$$\mathbf{y}_{k+1} = S(\mathbf{y}_k), \mathbf{y}_0 \in \mathbf{R}^n, k = 0, 1, \dots$$

satisfies

$$\|\mathbf{y}_k\| \rightarrow 0 \text{ as } k \rightarrow \infty$$

9. CONCLUDING REMARKS

This article has offered a brief introduction to the basic theory and methodology of Lyapunov stability, orbital stability, structural stability, and input-output stability for nonlinear dynamical systems. More subtle details for stability analysis of general dynamical systems can be found in the literature [3,5,9,11-13,16,17,19,20,23,26,27,29,30]. In cases where control was explicitly involved, stability and stabilization issues have also been studied [8,17,25,28,33].

Several important classes of nonlinear (control) systems have been omitted in the discussion of various stability issues: some general functional systems such as

systems with time delays [14], measure ordinary differential equations such as systems with impulses [2,31], and some weakly nonlinear systems such as piecewise linear and switching (non)linear systems. Discussion of more advanced nonlinear systems, such as singular nonlinear systems (perhaps with time delays), infinite-dimensional (non)linear systems, spatiotemporal systems described by nonlinear partial differential equations, and nonlinear stochastic (control) systems, are beyond the scope of this elementary expository article.

Finally, for more recent studies of system stability theories, the reader is referred to the reviews edited by Martynuk [22].

STANDING WAVE METERS AND NETWORK ANALYZERS

BURKHARD SCHIEK
ANDREAS GRONEFELD
Ruhr-Universität Bochum

1. MEASUREMENT OF NETWORKS AT MICROWAVE FREQUENCIES

Determining the characteristics of electrical networks (network analysis) is an important measurement tool both for developers of electrical circuits and systems and in production testing. The measurement of network characteristics at microwave frequencies employs different concepts than are used at lower frequencies, where measuring port voltages and currents readily allows determination of impedance (Z) or admittance (Y) parameters. At higher frequencies, neither high-impedance voltage probes nor low-impedance current measurements are feasible, because parasitic capacitance and inductance of

Figure 1. Drawbacks of voltage and current measurement versus the wave concept.

probes (L_s and C_p in Fig. 1) cannot be made small enough. Also, the physical dimensions of microwave circuits typically are no longer small with respect to the wavelength. A cable, connecting the port of a device under test with the measurement equipment, may easily transform the intended open circuit into a short, if its length happens to be an odd multiple of $\lambda/4$. Furthermore, short- or open-circuiting network ports, invariably linked to voltage and current measurements, may alter the behavior of microwave circuits (e.g., an amplifier, operated at those impedance extremes, may oscillate). And in waveguides, voltage and current are not even defined.

The above difficulties are circumvented if the network is embedded between defined generator and load impedances Z_0 (typically real and $50\ \Omega$) and described in terms of its power transfer characteristics. The “scattering” of the incident power wave a_1 into the transmitted wave b_2 and the reflected wave b_1 fully characterizes the two-port network of Fig. 1 in the forward direction.

Conceptually, waves represent the propagation of energy along a transmission line. The incident (forward) wave $a = U_f/\sqrt{Z_0}$ travels along the line, with a portion of it ($b = U_r/\sqrt{Z_0}$) being reflected at the line’s end. Adding both complex quantities in every location along the transmission line yields a sine-shaped pattern, the standing wave (Fig. 2). The ratio of its maximum to its minimum voltage is called the voltage standing wave ratio (VSWR) and is directly linked to the magnitude of the impedance Z_L , terminating the line.

$$\text{VSWR} = \frac{|U_f| + |U_r|}{|U_f| - |U_r|} = \frac{U_{\max}}{U_{\min}} = \begin{cases} \left| \frac{Z_L}{Z_0} \right|, & |Z_L| > Z_0 \\ \left| \frac{Z_0}{Z_L} \right|, & |Z_L| < Z_0 \end{cases} \quad (1)$$

Figure 2. Standing waves along a transmission line, terminated in Z_L .

The incident and reflected waves a_i and b_i at a network port (Fig. 1) are defined as linear combinations of the port currents and voltages:

$$a_i = \frac{U_i + I_i Z_0}{2\sqrt{Z_0}}, \quad b_i = \frac{U_i - I_i Z_0}{2\sqrt{Z_0}}$$

making it easy to compute the impedance Z_i at that port:

$$Z_i = \frac{U_i}{I_i} = Z_0 \frac{1 + \frac{b_i}{a_i}}{1 - \frac{b_i}{a_i}} = Z_0 \frac{1 + \Gamma_i}{1 - \Gamma_i}, \quad \Gamma_i = \frac{b_i}{a_i} \quad (2)$$

Γ is called the reflection coefficient. Similarly, the portion of the incident power transmitted from port i to port j is obtained by the transmission factor $t_{ji} = b_j a_i$.

In general, a two-port network is fully characterized by its 2×2 scattering matrix,

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}$$

which is composed of

$$\text{Reflection coefficients: } S_{11} = \left. \frac{b_1}{a_1} \right|_{a_2=0}, \quad S_{22} = \left. \frac{b_2}{a_2} \right|_{a_1=0}$$

$$\text{Transmission coefficients: } S_{21} = \left. \frac{b_2}{a_1} \right|_{a_2=0}, \quad S_{12} = \left. \frac{b_1}{a_2} \right|_{a_1=0}$$

The exact determination of scattering parameters, however, still requires the locus, where they are valid, to be fixed. If the measurement port at $x = 0$ in Fig. 2 is shifted to the left, the phase of incident and reflected waves changes and so does the reflection coefficient, which therefore depends on the locus. Especially at small wavelengths, measurement of S parameters stipulates the exact definition of

where the waves are recorded, leading to the concept of *measurement or reference planes*. These planes are thought to perpendicularly intersect the transmission lines leading to the ports of the network, such that the phase of the waves in each plane is constant. For scattering parameter S_{ij} , the incident wave in plane j is thus the reference for the emanating wave in plane i . S_{ij} therefore describes the transmission of energy between those planes.

As scattering parameters are ratios of emanating and incident waves, their computation does not require absolute measurement of the wave quantities. This important advantage allows the measurement of scattering parameters (with network analyzers) to inherently exhibit much higher precision than can be expected from a spectrum analyzer that relies on absolute measurement of its input power.

The remainder of this article will present a number of measurement systems for the determination of reflection coefficients (one-port network analyzer or reflectometer) and for full characterization of two-port networks. Although the concept of S -parameters is easily extended to N -ports, measurement of networks with more than two ports will not be covered, because most commercially available hardware is built for two-port measurements and can be used to characterize N -ports by simply terminating the unused $N-2$ ports in Z_0 .

2. REFLECTION MEASUREMENT TECHNIQUES

2.1. The Slotted Line for VSWR and Impedance Measurements

A very old technique for measuring the VSWR on a transmission line, to determine the impedance connected at its end, makes use of a slotted transmission line of characteristic impedance Z_0 (see, for example, Ref. 1, Chap. 2, for a very detailed outline; or see Ref. 2, Chap. 4).

The slot allows a small enough probe, as not to disturb the line's field, to be moved along the x axis of the transmission line and sample its electric field. The high-frequency voltage is converted to direct current (dc) by a diode detector and brought to an instrument for readout. Since the signal level of the probe must be kept low in order to avoid loading of the line, the detector operates in its square-law region and its output is proportional to the detected *power*, or the square of the voltage. Noting the maximum and minimum values of the detector output, while varying the position of the probe, allows computation of the VSWR, provided that the slot is long enough to reach both maximum and minimum.

As indicated by Eq. (1), measurement of the scalar VSWR is not sufficient to uniquely determine the complex impedance Z_L , terminating the line. In fact, since

$$\begin{aligned} \text{VSWR} &= \frac{|U_f| + |U_r|}{|U_f| - |U_r|} = \frac{1 + \left| \frac{U_r}{U_f} \right|}{1 - \left| \frac{U_r}{U_f} \right|} = \frac{1 + \left| \frac{b}{a} \right|}{1 - \left| \frac{b}{a} \right|} \\ &= \frac{1 + |\Gamma|}{1 - |\Gamma|} \rightarrow |\Gamma| = \frac{\text{VSWR} - 1}{\text{VSWR} + 1} \end{aligned}$$

only the *magnitude* of the reflection coefficient Γ is available. The *phase* of Γ is obtained by noting the *position* x_{\min} of the first minimum, appearing when the probe is moved away from Z_L . With the propagation constant

$$\beta = \frac{2\pi}{\lambda_{sl}}$$

of the slotted transmission line, the phase of Γ becomes

$$\varphi = 2\beta x - \pi$$

such that

$$\Gamma = |\Gamma|e^{j\varphi} = \frac{\text{VSWR} - 1}{\text{VSWR} + 1} e^{j(2\beta x - \pi)}$$

and the complex impedance Z_L may be computed from Γ using Eq. (2).

Although conceptionally simple, the slotted line technique suffers from several drawbacks and limitations:

1. The slotted transmission line is a costly precision device, exhibiting precise line impedance Z_0 , low losses, negligible loading due to the probe, and mechanical stability of the probe depth over the entire moving range.
2. Linearity errors and the limited dynamic range of the detectors reduce the accuracy, when measuring large VSWRs. By modulating the radiofrequency (RF) source and selective reception of the modulation frequency, noise can be reduced, increasing sensitivity and thus measurement dynamic (the so-called "modulated frequency technique").
3. The measurement procedure requires manual interaction and, in its simple form of Fig. 3, does not allow for swept frequency impedance measurements. If, however, only the magnitude of the reflection coefficient is of interest, Sorger [3] describes a setup that uses two slotted lines for swept frequency VSWR measurement.

Because slotted line reflection measurements are a very old technique, much research has been undertaken to alleviate the above limitations. Many ideas and extensions can be found in Ref. 2, covering the topic in more detail.

2.2. Using the Slotline with Multiple Probes

The biggest drawback of slotline measurements, the need for manual interaction, can be overcome if more than one

Figure 3. The slotted line measurement setup.

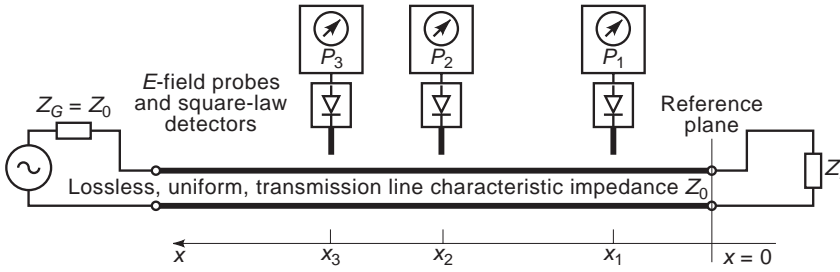

Figure 4. The multiprobe reflectometer.

probe taps to the field of the line in known and fixed positions. Figure 4 shows a system proposed by Caldecott [4] that uses three probes in arbitrary but known positions x_1 , x_2 , and x_3 . Caldecott proved that

$$\Gamma_L \approx \frac{P_1(e^{-j2\beta x_2} - e^{-j2\beta x_3}) + P_2(e^{-j2\beta x_3} - e^{-j2\beta x_1}) + P_3(e^{-j2\beta x_1} - e^{-j2\beta x_2})}{\sin[2\beta(x_2 - x_3)]\sin[2\beta(x_3 - x_1)] + \sin[2\beta(x_1 - x_2)]}$$

even providing complex measurability of the reflection coefficient, although only scalar power measurements ($P_1 \dots P_3$) are used.

Another interesting multiprobe reflectometer for swept frequency/swept power applications reported in Ref. 5 even provided an automatic Smith-chart display of the measured impedance.

2.3. The Six-Port Reflectometer

The idea of the foregoing section can be generalized to the so-called six-port reflectometer, developed by Hoer [6] and Engen [7] in the early 1970s. Figure 5 shows a general six-port junction, driven by a signal generator at port 5, ports 1 through 4 connected to power sensors (diode detectors, bolometers, thermocouple, etc.), and port 6 interfacing to the unknown impedance with reflection coefficient Γ_L .

As the mathematical derivation of the six-port theory is rather lengthy, the interested reader should refer to Refs. 2, 6, or 7 for details. In essence the 6×6 S-matrix of the six-port network is reduced to the form

$$b_i = Q_i a_6 + R_i b_6, \quad i = 1, \dots, 4 \quad (3)$$

by using $\Gamma_i = a_i/b_i$ to eliminate $a_1 \dots a_5$ (b_5 is also eliminated by omitting the fifth equation). The powers P_i are related to b_i by

$$P_i = |b_i|^2(1 - |\Gamma_i|^2)$$

Figure 5. The six-port reflectometer.

and, using Eq. (3), can be expressed as

$$P_i = (1 - |\Gamma_i|^2)\{|R_i|^2|b_6|^2 + 2\text{Re}(Q_i^* R_i) \text{Re}(a_6 b_6^*) + 2 \text{Im}(Q_i^* R_i) \text{Im}(a_6 b_6^*) + |Q_i|^2|a_6|^2\}$$

which may be written in matrix form as

$$(P_1 P_2 P_3 P_4)^T = [D](|b_6|^2 \text{Re}(a_6 b_6^*) \text{Im}(a_6 b_6^*) |a_6|^2)^T \quad (4)$$

with $[D]$ being a real-valued 4×4 matrix. Inverting Eq. (4) gives access to its right-hand-side vector, provided that $[D]$ is known and invertible with $[C]$ being its inverse,

$$(|b_6|^2 \text{Re}(a_6 b_6^*) \text{Im}(a_6 b_6^*) |a_6|^2)^T = [C](P_1 P_2 P_3 P_4)^T$$

such that Γ_L can be computed as

$$\Gamma_L = \frac{a_6}{b_6} = \frac{a_6 b_6^*}{b_6 b_6^*} = \frac{\text{Re}(a_6 b_6^*) + j \text{Im}(a_6 b_6^*)}{|b_6|^2} = \frac{\sum_{n=1}^4 C_{2n} P_n + j \sum_{n=1}^4 C_{3n} P_n}{\sum_{n=1}^4 C_{1n} P_n} \quad (5)$$

With just 12 of the 16 real-valued elements of $[C]$ appearing in Eq. (5), only 11 need to be computed, as Eq. (5) may be normalized to one of the 12 terms. They are determined by measuring *six known* reflection coefficients and using the complex equation [Eq. (5)] to establish a set of 12 linear, real-valued equations in the 12 unknowns.

Although such a calibration procedure to determine the elements of $[C]$ *must* be carried out before the six-port can be used for reflection measurements, it has the added advantage of providing error-corrected results. No a priori knowledge about the six-port is necessary, because the

calibration sufficiently characterizes $[C]$, which reflects the properties of the six-port junction.

Further advantages of this kind of instrument are that neither the signal generator nor the power sensors need to be perfectly matched. The mismatch of the power sensors must however be constant. Because only ratios of measured powers enter the calculation of Γ_L , the power sensors do not need to be absolutely calibrated for power measurements.

However, the power sensors must be linear; and because of their broadband nature, care must be taken to suppress spurious emissions from the signal generator.

Evaluation of Eq. (5) and the determination of $[C]$ require some amount of numerical processing. Six-port reflectometers are therefore almost always combined with microcontrollers to automate the process of calibration and measurement.

Internally, the six-port must be built such that the reduced matrix $[D]$ is invertible at all measurement frequencies. Details of the design process are outlined in Ref. 8 with a practical realization, using 0° and 90° couplers described in Ref. 9.

2.4. Reflection Measurement with the Directional Coupler

All of the impedance measurement methods described thus far evaluate the *sum* of incident and reflected waves, requiring at least two independent measurements for calculation of the reflection coefficient.

Alternatively, forward and reflected waves may be separated using a directional coupler. Such devices are common building blocks in microwave engineering and exist in a wide variety of designs, many of which are treated in Ref. 10, Chap. 8. The interested reader may also refer to Ref. 11 for some less common coupler structures and unusual applications. Figure 6 depicts the associated symbol of a directional coupler and its scattering matrix.

The important property of the directional coupler, used to separate incident and reflected wave, is in its decoupled port. Figure 7 illustrates that feeding a wave a_1 into port 1 results in wave $b_2 = \tau a_1$ and $b_3 = \kappa a_1$ being emitted at ports 2 and 3 with no energy being fed to port 4, the decoupled port. Similarly, port 2 is decoupled from port 3. Driving the coupler at port 1, terminating port 3 in Z_0 , and connecting a matched power detector to port 4 allows measurement of unknown reflection coefficients connected to port 2.

Directional couplers, also called “VSWR-bridges” or “reflection coefficient bridges,” appear in various forms, with the microstrip coupler, the resistive coupler, and the Wilkinson divider (Fig. 8) being the variants most often found.

Figure 6. The directional coupler.

Figure 7. Reflection measurement using a directional coupler.

All practical realizations of directional couplers exhibit finite *directivity*, meaning that a small amount of the power fed to port 1 will leak to port 4, even if port 2 and 3 are perfectly terminated in Z_0 . The directivity of a coupler is defined as

$$d = \frac{S_{14}}{\kappa\tau}$$

Mismatch at port 2 and even at the driving port 1 will further add to erroneous reflections being indicated by the wave b_4 , which ideally should be a measure of the reflection of Z_L only. All these errors must be kept low if the coupler is to be used for precision reflection measurement. Narrow-band precision couplers, exhibiting more than 50 dB directivity, have been built in waveguide and broad-band couplers, typically of the resistive bridge type, and exhibit more than 36 dB directivity over a bandwidth of more than three decades. As a rule of thumb, the directivity should be at least 10 dB better than the expected reflection coefficient of the measured device under test (DUT).

3. ARCHITECTURES OF NETWORK ANALYZERS

In order to measure the entire scattering matrix of a two-port, some means of measuring the transmitted waves as well as the reflected waves must be provided. Because reflection measurements, nowadays, are almost always carried out with directional couplers, we will use its symbol for denoting measurement of reflected waves. As in Fig. 7, the “mixer” symbol will denote a measurement point, at which the wave to be measured may be further processed in one of the following ways:

1. With power detectors, leading to scalar measurement of the wave

Figure 8. Some commonly used directional couplers.

2. With a homodyne receiver, potentially capable of providing amplitude and phase information
3. With a heterodyne receiver (hence the mixer symbol), providing amplitude and phase information

Depending on the type of detector used, network analyzers (NAs) are classified into one of the following types of analyzer:

3.1. Scalar Network Analyzer

The simplest and most economic approach to the measurement of scattering-parameters employs power (diode) detectors. Because these provide no phase information, only the magnitude of the S -parameters can be measured, hence the term *scalar network analyzer* (SNA). For many applications, however, the magnitude may be all that is needed. Calibration techniques, as described in Section 4, however, require the phase information and consequently cannot be applied to SNAs. Instead, normalization is all that can be employed with such an instrument.

Other drawbacks of SNAs are the limited dynamic range and the broad-band nature of the power detectors. As they record the entire power of a wave, regardless of its spectral origin, these instruments are susceptible to spurs or harmonics of the generator. If, for example, the harmonics of the radiofrequency (RF) source are suppressed by 30 dB, and the DUT has a high-pass or bandstop characteristic (return loss of a filter or an antenna), the SNA will show no less than -30 dB attenuation or return loss, regardless of the DUT's real properties.

It should be emphasized that the mere use of power detectors does not necessarily yield a scalar network analyzer. The six-port reflectometer, as described in Section 2.3, employs four scalar detectors to determine the complex reflection coefficient; a complete vector NA can be built by using two such reflectometers (see Refs. 8, 9, and 12), retaining all vector error-correction capabilities of those instruments [13,14], as discussed in Section 4.

3.2. Heterodyne (Vector) Network Analyzer

If the wave quantities are processed by heterodyne receivers, the phase information can be preserved by phase-locking the heterodyne oscillator to the RF source driving the DUT (Fig. 9), and complex measurement of the scattering parameters is possible. Besides providing a much higher dynamic range (over 120 dB for recent industry products versus 70 dB for SNAs), the ability to measure the complex S -parameters has the added benefit of allowing calibration techniques to enhance measurement accuracy. On the other hand, the inherent higher complexity of heterodyne vector network analyzers (VNAs) results in more expensive hardware. For broad-band systems, the heterodyne oscillator and its Phase Locked Loop (PLL) add considerably to the cost, because they must cover the system's entire bandwidth.

A cost reducing alternative exists by employing "harmonic mixing" (e.g., Ref. 35). In this case the local oscillator (LO) in Fig. 9 has to cover only one octave with all higher frequencies that are needed being supplied by the LO's harmonics. Harmonic mixing, however, leads to

Figure 9. Heterodyne receiver (LO): Local Oscillator, IF: Intermediate Frequency, BP: Bandpass filter, PFD: Phase-Frequency Detector, $H(s)$: Loopfilter.

higher mixer conversion loss and thus also reduces the instrument's dynamic range.

3.3. Homodyne Network Analyzers

In order to circumvent the need for a second microwave source and phase-locking circuitry, homodyne systems use the same generator for down-conversion that drives the DUT. Because the homodyne mixing process provides only the real part of the wave quantity, homodyne NAs need additional hardware (phase-shifters) to extract the complex information from two or more measurements (e.g., Ref. 15). Although relatively simple hardware concepts have been developed [16], homodyne NAs also suffer from their sensitivity to generator harmonics, limiting dynamic range. It is for that reason that homodyne systems are rarely used in the laboratory, although some realizations exist for industrial measurements.

Regardless of the kind of detector used, all practical realizations of the NA architectures introduced in the next sections should be built to provide:

- Good port match, properly terminating the DUT in the system impedance Z_0
- High directivity of the directional coupler for precise reflection measurement
- Low variation of transmission losses over the bandwidth of the system

3.4. Reflection and Transmission Measurement with the Unidirectional Network Analyzer

Unidirectional network analyzers (Fig. 10) extend the capability of a simple reflectometer to measure S_{11} and S_{21} of a two-port DUT.

With the measured quantity m_1 being proportional to a_1 , m_2 presenting a measure for the reflection b_1 , and m_3 presenting a measure for the transmission b_2 , S_{11} , and S_{21} can be expressed as

$$S_{11} = c_{11} \frac{m_2}{m_1}, \quad S_{21} = c_{21} \frac{m_3}{m_1} \quad (6)$$

The proportionality constants are usually obtained through normalization measurements of known reflection/transmission coefficients. Connecting a "Short" with $S_{11} = -1$ to port 1 yields

$$c_{11} = -1 \frac{m_1^S}{m_2^S}; \quad \text{and} \quad c_{21} = 1 \frac{m_1^T}{m_3^T}$$

Figure 10. Unidirectional network analyzer.

is obtained by connecting both ports (“Through”), such that $S_{21} = 1$.

For measurement of S_{22} and S_{12} (reverse direction), the DUT must be connected to the unidirectional NA with its ports reversed.

3.5. The Three-Receiver Network Analyzer Architecture for Full Two-Port Measurements

The need for manually reversing the DUT can be eliminated if a switch and another directional coupler is introduced into the system of Fig. 11. With the switch in position I, the RF source is connected to port 1 of the DUT, m_1 is proportional to a_1 , m_2 is a measure for b_1 , and m_3 is a measure for b_2 . The second contact of the switch terminates the coupler at port 2 in Z_0 , ensuring proper port match. With the switch in position II, port 2 of the DUT is excited, the coupler connected to port 1 of the DUT is terminated in Z_0 , and m_1 is now a measure for a_2 . As the three receivers m_1 , m_2 , and m_3 now provide different readings, depending on the position of the switch, their measurement values will from now on be referred to as m_i^I and m_i^{II} , the superscript denoting the position of the switch. The S -parameters of the DUT are therefore determined as

$$S_{11} = c_{11} \frac{m_2^I}{m_1^I}, \quad S_{21} = c_{21} \frac{m_3^I}{m_1^I}$$

$$S_{22} = c_{22} \frac{m_3^{II}}{m_1^{II}}, \quad \text{and} \quad S_{12} = c_{12} \frac{m_2^{II}}{m_1^{II}}$$

with the proportionality constants resulting from normalization measurements. Using a “Short” at port 1 and

port 2 and a “Through” connecting both ports yields

$$c_{11} = -1 \frac{m_1^I}{m_2^I}, \quad c_{21} = 1 \frac{m_1^I}{m_3^I}$$

$$c_{22} = -1 \frac{m_1^{II}}{m_3^{II}}, \quad \text{and} \quad c_{12} = 1 \frac{m_1^{II}}{m_2^{II}}$$

The switch should be well matched to keep measurement errors low, must be reproducible, and must provide sufficient isolation in order not to limit the dynamic range of the instrument.

3.6. The Four-Receiver Vector Network Analyzer

There seems to be little gained in extending the above-described three-receiver NA with a fourth receiver, as outlined in Fig. 12, because the complete S -matrix of a two-port can already be measured with three receivers. For *vector* network analyzers (VNA), however, the additional receiver provides simultaneous measurement capability of all waves and makes the architecture completely symmetrical around the DUT, resulting in interesting calibration capabilities, detailed in Sections 4.5, 4.6, and 5. The subtle change of moving the switch from *between* two receivers to *in front* of the receiver pairs radically alters the error model, even reducing the requirements of the switch (see Section 4.5). For measurements *without* error correction, however, the switch must, again, be as ideal as possible with respect to match, repeatability, and isolation.

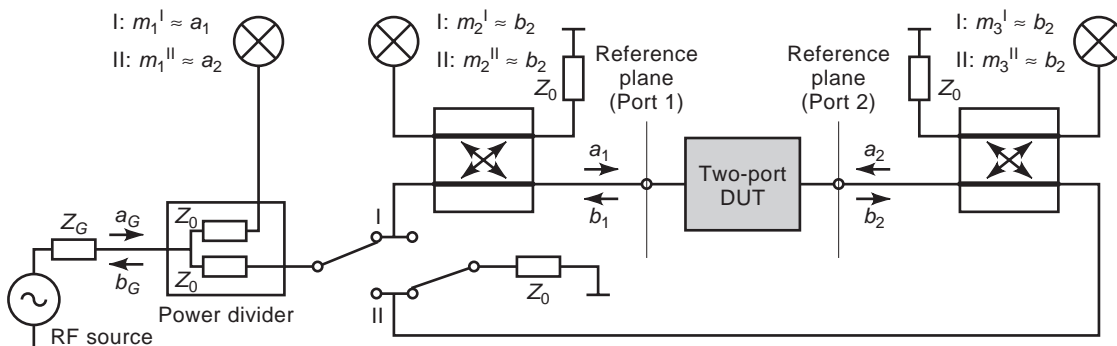

Figure 11. Bidirectional network analyzer with three receivers.

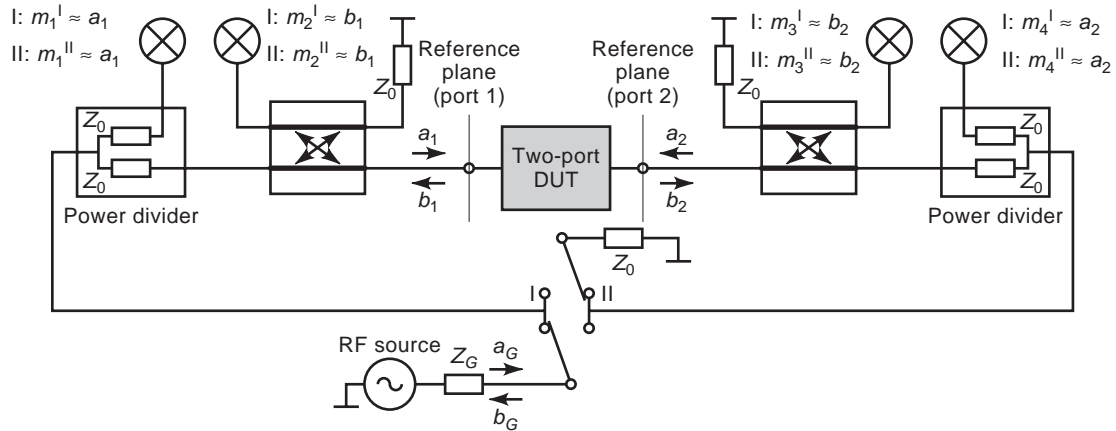

Figure 12. Bidirectional vector network analyzer with four receivers.

A four-receiver VNA measures the S -matrix of a two-port DUT as

$$S_{11} = c_{11} \frac{m_2^I}{m_1^I}, \quad S_{21} = c_{21} \frac{m_3^I}{m_1^I}$$

$$S_{22} = c_{22} \frac{m_3^II}{m_4^II}, \quad \text{and} \quad S_{12} = c_{12} \frac{m_2^II}{m_4^II}$$

with the proportionality factors determined through normalization measurements as described before.

4. ERROR MODELS, CALIBRATION, AND ERROR CORRECTION

For a long time, precision NAs required carefully designed and expensive hardware, ensuring a good port match for embedding the DUT between proper terminations and high coupler directivity for precise reflection measurement. Losses in the hardware had to be accounted for by reference measurements of devices with a known characteristic. With the advent of microprocessors, however, the focus has shifted toward calibration techniques that allow the imperfections of the hardware to be taken into account and corrected mathematically. An error model is needed for this purpose, and its parameters are determined through measurement of well-known one- or two-ports (calibration). This mathematical description of the non-ideal hardware is then used to correct the measurement of the DUT.

The error models, covered in subsequent sections, are used to model and correct all the linear errors of the VNA: transmission losses between the generator, the receivers, and the DUT; port match; and coupler directivity. Theoretically, the hardware of a VNA that provides these error-correction capabilities need no longer be built to high standards. Yet, commercially available systems still strive for good hardware performance for two reasons: first, in an effort to assist the calibration through good hardware performance and achieve even better accuracy; and, second, to provide an instrument that does not depend on time-consuming calibration procedures, allowing unco-

rected measurements for all those applications that can tolerate the reduced accuracy. However, commercially available instruments use the calibration capabilities for a considerable extension of their usable bandwidth. When the directivity of the directional couplers decreases to unsatisfactory values below a certain frequency, a built-in error correction mathematically enhances the directivity to usable values, extending the frequency range to as low as 9 kHz.

As all error models presented herein are linear and deterministic, a stringent requirement remains that the VNA hardware be linear (errors due to compression of receivers cannot be corrected) and stable.

With modern equipment achieving a short-term stability in the millidecibel range, the most prominent source of error in many cases remains in the cabling between the VNA and the DUT and the associated interface contacts. These contacting errors are statistical in nature and must be minimized by proper cable and connector selection and maintenance. As the transmission phase of coaxial cables varies over temperature and may change if the cable is bent, VNAs are usually equipped with special test-port cables, optimized for phasestability and mechanically protected against overbending.

The mathematical descriptions of the error models presented in the following sections make heavy use of matrix representations, leading to very compact expressions and similar structures for the different models. Alternatively, flowgraph techniques could be applied as in Refs. 17 and 18, leading to comparable results.

4.1. The Three-Term Error Model for Reflection Measurements

A reflectometer like the one of Fig. 13 can always be represented by a linear four-port, driven at the left port by the RF source, two ports connected to the receivers for measurement of the incident and reflected waves, and the DUT placed at the port to the right. In this general form, the underlying hardware of the reflectometer becomes unimportant, much like the fact that internal structure of the six-port reflectometer was of no concern in Section 2.3.

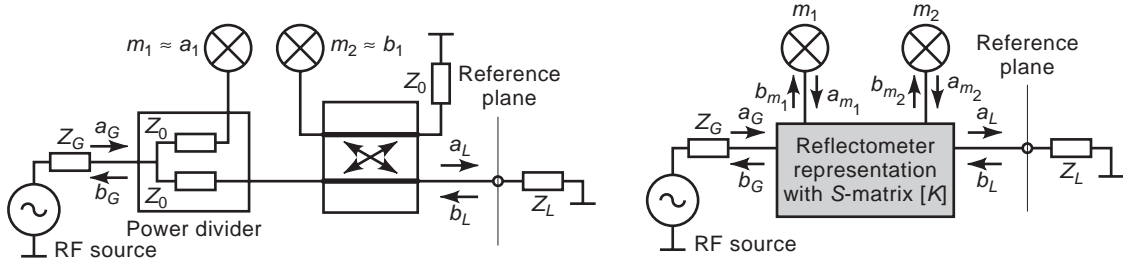

Figure 13. Four-port description of a reflectometer.

The waves incident to and reflected from this four-port relate to its S -matrix by

$$\begin{pmatrix} b_{m_1} \\ b_{m_2} \\ a_L \\ b_G \end{pmatrix} = [K] \begin{pmatrix} a_{m_1} \\ a_{m_2} \\ b_L \\ a_G \end{pmatrix} \quad (7)$$

The measured quantities m_1 and m_2 are proportional to the incident waves of the receivers ($m_1 = \eta_1 b_{m_1}$, $m_2 = \eta_2 b_{m_2}$), with the receiver constant η_i representing the entire transfer characteristics of the i th receiver, comprising mixer conversion, intermediate frequency (IF) amplification, and so on. Architectural details of the receiver are of no concern at this point. The only requirement is that η_i must be constant, implying stability of the receiver's phase and amplitude response. Let r_i be the reflection coefficients of the receiver inputs such that the conditions

$$\begin{aligned} m_1 &= \eta_1 b_{m_1}, & m_2 &= \eta_2 b_{m_2}, \\ a_{m_1} &= r_1 b_{m_1}, & a_{m_2} &= r_2 b_{m_2} \end{aligned} \quad (8)$$

result. Their use allows the elimination of the generator waves a_G and b_G in Eq. (7), according to the following scheme: The third equation of Eq. (7) is solved for a_G , and the result is inserted into the first two equations. In these, b_{m_i} is expressed through a_{m_i} and a_{m_i} in turn expressed by m_i , using Eq. (8). The resulting two equations relate the measured quantities m_1 and m_2 to the waves at the DUT and are arranged in matrix form as

$$\begin{pmatrix} b_L \\ a_L \end{pmatrix} = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \begin{pmatrix} m_2 \\ m_1 \end{pmatrix} = [G] \begin{pmatrix} m_2 \\ m_1 \end{pmatrix} \quad (9)$$

Every element of $[G]$ evolves as a function of K_i , r_i , and η_i , which need not be explicitly known. It suffices to determine $[G]$ through a process called calibration, in order to calculate the correct waves at the DUT from the raw measurements m_i :

$$\Gamma_L = \frac{b_L}{a_L} = \frac{G_{11}m_2 + G_{12}m_1}{G_{21}m_2 + G_{22}m_1} \quad (10)$$

Interestingly, this four-port/two-port reduction with its elimination of the generator waves has freed the error model [Eq. (9)] from any influence of the RF source. Power or impedance variations do not introduce measurement errors, provided that m_1 and m_2 are measured simultaneously.

Equation (10) can be further simplified by dividing numerator and denominator by m_1 and defining

$$m_{11} = \frac{m_2}{m_1} = \frac{\eta_2 b_{m_2}}{\eta_1 b_{m_1}} \quad (11)$$

as the uncorrected (raw) reflection measurement [compare with Eq. (6)] such that the error-corrected reflection coefficient becomes

$$\Gamma_L = \frac{b_L}{a_L} = \frac{G_{11}m_{11} + G_{12}}{G_{21}m_{11} + G_{22}} \quad (12)$$

The importance of Eq. (11) is twofold:

1. The ratio of two measurements enters the computation of the error-corrected result. Relative, rather than absolute, measurements are therefore still sufficient if an error model and error correction is used. And with the reflected wave measurement m_2 being referenced to the incident wave measurement m_1 , the theoretically derived insensitivity of the error model to power variations of the RF source becomes obvious.
2. The ratio of η_1/η_2 appearing in Eq. (11) indicates that amplitude and phase drifts of the receivers cancel if both receivers are built *equal*.

Both properties are essential for the high accuracy achievable with VNAs. The use of the latter property is especially important for accurate phase measurements at high frequencies.

4.1.1. Calibration of the Three-Term Error Model. Before error-corrected measurements using Eq. (12) can be carried out, the error matrix $[G]$ must be determined. For this calibration procedure, several one-ports (calibration standards) with known reflection coefficients are needed. As numerator and denominator of Eq. (12) may be multiplied by any complex number without altering the result, one of the error terms may arbitrarily be set to 1, with the other

three remaining to be computed. Without loss of generality, let $G_{11} = 1$ and Eq. (12) can be rearranged to yield a linear equation in the three remaining error terms:

$$-G_{12} + \Gamma^i m_{11}^i G_{21} + \Gamma^i G_{22} = m_{11}^i \quad (13)$$

The superscript i denotes the i th calibration measurement with known reflection coefficient Γ^i and the corresponding measured value m_{11}^i . Performing calibration measurements with three distinct and known reflection standards yields three linear inhomogeneous and independent forms of Eq. (13), sufficient to solve for the needed error terms.

In order to maximize the independence of the three equations, the three-term calibration is typically performed with those three impedances, which are furthest apart in the reflection plane:

$$\text{Open: } \Gamma^O = 1, \quad \text{Short: } \Gamma^S = -1,$$

$$\text{Match: } \Gamma^M = 0$$

Three-term reflectometer calibration is therefore also referred to as OSM calibration.

4.2. The Five-Term Error Model for Unidirectional Vector Network Analyzers

Extending a single reflectometer with a third receiver for transmission measurements yields the unidirectional NA of Fig. 10. Its error model comprises two parts: The reflectometer hardware to the left of the DUT, which is again represented by an error two-port $[G]$; and the hardware to the right of the DUT, which constitutes a physical two-port with a corresponding 2×2 S -matrix (Fig. 14).

As in Section 4.1, the reflection coefficient r_3 and the transfer characteristics η_3 of the receiver m_3 establish the conditions

$$a_{m_3} = r_3 b_{m_3} \quad \text{and} \quad m_3 = \eta_3 b_{m_3}$$

which are used to reduce $[T]$ to an error two-port that relates the waves a_2 and b_2 of the DUT to the measured value m_3 :

$$\begin{pmatrix} b_2 \\ a_2 \end{pmatrix} = \begin{bmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{bmatrix} \begin{pmatrix} m_3 \\ 0 \end{pmatrix} = [H] \begin{pmatrix} m_3 \\ 0 \end{pmatrix}$$

Figure 14. Hardware description of the transmission receiver m_3 .

Together with the error two-port of the reflectometer

$$\begin{pmatrix} b_1 \\ a_1 \end{pmatrix} = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \begin{pmatrix} m_2 \\ m_1 \end{pmatrix} = [G] \begin{pmatrix} m_2 \\ m_1 \end{pmatrix}$$

and the definition of the DUT's S -matrix

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \quad (14)$$

the error model (Fig. 15) can be expressed as

$$\begin{aligned} \begin{pmatrix} b_1 \\ b_2 \end{pmatrix} &= \begin{pmatrix} G_{11}m_2 + G_{12}m_1 \\ H_{11}m_3 \end{pmatrix} \\ &= [S] \begin{pmatrix} G_{21}m_2 + G_{22}m_1 \\ H_{21}m_3 \end{pmatrix} = [S] \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \end{aligned} \quad (15)$$

It is obvious that the two equations of Eq. (15) are not sufficient to solve for the entire S -matrix of the DUT. On the other hand, the “forward” S -parameters S_{11} and S_{21} cannot be error-corrected by themselves without the knowledge of S_{12} and S_{22} .

Error correction is therefore only possible if a second measurement with the DUT reversed is made. Denoting the measured values with superscripts f and r for forward and reverse measurement of the DUT, both vector equations of Eq. (15) can be combined into a matrix equation

$$\begin{aligned} &\begin{bmatrix} G_{11}m_2^f + G_{12}m_1^f & H_{11}m_3^r \\ H_{11}m_3^f & G_{11}m_2^r + G_{12}m_1^r \end{bmatrix} \\ &= [S] \begin{bmatrix} G_{21}m_2^f + G_{22}m_1^f & H_{21}m_3^r \\ H_{21}m_3^f & G_{21}m_2^r + G_{22}m_1^r \end{bmatrix} \end{aligned} \quad (16)$$

Again, Eq. (16) may be normalized to the incident waves m_1^f and m_1^r such that only the unconnected measurement ratios

$$\begin{aligned} m_{11} &= \frac{m_2^f}{m_1^f} = \frac{\eta_2 b_{m_2}^f}{\eta_1 b_{m_1}^f}, & m_{21} &= \frac{m_3^r}{m_1^f} = \frac{\eta_3 b_{m_3}^r}{\eta_1 b_{m_1}^f} \\ m_{12} &= \frac{m_3^r}{m_1^r} = \frac{\eta_3 b_{m_3}^r}{\eta_1 b_{m_1}^r}, & m_{22} &= \frac{m_2^f}{m_1^r} = \frac{\eta_2 b_{m_2}^f}{\eta_1 b_{m_1}^r} \end{aligned}$$

Figure 15. Error model of the unidirectional vector network analyzer.

remain [compare with Eq. (6)]. Solving the normalized version of Eq. (16) for $[S]$ yields the error-correction formula

$$[S] = \begin{bmatrix} G_{11}m_{11} + G_{12} & H_{11}m_{12} \\ H_{11}m_{21} & G_{11}m_{22} + G_{12} \end{bmatrix} \times \begin{bmatrix} G_{21}m_{11} + G_{22} & H_{21}m_{12} \\ H_{21}m_{21} & H_{21}m_{22} + G_{22} \end{bmatrix}^{-1} \quad (17)$$

4.2.1. Calibration of the Five-Term Error Model. Not all of the eight error terms contained in $[G]$ and $[H]$ are needed for error correction with Eq. (17), where H_{12} and H_{22} do not appear. Furthermore, the structure of Eq. (17) reveals its invariance to multiplication of *all* error terms with a constant. The remaining error terms may therefore be computed by rearranging Eq. (17) into a linear, homogeneous system of equations in the error terms,

$$\begin{bmatrix} -m_{11}^i & -1 & S_{11}^i m_{11}^i & S_{11}^i & 0 & S_{12}^i m_{21}^i \\ 0 & 0 & S_{21}^i m_{11}^i & S_{21}^i & -m_{21}^i & S_{22}^i m_{21}^i \\ 0 & 0 & S_{12}^i m_{22}^i & S_{12}^i & -m_{12}^i & S_{11}^i m_{12}^i \\ -m_{22}^i & -1 & S_{22}^i m_{22}^i & S_{22}^i & 0 & S_{21}^i m_{12}^i \end{bmatrix} \times \begin{pmatrix} G_{11} \\ G_{12} \\ G_{21} \\ G_{22} \\ H_{11} \\ H_{21} \end{pmatrix} = 0 \quad (18)$$

setting one error term to unity and solving the resulting inhomogeneous system of equations. $[S^i]$ denotes the S -matrix of the i th calibration standard. Five independent equations are needed to solve for the remaining five independent error terms, hence the name five-term error model.

The problem of *how many* two-port standards are needed and how they must be built to ensure five independent equations can be tackled in the following way: A suitable combination of standards must always comprise at least one standard with transmission ($S_{21} \neq 0$ and $S_{12} \neq 0$); otherwise, H_{11} and H_{21} cannot be determined [$S_{21} = S_{12} = 0$ implies $m_{21} = m_{12} = 0$, such that the fifth and sixth column

of Eq. (18) vanish]. Numerical investigations reveal that a two-port standard exhibiting transmission contributes at least two equations and may contribute four if it is not symmetric (i.e., $S_{11} \neq S_{22}$).

Because the use of reflection standards ($S_{21} = S_{12} = 0$) implies $m_{21} = m_{12} = 0$, the second and third equation of Eq. (18) degenerate, leaving only the first and fourth equation for determination of $[G]$; and with $S_{11} = \Gamma_s$, the first equation corresponds directly to Eq. (13) (three-term calibration) with $G_{11} = 1$. Transmissionless standards therefore contribute one equation per reflection coefficient connected to port 1.

Even though the general nature of Eq. (18) allows for calibration with any set of standards that yields five independent equations, traditionally the five-term model is calibrated using the three reflection standards Open, Short, and Match (contributing three equations), together with a direct connection of both reference planes, the Through standard (furnishing the remaining two equations). Figure 16 depicts this commonly used set of standards. Another name for this commonly used procedure is SOLT, which stands for Short, Open, Load, and Through.

Of course, care must be taken as to build the calibration standards such that their S -matrix or reflection coefficients match the postulated values used in the calibration process. All deviations of the standards' *real* values from the postulated *ideal* of Fig. 16 lead to inconsistencies in the equations of Eq. (18). Keeping these inconsistency errors small requires a smart choice and precisely built or modeled standards.

Because the Through standard requires a direct connection of both measurement ports, it is typically a very easy standard to realize in coaxial media. The same holds for the Short, which is easily manufactured to high precision ($< 1^\circ$ deviation at 20 GHz) in coaxial media. However, care must be taken as to ensure that the Short is connected directly to the reference plane, which is a potential problem if sexed connectors (N, SMA, K) are used. Bridging same-sexed connectors with adapters introduces a phase shift $2\beta l$ into the reflection coefficient, which must be known in order to substitute the shorts reflection coefficient by $-1e^{-2\beta l}$. The same holds if offset shorts with electrical length $2\beta l$ are used. For a frequency band where $2\beta l$ is between 40° and 320° , the latter can replace the open standard, which typically suffers from fringing capacities and radiation losses. Therefore, the open standards contained in commercially available calibration kits come with detailed information on those imperfections, modeling the frequency dependence of the open's capacitance by a polynomial to enhance accuracy. For the absolute impedance reference, the Match standard, precision crafting is needed for precision measurements.

4.3. The 10-Term Error Model for Vector Network Analyzers with Three Receivers

For all practical purposes, the applicability of the five-term error model is somewhat impaired by the need for manually reversing the DUT in order to obtain

Figure 16. Calibration standards for the TMSO five-term procedure. Through: $[S^T] = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$, Open: $S_{11}^O = 1$, Short: $S_{11}^S = -1$, Match: $S_{11}^M = 0$

error-corrected results. If a switch is incorporated into the VNA, as depicted in Fig. 11, this manual interaction can be automated, easing error-corrected measurements considerably.

In essence, the error model of the resulting bidirectional VNA with three receivers (see Section 3.5) consists of *two* five-term error models (Fig. 17). Because of the switch being located *between* m_1 and m_2 and m_1 and m_3 , different error two-ports are needed for either position of the switch.

With the switch in position I, the reflectometer comprising m_1 and m_2 can be represented by an error two-port $[G^I]$ and the reflectometer terminated in Z_0 and comprising m_3 by an error two-port $[H^I]$. In the second state of the switch, the four-port comprising m_1 and m_3 can be reduced to the error two-port $[G^{II}]$ and the reflectometer terminated in Z_0 and comprising m_2 by an error two-port $[H^{II}]$ with

$$\begin{aligned} \begin{pmatrix} b_1 \\ a_1 \end{pmatrix} &= [G^I] \begin{pmatrix} m_2^I \\ m_1^I \end{pmatrix}, & \begin{pmatrix} b_2 \\ a_2 \end{pmatrix} &= [H^I] \begin{pmatrix} m_3^I \\ 0 \end{pmatrix} \\ \begin{pmatrix} b_1 \\ a_1 \end{pmatrix} &= [H^{II}] \begin{pmatrix} m_2^{II} \\ 0 \end{pmatrix}, & \begin{pmatrix} b_2 \\ a_2 \end{pmatrix} &= [G^{II}] \begin{pmatrix} m_3^{II} \\ m_1^{II} \end{pmatrix} \end{aligned}$$

Using these relations together with Eq. (14) yields a vector equation for either state of the switch that can be combined into a matrix equation, very similar to Eq. (16):

$$\begin{aligned} &\begin{bmatrix} G_{11}^I m_2^I + G_{12}^I m_1^I & H_{11}^{II} m_2^{II} \\ H_{11}^I m_3^I & G_{11}^{II} m_3^{II} + G_{12}^{II} m_1^{II} \end{bmatrix} \\ &= [S] \begin{bmatrix} G_{21}^I m_2^I + G_{22}^I m_1^I & H_{21}^{II} m_2^{II} \\ H_{21}^I m_3^I & G_{21}^{II} m_3^{II} + G_{22}^{II} m_1^{II} \end{bmatrix} \end{aligned}$$

Normalization to the incident waves m_1^I and m_1^{II} now yields

$$\begin{aligned} &\begin{bmatrix} G_{11}^I m_{11} + G_{12}^I & H_{11}^{II} m_{12} \\ H_{11}^I m_{21} & G_{11}^{II} m_{22} + G_{12}^{II} \end{bmatrix} \\ &= [S] \begin{bmatrix} G_{21}^I m_{11} + G_{22}^I & H_{21}^{II} m_{12} \\ H_{21}^I m_{21} & G_{21}^{II} m_{22} + G_{22}^{II} \end{bmatrix} \end{aligned} \quad (19)$$

Error model for switch in position I

with

$$\begin{aligned} m_{11} &= \frac{m_2^I}{m_1^I} = \frac{\eta_2 b_{m_2}}{\eta_1 b_{m_1}}, & m_{21} &= \frac{m_3^I}{m_1^I} = \frac{\eta_3 b_{m_3}}{\eta_1 b_{m_1}} \\ m_{12} &= \frac{m_2^{II}}{m_1^{II}} = \frac{\eta_2 b_{m_2}}{\eta_1 b_{m_1}}, & m_{22} &= \frac{m_3^{II}}{m_1^{II}} = \frac{\eta_3 b_{m_3}}{\eta_1 b_{m_1}} \end{aligned}$$

where comparison with the five-term error model shows that m_2^{II} and m_3^{II} have switched their position as have the error terms for the second state of the switch, a consequence of the switch now reversing the DUT and the error two-ports.

With error correction according to the 10-term error model applied, the requirements of the switch as detailed in Section 3.5 become somewhat relaxed, because its mismatch errors and transmission losses are now accounted for. However, repeatability and leakage errors (finite isolation) are not contained in the error model.

4.3.1. Calibration of the 10-Term Error Model. As was the case with the five-term model, not all 16 error terms appear in Eq. (19). H_{12}^I , H_{22}^I , H_{22}^{II} , and H_{22}^{II} are not needed for error correction and cannot be determined by the calibration procedure.

Rearranging Eq. (19) as a linear homogeneous system of equations in the remaining error terms, as demonstrated in Section 4.2.1 finds the four equations to be decoupled: Two equations depend solely on error terms of $[G^I]$ and $[H^I]$, and the other two equations depend only on $[G^{II}]$ and $[H^{II}]$:

$$\begin{bmatrix} -m_{11}^i & -1 & S_{11}^i m_{11}^i & S_{11}^i & 0 & S_{12}^i m_{21}^i \\ 0 & 0 & S_{21}^i m_{11}^i & S_{21}^i & -m_{21}^i & S_{22}^i m_{21}^i \end{bmatrix} \mathbf{e}^I = 0,$$

$$\mathbf{e}^I = (G_{11}^I, G_{12}^I, G_{21}^I, G_{22}^I, H_{11}^I, H_{21}^I)^T$$

$$\begin{bmatrix} 0 & 0 & S_{12}^i m_{22}^i & S_{12}^i & -m_{12}^i & S_{11}^i m_{12}^i \\ -m_{22}^i & -1 & S_{22}^i m_{22}^i & S_{22}^i & 0 & S_{21}^i m_{12}^i \end{bmatrix} \mathbf{e}^{II} = 0,$$

$$\mathbf{e}^{II} = (G_{11}^{II}, G_{12}^{II}, G_{21}^{II}, G_{22}^{II}, H_{11}^{II}, H_{21}^{II})^T$$

With one of the error terms of both \mathbf{e}^I and \mathbf{e}^{II} set to 1 (e.g., $G_{11}^I = G_{11}^{II} = 1$), two sets of five independent equations must be supplied by the calibration measurements in order to solve the resulting inhomogeneous system for the remaining 10 error terms.

Error model for switch in position II

Figure 17. Error model of the bidirectional vector network analyzer with three receivers.

A similar reasoning (compared with Section 4.2.1) as to how many and what kind of standards are needed is applicable here. At least one standard with transmission ($S_{21} \neq 0$ and $S_{12} \neq 0$) is needed in order to determine $[H^I]$ and $[H^{II}]$. Because of the different error terms, such a standard will supply a total of four equations for both positions of the switch. Reflection two-ports ($S_{21} = S_{12} = 0$), on the other hand, still contribute one equation for each of their two reflection coefficients S_{11} and S_{22} .

The same standards as with the five term error model (referred to as TMSO, Through-Match-Short-Open, or SOLT, Short-Open-Load-Through) are commonly used to calibrate the 10-term model, with the reflection standards now being reflection two-ports.

Because of the decoupled nature of Eq. (19), the reflection two-ports may be realized as one-ports by first connecting the calibration impedance to port 1 and noting the measurement values with the switch in position I. Then the appropriate calibration impedance is connected to port 2 and the measurements are taken with the switch in the second position [because these standards do not exhibit transmission, the corresponding transmission receiver (m_3^I, m_2^{II}) need not be considered]. With respect to the commonly used TMSO standards, this sequential procedure eliminates the need for two identical reflection standards but allows usage of one physical match—short and open—as reflection one-ports.

4.4. The Crosstalk Including 12-Term Error Model for Three-Receiver VNAs

Several commercially available VNAs provide a 12-term calibration capability [17], expanding the above-described 10-term error model by two error terms that characterize forward and reverse isolation. Their inclusion aims at extending the dynamic range for measurements where finite isolation of the switch or coupling over the DUT adversely affects measurement accuracy at high insertion loss levels of the DUT.

For that purpose, an additional isolation standard (no transmission) with, for now, arbitrary reflection coefficients r_1 and r_2

$$[S^X] = \begin{bmatrix} r_1 & 0 \\ 0 & r_2 \end{bmatrix} \rightarrow [M^X] = \begin{bmatrix} m_{11}^X & m_{12}^X \\ m_{21}^X & m_{22}^X \end{bmatrix}$$

must be measured (alternatively the transmission measurement of one of the reflection standards may be exploited). The transmission terms m_{12}^X and m_{21}^X of its measurement matrix are a measure of the crosstalk level and can be used for correcting the measured transmission values of the DUT:

$$[S] = \begin{bmatrix} G_{11}^I m_{11} + G_{12}^I & H_{11}^{II} (m_{12} - m_{12}^X) \\ H_{11}^I (m_{21} - m_{21}^X) & G_{11}^{II} m_{22} + G_{12}^{II} \end{bmatrix} \\ \times \begin{bmatrix} G_{21}^I m_{11} + G_{22}^I & H_{21}^{II} (m_{12} - m_{12}^X) \\ H_{21}^I (m_{21} - m_{21}^X) & G_{21}^{II} m_{22} + G_{22}^{II} \end{bmatrix}^{-1}$$

However, this simple correction scheme can only improve results if the reflection coefficients of the isolation standard match the reflection coefficients of the DUT. For well-matched DUTs, the isolation terms can be taken from the measurement of the Match standard $[S^M]$. High transmission dynamic DUTs (e.g., filters), however, typically exhibit strongly varying reflection coefficients over frequency. If two identical DUTs are available, an isolation standard that satisfies the above condition can be generated by connecting the first DUT with port 1 to port 1 of the VNA and the second DUT with port 2 to the VNAs second port. The unused ports of the DUTs are terminated in Z_0 . Consequently, the isolation measurement must be repeated with a suitable isolation standard whenever DUTs with differing reflection coefficients are to be measured.

Considering the above limitations, the cross-talk reduction with the 12-term model should be regarded as a cross-talk *normalization* rather than as a *calibration*.

In Section 4.6, it will be shown that for an error model to correctly include cross-talk, eight error terms are needed for its characterization.

4.5. The Seven-Term Error Model for Vector Network Analyzers with Four Receivers

The addition of a fourth receiver to independently measure all four waves at the DUT, as depicted in Fig. 12, leads to very interesting instrument properties and calibration possibilities. The DUT is now embedded in a symmetrical test set, consisting of two reflectometers, each of which can be represented by an error two-port (see Section 4.1, which discusses four-port/two-port reduction).

The subtle but far-reaching advantages of this architecture and the accompanying error-model are as follows

1. The error model (Figs. 18 and 19) is valid for *either* position of the switch, reducing the number of error terms to eight and the number of two-port calibration standards required to three.
2. The four-receiver architecture provides redundant information in the calibration measurements that can be exploited to allow calibration with *partially unknown* standards. Section 5 details these important and powerful techniques.
3. The switch is no longer part of the error two-ports. Instead it has been moved into the generator port of the reflectometers, whose waves were eliminated during the four-port/two-port reduction. Therefore, the imperfections of the switch no longer influence the quality of an error-corrected measurement. The

$$\text{Through: } [S^T] = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \text{Open: } [S_{11}^O] = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \\ \text{Short: } [S^S] = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, \quad \text{Match: } [S^M] = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

Figure 18. Calibration standards for the TMSO (SOLT) 10-term procedure.

Figure 19. Seven-term error model of the bidirectional vector network analyzer with four receivers.

switch may be mismatched, may exhibit transmission losses and finite isolation, and does not even need to be repeatable.

The mathematical derivation of the seven-term error model unfolds in the usual way. With

$$\begin{pmatrix} b_1 \\ a_1 \end{pmatrix} = [G] \begin{pmatrix} m_2 \\ m_1 \end{pmatrix}, \quad \begin{pmatrix} b_2 \\ a_2 \end{pmatrix} = [H] \begin{pmatrix} m_3 \\ m_4 \end{pmatrix}, \quad (20)$$

and

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = [S] \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}$$

vector equations for both positions of the switch (I and II) are obtained and combined into a matrix equation:

$$\begin{bmatrix} G_{11}m_2^I + G_{12}m_1^I & G_{11}m_2^{II} + G_{12}m_1^{II} \\ H_{11}m_3^I + H_{12}m_4^I & H_{11}m_3^{II} + H_{12}m_4^{II} \end{bmatrix} = [S] \begin{bmatrix} G_{21}m_2^I + G_{22}m_1^I & G_{21}m_2^{II} + G_{22}m_1^{II} \\ H_{21}m_3^I + H_{22}m_4^I & H_{21}m_3^{II} + H_{22}m_4^{II} \end{bmatrix} \quad (21)$$

The eight measurement values contained in Eq. (21) can be condensed to four by expanding Eq. (21) as

$$\begin{aligned} & \begin{bmatrix} G_{12} & 0 \\ 0 & H_{12} \end{bmatrix} \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix} \\ & + \begin{bmatrix} G_{11} & 0 \\ 0 & H_{11} \end{bmatrix} \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \\ & = [S] \left\{ \begin{bmatrix} G_{22} & 0 \\ 0 & H_{22} \end{bmatrix} \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix} \right. \\ & \quad \left. + \begin{bmatrix} G_{21} & 0 \\ 0 & H_{21} \end{bmatrix} \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \right\} \end{aligned}$$

and right-multiplying both sides with the inverse measurement matrix of the first and fourth receiver. The

result is much simplified error-model representation

$$\begin{aligned} & \begin{bmatrix} G_{12} & 0 \\ 0 & H_{12} \end{bmatrix} + \begin{bmatrix} G_{11} & 0 \\ 0 & H_{11} \end{bmatrix} [M] \\ & = [S] \left\{ \begin{bmatrix} G_{22} & 0 \\ 0 & H_{22} \end{bmatrix} + \begin{bmatrix} G_{21} & 0 \\ 0 & H_{21} \end{bmatrix} [M] \right\} \end{aligned} \quad (22)$$

with a 2×2 measurement matrix

$$[M] = \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix}^{-1} = \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix}$$

With the measurement values pertaining to the incident waves m_1^I and m_4^I residing on the main diagonal of the right submatrix and the off-diagonal elements being small, the matrix is guaranteed to be invertible. For $m_4^I = m_1^{II} = 0$ (three receiver analogy), the entries of $[M]$ are normalized with respect to the incident waves m_1^I and m_4^I . The measurement matrix $[M]$ is therefore attributed S -parameter character. Furthermore, the computation of $[M]$ provides a first level of error correction, because finite isolation of the switch is eliminated. This is achieved by the fourth receiver, which precisely measures the level of the switch's leakage signals through m_1^{II} and m_4^I .

Equation (22) is easily returned to the structure of Eq. (21), with the four measurement values now being direct counterparts of the corresponding error-corrected S -parameters of the DUT:

$$\begin{aligned} & \begin{bmatrix} G_{11}m_{11} + G_{12} & G_{11}m_{12} \\ H_{11}m_{21} & H_{11}m_{22} + H_{12} \end{bmatrix} \\ & = [S] \begin{bmatrix} G_{21}m_{11} + G_{22} & G_{21}m_{12} \\ H_{21}m_{21} & H_{21}m_{22} + H_{22} \end{bmatrix} \end{aligned} \quad (23)$$

It may be interesting to note that $[G]$ and $[H]$ are of the cascading *transfer matrix* type. This type of matrix also appears in all other error models introduced in this section. The fact that transfer matrices exhibit a singularity if the underlying network has zero transmission can safely be ignored as far as error two-ports of practical reflectometer or network analyzer realizations are concerned. Those networks *must* exhibit transmission in order to perform the desired function. The device under test, however, may be perfectly isolating and should therefore always be represented by its S -matrix (Section 5.1.1 introduces *pseudo-transfer matrices* to work around that singularity).

4.5.1. Calibration of the Seven-Term Error Model. With Eq. (23) being of the same structure as the five-term model [Eq. (16)] and the 10-term model [Eq. (19)], the determination of the error terms proceeds in the same way. Equation (23) is rearranged into a linear homogeneous system

of equations

$$\begin{bmatrix} -m_{11}^i & -1 & S_{11}^i m_{11}^i & S_{11}^i & 0 & 0 & S_{12}^i m_{21}^i & 0 \\ 0 & 0 & S_{21}^i m_{11}^i & S_{21}^i & -m_{21}^i & 0 & S_{22}^i m_{21}^i & 0 \\ -m_{12}^i & 0 & S_{11}^i m_{12}^i & 0 & 0 & 0 & S_{12}^i m_{22}^i & S_{12}^i \\ 0 & 0 & S_{21}^i m_{12}^i & 0 & -m_{22}^i & -1 & S_{22}^i m_{22}^i & S_{22}^i \end{bmatrix} \mathbf{e} = 0,$$

$$\mathbf{e} = (G_{11}, \dots, G_{22}, H_{11}, \dots, H_{22})^T$$

with every calibration measurement i contributing four equations. One error term is set to 1, and seven independent equations are required to solve for the remaining seven error terms. It turns out that the eight equations stemming from the measurement of two calibration two-ports are not sufficient to provide the necessary rank of 7. Measurement of a third calibration two-port is needed such that a total of 12 equations exist.

The resulting surplus in information can be used in one of the following ways:

1. The linear system with all 12 equations is solved in the least-squares sense (e.g., see Ref. 19), using the extra equations to minimize residual errors (contacting or repeatability errors).
2. Even though contacting errors cannot be accounted for due to their statistical nature, in Ref. 20, the extra information is used to assess these errors by deriving error bounds. As these techniques are not yet widely used, they will not be further treated here.
3. The calibration standards can be permitted to have unknown parameters [13,21], which are determined using the extra information contained in the additional equations. Because the construction of standards, which do not have to be fully known, can result in considerable savings, this “self-calibration” technique is of much practical importance. Section 5 has the details.

Performing a seven-term calibration with completely known standards is most easily done using the TMS procedure, where the three calibration two-ports

$$\text{Through: } [S^T] = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \text{Match: } [S^M] = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$$

$$\text{Short: } [S^S] = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}$$

are used. Comparison with the 10-term and the 5-term model shows that the third reflection standard is no longer needed. Using a short, instead of an open, as the third standard is in many cases the more convenient choice, because shorts can be manufactured to higher precision in coaxial media or waveguides (see Section 4.2.1). At low frequencies, however, using an open may be the more

advantageous choice, as the test port serves as a comparatively good open up to about 100 MHz.

The computed error terms are used for error correction by simply solving Eq. (23) for $[S]$:

$$[S] = \begin{bmatrix} G_{11}m_{11} + G_{12} & G_{11}m_{12} \\ H_{11}m_{21} & H_{11}m_{22} + H_{12} \end{bmatrix} \times \begin{bmatrix} G_{21}m_{11} + G_{22} & G_{21}m_{12} \\ H_{21}m_{21} & H_{21}m_{22} + H_{22} \end{bmatrix}^{-1}$$

4.5.2. Calibration of the Seven-term Error Model using an Unknown Through. For applications where a Through standard of known properties is not available, the seven-term error model may be calibrated by performing simple reflectometer calibrations for the error two-ports $[G]$ and $[H]$, according to Section 4.1.1, and using a transmission standard whose only known property is its reciprocity (e.g., $S_{21} = S_{12}$).

Such a calibration method may, for instance, be desirable for on-wafer measurements where nonaligned measurement ports render a known Through difficult to build [22]. Calibration without an unknown Through was first introduced in Ref. 23 and is very simple to derive if the cascade structure of the error model (Fig. 19) is written using transfer matrices. With the error two-ports $[G]$ and $[H]$ already in that notation [Eq. (20)], the difference to Eq. (22) is in the description of the DUT

$$\begin{pmatrix} b_1 \\ a_1 \end{pmatrix} = [\Sigma] \begin{pmatrix} a_2 \\ b_2 \end{pmatrix} = \frac{1}{S_{21}} \begin{bmatrix} -\Delta S & S_{11} \\ -S_{22} & 1 \end{bmatrix} \begin{pmatrix} a_2 \\ b_2 \end{pmatrix} \quad (24)$$

and in the evolving measurement matrix

$$\begin{bmatrix} m_1^I & m_1^H \\ m_2^I & m_2^H \end{bmatrix} \begin{bmatrix} m_3^I & m_3^H \\ m_4^I & m_4^H \end{bmatrix}^{-1} = [P] = [G]^{-1}[\Sigma][H]$$

with the latter now also being a transfer matrix.

Performing reflectometer calibrations, as described in Section 4.1.1, for both error two-ports establishes three of the four error terms in $[G]$ and $[H]$, leading to the preliminary error matrices $[\tilde{G}]$ and $[\tilde{H}]$, with one error term normalized to 1. Without loss of generality, let us assume $\tilde{G}_{11} = \tilde{H}_{11} = 1$. This knowledge of $[G]$ and $[H]$, except for a common factor, can be expressed as

$$[P] = [G]^{-1}[\Sigma][H] = \frac{1}{K_G} [\tilde{G}]^{-1}[\Sigma]K_H[\tilde{H}]$$

$$= \alpha [\tilde{G}]^{-1}[\Sigma][\tilde{H}]$$

$$\alpha = \frac{K_H}{K_G}$$

The still unknown term α can be regarded as the seventh error term, still needed for a full two-port calibration. As the determinant of the transfer matrix of a reciprocal

two-port is unity, using such a device for calibration produces the equation

$$\begin{aligned} \det[P^{\text{reci}}] &= \alpha^2 \det[\tilde{G}]^{-1} \det[\Sigma^{\text{reci}}] \det[\tilde{H}] \\ &= \alpha^2 \frac{\det[\tilde{H}]}{\det[\tilde{G}]} \end{aligned}$$

which is solved for α :

$$\alpha = \pm \sqrt{\frac{\det[\tilde{G}]}{\det[\tilde{H}]} \det[P^{\text{reci}}]} \quad (25)$$

According to Ref. 23, the correct root in Eq. (25) is most easily found using

$$S_{21}^{\text{reci}} = \frac{\alpha}{P_{22}^{\text{reci}}}$$

if the phase of the reciprocal transmission-factor is known to $\pm 90^\circ$.

4.6. The Crosstalk Correcting 15-Term Error Model for Four-Receiver VNAs

Whenever energy emanating from the measurement planes finds a path to leak around the DUT or a coupling path between the reflectometers of the VNA exists (Fig. 20), the error models of Sections 4.2–4.5 cannot adequately handle the associated cross-talk error. On-wafer measurements typically suffer from this kind of leakage error, due to the small separation of the measurement planes and the radiation of the probe tips.

An error model, capable of accounting for those leakage errors, was first detailed in Ref. 24 and is also termed *full-model* [14]. It can be derived by describing the four-receiver VNA's hardware as a general eight-port. The coupling between the reflectometers may be arbitrary and nonreciprocal but must be linear and not affected by the parameters of the DUT. Comparable with the four-port/two-port reduction, introduced in Section 4.2.1, the reflection coefficients and conversion constants of the four

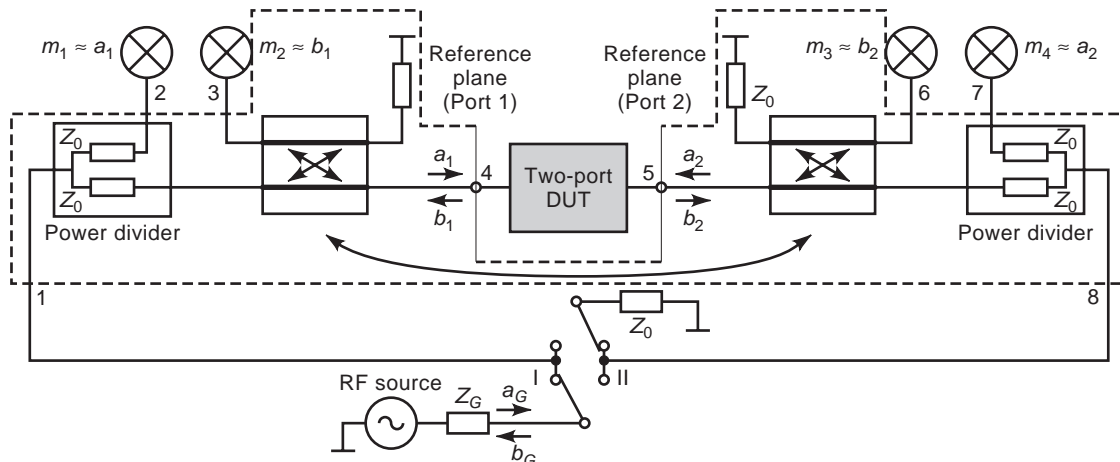

Figure 20. Eight-port hardware representation of the vector network analyzer, including coupling of the reflectometers.

Figure 21. Fifteen-term error-model of the four-receiver vector network analyzer.

receivers are used to eliminate the reflected waves at the receivers and the generator waves a_G and b_G .

The resulting error four-port $[C]$ (Fig. 21) relates the measured values m_i ($i = 1, 2, 3, 4$) to the waves a_1, a_2, b_1, b_2 at the DUT such that its S -matrix can be computed from the measurement data and $[C]$. Because the switch is not part of the error network and the waves of the RF source are eliminated in Eq. (26), the properties of the switch have no influence on the quality of error correction, and the same error network may be used for either state of the switch.

The mathematical formulation of the error model is derived by partitioning the 4×4 matrix $[C]$ into four 2×2 matrices. With

$$\begin{pmatrix} b_1 \\ b_2 \\ a_1 \\ a_2 \end{pmatrix} = [C] \begin{pmatrix} m_1 \\ m_4 \\ m_2 \\ m_3 \end{pmatrix} = \begin{bmatrix} [G] & [E] \\ [F] & [H] \end{bmatrix} \begin{pmatrix} m_1 \\ m_4 \\ m_2 \\ m_3 \end{pmatrix} \quad (26)$$

the two vector equations

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = [G] \begin{pmatrix} m_1 \\ m_4 \end{pmatrix} + [E] \begin{pmatrix} m_2 \\ m_3 \end{pmatrix}$$

$$\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = [F] \begin{pmatrix} m_1 \\ m_4 \end{pmatrix} + [H] \begin{pmatrix} m_2 \\ m_3 \end{pmatrix}$$

can be derived to express the waves at the DUT as

$$[G] \begin{pmatrix} m_1 \\ m_4 \end{pmatrix} + [E] \begin{pmatrix} m_2 \\ m_3 \end{pmatrix} = [S] \left\{ [F] \begin{pmatrix} m_1 \\ m_4 \end{pmatrix} + [H] \begin{pmatrix} m_2 \\ m_3 \end{pmatrix} \right\}$$

An equation of this type is obtained for measurement in either position of the switch, and combining both vector equations into a matrix equation yields

$$[G] \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix} + [E] \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \\ = [S] \left\{ [F] \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix} + [H] \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \right\}$$

which simplifies to

$$[G] + [E][M] = [S]([F] + [H][M]) \quad (27)$$

by introduction of the measurement matrix

$$[M] = \begin{bmatrix} m_2^I & m_2^{II} \\ m_3^I & m_3^{II} \end{bmatrix} \begin{bmatrix} m_1^I & m_1^{II} \\ m_4^I & m_4^{II} \end{bmatrix}^{-1} = \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix}$$

Comparison with the formulation of the seven-term model [Eq. (22)] reveals the very close relationship, because their structure and even the measurement matrix are identical. In fact, the seven-term error model evolves as a special case of the more general 15-term model. Consequently, the eight off-diagonal error terms that default to zero in Eq. (21), where no leakage is assumed, are needed in the 15-term model to correctly describe the crosstalk.

4.6.1. Calibration of the 15-Term Error Model. Determination of the 16 error terms in the error quadrants $[G]$, $[E]$, $[F]$, and $[H]$ is achieved by expanding Eq. (27) into a system of four linear equations in the error terms per calibration measurement [25]. One error term may be arbitrarily set to one, and the resulting inhomogeneous system may be solved for the remaining 15 error terms. Care must be taken to choose one of the error terms *on* the diagonal of the error-quadrants for this normalization, because the *off*-diagonal elements vanish in the case of a leakage-free error four-port.

It turns out that at least five completely known and distinct calibration two-ports must be measured to determine the 15 error terms [25,26]. With five calibration measurements, 20 equations in the 15 unknowns exist, but only 15 are needed. Analogous to Section 4.5, either five suitable equations may be neglected or the system of 20 equations in 15 unknowns is solved in the least-squares sense. Use of partially unknown standards and their

determination through self-calibration is the third option and is outlined in Section 5.3.

An especially well-suited combination of standards for the 15-term model, first mentioned in Ref. 25, consists of a Through two-port and the three reflection one-ports match, short, and open, combined to yield four reflection two-ports such that calibration is performed with the five two-ports of Fig. 22.

Contrary to the 7-term, 5-term, or 10-term error-models, the 15-term model does not allow reflection two-ports to be measured sequentially, by separating the reflection measurements at both ports. Due to the presence of crosstalk that must be precisely measured, both ports need to be terminated in the prescribed impedance while performing the calibration measurement. Cyclically interchanging the three reflection one-ports to create the calibration standard lets this Tms0 procedure get by with one match-, short-, and open standard. Lowercase letters are used to indicate that match, short, and open are one-ports and need to be combined to form the necessary calibration two-ports.

Once all error terms are known, the measured values of an arbitrary DUT are to be error-corrected. Contrary to the calibration process, error correction is performed with every measurement. Numerical efficiency is therefore in demand.

Equation (27) is easily solved for the S -matrix $[S]$ of the DUT

$$[S] = \{[G][M] + [E]\} \{[H][M] + [F]\}^{-1}$$

and devises a very simple algorithm for the error-correction process. Only 2×2 matrices need to be manipulated.

Figure 23 (taken from Ref. 27) demonstrates the capabilities of the 15-term procedure in the presence of an artificial leakage error between the measurement planes. Figure 24 depicts the setup. The DUT is a 20 dB attenuator, and the crosstalk is modeled by a second 20 dB attenuator in parallel to the DUT.

Although the presence of the leakage error corrupts the result in a way that the uncorrected data bears no resemblance with the transfer characteristics of the DUT, correcting the data according to the 15-term procedure recovers the attenuation value with good precision, even though the amount of crosstalk is of the same magnitude as the DUT's transmission.

5. MODERN SELF-CALIBRATION TECHNIQUES FOR FOUR-RECEIVER VNAs

Calibration of four-receiver VNAs according to the 7-term or the 15-term error model yields five redundant equations that are not needed for the computation of the error terms. Using this extra information for the determination of unknown parameters of the calibration standards is a

Figure 22. Calibration standards for the 15-term Tms0 procedure. $S^T = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$, $S^{MS} = \begin{bmatrix} 0 & 0 \\ 0 & -1 \end{bmatrix}$, $S^{OM} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}$, $S^{SO} = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}$, $S^{OS} = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$

Figure 23. Transmission measurement of a 20 dB attenuator (corrected/uncorrected). (From Ref. 27, with permission.)

very powerful technique that allows the calibration to be performed with *partially known* standards. Besides reducing the cost of standards, self-calibration techniques also enhance the accuracy of the calibration as inconsistency errors are reduced.

One of the most popular self-calibration representative, introduced in 1979 by Engen and Hoer [13] for the double six-port reflectometer (seven-term error model), is the TLR procedure. It allows calibration with the following standards:

- (T)hrough (direct connection of both measurement planes)
- (L)ine (a line of unknown electrical length, between 20° and 160° , perfectly matched)
- (R)eflect (unknown, but symmetrical reflection standard)

The L standard and the R standard are only partially known, with no requirements imposed on the reflect, except that the same reflect has to be used on both measurement planes. Its value and the exact electrical length of the line are determined through the self-calibration process. Different methods can be employed for the determination of the unknown parameters of the standards, three of which are as follows:

1. The *linear* system of equations in the error terms [Eqs. (23) and (27)] is treated as a *nonlinear* system in the error terms *and* the unknowns of the standards. This nonlinear system is solved iteratively

Figure 24. Measurement setup of a network analyzer with artificial cross-talk.

[28] or, where possible, analytically, providing a simultaneous solution of error terms and unknowns of the standards [17,18,29].

2. For a unique solution of the error terms to exist, 5 of the 12 (respectively, 20) equations must be linearly dependent. If the 12×8 (20×16) coefficient matrix of the homogeneous linear system of equations [Eqs. (23) and (27)] can be *analytically* brought to tridiagonal form, the last five lines are required to vanish, resulting in five equations in which only measurement values and parameters of the standards appear. It may be argued that the analytical reduction of a 20×16 or even a 12×8 matrix to tridiagonal form is impracticable. However, Eqs. (23) and (27) are sparse enough to render the derivation of self-calibration equations according to this scheme feasible, even for the 15-term error model (30). Once the unknown parameters of the standards are determined, the standards are completely known and so are all nonzero entries of the tridiagonal matrix, which is then used to compute the error terms by a backsubstitution process [19, p. 37].
3. The formulation of the error model is rearranged to yield relations between the standards' *S*-parameters and the measured values, eliminating the error terms. These relations are exploited to solve for the unknown parameters of the calibration standards which are then completely known and can be used to solve the linear system of equations [Eqs. (23) and (27)] for the error terms. In the following sections, this method, which is based on similarity transformations [21,27], will be presented for the 7-term and the 15-term error model.

5.1. Self-Calibration for the Seven-Term Error Model

Elimination of the error parameters to arrive at a relation between the standards' parameters and the measurement values was first described by Eul and Schiek [21] and is most easily achieved by using transfer parameters to describe the cascade structure of the error model (Fig. 19). See Eq. (24) in Section 4.5.2.

As transfer parameters exhibit a singularity for transmissionless two-ports ($S_{21} = 0$), this representation of the error model is less suited for the computation of the error terms, which is why the *S*-parameter representation [Eq. (22)] was chosen in Section 4.5. The seven-term error model, however, may as well be written using Eq. (24) with the three calibration measurements yielding three such equations.

Solving the *i*th calibration measurement for [*H*]

$$[H] = [\Sigma_i]^{-1}[G][P_i]^{-1} \quad (28)$$

and substituting Eq. (28) into the remaining calibration measurements *j* and *k* yields

$$\begin{aligned} [P_j][P_i]^{-1} &= [G]^{-1}[\Sigma_j][\Sigma_i]^{-1}[G] \quad \text{and} \\ [P_k][P_i]^{-1} &= [G]^{-1}[\Sigma_k][\Sigma_i]^{-1}[G] \end{aligned} \quad (29)$$

Recognizing Eq. (29) as similarity transformations, the equality of the eigenvalues of the similar matrices is equivalent to the equality of their determinants and traces; hence

$$\begin{aligned} [A] &= [X][B][X]^{-1} \Rightarrow \det[A] = \det[B] \\ \text{trace}[A] &= a_{11} + a_{22} = \text{trace}[B] = b_{11} + b_{22} \end{aligned}$$

which yields the four equations

$$\begin{aligned} \det\{[P_j][P_i]^{-1}\} &= \beta_1 = \det\{[\Sigma_j][\Sigma_i]^{-1}\}, \\ \text{trace}\{[P_j][P_i]^{-1}\} &= \beta_2 = \text{trace}\{[\Sigma_j][\Sigma_i]^{-1}\} \\ \det\{[P_k][P_i]^{-1}\} &= \beta_3 = \det\{[\Sigma_k][\Sigma_i]^{-1}\}, \\ \text{trace}\{[P_k][P_i]^{-1}\} &= \beta_4 = \text{trace}\{[\Sigma_k][\Sigma_i]^{-1}\} \end{aligned} \quad (30)$$

The combination of both equations in Eq. (29) leads to a fifth condition for the standards' parameters:

$$\begin{aligned} \text{trace}\{[P_j][P_i]^{-1}[P_k][P_i]^{-1}\} \\ = \beta_5 = \text{trace}\{[\Sigma_j][\Sigma_i]^{-1}[\Sigma_k][\Sigma_i]^{-1}\} \end{aligned} \quad (31)$$

These five equations in Eqs. (30) and (31), in which only the transfer parameters of the standards and measurement values appear, can be used to compute a maximum of five unknown parameters of the standards.

5.1.1. The General TAN Procedure. One possibility to distribute the five unknowns among the three calibration standards is the general TAN procedure, where a Through standard (of known transmission factor t), a well-matched Attenuator (with unknown forward and reverse attenuation k_f and k_r), and a symmetrical, but not necessarily reciprocal, Network standard (with unknown reflection r and unknown transmission coefficients u_f and u_r) are used for calibration:

$$\begin{aligned} [\Sigma_T] &= \begin{bmatrix} t & 0 \\ 0 & 1/t \end{bmatrix}, \quad [\Sigma_A] = \begin{bmatrix} k_r & 0 \\ 0 & 1/k_f \end{bmatrix} \\ [\Sigma_N] &= \frac{1}{u_f} \begin{bmatrix} u_f u_r - r^2 & r \\ -r & 1 \end{bmatrix} \end{aligned}$$

The inclusion of the known parameter t is for convenience if connector sex dictates the use of a nonzero length Through.

As the A -standard may also turn into a well-matched Line standard (L) with $k_f = k_r = e^{-\gamma l}$, or into a double Match standard (M) with $k_f = k_r = 0$, and as the N standard may degenerate to a Reflection standard (R) with $u_f = u_r = 0$, the general TAN procedure also covers the most popular TLR and TMR self-calibration procedures.

However, the singularity of the transfer matrices $[\Sigma_A]$ and $[\Sigma_N]$ and the accompanying measurement matrices $[P_A]$ and $[P_N]$ for the case of vanishing transmission (M, R standard) must be taken care of. For that purpose, pseu-

dotransfer matrices are introduced [31] by separating the matrix of the measured quantities $[P]$ from its determinant Δm , which may be zero. The residual part of the matrix is denoted $[\tilde{P}]$

$$\begin{aligned} [P] &= \begin{bmatrix} m_1^I & m_1^{II} \\ m_2^I & m_2^{II} \end{bmatrix} \frac{1}{m_3^I m_4^{II} - m_3^{II} m_4^I} \begin{bmatrix} m_4^{II} & -m_3^{II} \\ -m_4^I & m_3^I \end{bmatrix} \\ &= \frac{1}{\Delta m} [\tilde{P}] \end{aligned} \quad (32)$$

with

$$\begin{aligned} \Delta m &= m_3^I m_4^{II} - m_3^{II} m_4^I \text{ and} \\ [\tilde{P}] &= \begin{bmatrix} m_1^I & m_1^{II} \\ m_2^I & m_2^{II} \end{bmatrix} \begin{bmatrix} m_4^{II} & -m_3^{II} \\ -m_4^I & m_3^I \end{bmatrix} \end{aligned}$$

Combination of the determinant of the measurement matrix with the transfer matrix of the standard belonging to it yields the pseudotransfer matrices

$$\begin{aligned} \Delta m_A[\Sigma_A] &= \frac{\Delta m_A}{k_f} \begin{bmatrix} k_r k_f & 0 \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} \kappa_r & 0 \\ 0 & 1/\kappa_f \end{bmatrix} = [\Sigma_A^p] \\ \Delta m_N[\Sigma_N] &= \frac{\Delta m_N}{u_f} \begin{bmatrix} u_f u_r - r^2 & r \\ -r & 1 \end{bmatrix} = \frac{1}{\mu_f} \begin{bmatrix} \mu_f \mu_r - \rho^2 & \rho \\ -\rho & 1 \end{bmatrix} \\ &= [\Sigma_N^p] \end{aligned}$$

with

$$\begin{aligned} \kappa_f &= \frac{k_f}{\Delta m_A}, \quad \kappa_r = k_r \Delta m_A, \\ \mu_f &= \frac{u_f}{\Delta m_N}, \quad \mu_r = r_r \Delta m_N, \quad \rho = r \end{aligned} \quad (33)$$

and modifies Eqs. (30) and (31) as

$$\begin{aligned} \det\{[\tilde{P}_A][P_T]^{-1}\} &= \beta_1 = \det\{\Delta m_A[\Sigma_A][\Sigma_T]^{-1}\} \\ &= \det\{[\Sigma_A^p][\Sigma_T]^{-1}\} \\ \text{trace}\{[\tilde{P}_A][P_T]^{-1}\} &= \beta_2 = \text{trace}\{\Delta m_A[\Sigma_A][\Sigma_T]^{-1}\} \\ &= \text{trace}\{[\Sigma_A^p][\Sigma_T]^{-1}\} \\ \det\{[\tilde{P}_N][P_T]^{-1}\} &= \beta_3 = \det\{\Delta m_N[\Sigma_N][\Sigma_T]^{-1}\} \\ &= \det\{[\Sigma_N^p][\Sigma_T]^{-1}\} \\ \text{trace}\{[\tilde{P}_N][P_T]^{-1}\} &= \beta_4 = \text{trace}\{\Delta m_N[\Sigma_N][\Sigma_T]^{-1}\} \\ &= \text{trace}\{[\Sigma_N^p][\Sigma_T]^{-1}\} \end{aligned}$$

$$\begin{aligned} \text{trace}\{[\tilde{P}_A][P_T]^{-1}[\tilde{P}_N][P_T]^{-1}\} &= \beta_5 \\ &= \text{trace}\{[\Sigma_A^p][\Sigma_T]^{-1}[\Sigma_N^p][\Sigma_T]^{-1}\} \end{aligned} \quad (34)$$

Because at least one standard must exhibit transmission, this property is, without loss of generality, attributed to the T standard, which therefore may be represented by a regular transfer matrix.

With β_i being nonsingular complex values, computed from the measurement values of the four receivers, according to Eq. (32), the first two equations of Eq. (34) can be used to determine the transmission coefficients of the A standard,

$$\frac{\kappa_r}{\kappa_f} = \beta_1, \quad \frac{\kappa_r}{t} + \frac{t}{\kappa_f} = \beta_2$$

which compute as

$$\kappa_r = t \left(\frac{\beta_2}{2} \pm \sqrt{\frac{\beta_2^2}{4} - \beta_1} \right) \quad \text{and} \quad \kappa_f = \frac{\kappa_r}{\beta_1} = \frac{t^2}{t\beta_2 - \kappa_r} \quad (35)$$

Similarly, the other parameters may be derived from the remaining equations in Eqs. (34) as

$$\mu_f = \frac{t^2 - \kappa_f \kappa_r}{t\kappa_f(\beta_5 - \kappa_r\beta_4)}, \quad \mu_r = \mu_f \beta_3 \quad (36)$$

$$\rho = \pm \sqrt{\mu_f \mu_r - \frac{\beta_4 \mu_f}{t} + \frac{1}{t^2}} \quad (37)$$

Using Eq. (33), the parameters of the transfer matrices of the standards $[\Sigma_A]$ and $[\Sigma_N]$ are computed from the above-derived pseudotransfer parameters.

The root ambiguity in Eq. (35) is solved with a priori knowledge of the A standard's transmission factor. If the standard exhibits attenuation ($|k_r| < 1$), the root whose magnitude is below 1 will be chosen, because the standard is passive. If a line standard with $|k_f| = |k_r| \approx 1$ is used, the phase of the line's transmission factor must be known to $\pm 90^\circ$ in order to select the correct root.

The root choice in Eq. (37) requires the same kind of information about the phase of the N standard's reflection coefficient, which must be known to $\pm 90^\circ$.

Equations (35)–(37) allow the computation of the calibration standards for the general TAN calibration procedure, also accounting for the special cases of the TMN, TMR, TAR, TLN, and TLR procedures, where the second and/or third standard are double one-ports without transmission.

Calibrating with TMN standards ($k_f = k_r = 0$), for instance, reduces Eqs. (35)–(37) to

$$\mu_f = \frac{\beta_2}{\beta_5}, \quad \mu_r = \frac{\beta_2 \beta_3}{\beta_5}, \quad \rho = \pm \sqrt{\mu_f \mu_r - \frac{\beta_4 \mu_f}{t} + \frac{1}{t^2}}$$

TAR (TLR), on the other hand, has arbitrary k_f and k_r with $\mu_f = \mu_r = 0$, reducing the set of unknowns to

$$\kappa_r = t \left(\frac{\beta_2}{2} \pm \sqrt{\frac{\beta_2^2}{4} - \beta_1} \right), \quad \kappa_f = \frac{\kappa_r}{\beta_1}$$

$$\rho = \pm \frac{1}{t} \sqrt{1 - \frac{\beta_4(t^2 - \kappa_f \kappa_r)}{\kappa_f(\beta_5 - \kappa_r \beta_4)}}$$

For the TMR procedure [32], $k_f = k_r = 0$ and $\mu_f = \mu_r = 0$. Only the unknown reflection r needs to be determined, yielding

$$\rho = \pm \frac{1}{t} \sqrt{1 - t \frac{\beta_2 \beta_4}{\beta_5}}$$

As before, the reflection coefficient must be known a priori to $\pm 90^\circ$ in order to resolve the root ambiguity. Technically this is done by choosing the solution that is closest to the estimated reflection coefficient of the R standard. Its choice as a short or an open is common practice (although not required) and provides the necessary information. Furthermore, the *true* value of r is determined by the self-calibration process and can be used to check the quality of the calibration, in those cases in which the R standard is completely known.

It should be noted that the perfect match of the A , L , or M standard in the above-described procedures is the only absolute impedance standard and must always be a known quantity, determining the reference impedance of the calibration. The R standard is not required to be known exactly, and the only demand is that the same reflection is presented to both ports. By connecting the same reflection standard first to port 1 and then to port 2, this requirement is easily met. Possible inconsistencies between the phase-reference planes of the different standards, which may creep in without the use of self-calibration, can therefore not occur. The postulated symmetry of the R standard uniquely sets the phase reference at equal offsets to the test ports. These offsets are zero if the transmission factor t of the through corresponds to its true electrical length.

Besides allowing the calibration of the seven-term error model with partially known standards, self-calibration also provides an interesting means of verifying the quality of the calibration if the calibration standards are fully known. In this case, all deviations of the computed parameters of the standards from their *known* values indicate imperfections of the calibration process.

5.2. Employing Self-Calibration for s_r -Measurements

The scheme introduced above for determining the transmission factor of the A standard can be used in a straightforward manner to obtain error-corrected measurements of the electrical length of an unknown line: Measurements of a through and the unknown line yield the measurement matrices $[P_T]$ and $[\tilde{P}_A]$ which using Eq. (34) make β_1 and β_2

available. With the transmission factor of a line being

$$e^{-\gamma l} = k_f = k_r = \frac{k_r}{\Delta m_A}$$

Eq. (35) can be used to solve for γl . Furthermore, if the mechanical length l of the line is known, the complex propagation constant γ containing ϵ_r is available with very high precision, even though up to this point no calibration has been performed.

5.3. Self-Calibration for the 15-Term Error Model

Contrary to the above-presented self-calibration scheme for the seven-term error model, self-calibration formulas for the 15-term model can be derived without the need for transfer parameters and their associated singularity problems.

As was shown in Section 4.6, the 15-term model is calibrated using five calibration measurements

$$[G] + [E][M_n] = [S_n]([F] + [H][M_n]) \quad (n = 1, \dots, 5) \quad (38)$$

Using four of those equations, named i, j, k , and l , most of the error parameters can be eliminated, arriving at

$$\begin{aligned} & \Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k} \\ &= ([H] + [F][M_k])^{-1} \Delta S_{j,k}^{-1} \Delta S_{i,j} \\ & \quad \times \Delta S_{i,l}^{-1} \Delta S_{l,k} ([H] + [F][M_k]) \end{aligned} \quad (39)$$

with

$$\Delta S_{m,n} = [S_m] - [S_n], \quad \Delta M_{m,n} = [M_m] - [M_n] \quad (m, n = 1, \dots, 5)$$

see Ref. 27 for a comprehensive outline of the derivation).

Equation (39) again constitutes a similarity transform, resulting in the two nonlinear relations

$$\begin{aligned} & \text{Trace}\{\Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k}\} \\ &= b_1 = \text{Trace}\{\Delta S_{j,k}^{-1} \Delta S_{i,j} \Delta S_{i,l}^{-1} \Delta S_{l,k}\} \\ & \text{Det}\{\Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k}\} \\ &= b_2 = \text{Det}\{\Delta S_{j,k}^{-1} \Delta S_{i,j} \Delta S_{i,l}^{-1} \Delta S_{l,k}\} \end{aligned} \quad (40)$$

between the measured values $[M_n]$ and the standards' S -parameters (invariance of the eigenvalues of similar matrices).

Because only four calibration measurements are used by Eq. (39), the fifth standard $[S_m]$, $[M_m]$ may be substituted into Eq. (39) to yield two more similarity transformations:

$$\begin{aligned} & \Delta M_{j,k}^{-1} \Delta M_{m,j} \Delta M_{m,l}^{-1} \Delta M_{l,k} \\ &= ([H] + [F][M_k])^{-1} \Delta S_{j,k}^{-1} \Delta S_{m,j} \\ & \quad \times \Delta S_{m,l}^{-1} \Delta S_{l,k} ([H] + [F][M_k]) \end{aligned} \quad (41)$$

(i th standard replaced by m th standard) and

$$\begin{aligned} & \Delta M_{m,k}^{-1} \Delta M_{i,m} \Delta M_{i,l}^{-1} \Delta M_{l,k} \\ &= ([H] + [F][M_k])^{-1} \Delta S_{m,k}^{-1} \Delta S_{i,m} \\ & \quad \times \Delta S_{i,l}^{-1} \Delta S_{l,k} ([H] + [F][M_k]) \end{aligned} \quad (42)$$

(j th standard replaced by m th standard).

Together with Eq. (40), the resulting trace and determinant equalities provide six nonlinear self-calibration equations, sufficient for computation of the maximally five unknowns that the 15-term error model allows for.

It is interesting to note that the derivation of Eq. (39) holds as long as the structure of the error model [Eq. (38)] is unchanged. The calibration standards and/or the measurement matrix $[M]$ may therefore also be expressed in T -(transfer) parameters or even in chain parameters, using voltages and currents instead of waves. Even the extension to the error model of an N -port VNA, as described in Ref. 24, is straightforward. In this case, all quadrants of the error matrix, the standards' S - (T -) matrix, and the measurement matrices are $N \times N$ matrices. The invariance of the eigenvalues of the two similar matrices in Eq. (39) yields N relations between the measured values and the standards.

5.3.1. The Tmrg Procedure. The self-calibration equations [Eqs. (39), (41), and (42)] permit construction of a multitude of self-calibration procedures, allowing calibration with the set of standards, best suited for a specific application. A particularly interesting variant, the Tmrg procedure, refining the Tmso procedure of Section 4.6 shall now be introduced.

Whereas Tmso requires a *perfect* match, short and open, the above-derived formalism allows the reflection coefficients of the short and open to be computed through self-calibration. Furthermore, a nonzero but known reflection coefficient may be used as the m standard, reducing its requirement from *perfect* to *known*.

Comparable with Fig. 22, Fig. 25 shows the five standards to be constructed from a Through (with known transmission factor t) and three reflection one-ports with reflection coefficients m, r , and g . The first four standards suffice for the determination of the unknown reflection coefficients r and g .

Substituting the standards i, j, k , and l into Eq. (39) and evaluating the product of S -matrix differences yield

$$\begin{aligned} & \Delta S_{j,k}^{-1} \Delta S_{i,j} \Delta S_{i,l}^{-1} \Delta S_{l,k} = [B] \\ &= \frac{1}{t_2 - rm} \begin{bmatrix} t^2 C_1 - m^2 C_2 & t(m C_2 - g C_1) \\ t(r C_1 - m C_2) & t^2 C_2 - rg C_1 \end{bmatrix} \end{aligned}$$

with

$$C_1 = \frac{r - m}{r - g}, \quad C_2 = \frac{g - r}{g - m}$$

$$[S_{(t)}^T] = \begin{bmatrix} 0 & t \\ t & 0 \end{bmatrix}, \quad [S_{(m)}^m] = \begin{bmatrix} r & 0 \\ 0 & m \end{bmatrix}, \quad [S_{(g)}^{mg}] = \begin{bmatrix} m & 0 \\ 0 & g \end{bmatrix}, \quad [S_{(t)}^g] = \begin{bmatrix} g & 0 \\ 0 & r \end{bmatrix}, \quad [S_{(m)}^{tg}] = \begin{bmatrix} r & 0 \\ 0 & g \end{bmatrix}$$

Figure 25. Calibration standards for the 15-term Tmrg self-calibration procedure.

resulting in

$$\begin{aligned} & \text{trace}\{\Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k}\} \\ & = \text{trace}[B] = b_1 = \frac{m^2(g-m+gr(m-r))+t^2(r-g)}{(rm-t^2)(m-g)} \end{aligned} \quad (43)$$

$$\begin{aligned} & \det\{\Delta M_{j,k}^{-1} \Delta M_{i,j} \Delta M_{i,l}^{-1} \Delta M_{l,k}\} \\ & = \det[B] = b_2 = \frac{(t^2-mg)(r-m)}{(t^2-rm)(m-g)} \end{aligned} \quad (44)$$

Equation (44) can be solved to yield a linear relation for r

$$r = \frac{b_2 t^2 (g-m) + m(gm-t^2)}{b_2 m (g-m) + (gm-t^2)} \quad (45)$$

and can be combined with Eq. (43) to form a quadratic equation for g

$$g^2 - g \frac{2mt^2 a_1 a_2}{m^2 a_3 - t^2 b_2^2} + \frac{t^4 a_3 - t^2 m^2 b_2^2}{m^2 a_3 - t^2 b_2^2} = 0 \quad (46)$$

with

$$\begin{aligned} a_1 &= b_1 - 1 - 2b_2, \quad a_2 = b_2 + 1 \\ a_3 &= (b_1 - 1)(b_2 + 1) - b_2(2 + b_2) \end{aligned}$$

Choosing the proper root for g requires knowledge about the sign of that reflection standard. Using a short for g and an open for r provides the necessary sign information and makes the standards sufficiently distinct for subsequent use as fully known calibration standards.

The only parameters that must be known are the transmission coefficient t of the T standard and the reflection m . The quantity m should be small for numerical reasons and must be known, but the standard is not required to be an *ideal* match.

As only one set of reflection one-ports is physically required, the postulated equality of the reflection coefficients that enter the different standards is guaranteed, an important advantage over calibration procedures, which require the *same* reflection coefficient to be connected to both ports simultaneously.

6. OUTLOOK AND RELATED TOPICS

The continuously growing need for fast (production) and precision (laboratory) network measurements has led to the development of sophisticated instrumentation equipment [33–35] and many optimized calibration procedures. This process is expected to continue, with the focus shifting toward even higher frequencies (>110 GHz), on-wafer crosstalk correction, and N -port measurements [36,37]. A lot of interest is spawned by the communication

industry—for instance, in the characterization of IC packages (N -port measurements) and in high production throughput. Semiautomatic calibration procedures, avoiding the necessity of reconnecting the calibration standards for every calibration, address this need but are not covered here. The interested reader is referred to Ref. 38 for an overview. References 39 and 40 describe commercially available solutions.

Finally, Refs. 20 and 41 present statistical methods to assess errors not originally contained in the error model, like repeatability or contacting errors. Because these errors meanwhile constitute the accuracy limit of error-corrected network analyzer measurements, their inclusion is expected to further boost measurement accuracy.

STRIP TRANSMISSION LINES

PROTAP PRAMANICK
K & L Microwave, Inc.
Salisbury, Maryland
PRAKASH BHARTIA
Natel Engineering Co., Inc.
Chatsworth, California

1. BASIC CONFIGURATION

The stripline, shown in Fig. 1 is the oldest planar transmission line that has been in use in microwave integrated circuits since its creation by R.M. Barrett in 1950 [1]. In its simplest form, it consists of a conducting strip, of width W and thickness t , separated from a pair of common conducting ground planes of theoretically infinite extent compared to the width W of the strip conductor, $W \ll a$; where a is the width of the ground plane. The ground planes are separated by a thickness b , and the entire space is homogeneously filled with a dielectric material of complex dielectric constant $\epsilon_r(1 - j \tan \delta)$. The ground planes are kept at the same potential. In a balanced stripline, the strip conductor is equidistant from the ground planes. In an unbalanced stripline, there is an offset and the strip is not

Figure 1. Balanced stripline configuration.

Figure 2. Unbalanced stripline configuration.

equidistant from the two ground planes as shown in Fig. 2. The first significant theoretical investigation on stripline was carried out by S. Cohn in the mid 1950s [2]. While Sanders Associates used the tradename *triplate* [3], the term *stripline* was first introduced by Airborne Instruments Laboratories (AIL).

2. MODES IN A STRIPLINE AND THE MAXIMUM USABLE FREQUENCY

Although striplines can support waveguide-type modes (TE or TM), the fundamental mode of propagation is the transverse electromagnetic (TEM) mode having no cutoff frequency. The field configuration for the fundamental mode is shown in Fig. 3. The usable single-mode bandwidth of a stripline is determined by the cutoff frequency of the lowest-order waveguide mode. For that mode, the two ground planes have the same potential, the electric field is normal to the strip, and the ground planes and the longitudinal electric field are zero with cutoff frequency [4]

$$f_c = \frac{c}{\sqrt{\epsilon_r} \left(2 \frac{W}{b} + 4 \frac{d}{b} \right) b} \quad (1)$$

where c is the velocity of light in free space (3×10^8 m/s) and $4b/d$ is a function of the cross section of the stripline. For a balanced stripline when $t/b = 0$ and $W/b > 0.35$, then $4d/b$ is a function of b/f_c alone and is given in Table 1 in [4].

Figure 3. Field configuration of the fundamental mode of stripline.

3. CHARACTERISTIC IMPEDANCE OF A BALANCED STRIPLINE

The characteristic impedance of a balanced strip transmission line can be accurately calculated from [5]

$$Z_0 = \frac{60}{\sqrt{\epsilon_r}} \ln \left[\frac{4b}{\pi d} \right] \quad (2)$$

For $W/b < 0.35$, where

$$d = \frac{W}{2} \left[1 + \frac{t}{\pi W} \left(1 + \ln \frac{4\pi W}{t} + 0.51\pi \left(\frac{t}{W} \right)^2 \right) \right] \quad (3)$$

and

$$Z_0 = \frac{94.15}{\sqrt{\epsilon_r}} \frac{1}{\frac{C_f}{\epsilon} + \frac{W}{b \left(1 - \frac{t}{b} \right)}} \Omega \quad (4)$$

for $W/b \geq 0.35$, where

$$\frac{C_f}{\epsilon} = \frac{1}{\pi} \left\{ \frac{2}{1 - \frac{t}{b}} \ln \left(\frac{1}{1 - \frac{t}{b}} + 1 \right) \right\} - \frac{1}{\pi} \left\{ \left(\frac{1}{1 - \frac{t}{b}} - 1 \right) \ln \left(\frac{1}{\left(1 - \frac{t}{b} \right)^2} - 1 \right) \right\} \quad (5)$$

where $2C_f/\epsilon$ is the per unit length fringing field capacitance between the strip and each ground plane and $\epsilon = \epsilon_0 \epsilon_r$; $\epsilon_0 = 8.854e^{-12}$ F/m (permittivity of free space).

4. CHARACTERISTIC IMPEDANCE OF AN UNBALANCED STRIP TRANSMISSION LINE

The characteristic impedance of an unbalanced stripline (shown in Fig. 2) is given by [5]

$$Z_0 = \frac{120\pi}{\sqrt{\epsilon_r} \frac{C}{\epsilon}} \quad (6)$$

where C/ϵ is the per unit length static capacitance between the strip and the two ground planes, normalized by the permittivity ϵ of the medium:

$$\frac{C}{\epsilon} = \frac{C_{p1}}{\epsilon} + \frac{C_{p2}}{\epsilon} + \frac{2C_{f1}}{\epsilon} + \frac{2C_{f2}}{\epsilon} \quad (7)$$

$$\frac{C_{p1}}{\epsilon} = \frac{2 \frac{W}{b-s}}{1 - \frac{t}{b-s}} \quad (8)$$

$$\frac{C_{p2}}{\epsilon} = \frac{2 \frac{W}{b+s}}{1 - \frac{t}{b+s}} \quad (9)$$

The per unit length fringe field capacitances C_{f1} and C_{f2} are obtained from Eq. (5) by replacing b with $(b - S)$ and

Figure 4. Variation of characteristic impedance Z_0 with W/b and t/b .

$(b + S)$ respectively. The above formulae are applicable to single strips only. Figure 4 shows the variations of Z_0 with W/b for various values of t/b , for a balanced stripline.

5. THE PROPAGATION CONSTANT IN A STRIPLINE

The propagation constant β of a stripline is given by

$$\beta = \frac{2\pi}{\lambda_g} = \frac{2\pi\sqrt{\epsilon_r}}{\lambda_0} \text{ radians per unit length} \quad (10)$$

where λ_g and λ_0 are the wavelengths in the stripline and free space, respectively.

6. SYNTHESIS OF STRIPLINES

In order to obtain the structural dimensions for a stripline to be designed, when the characteristic impedance Z_0 and the substrate dielectric constant ϵ_r are given, the following formulas are used [6]:

$$W = W_0 - \Delta W_0 \quad (11)$$

$$W_0 = \frac{8(b - t)\sqrt{B + 0.568}}{\pi(b - 1)} \quad (12)$$

$$\Delta W_0 = \frac{t}{\pi} \left\{ 1 - 0.5 \ln \left[\left(\frac{t}{2b - t} \right)^2 + \left(\frac{0.0796t}{W_0 - 0.26t} \right)^m \right] \right\} \quad (13)$$

$$B = e^{(Z_0\sqrt{\epsilon_r})/30} \quad (14)$$

$$m = 6 \left[\frac{b - t}{3b - t} \right] \quad (15)$$

There is no closed-form design equation for the unbalanced stripline shown in Fig. 2. An iterative procedure based on analysis and optimization is used to synthesize an unbalanced stripline for a given characteristic impedance Z_0 and substrate dielectric constant ϵ_r .

7. ATTENUATION CONSTANT IN STRIPLINES

The attenuation constant of a stripline, balanced or unbalanced, is given by [4]

$$\alpha = \alpha_c + \alpha_d \text{ nepers per unit length} \quad (16)$$

The attenuation constant α_c due to conductor loss in the line at a frequency f in gigahertz is obtained from [7]

$$\alpha_c = \frac{\pi\sqrt{\epsilon_r}f}{0.2998} \left[1 - \frac{Z_0'}{Z_0} \right] \text{ Np/m} \quad (17)$$

where Z_0 is the characteristic impedance of the line and Z_0' is the characteristic impedance of the line when W , t , and b are replaced by $W = W + \delta_s$, $t + \delta_s$, and $b - \delta_s$, respectively in Eqs. (2)–(5) and

$$\delta_s = 0.0822\sqrt{\frac{\delta_s}{f}} \text{ mils} \quad (18)$$

is the skin depth at the frequency f in GHz and δ is the conductivity relative to copper.

The attenuation constant α_d due to dielectric loss is given by

$$\alpha_d = \frac{\beta \tan \delta}{2} \text{ Np/m} \quad (19)$$

The Q factor of a stripline is given by

$$Q = \frac{8.686\pi\sqrt{\epsilon_r}}{\lambda_0\alpha} \quad (20)$$

8. THE POWER-HANDLING CAPABILITY OF STRIPLINES

The average power P (in kilowatts) that can be carried by a matched balanced stripline with rounded edges is shown in Fig. 5 [4]. The ground plane–ground plane thickness is measured in inches. Although the strip edges are assumed to be round, an approximate value of Z_0 can be obtained from either Fig. 4 or from the analysis equations presented above.

9. STRIPLINE DISCONTINUITIES

Stripline discontinuities are as essential an element of microwave circuits as their uniform line counterparts. Any arbitrary discontinuity in a stripline can be decomposed into a few basic forms of discontinuity: an abrupt change in width or step discontinuity, a gap, a circular hole in the strip, an open-end, a cross junction, a T junction, and an angled bend. The appearance of discontinuities causes alterations in the electromagnetic field configurations of an otherwise uniform stripline. Therefore the modified field configuration can be taken into account by appropriate incorporation of a shunt or a series capacitance or inductance. For example, an open-end can be represented by a shunt capacitance. Figure 6 shows the

Figure 5. Average power-handling capability of a stripline with rounded trip edges.

configurations and the corresponding equivalent circuits of the discontinuities [8–10]. The equivalent width D , shown by the dashed lines, is obtained by conformal mapping techniques

$$D = b \frac{K(k)}{K(k')} + \frac{t}{\pi} \left(1 - \ln \frac{2t}{b} \right) \quad (21)$$

for $W/b \leq 0.5$, where $K(k)$ is the complete elliptic integral of the first kind:

$$k = \tanh \left(\frac{\pi W}{2b} \right) \quad (22)$$

$$K(k) = \int_0^1 \frac{dx}{\sqrt{(1-x^2)(1-k^2x^2)}} \quad (23)$$

The associated complementary elliptic integral is defined as

$$K(k') = K(\sqrt{1-k^2}) \quad (24)$$

and

$$D = W + \frac{2b}{\pi} \ln 2 + \frac{t}{\pi} \left(1 - \ln \frac{2t}{b} \right) \quad (25)$$

for $W/b > 0.5$.

9.1. Step Discontinuity

A change in strip width or step discontinuity is essential for the design of stripline matching transformers and low-pass filters. The equivalent-circuit parameters, shown in Fig. 6a, are given by

$$X = Z_1 \frac{2D_1}{\lambda_g} \ln \csc \frac{\pi D_2}{D_1} \quad (26)$$

$$l_1 = -l_2 = \frac{b \ln 2}{\pi} \quad (27)$$

The normalized scattering matrix of the discontinuity can be written as

$$[S] = \frac{1}{\Delta S} \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix}$$

$$S_{11} = (Z_2 - Z_1 + jX) e^{-j2\beta l_1}$$

$$S_{12} = S_{21} = 2\sqrt{Z_1 Z_2} \quad (28)$$

$$S_{22} = (Z_1 - Z_2 + jX) e^{-j2\beta l_2}$$

$$\Delta S = S_{11}S_{22} - S_{12}S_{21}$$

The equivalent network for equal normalizations at the input and the output ports includes a transformer as shown in Fig. 6a.

9.2. Gap Discontinuity

A series capacitance in a stripline is realized by a gap discontinuity as shown in Fig 6b. The equivalent circuit is, however, a π -network of one series and two shunt capacitances. The series component is due to the fringing capacitance from one strip to the other strip, and the shunt components are due to the field disturbance at the edge of each strip. As the gap increases, the series capacitance decreases and the two shunt capacitances tend toward that of an open-ended stripline. The normalized susceptance parameters of the equivalent π -network are given by

$$\overline{B}_A = \frac{1 + \overline{B}_a \cot(\beta s/2)}{\cot(\beta s) - \overline{B}_a} = \frac{\omega C_1}{Y_0} \quad (29)$$

$$2\overline{B}_B = \frac{1 + (2\overline{B}_b + \overline{B}_a) \cot(\beta s/2)}{\cot(\beta s/2) - (2\overline{B}_b + \overline{B}_a)} - \overline{B}_A = \frac{2\omega C_{12}}{Y_0} \quad (30)$$

$$\lambda \overline{B}_a = 2b \ln \left\{ \operatorname{sech} \left(\frac{2b}{\pi s} \right) \right\} \quad (31)$$

$$\lambda \overline{B}_b = b \ln \left\{ \coth \left(\frac{\pi s}{2b} \right) \right\} \quad (32)$$

9.3. Circular Hole Discontinuity

A hole discontinuity in a stripline is introduced to realize reactive tuning in filters and resonators. Such discontinuities are predominantly inductive in nature. The most common hole discontinuity is a circular hole discontinuity

Figure 6. Stripline discontinuities and the equivalent networks: (a) step; (b) gap; (c) circular hole; (d) open-end; (e) T junction; (f) bend.

as shown in Fig. 6c. The susceptance parameters of the equivalent π -network are given by

$$\overline{B}_A = \frac{1 + \overline{B}_a \cot(\beta r)}{\cot(\beta r) - \overline{B}_b} \quad (33)$$

$$2\overline{B}_B = \frac{1 + 2\overline{B}_a \cot(\beta r)}{\cot(\beta r) - \overline{B}_b} - \overline{B}_A \quad (34)$$

where

$$\overline{B}_b = -\left(\frac{3bD}{16\beta r^3}\right), \quad \overline{B}_a = \frac{1}{3B - b} \quad (35)$$

It is to be noted that the equivalent networks for gap and circular hole discontinuities depend on where the reference plane is considered to be situated.

9.4. Open-End Discontinuity

An open-end discontinuity occurs whenever an open-circuited stripline stub is used in matching networks, filters, and so on. Figure 6d shows a stripline open-end and two equivalent networks. The network can be a shunt capacitance C_{oc} or an extended length Δl . The second

representation assumes that a perfect magnetic wall exists at a distance Δl from the physical open circuit. The open-circuit capacitance is given by

$$C_{oc} = \frac{1}{\omega Z_0} \tan^{-1} \left[\frac{\xi + 2W}{4\xi + 2W} \tan(\beta\xi) \right] \quad (36)$$

where

$$\lambda = \frac{\lambda_0}{\sqrt{\epsilon_r}}, \quad \beta = \frac{2\pi}{\lambda}, \quad \xi = 0.2206b \quad (37)$$

The length extension Δl can be obtained from the open-end capacitance

$$\Delta l = \frac{1}{\beta} \tan^{-1}(Z_0 \omega C_{oc}) \quad (38)$$

The reflection coefficient from the open-end discontinuity can be calculated as

$$S_{11} = \frac{1 - jZ_0 \omega C_{oc}}{1 + jZ_0 \omega C_{oc}} \quad (39)$$

In the equations above, Z_0 is the characteristic equation of the stripline.

9.5. T-Junction Discontinuity

A T-junction discontinuity occurs in stripline stub matching, stub-loaded lowpass and bandpass filters, branchline couplers, hybrid rings, and many other components. Figure 6e shows the stripline T junction and the equivalent network. The network parameters are obtained from

$$\frac{X_a}{Z_1} = - (0.785n)^2 \frac{D_3^2}{D_1\lambda} \quad (40)$$

$$\begin{aligned} \frac{X_b}{Z_1} = & -\frac{X_a}{2Z_1} + \frac{1}{n^2} \left\{ \frac{B_1}{2Y_1} + \frac{2D_1}{\lambda} \left[0.6931 + \frac{\pi D_3}{6D_1} + 1.5 \left(\frac{D_1}{\lambda} \right)^2 \right] \right\} \end{aligned} \quad (41)$$

for $D_3/D_1 < 0.5$, and

$$\frac{X_b}{Z_1} = -\frac{X_a}{2Z_1} + \frac{2D_1}{\lambda n^2} \left\{ \ln \frac{1.43D_1}{D_3} + 2 \left(\frac{D_1}{\lambda} \right)^2 \right\} \quad (42)$$

for $D_3/D_1 > 0.5$. The transformer turns ratio n is given by

$$n = \frac{\sin \left(\frac{\pi D_3}{\lambda} \right)}{\frac{\pi D_3}{\lambda}} \quad (43)$$

and

$$\frac{B_1}{2Y_1} = \frac{2D_1}{\lambda} \left[\ln \csc \frac{\pi D_1}{2D_1} + 0.5 \left(\frac{d_1}{\lambda} \right)^2 \cos^4 \frac{\pi D_3}{2D_1} \right] \quad (44)$$

In these equations D_1 and D_3 are the widths of the equivalent parallel-plate waveguides for strips of widths W and W' , respectively; Z_1 and Z_3 are the corresponding characteristic impedances; and Y_1 and Y_3 are the respective characteristic admittances. The normalized scattering matrix of the T junction is obtained from

$$S_{11} = S_{22} = \frac{j2(Z_3/n^2)X_a - (Z_1^2 + 2X_a X_b + X_a^2)}{(Z_1 + jX_a)\Delta} \quad (45)$$

$$S_{12} = S_{21} = \frac{2Z_1(Z_3/n^2 + jX_a)}{(Z_1 + jX_b)\Delta} \quad (46)$$

$$S_{13} = S_{23} = S_{31} = S_{32} = \frac{2\sqrt{Z_1 Z_2}/n^2}{\Delta} \quad (47)$$

$$S_{33} = \frac{Z_1 - 2(Z_3/n^2) + j(X_a + 2X_b)}{\Delta} \quad (48)$$

and

$$\Delta = Z_1 + \frac{2Z_3}{n^2} + j(X_a + 2X_b) \quad (49)$$

9.6. Bend Discontinuity

A bend discontinuity occurs mainly in stripline transitions and hybrids. Figure 6f shows a stripline bend discontinuity and the equivalent network. The parameters of the network are obtained from the following equations, derived from Babinet's principle and the equivalent parallel-plate waveguide model:

$$\lambda \bar{X}_a = 2D \left\{ \psi(x) + 1.9635 + \frac{1}{x} \right\} \quad (50)$$

$$\bar{X}_b = -\frac{\lambda}{2\pi D} \cot \frac{\theta}{2} \quad (51)$$

With θ , in degrees, x is given by

$$x = 0.5 \left\{ 1 + \frac{\theta}{180} \right\} \quad (52)$$

and

$$\psi(x) = 0.5223 \ln(x) + 0.394 \quad (53)$$

Equation (53) is an approximation of the T function [11]. Accurate values of the T function for various x values are available in Ref. 11.

The reference planes T_1 and T_2 meet at an angle θ . This modifies the scattering parameters of the bend by multiplying S_{11} and S_{22} by $e^{j2\beta\zeta}$ and S_{12} and S_{21} by $e^{j\beta\zeta}$, where

$$\zeta = (D - W) \tan \frac{\theta}{2} \quad (54)$$

10. STRIPLINE COMPONENTS

Virtually every microwave circuit component can be realized using stripline technology. Its planar form makes the components inexpensive and easily mass-producible using the printed circuit board technique. Presence of top and ground shields makes the components almost completely radiation-free. In addition to that, the homogeneous dielectric filling offers the minimum frequency dispersion of component characteristics. The only limitations are relatively high insertion loss due to lossy plastic-type dielectric filling and low power-handling capability compared to waveguides and onset of waveguide modings at high frequencies.

The passive components that can be realized using stripline technology are the direct-coupled hybrids, power dividers, directional couplers, filters, and matching transformers. Such components in conventional forms

Figure 7. (a) Single section branchline coupler; (b) circular form of branchline coupler.

are completely uniplanar and do not need any via holes or groundings through the substrate. Figure 7 shows the simplest form of a direct-coupled hybrid, which is a 90° branchline hybrid. Figure 7a shows the layout of the metallization between the circuit boards, and Fig. 7b shows the circular form of a branchline hybrid. It consists of two mainlines coupled by two λ/4 line sections spaced λ/4 apart, where λ is the wavelength at the center frequency of the operating band. The coupling factor is determined by the ratio of the impedances of the shunt and the series arms and is optimized to satisfy the impedance match over a desired bandwidth. For a 90° phase difference between the two output ports the following conditions hold good:

$$\frac{P_2}{P_3} = \left(\frac{Z_0}{Z_p}\right)^2 \tag{55}$$

$$\left(\frac{Z_0}{Z_R}\right)^2 = \left(\frac{Z_0}{Z_P}\right)^2 + 1 \tag{56}$$

A two-branch, or a single-section, hybrid is a very common structure. However, it has a very narrow bandwidth. This drawback is overcome by using a multisection branchline hybrid as shown in Fig. 8. However, such multisection branchline hybrids often pose another problem. They require too wide a range of impedances, which in turn

Figure 8. A multisection branchline hybrid for wide bandwidth.

requires very narrow or very wide and physically realizable striplines. Analytical design methods for branchline hybrids are available in Refs. 12 and 13.

A matched hybrid ring magic T is a special type of ring form of the branchline hybrid in which the circumference is an odd multiple of $3\lambda/2$. As a result, the phase difference between split powers that meet at different ports is either 0° or 180° .

The conductor pattern of the simplest version of stripline hybrid is shown in Fig. 9a. If a signal is input to port B, it splits into equal halves and these equal halves meet at ports A and C with 0° phase difference and with 180° phase difference at port D. Typical frequency response of a stripline hybrid T is shown in Figs. 9b and 9c [13]. Usually around 20% bandwidth is obtained in a stripline hybrid T. In addition, the 180° phase difference is more frequency-dependent than the 0° response as shown in Fig. 9c. Stripline hybrid T is used in single-sideband generators and mixers.

Figure 10a shows the conductor pattern of a stripline inline power divider. It is a broadband equal phase power

splitter. An inline power divider was invented by Wilkinson [14] in 1960. Hence they are also known as “Wilkinson power dividers.” The one shown in Fig. 10a is known as the uncompensated power divider. Figure 10b shows the compensated version. The compensated divider offers a slightly better performance. A single section Wilkinson power divider offers one octave bandwidth. For larger bandwidth multisection power divider, shown in Fig. 11, is used. For excellent accounts of Wilkinson power dividers, one should consult Refs. 14 and 15.

The schematic of a parallel-coupled line coupler is shown in Fig. 12a. There can be two types of parallel coupling in stripline. Figure 12b shows edge coupling, and Fig. 12c shows broadside coupling. Both are very popular in many applications where weak coupling (< 10 dB) is required. However, broadside couplers can achieve tighter couplings up to -3 dB. The coupling coefficient is given by

$$C = -20 \log |S_{12}| = -20 \log \left| \frac{Z_{oe} - Z_{oo}}{Z_{oe} + Z_{oo}} \right| \text{dB} \quad (57)$$

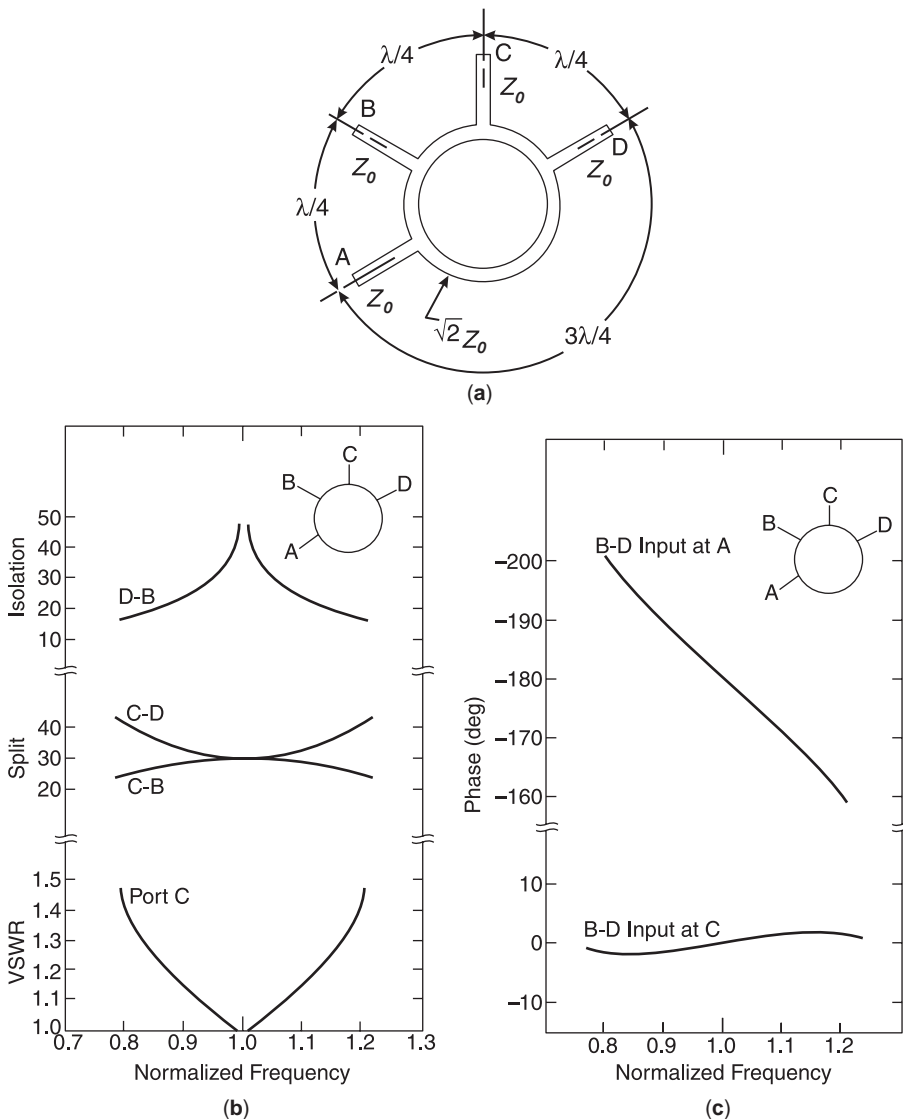

Figure 9. (a) Conductor pattern of stripline hybrid ring; (b) response curve for $(\frac{3}{2}\lambda)$ hybrid ring magic T, with power split and isolation expressed in dB; (c) phase response curve.

Figure 10. (a) Uncompensated single-section Wilkinson power divider; (b) compensated single-section Wilkinson power divider.

Moreover, for a system impedance of Z_0 , the perfect matching condition gives

$$Z_0^2 = Z_{oe}Z_{oo} \tag{58}$$

Equations (57) and (58) are valid only at the center frequency of the operating band where the electrical length of the coupled section is exactly 90° , or in other words, the coupled section is quarter wavelength long.

For a specified coupling coefficient, the design equations become

$$Z_{oe} = Z_0 \sqrt{\frac{1 + 10^{-C/20}}{1 - 10^{-C/20}}} \tag{59}$$

$$Z_{oo} = Z_0 \sqrt{\frac{1 - 10^{-C/20}}{1 + 10^{-C/20}}} \tag{60}$$

Once Z_{oe} and Z_{oo} are known, the physical dimension of the coupled-line structure can be obtained from coupled stripline equations [16, 17]. The frequency response of a par-

allel-coupled stripline coupler is given by

$$C(\theta) = \frac{jC \sin \theta}{\sqrt{1 - C^2 \cos \theta + j \sin \theta}} \quad (61)$$

where C is the midband coupling and θ is the electrical length of the coupled section. As stripline is a transmission line with homogeneous dielectric filling, it has infinite directivity at the center frequency. Figure 12d shows the typical frequency response of a stripline parallel-coupled line coupler.

For many applications, the single-section coupler offers inadequate bandwidth. Therefore, the designer should

have recourse to a multisection design. A multisection coupler is a cascaded combination of more than one single-section couplers as shown in Fig. 13 [5,18].

The coupling coefficient for an n -section symmetric coupler can be written as

$$C(\theta) = \left| \frac{V_2}{V_1} \right| = C_1 \sin(n\theta) + (C_2 - C_1) \sin[(n - 2)\theta] + \dots + (C_i - C_{i-1}) \sin[(n - 2i + 2)\theta] + \dots + (C_{[(n+1)/2]} - C_{[(n-1)/2]}) \sin \theta \quad (62)$$

If the desired coupling response is maximally flat, then C_i satisfies a set of $\frac{1}{2}(n - 1)$ linear equations obtained from

$$\left[\frac{d^r C(\theta)}{d\theta^r} \right]_{\theta = \pi/2} = 0 \tag{63}$$

$$r = 2.4.6, \dots, n - 1$$

The design concept is based on the fact that the backward coupled wave of TEM (transverse electromagnetic mode) coupler corresponds to the reflected wave of a quarter-wave

detailed account of the parallel-coupled stripline coupler, the reader is referred to the article by Fubini et al. [18].

Virtually all types of filters can be realized using stripline technology. Stripline filter technology is as old as stripline technology itself. Fubini et al. [19] reported the oldest work on high- Q stripline components. It was followed by Bradley's work [20]. However, it was Seymore Cohn's paper on parallel-coupled transmission-line resonator filters that presented the first methodical approach and realization of stripline bandpass filters [24]. Figure 14 shows the conductor pattern of several capacitively coupled stripline resonator filters. The reader is referred to the article by Cohn [23] for design information. Since each resonator is a half-wavelength long at the center frequency of the passband, the lowest-frequency spurious passband occurs at twice the center frequency.

Figure 15 shows the conductor pattern of stripline interdigital filter as reported by Matthaei [21] and Cristal [22].

Unlike the half wavelength resonators in filters reported by Cohn [23], interdigital filters use quarter-wavelength resonators that need grounding of one of two ends of a resonator. However, the interdigital configuration has two advantages: (1) it is compact, and (2) since each resonator is a quarter-wavelength long at the center frequency of the passband, the lowest-frequency spurious passband occurs at thrice the center frequency of the passband. The reader is referred to Ref. 22 for design information. Ozaki and Ishi [24] and Young's reprint volume [26] present thorough discussions of the theories of parallel-coupled stripline bandpass filters. Most stripline bandpass filters use Teflon or plastic-type substrate having moderate or high dielectric loss. Hence dielectric loss plays the dominant role in filter's insertion loss. Figure 16 shows the insertion loss response of a typical stripline edge-coupled bandpass filter.

Considerable interest has developed in the recent (as of 2004) past in hard substrate stripline technology. In this technology the top and the bottom halves of a ceramic substrate stripline are glued together using a glass-based material. Filters using this technology offer very good insertion loss performance. Figure 17 shows the photograph of an X-band alumina substrate bandpass filter. Such filters are extremely rugged and have excellent reliability, especially for space born applications.

Besides bandpass filters, other types of filters are also successfully realized using stripline technology. Figure 18 shows the conductor patterns of stripline lowpass, bandstop, and highpass filters. Design information on these structures is available in Refs. 25 and 26. Figure 19 compares the frequency response of a stripline elliptic function lowpass filter with that of its lumped-element version. The conductor pattern of the filter has been shown in the inset.

Besides the passive components described above, there are a large number of microwave active components and subsystems that use stripline passive components.

A stripline is a signal-carrying conductor sandwiched between two layers of dielectric that are shielded by ground planes. The simplest and classic cross section of a stripline is shown in Fig. 1. In this standard stripline, the dielectric is homogeneous and both the ground plates are held at the same potential. The resultant structure implies that the balanced homogeneous stripline supports ideally perfect transverse electromagnetic (TEM) waves, which is in contrast to the microstrip line, shown in Fig. 2, where not only the signal-carrying conductor is exposed and may radiate, but also this structure operates in a highly inhomogeneous environment and, hence, it supports a fundamental mode that is strictly a hybrid mode but can be approximated within certain limits by a quasi-TEM mode. Analysis of striplines is usually easier than the analysis of a microstrip circuit.

In practice, however, actually the interest is focused on stripline-like circuits based on multilayered and inhomogeneous configurations. First, the practical stripline is not an ideal one, but a three-layer configuration with the center conductor to be offset and surrounded by a thin airgap, because small airgaps are often inadvertently introduced during the fabrication process [1]. The model used by researchers for the analysis of such practical structure is shown in Fig. 3. On the other side, in practical antenna feed and new environments such as monolithic microwave integrated circuits (MMIC) and printed circuit boards (PCB), multilayer stripline structures like that of the Fig. 4 are employed. These structures are usually composed of a metal strip conductor sandwiched by two layers of different dielectric constant and upper/lower planes that may not be symmetrically located. Finally, the suspended stripline configuration (SSL) is actually in spread use for coupler and filter applications, caused primarily by its high unloaded Q-factor. Suspended stripline has the center conductor pattern etched on a very thin layer of low dielectric constant; both the conductor and thin dielectric layer are suspended in the air between the two ground planes, as shown in Fig. 5. In some cases, strip conductors are placed on both sides of the dielectric layer, to construct directional couplers of high coupling parameter.

As a result of the inhomogeneous configurations used by engineers in practice, it is impossible for a pure TEM wave to propagate along such a transmission line. These

Figure 5. Suspended stripline configuration.

structures are referred in the literature as striplines (usually, multilayer or inhomogeneous stripline). In the case of SSL, some authors refer to it as inverted or suspended microstrip. However, because of the almost negligible thickness of the dielectric layer that sustains the metal strip, and the presence of two ground planes, most of the authors consider that this structure is a particular case of stripline.

1. SOME ADVANTAGES AND DRAWBACKS. MAIN CHARACTERISTICS AND APPLICATIONS

Both stripline and microstrip circuits are planar structures in that their properties can be controlled by changing one dimension of the circuit. This is requirement key for a transmission structure to be suitable as a circuit element in microwave integrated circuits. For example, the characteristic impedance of a stripline can be controlled by changing the width of the line [2].

In antenna applications, we find the greatest use of the stripline in the feed structure. A popular modern antenna element is a microstrip patch radiating element being fed by a stripline. We can use the stripline, however, in various sections of the feed structures. Some common applications include power dividers, directional couplers, coupled parallel lines, mixers, and switches. We also extensively use stripline components such as bandpass and bandstop filters and direct coupled hybrids.

In such applications, striplines can provide some significant advantages [3]. The stripline is compact and can hence replace bulky waveguides. Producing stripline components on a large scale requires the manufacturing and testing of only one component. An unlimited number of identical components can be manufactured with the same template. Therefore, in commercial applications, striplines can be significantly less expensive than waveguides. In addition, all components required to make up the complete circuit can be placed on a single substrate, which allows for compact circuit designs and circuits that can be flush-mounted on any desired surface. This property is particularly useful to engineers in the design of airborne antenna arrays and wireless communication antennas. Furthermore, the placement of all components on a single substrate eliminates the need for interconnections, usually the source of unreliable manufacturing.

At lower frequencies, a good choice of the substrate material can lead to significant savings in circuit size, which reduces the weight and cost of many transmit and receive systems. Although traditional waveguides can usually handle higher power levels than striplines can, in most applications, the stripline feed structures have adequate power-handling capabilities. In fact, the power-handling capability of the stripline is greater than that of microstrip circuits. Also, the structured design of a stripline circuit allows for the easy interchange of components to replace defective ones. Moreover, the stripline provides an important advantage in some millimeter-wave antenna applications over the microstrip feed: Although microstrip is a radiating element in nature, especially at higher

frequencies, the stripline has probed its effectiveness in suppressing backradiation from the antenna.

Along with these advantages, several drawbacks should be taken into account in the design of stripline components. For example, the manufacturing of a stripline circuit is a complex task because of its sensitivity to small manufacturing errors. At microwave frequencies, all dimensions of the circuit are important, and small errors can lead to serious degradations in the operation of stripline circuits. In addition, and in contrast to microstrip lines, small adjustments or tuning cannot be easily incorporated after the circuit has been fabricated because it is an enclosed medium. A stripline circuit also suffers from some practical difficulties because the line must be excited by either a coaxial line or a waveguide. In either case, the connection is a sharp discontinuity requiring matching circuits to reduce reflections.

The multilayer structure of the practical stripline leads to dielectric-dielectric and dielectric-metal interfaces. Therefore, the electromagnetic fields must satisfy different boundary conditions at these interfaces. A complete analysis of stripline circuits is hence a complex electromagnetic problem requiring extensive computer resources. Usually, a quasi-TEM (quasi-static) analysis suffices to characterize the transmission line by means of the characteristic impedance and the transmission constant. However, even a quasi-static analysis of multiple striplines in proximity to each other is a complicated task, and actually a lack of useful design models and closed-form equations suitable for the analysis of multilayer three-dimensional (3-D) packaging structures exists. Moreover, the unbalanced inhomogeneous multilevel and multiconductor geometries employed by engineers in antenna feed and MMIC boards give rise to leaky modes and residual wave currents that result in increased attenuation, crosstalk, and other undesirable spurious effects. To minimize these effects and enhance the performance of the stripline configurations, in many cases, it is not only desirable, but necessary, to perform a full-wave analysis that takes into account the high-order evanescent and spurious modes. A continuous effort has been made in the last years in this field, and some numerical techniques employed in the classic and recent literature are presented in Section 3.

2. SOME INITIAL DESIGN CONSIDERATIONS

The design of a stripline circuit begins with the choice of dielectric material to form the substrate over which the circuit is to be printed. No one material is ideal for all stripline applications. The desired properties of the dielectric material are usually in conflict with each other, which results in a tradeoff for each requirement. Some aspects of the material that require attention are the dielectric constant and its variation with temperature or frequency, the energy dissipation in the material, and the homogeneity of the material. Other characteristics that play a part in circuit design are the dimensional stability of the material as the operating temperature or humidity changes, the resistance of the material to water, and the chemicals involved in the printing. The tensile and structural strength

of the material, its machinability, and thermal conductivity are also important material properties [1].

The choice of dielectric material helps determine the losses, the characteristic impedance, and the power-handling capability of the line. The choice depends on whether we are interested in peak power or continuous-wave (CW) power. For example, in pulsed radar systems, the peak power is significantly higher than the average power, which may lead to arcing in the dielectric substrate. Sharp edges that lead to concentration of fields are a principal cause of arcing. Smoother bends, such as a mitered bend, can help reduce the effect of a sharp corner. The average power capability is mainly a function of the permissible temperature rise of the center conductor and the surrounding material. The thermal conductivity and dielectric losses play a key role in determining the maximum permissible CW power [1,4]. In a recent study, both transmission line theory and thermal modeling based on finite element analysis were combined to estimate the temperature rise within a stripline [5]. This study defines a method for assessing the effect of stripline design on its thermal performance, and it shows that higher dielectric materials used by engineers for size reduction of the circuit, despite their higher power loss, can produce smaller striplines with similar internal temperature rise than that of standard materials. This capability is because of the higher thermal conductivity of the materials with higher dielectric constant.

The combination of guided wave circuits with radiating elements leads to a new set of tradeoffs. The properties of materials and structures that enhance printed circuit performance tend to reduce radiation performance. Furthermore, direct-current (dc) biased circuits and the packaging for the stripline feed structure disturb antenna characteristics [6].

Stripline feed circuits usually work at power levels lower than those of waveguides. Hence, a coaxial cable to stripline transition usually launches a signal onto the feedline. The coaxial cable supports a pure TEM mode, whereas the multilayer and practical stripline supports a quasi-TEM mode, which makes the transition relatively simple, and matching circuits can be designed to ensure a good match. A transition section is needed if the ground spacing of the stripline is not the same as the dimensions of the cable. If the transition from cable to stripline is ignored, the high capacitance at the transition can lead to effective shorts circuits, which causes most of the transmitted energy to be reflected. Broadwall transitions from the side of cable are also possible.

Figure 6. Narrowband directional coupler.

Figure 7. Multisection directional coupler.

3. APPLICATIONS AND ANALYSIS

The simplest and least expensive directional couplers or power dividers are by a direct coupled line or a branch line, which allows for single-plane construction as shown in Fig. 6. The ratio of the series and shunt impedances determines the coupling coefficients. This structure is narrowband in nature, and a more broad-band coupler can be made by extending the circuit to include multiple sections as shown in Fig. 7. A three-section stripline coupler is about the maximum that can be designed without the lines getting too thin to be reliably manufactured [1]. Broadband couplers can also be designed by having a main line parallel to a secondary line as shown in Fig. 8. This configuration, or coupled parallel lines, is one of the most useful and widely applied stripline structures for broad-band applications in the design of planar hybrids, bandpass filters, and directional couplers. Moreover, the conventional wideband stripline flat coupler formed by two coupled parallel lines presents some advantages with respect to the microstrip coupler. Not only does it present ultra-wideband operation, but it also presents flat coupling over the band, smaller size and volume, and perfect shielding [1].

Suspended stripline couplers have also been widely used by engineers. In this case, the coupled line consists of two strip conductors on both sides of a thin dielectric substrate, inside an air environment and enclosed by two ground planes. To improve directivity, a novel suspended stripline coupler has been recently reported [7]. In this configuration, parallel capacitance is added to each port of the coupled line to reduce the difference of the phase velocities between the even and the odd mode, which improves the performance of the device in its return losses and isolation. A direct application of this structure is a low-loss serial power combiner suitable for amplifier applications.

Another common application of striplines is the stripline circulator. In the traditional stripline circulator, or ferrite junction circulator, the striplines conforms the

Figure 8. Broad-band directional coupler.

ports of the device and merges a metal disk sandwiched by two ferrite disks on top and bottom. Magnetic dc bias field is applied perpendicular to the plane of the ferrite disks [8]. Recently, novel designs have been proposed in the literature, and a growing interest in the ferrite coupled line (FCL) circulators has taken place [9]. Such a device is a possible alternative to conventional ferrite junction circulators, mainly because it is simpler and cheaper to fabricate, it needs only a weak biasing field, and its bandwidth is potentially very wide. It can be realized by cascading an FCL section, which resembles two parallel coupled lines embedded in a ferrite substrate, with a T-junction or hybrid coupler. In these devices, the FCL sections are typically much larger than the T-junctions or hybrid couplers. Therefore, the losses in the circulators are mainly caused by the FCL sections. The potential disadvantages of such a long narrow shape and its associated problems related to losses and ferrite fabrication can be alleviated by appropriate folding techniques, such as those reported in Ref. 10.

Stripline filter design is well documented in classic literature [1]. The most common bandpass filter in general use by engineers for stripline applications is the side-coupled filter, which makes use of open-circuit sections of stripline that act as half-wave resonators. To package the filter in an overall stripline circuit, it may be desirable to fold side-coupled filters to avoid the large size of the half-wave resonators. An alternative half-wave resonator filter is the end-coupled filter, in which the resonators are coupled by small capacitive gaps. This configuration can be meandered in a serpentine fashion to minimize its overall length. For wideband applications, the most effective type of filter is the direct-coupled stub filter, formed by a series of short-circuited quarter-wavelength stubs separated by quarter-wavelength sections of line. We may use equivalent circuit elements in place of the quarter-wavelength stub to achieve the actual impedance levels necessary for the short-circuited sections.

Recently, however, interest has been focused on the multilayered striplines filters, to obtain high-quality factors or tunable filters, like those based on suspended stripline configurations, and to employ them in LTCC environments. Low-temperature cofire ceramic or LTCC is one of the key technologies for integration of millimeter-wave systems and RF module applications because of its good metal conductivity, excellent high-frequency characteristics, and three-dimensional integration capability. For high-performance LTCC applications, stripline structures represent the most ideal transmission line, because dispersion and radiation are negligible and ground planes provide effective shielding. In this way, multiconductor stripline structures, with four or more layers and via holes or excitation vias connecting the different conductor layers, have been reported on the design of LTCC stripline filters for millimeter waves [11,12].

The suspended stripline is a versatile transmission medium for millimeter-wave frequencies, because of its low loss and the option of fabricating double-sided circuits. Its low unloaded Q-factor makes the suspended stripline an attractive approach for implementation of filters at high frequencies [13]. One major drawbacks of these filters is

the filter length. A miniature suspended stripline filter has been reported in Ref. 14. This filter is based on an interdigital structure in which its key element is a short-circuit, branched, and folded quarter-wave resonator that allows a reduction of its length by about 75% in the overall structure. Suspended stripline has been also used by engineers in the design of tunable interdigital filters. The varactor-tuned RF filter [15] is similar to the capacitively loaded combline filter, but it is adapted for interdigital topology and conforms to a symmetric filter of coupled resonators. The tuning element is a reversed-biased varactor diode. The resonators are shortened fingers of suspended strips with varactor diodes at the ends. The filter has a 60% tuning range at about 1 GHz with insertion loss better than 3 dB. Another way to improve the Q-factors of stripline resonators, instead of using suspended stripline configuration, is the implementation of small air cavities over the strip conductor and the bottom ground plane [16] in LTCC substrate.

In antenna applications, a stripline is the feedline to the antenna. The stripline must be shielded from the radiating element. In most applications, the stripline feeds the radiating element through a slot in a ground plane. An example of a stripline feed exciting a microstrip antenna element is shown in Fig. 9.

For good radiation characteristics, the patch antenna in Fig. 6 must be built on low relative permittivity materials ($\epsilon_r \approx 1$) to reduce the concentration of fields in the substrate. Furthermore, the substrate should be thick so that the fields caused by the patch and its image do not cancel each other. Thick substrates are also useful to engineers in building antennas with large bandwidths. A material that satisfies these properties is foam [2]. The microstrip antenna is etched on one side of a thick foam layer with the ground plane on the other side of the foam. The nonresonant slot is cut into the ground plane with a stripline under the ground plane exciting the slot. This stripline-slot-foam-inverse-patch (SSFIP) structure was introduced in Ref. 3.

The stripline could be etched on a foam without the ground plane backing the antenna element. However, the antenna must be mounted on some surface. If the ground plane is removed, the feed structure is affected by the

Figure 9. Microstrip patch antenna fed by a stripline through a slot.

mounting. The metal ground plane protects the stripline from the surface. The mounting surface must be distant from the feed, whereas for maximum coupling, the feed must be as close as possible to the slot. Hence, the feed is an unbalanced stripline. Furthermore, the SSFIP element is designed with metal walls to eliminate the propagation of parallel plate modes.

The stripline feed is compact and efficient and it presents some advantages over a microstrip feed, because the cross-polarization level is lower and the interactions between the radiating elements and the feeding network, such as the shift in the resonant frequency and the backradiation from the feeding network, are suppressed. But stripline feed leads to some complications. To have sufficient coupling across the slot, the widths of the stripline must be greater than that of the microstrip. Furthermore, completely enclosed striplines can lead to resonant frequencies or parallel plate modes, presented in the multilayer feeding structures. Mode suppression pins or electrical posts or vias that short the two ground planes in some strategic points can prevent resonant modes. The resulting structure can be complicated, and design of the feed structure requires considerable effort. Beyond the fabrication complexity involved, these posts create imperfect waveguides that might considerably affect the predictability of the circuit performance. It has been demonstrated, by means of full-wave analysis based on method of moments (MoM), that vias considerably modify the impedance and resonant characteristics of the patch antenna [17]. This effect becomes substantial and must be included in the design tool. In this work, the radiation efficiency of patch antennas with and without vias is studied, and proper location of the posts is shown to drastically reduce power in the parallel-plate mode. At higher frequencies, smaller via-spacing must be used by engineers around the slot to ensure that resonances do not occur. One way we could avoid the posts would be to use striplines with two different dielectric layers, but this is only acceptable as long as coupling to both sides of the stripline is not necessary. A new solution proposed involves such inhomogeneous stripline only in the vicinity of the microstrip-to-stripline coupling slot [18]. The TEM parallel plate mode is excited in such structure at a much lower level. Recently, the frequency-dependent behavior of the spurious mode power ratio to the input power of the antenna has been discussed, and it has been found that this ratio is very small when the antenna is operated at the resonant frequency of the patch [19]. This efficient method can avoid excessively geometrical complex solutions for the suppression of the parallel plate mode in the stripline feed.

Striplines can feed other particular antenna structures, such as meander slot antennas, Vivaldi notch antenna arrays, bowtie antennas, and cylindrical rectangular microstrip antennas.

However, a complete analysis of stripline feeds is a complicated task. In general, no closed-form solutions exist for the currents on the striplines and the fields in the surrounding media. Engineers have used a numerical solution, using such techniques as the MoM [20–23], to solve for the fields and currents on the stripline. The initial solution techniques accounted for only the quasi-TEM dominant mode; that is, they applied a quasi-static analysis.

In Ref. 24, the authors analyzed the crosstalk and coupling between multiconductor transmission lines such as striplines, suspended striplines, and microstrip lines based on modal analysis in the frequency domain. This approach is extended in the commercially available software packages LINPAR [25] and MATPAR [26]. A time-domain analysis of the multiconductor transmission problem [27] allows for the tracking of digital waveforms as the propagate along the stripline.

In Ref. 28, a dual-polarized slot-coupled printed antenna with a stripline feed is analyzed. They assumed a quasi-TEM mode on the stripline associated with the standing wave because of the serial impedance caused by the slot. Stripline feeds for infinite arrays can be analyzed with Floquet modes [29]. In Ref. 29, the stripline feeds an open slot array. Electric and magnetic currents are used by engineers in conjunction with the equivalence principle to separate the feed region from the radiation region. The currents on the feed structure are obtained by solving the coupled integral equations for the two regions [30].

Nowadays, as the frequency of operation and power levels have increased, the quasi-TEM approximation is less applicable. Full-wave techniques account for all modes, propagating and evanescent [31]. Furthermore, for high-performance circuits, where spurious and high-order modes effects must be taken into account in complex multilayered geometries, full-wave analysis is needed. In fact, the existence of leaky modes that leak power into the parallel plate surrounding medium on printed-circuit transmission lines has recently been the subject of considerable interest. These modes are usually undesirable because they result in increased attenuation, crosstalk, and interference with bound modes. The part of the continuous spectrum not represented by leaky modes has been studied, and it was termed *residual wave*. Some authors have studied the excitation of leaky modes and residual waves [32,33] in multilayered stripline structures. In these studies, a quasi-analytical method and closed-form representation are derived, which can help the proper understanding of these spurious effects. The practical reduction in the crosstalk and parallel plate mode coupling between adjacent striplines in LTCC packages is commonly accomplished by the insertion of plated via holes, in a fashion similar to the stripline antenna feeding structures. Full-wave three-dimensional simulators have been used by engineers to analyze the impact of the via holes in the stripline structure. It has been demonstrated that the radiation loss and the coupling increases if the fences are placed too close to the stripline [34,35]. In Ref. 34, it is shown that placement of a via hole fence closer than three times the substrate height to the strips increases radiation and coupling. It must be apparent that shorting posts must be performed carefully in the stripline and antenna feeding designs. Moreover, from the point of view of planar process, shorting posts increase significantly the fabrication complexity. An alternative leakage suppression structure with a two-dimensional photonic bandgap lattice etched in the ground planes has been reported [36].

Because of the application of via holes in striplines structures to suppress the leakage parallel-plate modes, the necessity of 3-D full-wave analysis becomes more

apparent. With the increase of operating frequencies and higher circuit densities, issues like crosstalk, signal delay, and distortion are becoming more predominant in the design procedure. At high frequencies, we must take great care with physical layout and interconnects to minimize parasitics, and technological effort in high-density packaging is leading to the design of true three-dimensional circuits, in which accurate signal timing depends on three-dimensional analysis of interconnect, for which we cannot use conventional two-dimensional analysis.

The most popular approach to analyze striplines and microstrip lines is the integral equation (IE) formulation in either the space [37] or spectral domain [38,39]. In Ref. 39, a cylindrical cavity-backed SSL antenna is analyzed. The SSL feed is particularly attractive in the higher microwave and millimeter frequency regions. In Ref. 40, the analysis of a similar structure, the cavity backed circular aperture antenna with suspended stripline feed, using the finite element method (FEM) is reported. A more rigorous analysis of metal-dielectric bodies such as stripline feeds is possible with subsectional analysis [41]. The finite difference time-domain (FDTD) method is also used by engineers in the analysis of multilayered striplines. In Ref. 42, the current and electric field distribution of a PCB stripline structure is reported applying the FDTD method. In Ref. 43, FDTD analyzes an endfire tapered slot phased array with stripline feed. In this study, the effect of the plated vias is included in the analysis, and this allows us to place the vias in the proper points to eliminate impedance anomalies in the antenna. The FDTD method presents the advantage that it provides the transient response as well as the frequency domain data, but it is a time-consuming technique. MoM and FEM techniques, as we have seen before, are also extensively used by engineers in the stripline analysis. MoM offers the advantage, in this particular case of multilayered striplines, of only requiring the discretization of the conducting interconnects, and hence, it can simulate bigger and more complicated structures. The integral equation technique starts with the development of the Green functions for the problem. MoM is then applied to the integral equation to obtain an approximate solution for the currents in the interconnects. A significant part of the computational effort in MoM is associated with the calculation of the elements in the reaction or impedance matrix. These elements can be represented as Sommerfeld-type integrals, which are highly oscillatory and slowly convergent. A full-wave layered-interconnect simulator (UA-FWLIS) that claims to overcome this problem has been recently reported [44]. In this method, the reaction elements of the MoM have been analytically evaluated. The method is directly involved in the analysis of coupling in a multilayered stripline circuit.

1. HISTORICAL PERSPECTIVE

The introduction of radio (or “wireless”) telegraphy into the U.S. fleet in 1910 marked the beginning of the submarine’s role as a capable ally with the surface ship in times of conflict. In those early years, submarine antennas were of either the hull-terminated loop type (introduced in 1919) or the flat-top (T) variety; the latter were modeled after those found on small aircraft and surface ships of the period. Figures 1a and 1b are views of these post- and pre-World War I (WWI) antennas, respectively. Operationally, the antennas were used for reception under water at very low frequencies (to a depth of ≤ 20 feet at 16 kHz), but had to be exposed by raising the vessel to the ocean surface for the purpose of transmission.

Throughout the late 1920s and early 1930s antenna designs grew in sophistication as the introduction of radar and other intelligence gathering functions became part of the submarine’s sensor suite. Figure 2 is a photograph of a typical antenna system aboard a WWII-era diesel-powered submarine. With the arrival of nuclear propulsion in the mid-1950s, antenna technology was pushed still further, as the new submarine was able to remain submerged for months while still maintaining communications with the outside world using the *buoyant cable antenna* (BCA, discussed in Section 3).

Submarine antenna technology thus owes its evolution to developments in naval operational requirements as well as advances in the applied sciences. In this article, some important elements of submarine antenna design are discussed and some representative examples are shown.

2. THE SEA AS A WAVE PROPAGATION MEDIUM

The electrical properties of the ocean play an important role in determining how a submarine antenna is to be used effectively. Whether the antenna is on, near, or below the surface, these properties influence not only the appropriate type of antenna to use but also the rate of data

(a)

(b)

transfer, which in most cases is of paramount importance when timely decisions must be made and actions carried through. Thus, an understanding of these properties is a part of a submarine antenna designer's repertoire and is briefly discussed here.

Aside from its important thermodynamic properties, water is an electrically polar material with a nonzero net molecular dipole moment that causes the molecule to rotate in the presence of an applied alternating electric field. Over a wide spectrum of frequencies, the rotation of an ensemble of water molecules has been shown to possess a loss peak in the vicinity of 17 GHz at 20°C, commonly called the *relaxation* frequency. The reciprocal of the corresponding angular frequency is the time constant required for the molecules to reach spatial equilibrium once the field is removed (about 9.3 ps). Above and below the relaxation frequency, the loss decreases. The real part of the permittivity decreases above the relaxation frequency but is a constant below it over a wide frequency range with a value of 80, a commonly quoted figure.

The difference between seawater and freshwater is the presence of ionic conductivity, due to the inclusion of natural salts. On a perkilogram basis, the world-average salt content in seawater at 3.5°C is about 35 g (written as 35 parts per thousand, or 35‰), which corresponds to a conductivity σ of 3.2 siemens per meter (S/m). The widely used conductivity value of 4 S/m is equivalent to a salinity of 29‰ at 20°C.

As a propagation medium of electromagnetic waves, seawater permits, with minimal attenuation, the

Figure 3. Suboptical wavelength model of seawater at room temperature. In the circuit, $R_1 = 250 \Omega$, $R_2 = 21 \text{ m}\Omega$, $C_1 = 43 \text{ pF}$, and $C_2 = 583 \text{ pF}$. The circuit model is valid for frequencies from near DC to 40 GHz.

penetration of extremely long (greater than 300 Mm) or optical (blue-green spectrum, near 500 nm) wavelengths. Between these extremes the dielectric properties of seawater limit the wave’s depth of penetration and thus determine how antennas are to be advantageously used.

The dielectric properties of seawater below optical frequencies may be visualized with the diagram in Fig. 3. In the figure, a hypothetical cube (1 m on the side) of seawater is placed between two conducting plates to form a capacitor. Since the relative complex permittivity ϵ_r of seawater has been shown to vary with frequency [1], the corresponding complex admittance Y (S/m) across the capacitor terminals may be modeled by a lumped RC network which permits a simple interpretation [2]. In the circuit, R_1 is the reciprocal of the ionic conductivity σ . Resistor R_2 and capacitor C_2 represent the rotational behavior the water molecules constituting the cube in the presence of an applied alternating field. The product $\tau = R_2 C_2$ is the time constant or *relaxation time* required for the molecules to reach spatial equilibrium (12.3 ps). Finally, capacitor C_1 represents the dielectric constant of water at near-infrared frequencies, the limit of the model. In terms of the circuit admittance Y , the relative complex permittivity ϵ_r and attenuation α (Np/m) of seawater are computed by

$$\epsilon_r = \frac{\eta_0 Y}{jk} \tag{1}$$

$$\alpha = \text{Re}(\sqrt{jk\eta_0 Y})$$

where k is the free-space propagation constant ($2\pi/\lambda$) and η_0 is the intrinsic wave impedance of free space (approximately $120\pi \Omega$). Figure 4 is a plot of the plane-wave attenuation of water with ionic conductivity σ (S/m) as a parameter.

3. ANTENNA TYPES AND SERVICES

Because of the need for living and working space of personnel, weapon storage and deployment machinery, and numerous other devices, the submarine antenna is designed to occupy as little space as possible. Since modern submarine communications are carried out over a multi-decade frequency range from 30 Hz to 50 GHz, antennas exhibiting broadband behavior (with respect to either terminal impedance or pattern) to accommodate multiple

Figure 4. Plane-wave attenuation of water (20°C) with ionic conductivity (σ) as the parameter.

functions are highly desirable. Moreover, careful attention is paid in the early design stages to cositing issues, in order to pinpoint and mitigate electromagnetic interference between various groups of antennas.

Submarine antennas generally fall into one of two broad categories: mast and buoyant. A *mast antenna* is a structure that is extended electromechanically from the topmost portion of the ship known as the *sail*, which breaks through the ocean surface to enable communications. In this posture, the antenna is said to be deployed at *periscope depth* (P/D). A buoyant antenna, in contrast, is deployed from the submerged vessel and allowed to float upward to the ocean surface or to a predetermined depth, depending on the frequency. Once deployed, the antenna is either trailed behind the vessel or fixed in a stationary position. Buoyant towed systems, which are generally low in profile, are thus said to be operated at *speed and depth* (S/D). Figure 5 illustrates the various antenna categories used by a submarine, as determined by its operational posture at sea.

Submarine antennas are typically surrounded by insulation to protect against the effects of corrosion and hydrostatic pressure. For masts, the dielectric is usually a structural composite such as fiberglass or other nonmetallic material with a high strength-to-weight ratio. Buoyant systems may use rigid syntactic foams, hollow fiberglass housings and/or flexible foam polymers to withstand pressure or accommodate storage on a reel within

Figure 5. Antenna deployment with submarine depth.

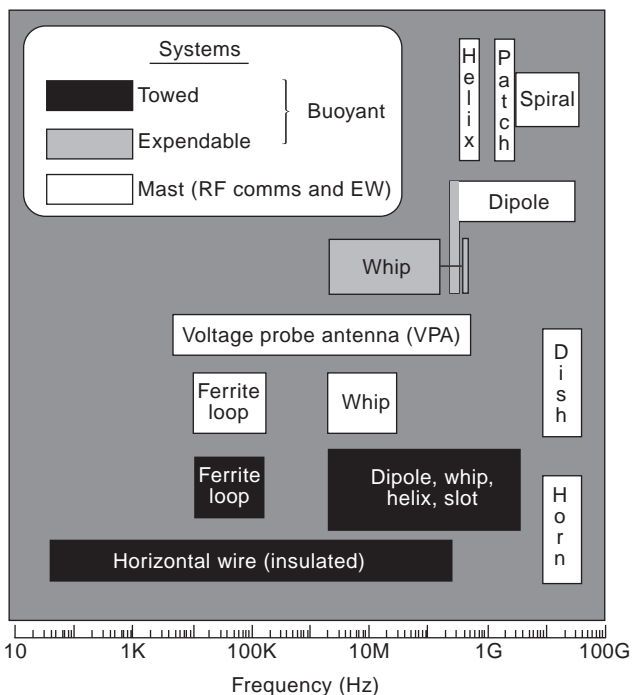

Figure 6. Antenna types by category of use and frequency.

the vessel. Figure 6 plots antennas by generic type (whip, loop, etc.) as a function of frequency.

3.1. Mast Antennas

Mast antennas are structurally attached to the submarine and are exposed above the ocean surface at periscope depth (or with the vessel on the surface) to permit communication or detect signals. They are divided into two categories, by function:

1. *Radiofrequency Communications (RF Comms)*. These are antennas used for services ranging from VLF navigation through UHF satellite (with low to moderate gain); above 10 GHz, large aperture (high gain) antennas are employed.
2. *Electronic Warfare (EW)*. This category describes a suite of antenna sensors used (singly or in groups) to

identify the presence and/or direction of electromagnetic emission(s) generated by friendly or hostile forces over multidecade wavelengths from VLF through millimeter waves. Depending upon the nature of the emission(s), electronic warfare antennas may be used in a variety of ways within three functional groups.

- *Electronic Attack (EA)*. This subcategory comprises antennas used either (1) for jamming or deception (nondestructive) or (2) as a weapon for degrading or neutralizing an electromagnetic energy source emitted by a hostile force (destructive).
- *Electronic Protection (EP)*. These are passive or active sensors designed to protect or mask personnel, facilities, and equipment from the effects of directed energy emission from hostile or friendly sources.
- *Electronic Warfare Support (ES)*. Formally known as *electronic surveillance measures (ESM)*, the antennas and subsystems in this group are used for locating [i.e., direction finding (DF)] and identifying electromagnetic sources for targeting, threat recognition, and other tactical actions.

The physical disposition of the various mast antenna types found on a typical submarine sail is shown in Fig. 7a. Radiofrequency communication masts are, in general, standalone (i.e., dedicated) systems. Electronic warfare mast systems differ in packaging; they are either standalone or mechanically integrated with other functions. An example of the latter includes antennas placed together with the submarine’s periscope optics system, to acquire visual information while simultaneously collecting electromagnetic emission data.

Depending on the frequency and specific use, the antennas generally assume a multitude of forms such as monopoles, loops, or quadrifilar helices. Figure 8a is a photograph of typical mast antennas used in the UHF (225–400 MHz) range; Fig. 8b is an EW antenna stack consisting of spiral, dipole and horn antennas for 200 MHz–40 GHz. More recently, emerging requirements for real-time data exchange with other battle groups have shifted emphasis toward the design of antennas with larger apertures (and hence higher gain). These requirements are generally met at frequencies above 10 GHz, where efficient

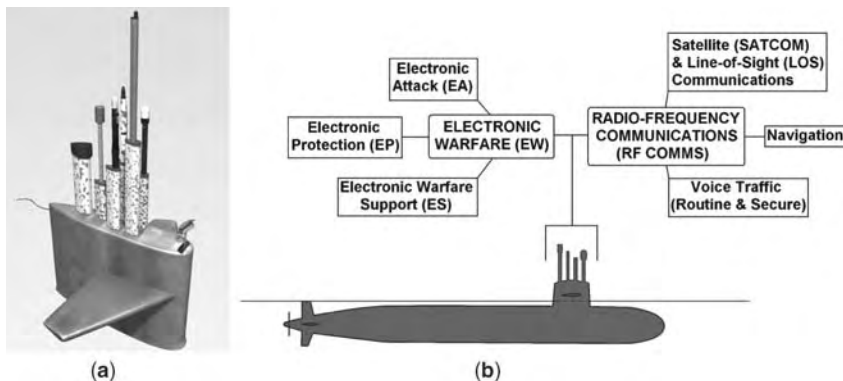

Figure 7. Mast antenna systems: (a) systems erected from the submarine sail; (b) tree diagram of typical functions.

Figure 8. Mast antennas: (a) UHF antennas (RF communications); (b) multiband DF/ES system (periscope).

antennas are not unduly large. One key relationship for selecting the approximate size of an antenna for a given maximum directivity D_{\max} is given by [3]

$$D_{\max} = (ka_e)^2 + 2ka_e \quad (2)$$

where a_e is the equivalent radius of a sphere that has the same overall volume as the antenna and k is the propagation constant (defined earlier). Figure 9 is a plot of (2) for some selected antennas at a given frequency (250 MHz).

Larger directivities with the added advantage of beam-steering are achievable with phased arrays; a comprehensive review of these larger aperture systems applied to submarines is given by Craig [4].

Figure 9. Variation of maximum directivity with antenna volume at 250 MHz.

3.2. Buoyant Antennas

In contrast with mast systems, buoyant antennas are deployed when the vessel is submerged. There are two sub-categories of buoyant systems typically used by a submarine:

1. *Towed.* A towed antenna is one that is deployed from the submerged submarine, typically from a location near the trailing edge of the sail. The antenna floats upward toward a predetermined equilibrium position near or on the ocean surface, whereupon it is dragged behind the vessel at a certain velocity. The velocity and depth with which the antenna is towed behind the submarine is dictated by the operating frequency, together with hydrodynamic and other considerations. There are several types of towed antennas, each with different purposes as described below:

- *Buoyant Cable Antenna (BCA).* The BCA is a thin (nominal overall diameter of 0.65 in.) insulated wire antenna terminated at the far end to seawater with a suitable grounding electrode. The mainstay of low-silhouette communications since 1960, the frequency range of the BCA extends from about 30 Hz to 180 MHz and is used for navigation, voice, and related tasks,
- *Towed Buoy.* A towed buoy is a device that is used to keep a trailed insulated wire (or other) antenna at a steady depth beneath (or above) the ocean surface, or as a platform for carrying an antenna on the sea surface.

2. *Expendable.* An expendable antenna is used for emergency signaling applications. After reaching the sea surface when jettisoned from a submerged vessel, the antenna performs its intended function and afterward “scuttles” or self-destructs after a preset time limit.

As noted above, buoyant antennas take numerous forms depending on their intended application. The challenge in their design lies in simultaneously satisfying numerous constraints which are generally competitive in nature.

3.2.1. Buoyant Cable Antenna (BCA).

Since the early 1960s the mainstay of low-silhouette submarine communications has been the buoyant cable antenna (BCA). The BCA is essentially a transmission line antenna, as shown in Fig. 10, consisting of an insulated flexible wire. It derives its buoyancy from a foamed watertight polyethylene jacket that envelops the antenna element and transmission line and derives its tensile strength with Kevlar strength members imbedded between the jacket and insulated wire. The antenna structure as a whole is also resilient in that long-term exposure to large hydrostatic pressures—as experienced during deep submergence—does not seriously degrade its buoyancy over its operational life. Its evolution from transmission line to antenna is shown succinctly in Fig. 11; Fig. 12 is a collection of BCA electrodes.

Figure 10. Buoyant cable antenna (BCA). Electrodes E_1 and E_2 in the diagram are grounding electrodes. Antenna size relative to submarine is exaggerated to show detail.

The reception of extremely low frequency (ELF; 30–300 Hz) broadcasts uses two helical grounding electrodes similar to E_2 (see Fig. 10), which are molded into the transmission-line portion of the BCA; the distance between them is about 1000 f. With only one end of each electrode connected to a lead from a twisted-pair transmission line, the insulated conductor spanning the distance between them serves as the antenna element. This aspect is discussed in further detail later.

3.2.1.1. BCA Input Impedance. Two important properties of the buoyant cable antenna are discussed in this section: (1) the circuit characteristics, which permit the determination of the feedpoint impedance and (2) the radiation pattern, which is due to the current distributed along its length. Given the physical dimensions of the antenna, both properties may be used to determine, for example, its range of transmission (or reception) or the operating bandwidth in the presence of seawater.

As shown in Fig. 11, the conversion from a conventional coaxial transmission line into an antenna amounts to splitting a symmetric structure, followed by an exchange of the outer shell from metal—with very high conductivity—to a finitely conducting medium.

The impedance presented at the feedpoint of a conventional transmission line, it will be recalled, is represented by

$$Z_{in} = Z_0 \frac{[Z_L + Z_0 \tanh(\gamma L)]}{[Z_0 + Z_L \tanh(\gamma L)]} \tag{3}$$

Figure 11. Evolution of a buoyant cable antenna. Starting from the top: a coaxial line with metal outer conductor; stripping away of the outer conductor, exposing the insulation; replacement of the outer conductor with seawater. The transmission line’s center conductor is terminated to the outer conductor (metal or seawater) through an impedance Z_s . Practical BCAs generally use a short circuit ($Z_s \rightarrow 0$) termination. (© 2004 IEEE.)

Figure 12. BCA grounding electrodes (see Fig. 10).

where Z_0 is the characteristic impedance of the line, Z_L is the termination (or load) impedance, γ and L are the complex propagation constant and length of the line, respectively.

Because the antenna cross section is small compared with its length (for flexibility), the equivalent circuit of the antenna retains a transmission-line-like character (subject to certain conditions) and is described through *distributed* circuit elements as in the former case. The constants Z_0 and γ are thus modified to account for the presence of seawater [5].

3.2.1.2. BCA Radiation Pattern and Gain. With reference to the coordinate system shown in Fig. 13, Figs. 14a–14c are plots of the computed magnitude of the pattern factors for a 100-ft-long antenna element VLF-VHF BCA element (length L in Figs. 10 and 13) with a short-circuit termination, attached to a coaxial transmission line [6].

Figure 15 depicts a calculation of the total system gain. In the plot, the length of the transmission line connecting

Figure 13. VLF-VHF buoyant cable antenna element of length L : orientation in space.

Figure 14. Patterns in the x - y plane (a), x - z plane (b), and y - z plane (c) (where $|E|$ is a function of θ at $\phi = 90^\circ$). (© 2004 IEEE.)

Figure 15. Gain ($\theta = 0^\circ$ and $\varphi = 0^\circ$) of the VLF-VHF portion of the buoyant cable antenna system with a short-circuited termination shown in Figs. 10–14. (© 2004 IEEE.)

the antenna to the ship is assumed to be 1500 ft; the antenna is a 0.65-in.-diameter cable, 100 ft long, with a short-circuited termination. As the plot indicates, the system gain in this case has a maximum value of -55 dB at 5 MHz. Thus a 500-W transmitter attached to the input terminals of the BCA results in an output power of 1.5 mW, sufficient in some cases for long-haul HF ionospheric communications.

3.2.1.3. Frequency Range of the VLF-VHF BCA. As indicated by Fig. 15, the frequency range of the higher-frequency portion of the BCA is bounded by the gains of the transmission line and the antenna element. It should be noted that the gain is negative for both the (lossy) transmission line and the antenna. The overall peak gain in the range of 2–30 MHz enables the BCA to be used for transmitting in a limited fashion; for reception, it is generally useful from 10 kHz to 180 MHz; the upper limit is that frequency where the coaxial transmission-line attenuation and amplifier gain are equal in magnitude. Several models of the solid-state inline amplifier are shown in Fig. 16.

3.2.1.4. ELF Reception with the BCA. As mentioned earlier, the reception of ELF is made with the antenna element between grounded electrodes E_2 . Although the antenna is physically long (1000 ft), its length is a very small fraction of a wavelength in that part of the spectrum and the antenna is operating within the near (or quasi-static) zone. In this instance its field pattern is, in general, a function of the radial distance away from the antenna. For a given electric field E penetrating the ocean, an open-circuit voltage V will exist at the input terminal of the antenna that varies directly with electrode spacing d . This can be written as

$$V = |E|d \quad (4)$$

Figure 16. Solid-state inline amplifiers for a buoyant cable antenna: *left*—rigid chassis design (ca. 1970); *right*—flexible bellows model (1980–present).

where $|E|$ is the magnitude of the electric field. The ELF antenna is located away from the submarine to minimize the pickup of hull-generated noise.

3.2.2. Towed Buoy. Towed buoys are buoyant bodies that are used whenever a submerged submarine is too deep to deploy a buoyant cable antenna. The body may be used stabilize the position of an antenna, affixed to it, at some shallow distance beneath the ocean surface, or as a means for carrying antennas on the surface. Since the early 1960s, the U.S. Navy has developed various antenna/tow body configurations for operation at various sea conditions and frequencies. The tow bodies were designed by various organizations within the Navy, and Fig. 17 is a composite of some early designs. The design shown in part (a) was known as the AN/BRA-10, the first static (non-towed) buoy. The antenna, mounted topside, is a VHF/UHF whip. The configuration in (b) was known as the AN/BRA-27, which was perhaps the first *dynamic* radio buoy. It played an important role during the 1962 Cuban missile crisis [6].

Advances in tow body research through the years have resulted in hydrodynamic shapes with improved tow speed, reliability, wake, and depth control characteristics. Figure 18 shows several of these newer designs. Pressure transducers placed inside the tow bodies become part of an electromechanical feedback system that provides depth control when coupled to a winch; other designs use buoyancy tanks within the buoy to regulate the depth.

(a)

(b)

Figure 17. Early antenna/tow body configurations: (a) AN/BRA-10, the first *static* buoy (ca. 1960); (b) AN/BRA-27, the first *dynamic* buoy (ca. 1962).

With the exception of experimental work with HF and UHF antennas, the tow bodies in Fig. 18a have been used for towing ferrite core loop antennas to permit continuous VLF reception. More recently, improvements in antenna

(a)

(b)

Figure 19. High-lift auxiliary wire: (a) antenna being towed; (b) ferrite core loop assembly.

design to address the need for hemispherical coverage have resulted in the development of the HF (2–30-MHz) high-lift auxiliary wire. In this system, an insulated buoyant wire and loop antenna are placed collinearly, and, with their output signals properly combined, generate the desired hemispherical coverage pattern. Figure 19 shows the towed system and loop antenna.

The most recent work on the *low-profile antenna* (LPA), a UHF (240–320-MHz) transmit/receive system, has focused on both antenna and tow body designs. Figure 20 shows the tow body under test. Generically of the *planing craft* variety, the slender tow body (or module, with a length-to-diameter ratio of 16) is able to generate lift during tow to minimize signal outages due to seawater washover during tow [7]. This important design feature ensures more consistent performance when towed against

or along ocean wave crests and troughs (known as cross or following sea, respectively). It is also fitted with spray diverters over the top (skyward) side as a secondary means for washover reduction.

In Fig. 21, several antennas enclosed within the module are shown. Figure 21a is a small tunable UHF slotted-cylinder antenna (dielectrically loaded), while Fig. 21b is a GPS/iridium phone antenna. When mounted on a two-axis gimbal, the low center of gravity resulting from its conical shape forces this phone antenna to always face upward, regardless of the pitch and yaw movement of the tow body.

3.2.3. Expendables. An expendable antenna is used in emergency situations. Its purpose is to call for assistance in case a submarine is disabled. Over the years, various types of expendables have been devised, but their main operational characteristic involves the one-way transmission of a message. The general sequence of operation is as follows:

1. *Deployment*—the antenna unit is ejected from the submerged vessel,
2. *Formation*—the antenna unit surfaces and assumes its operational position. In some cases the buoy arrives at the ocean surface in a compressed shape, whereupon the use of an explosive charge or gas pressure exerts forces that cause the antenna to unfurl for operation.
3. *Transmission*—the sending of a prerecorded message,
4. *Destruction*—self-disposal of the unit.

The expendable system includes a miniature battery-powered transmitter, together with the necessary circuitry for data storage and retrieval. Built-in test equipment (BITE) for pinpointing problems that would impede operation on deployment, are integrated within some of these devices. The expendables shown in Fig. 22 are of the free-floating (FF) type, meaning that they are untethered.

4. DESIGN CONSIDERATIONS

4.1. Mast Antennas

The design of mast antennas is similar in principle to the design of antennas used in commercial systems, except for the following special precautions:

- *Size*—antenna weight is part of the total submarine payload and must be accounted for.
- *Bandwidth*—the antenna bandwidth is determined by its physical size relative to the wavelength; a tradeoff must be performed with weight considerations to arrive at a satisfactory compromise.
- *Heat dissipation*—there must be provisions for heat-sink design when antennas dissipate considerable heat (typically generated by impedance matching circuits for electrically short monopoles enclosed in a radome).
- *Shock load*—the antenna structure must be able to withstand high impulsive forces, such as those experienced during explosions.
- *Vortex shedding on masts*—a vertical structure of arbitrary cross section towed against a fluid (in this case a mast against seawater) sets up a series of alternating low pressure zones in the fluid, which are

Figure 21. LPA antennas: (a) dielectrically loaded UHF (240–320 MHz, tunable slot antenna; (b) GPS/iridium phone antenna (1.2–1.8 GHz).

Figure 22. Expendable antennas: (a) ejection from submerged vessel; (b) formation of UHF folded dipole antenna (AN/BRT-6) on sea surface; (c) VHF (160–175 MHz) submarine launched one way transmitting (SLOT) buoy (AN/BRT-1); (d) UHF (406 MHz) submarine emergency position indicating radio beacon (SEPIRB, T-1630/SRT). In (c) the whip antenna is exposed, while in (d) the antenna is under the protective black cap, respectively.

located at the wake or trailing edge of the mast. The resulting movement of the mast toward and away from these zones can cause a structural resonance in the mast at a certain critical tow velocity, often with destructive effects. The satisfactory design of a mast shape thus begins with an understanding of the operating envelope the structure it is likely to work within (subject to numerous other factors) followed by experiments on scale models, combined with numerical fluiddynamic computations.

- *Wave slap*—a term used to describe the pressure load a fluid places against an immovable object. A pressure of 9 lb/in.² above atmospheric is used as the most stringent figure for an acceptable design.
- *Vibration*—the ship vibration spectrum must be considered in order to properly locate the antenna for optimum operation.
- *Pressure tolerance*—the completed system (antennas and radome) must withstand large hydrostatic pressures; a minimum of 450 lb/in.² is typical.
- *Ease of repair/maintainability*—the antenna must be simple to repair or replace on site (pier-side) or at a

maintenance depot with a minimum of effort. This forces the design to be robust with a minimum of tuning screws, adjustment bars, and other devices.

- *Placement*—spacing between antennas within and between masts must be chosen properly to prevent interference by mutual coupling.

4.2. Towed Buoy and Buoyant Cable Antennas

Antennas for tow bodies must withstand very large hydrostatic pressure yet must be light enough to float on the ocean surface. The following precautions, when added to the criteria outlined above, represent a comprehensive (although not exhaustive) set of guidelines:

- *Stability*—the tow body must be hydrodynamically stable with minimal mechanical hysteresis.
- *Tow body drag*—this must be kept to a minimum so that leader cable “strumming” and other stress effects are minimized.
- *Hydrophobicity*—the tow body’s surface must be able to quickly shed water spay, usually accomplished with paints or other special coatings.

- *Corrosion resistance*—careful selection of metals is needed to minimize or prevent the generation of galvanic currents (and its resultant destructive effects).

The buoyant cable antenna is a relatively simple structure, which can be maintained with a minimum of equipment, or disposed of if it is considered to be beyond repair.

5. MATERIALS

The materials chosen for the structural and electrical performance of submarine antennas are dictated by requirement. In certain applications where the design may be a “one-time use” device, inexpensive materials are chosen; at the other end of the spectrum, where high strength is required, resilient materials are needed.

5.1. Metals

For prototyping work, various grades of brass, copper, or aluminum are used; the choice is determined primarily by cost or application. Silver, gold or bronze are used whenever RF connectors, grounding electrodes, or circuit board mating pins are required to have high conductivity, corrosion resistance, or hardness, respectively. In special cases, stainless steel or titanium is used whenever resistance to corrosion or strength combined with light weight is desired.

5.2. Insulators and Dielectrics

Most ceramics and glasses used in submarine antenna applications require moderate dielectric constants ($\epsilon_r' 3\text{--}7$) and moderately low-loss tangents ($\tan \delta < 10^{-2}$). In instances where heat dissipation is necessary, ceramics such as beryllium oxide (BeO) or aluminum nitride (AlN) are usually employed. For applications requiring high dielectric strength and very low loss ($\tan \delta < 10^{-4}$), Teflon (TFE) or Noryl (PPO) are typically used. Noryl has been used as a radome material for microwave antennas. More recently, the introduction of printed antennas in submarine mast applications has utilized low-loss TFE laminates. Certain buoyant antennas have made use of syntactic foam, a strong and lightweight material that is made by mixing glass microspheres with a binding agent, such as epoxy. In critical applications requiring low dielectric loss, care must be exercised when choosing each component. For certain radome applications, electrical-grade fiberglass (G-10) and (more recently) quartz epoxy composites have been used.

6. TESTING

The electrical and mechanical testing facilities for submarine antennas are unique. In this section, brief overviews of the facilities used by the U.S. Navy are presented.

6.1. Electrical

The measurement of the low-angle radiation pattern and input impedance of BCA and mast antennas is carried out at the Navy’s Fisher’s Island facility in Long Island

Sound, NY, a location far from human-produced noise (Fig. 23). The facility has a naturally formed saltwater tidal pond (a) that serves as the BCA testbed. With the antenna floating on the pond, measurement “cuts” in the azimuth plane are made at a distance of approximately one mile from the pond (b) at a very shallow (about $\frac{1}{23}$ rd of a degree) elevation angle.

The circular area located near the tidal pond, to the right in Fig. 23c, is the mast antenna testing facility (c). It comprises a concrete pool lined with radials to simulate a ground plane. When testing is required, the pool is filled with seawater from the neighboring Sound. A control room immediately below the pool (not shown) serves as an instrument room where measurements are taken. Mast and BCA antenna measurements are made over the frequency range of 10 kHz–400 MHz.

The test site denoted by Fig. 23d is the *submarine sensor test platform* (SSTP), used for measuring the radar cross section (RCS) of mast antennas over seawater and under realistic time-varying conditions. Shown closer in Fig. 24, the sledlike steel structure comprises ballast tanks in the forward section for controlling the degree of buoyancy; the crane/mounting platform assembly is located in the rear. In operation, the platform is operated by a winch and is guided by a rail system to a location 900 ft offshore. At this location, important parameters such as antenna impedance, azimuthal plane patterns, and RCS measurements are determined. An RCS measurement range that complements the SSTP is shown in Fig. 25. In that setup, the RCS target is calibrated in free space, away from multipath and clutter effects to obtain meaningful results from the SSTP.

In addition to the measurements performed at the Fisher’s Island facility, antenna and RCS measurements are made at one of the two radiofrequency anechoic chambers that simulate freespace, located at the laboratory grounds. This is done in order to compare the performance of the antennas with and without the presence of seawater. The larger tapered chamber shown in Fig. 26a is used

Figure 23. Aerial view of Fisher’s Island, NY testing facility: (a) BCA tidal pond testbed; (b) mile-site, (c) mast antenna radial ground plane test range; (d) submarine sensor test platform (SSTP; see text).

Figure 24. SSTP (with a mast system mounted topside) transiting on guiderails toward test position in Long Island Sound, NY. The frequency range of testing is 100 MHz–18 GHz.

for measuring pattern and RCS data in the frequency range of 100 MHz–50 GHz; the smaller (compact) range is used from 2 to 50 GHz.

Another unique facility for testing antennas under controlled conditions is the overwater arch, shown in Figs. 26b and 26c. The arch is a 70 × 90-ft concrete bed filled with seawater to enable radiation pattern testing in the 100 MHz–18 GHz range. With the antenna under test (AUT) placed in the center of the pool, a source antenna above “illuminates” the AUT throughout a predetermined range of elevation angles. The platform on which the AUT is mounted can be rotated to obtain pattern data in the azimuthal plane.

6.2. Mechanical

The ultimate success and adoption of an antenna design for submarine application is not dependent solely on

the satisfactory meeting of desired electrical characteristics. Its ability to survive repeated exposure in the ocean environment, together or separately with other effects such as explosions, which deliver the extremes of hydrostatic pressure, temperature, vibration, and shock on it, thus requires significant effort in its mechanical design. In order to verify a submarine antenna’s mechanical design integrity, the laboratory has numerous devices and methods suited for this purpose. In this section, a brief overview of the more common mechanical test devices is presented.

6.2.1. Ship Motion, Vibration, and Shock. The forces imparted on a mast due to the typical movements of a ship at sea (roll, heave, pitch, and yaw) are satisfactorily simulated with the device shown in Fig. 27a. This device, known as the *submarine mast-mounted motion table* (SMMT), is computer-controlled and permits 6 degrees of freedom in movement at selected velocities. In this manner, the resultant bending, twisting, or other related movements of the mast and antenna (viewed as a load) may be assessed. A related device, shown in Fig. 27b, is used for generating vibrational forces. As in the case of the motion table, the vibrating table is computer controlled to create a time-dependent vibration profile with respect to frequency, intensity, duration, or cycling.

Shock testing is typically performed in a large open area, such as a pond or a lake to permit the propagation of shock waves due to an intense underwater explosion (UNDEX). The amount and type of explosive charge used depends on the device tested. A high-brissance (large shock/shear-wave-generating) explosive, such as HBX-1, is typically used. Figure 27c is a view of the UNDEX facility at Briar Point pond, operated by the Naval Surface Warfare Center (Carderock, MD Division) and under the auspices of the Army’s Aberdeen Proving Grounds.

6.2.2. Hydrostatic Pressure and Environmental Testing. The hydrostatic tank in Fig. 28a is used for testing the

(b)

Figure 28. (a) Hydrostatic pressure tank; (b) temperature/humidity chamber.

pressure tolerance of mast or buoyant antennas and their associated components. The device under test (DUT) is placed inside the tank, which is filled with water. On closure and sealing of the thick-domed cover, the pressure in the tank may be raised from the ambient atmospheric level to values in excess of 5000 lb/in.². After removal from the tank, the DUT may be visually checked for leaks, cracks, or other destructive effects. Properties such as an antenna's input impedance may be made to determine the effects of pressure on it.

The effects of temperature and humidity on an antenna are determined with the chamber shown in Fig. 28b. The chamber is capable of producing wide extremes in either quantity to examine effects such as variations in brittleness or pliability of candidate insulating materials for

antennas, copper plating delamination of printed antennas, and for first-article tests to determine the degree of compliance of a given DUT with prescribed military standards.

SUPERCONDUCTING CAVITY RESONATORS

HASAN PADAMSEE
Cornell University

A key component of the modern particle accelerator [1] is the device that imparts energy to the charged particles. This is an electromagnetic radio frequency (RF) cavity resonating at microwave frequencies typically between 50 MHz and 3000 MHz. Traditionally, accelerating devices are normal conducting cavities typically made from copper [1]. One of the main incentives for using superconducting cavities is that the dissipation in the walls of the copper structure can be substantially reduced. This is especially beneficial for accelerators that operate in a continuous wave (CW) mode or at a high duty factor

(e.g., $>1\%$). Superconducting cavities economically provide high CW operating fields. Another benefit is that superconducting cavities can be designed to have a large beam aperture that reduces the beam cavity interactions, allowing higher beam quality and higher beam current.

There are two distinct types of superconducting cavities, depending on the velocity of the particles. The first category is for accelerating charged particles that move at nearly the speed of light, such as electrons in a high-energy linear accelerator [e.g., at TJNAF [2] at Jefferson Lab in Newport News, VA] or a storage ring [e.g., LEP [3] at CERN in Switzerland]. The second type is for particles that move at a small fraction (e.g., 0.01 to 0.3) of the speed of light, such as the heavy ions emerging from a dc high-voltage Van de Graaff accelerator. ATLAS [4] at Argonne National Lab, Argonne, IL is the longest-running heavy ion accelerator facility. Figure 1(a) is a sketch of the typical superconducting accelerating structure of the first type, and Fig. 2(a) is a corresponding photograph [5].

Figure 1. (a). An accelerating structure for velocity of light particles. The resonant frequency for superconducting structures is typically between 350 MHz and 3000 MHz. The cell length is half a wavelength ($\lambda/2$) long. The phase of the electric field on the axis of each cell is shown for the accelerating mode. Ports outside the cell region are for input power couplers and higher order mode power output couplers. In many applications, the power induced by the beam in higher order modes has to be removed by output couplers. (b) An accelerating structure for low-velocity particles, such as heavy ions. The resonant frequency is typically between 50 MHz and 150 MHz. The accelerating gaps are $\beta_1\gamma_2$ in length, where $\beta = v/c$ and v is the velocity of the heavy ions.

There are five accelerating cells that resonate in the transverse magnetic $(TM)_{010}$ mode of the cylindrical cavity. As the particle traverses each half-wavelength ($\lambda/2$) accelerating gap in half a radio-frequency (RF) period, it sees a longitudinal electric field pointing in the same direction for continuous acceleration. Figure 1(b) is a sketch for a structure for low velocity particles, and Fig. 2(b) is a corresponding photograph [6]. A coaxial transmission line a quarter wavelength long resonates in the transverse electromagnetic (TEM) mode. A drift tube is suspended from the end of the hollow center conductor. The structure has two accelerating cells between the ends of the drift tube and the beam hole openings located in the outer conductor of the coax. The accelerating gap is $\beta\lambda/2$, where $\beta = v/c$. As β is small, λ must be chosen to be large, to achieve a useful

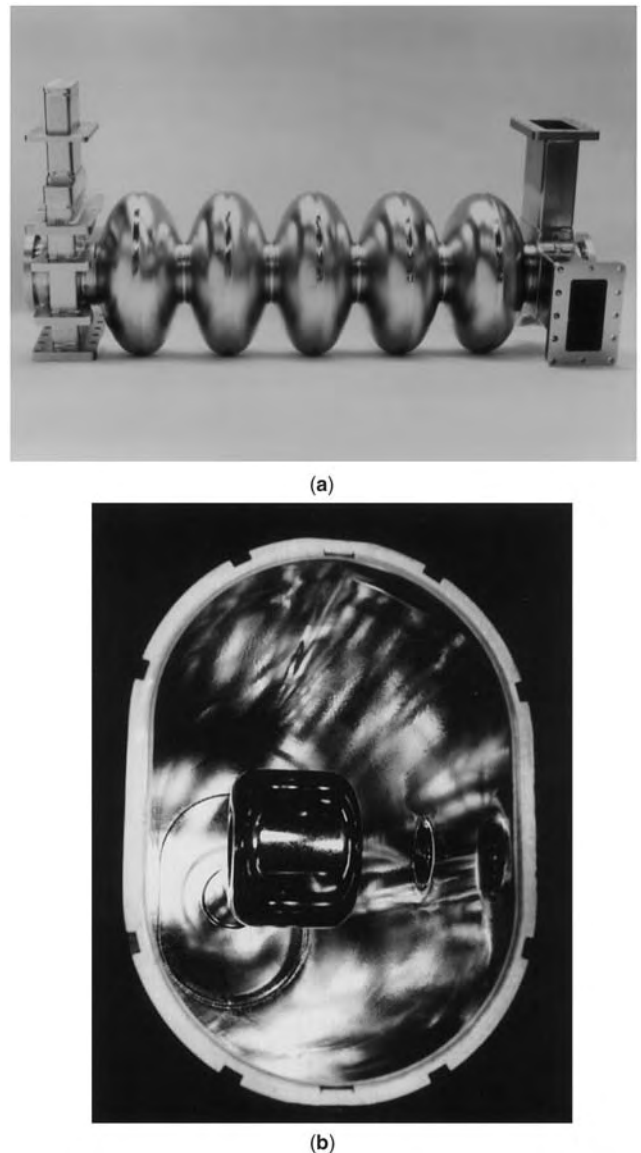

Figure 2. (a) Five-cell 1.5 GHz niobium cavity developed at Cornell University (Ithaca, NY), now used at TJNAF. (b) A quarter-wave resonator from niobium developed for the JAERI (Tokai, Japan) heavy ion linac.

acceleration. Therefore, a low resonant frequency is chosen, typically 100 MHz. The wavelength also sets the height of the quarter-wave resonator. The example of Fig. 2 has a manageable height of less than 1 m.

Large-scale application of superconducting cavities to electron and ion accelerators is now established at many laboratories around the world [7]. These accelerators provide high-energy electron and positron beams for elementary particle research, medium-energy electron beams for nuclear physics research, low-energy, heavy ion beams for nuclear research, and high-quality electron beams for free electron lasers. Altogether more than 500 m of superconducting cavities have been installed worldwide and successfully operated at accelerating fields up to 6 MV/m to provide a total of more than 2.5 GV for a variety of accelerators.

The two most salient characteristics of an accelerating cavity are its average accelerating field, E_{acc} , and the quality factor Q_0 . The typical accelerating field at which $\beta \approx 1$ superconducting cavities are now operated routinely is $E_{acc} = 5$ MV/m, and the typical Q_0 value is 2×10^9 . The corresponding numbers for low-velocity structures are 3 MV/m and 10^9 . Accelerating fields as high as 40 MV/m and Q_0 values as high as 10^{11} have been reached in high-performance $\beta \approx 1$ superconducting test cavities.

The strongest incentive to use superconducting cavities is in accelerators that operate in a CW mode, or at a high duty factor ($> 1\%$). For CW operation, the power dissipation in the walls of a structure built from normal conducting material (such as copper) is substantial. Therefore, the typical CW operating field for a copper cavity is usually kept below 1 MV/m. The microwave surface resistance of a superconductor is typically five orders of magnitude lower than that of copper, and therefore, the Q_0 is five orders of magnitude higher. For applications demanding high CW voltage, such as increasing the energy of electron storage rings, the advantage of superconducting cavities becomes clear. As the dissipated power increases with the square of the operating field, only superconducting cavities can economically provide the needed voltage. For example, LEP requires 2.5 GV to double its energy from 50 GeV to 100 GeV per beam. If copper cavities were to be used, both the capital cost of the klystrons and the ac power operating cost would become prohibitive at the higher accelerating field. Several megawatts/meter of ac power would be required to operate a copper cavity at 5 MV/m. There are also practical limits to dissipating high power in the walls of a copper cavity. When more than 100 kW is dissipated in a copper cell, the surface temperatures exceeds 100°C , causing vacuum degradation, stresses, and metal fatigue due to thermal expansion. High accelerating fields (≈ 100 MV/m) can be produced in copper cavities, but only for microseconds, and the peak RF power needed [1] becomes enormous (many hundreds of megawatts).

Apart from the general advantages of reduced RF capital and reduced RF associated operating costs, superconductivity offers certain special advantages that stem from the low-cavity wall losses. Because of the low-power dissipation at high accelerating field, one can afford to make the beam hole of the superconducting cavity much larger

than for a normal conducting cavity. The large beam hole substantially reduces the beam-cavity interaction [or wake fields [1]], allowing better beam quality and higher current for improving the precision and reaction rates of physics experiments. For the intense proton linacs, where scraping of the proton beam tails is a major worry because of radio-activation of the accelerator, the wide beam hole greatly reduces the risk of beam-loss-induced radioactivity.

1. RF SUPERCONDUCTIVITY BASICS

The remarkable properties of superconductivity are attributed to the condensation of charge carriers into Cooper pairs, which move frictionlessly. At $T = 0$ K, all charge carriers are condensed. At higher temperatures, some carriers are unpaired; the fraction of unpaired carriers increases exponentially with temperature, as $e^{-\Delta/kT}$, until none of the carriers are paired above T_c . Here 2Δ is the energy gap of the superconductor, the energy needed to break up the pairs. In this simplified picture, known as the *London two-fluid model*, when a dc field is turned on, the pairs carry all the current, shielding the applied field from the normal electrons. Electrical resistance vanishes.

In the case of RF currents, however, dissipation does occur for all $T > 0$ K, albeit very small compared with the normal conducting state. Although the Cooper pairs move frictionlessly, they do have inertial mass. For high-frequency currents to flow, forces must be applied to bring about alternating directions of flow. Hence an ac electric field will be present in the skin layer, and it will continually accelerate and decelerate the normal carriers, leading to dissipation proportional to the square of the RF frequency. The two-fluid model provides a simple explanation for the quadratic frequency and the exponential temperature dependence of the RF surface resistance. The power dissipated is proportional to the internal electric field (proportional to the RF frequency) and to the normal component of the current. The “normal” component of the current, being proportional to the interior electric field, gives another factor proportional to the RF frequency. The normal component of the current also depends on the number of carriers thermally excited across the gap 2Δ and is given by the Boltzmann factor $e^{-\Delta/kT}$.

Besides the phenomenally low RF surface resistance, other important fundamental aspects are the maximum surface fields that can be tolerated without increasing the microwave surface resistance substantially or without causing a breakdown of superconductivity. The accelerating field, E_{acc} , is proportional to the peak surface RF electric field (E_{pk}), as well as the peak surface RF magnetic surface field (H_{pk}).

The ultimate limit to the accelerating field is the RF critical magnetic field. Theoretically, this is equal to the superheating critical magnetic field. In the Ginzburg-Landau phenomenological theory of superconductivity [8], surface energy considerations lead to estimates for superheating critical field in terms of the thermodynamic critical field, H_c , and the Ginzburg-Landau parameter, κ ,

as follows:

$$\begin{aligned} H_{\text{sh}} &\approx \frac{0.89}{\sqrt{\kappa}} H_c & \text{for } \kappa \ll 1 \\ H_{\text{sh}} &\approx 1.2 H_c & \text{for } \kappa \approx 1 \\ H_{\text{sh}} &\approx 0.75 H_c & \text{for } \kappa \gg 1 \end{aligned} \quad (1)$$

For the most commonly used superconductor, niobium, H_{sh} , is about 230 mT, which translates to a maximum accelerating field of 55 MV/m for a typical $\beta = 1$ niobium structure and roughly 30 MV/m for a $\beta < 1$ niobium structure.

Typically, cavity performance is, however, significantly below the theoretically expected surface field. One important phenomenon that limits the achievable RF magnetic field is “thermal breakdown” of superconductivity, originating at submillimeter-size regions of high RF loss, called “defects.” When the temperature outside the defect exceeds the superconducting transition temperature, T_c , the losses increase, because large regions become normal conducting. Several measures have been developed to overcome thermal breakdown, such as (a) improving the thermal conductivity of niobium by purification or (b) using thin films of niobium (or lead) on a copper substrate cavity.

In the early stages of the development of superconducting cavities, a major performance limitation was the phenomenon of “multipacting.” This is a resonant process in which a large number of electrons builds up within a small region of the cavity surface because the secondary electron emission coefficient of the surface is greater than unity. The avalanche absorbs RF power, making it impossible to raise the fields by increasing the incident RF power. The electrons impact the cavity walls, leading to a large temperature rise and eventually to thermal breakdown. With the invention of the spherical cavity shape [9] (and later the elliptical cavity shape [10]), multipacting is no longer a significant problem for velocity-of-light structures. Multipacting is still an impediment for structures for low-velocity particles but can be reduced by long periods of exposure to high RF power, called *conditioning*, during which the secondary electron emission is reduced by long-term electron bombardment.

In contrast to the magnetic field limit H_{sh} , there is no known theoretical limit to the tolerable surface electric field. Continuous wave electric fields up to 145 MV/m [11] and pulsed electric fields up to 220 MV/m [12] have been imposed on a superconducting niobium cavity surface without any catastrophic effects. However, at high electric fields, an important limitation to the performance of superconducting cavities arises from the emission of electrons from high electric field regions of the cavity. Power is absorbed by the electrons and deposited as heat when electrons impact the cavity walls. If the emission grows intense, it can even initiate thermal breakdown. There have been extensive studies about the nature of field emission sites as well as development of techniques to avoid emission sites and to destroy them [13].

For low-velocity accelerators, there is an important additional performance consideration. Ambient acoustic

noise (microphonics) excites mechanical vibrational modes of the cavity, causing the resonant frequency to vary. The resonant cavities are extended, loaded structures (e.g., drift tubes supported by pipes) and generally have reduced mechanical stability. The cavity RF phase must be synchronized with an RF clock. This requires rapidly tuning the cavity to cancel the effects of acoustically induced mechanical distortions [14].

2. FIGURES OF MERIT FOR A SUPERCONDUCTING CAVITY

We show how to calculate the important physical quantities, such as resonant frequency, accelerating field, peak electric and magnetic fields, power dissipation, quality factor Q_0 , and shunt impedance for a simple cavity, the cylindrically symmetric pillbox. The treatment is basic to both normal conducting and superconducting cavities (see CAVITY RESONATORS). We also work out illustrative values. Similar analytic calculations can be carried out for a coaxial (TEM) quarter-wave resonator, as illustrative of an accelerating structure for low-velocity particles. Only simple structures can be calculated analytically. For real structures with beam holes, it is necessary to use field computation codes, such as (a) URMEL [15] for cylindrically symmetric structures and (b) MAFIA [16] for three-dimensional geometries.

For a cylinder of length d and radius R , the electric (E) and magnetic (H) fields for the standing wave TM_{010} mode are

$$\begin{aligned} E_z &= E_0 J_0 \left(\frac{2.405 \rho}{R} \right) e^{i\omega t}, \\ H_\phi &= -i \sqrt{\frac{\epsilon_0}{\mu_0}} E_0 J_1 \left(\frac{2.405 \rho}{R} \right) e^{i\omega t} \end{aligned} \quad (2)$$

where all other field components are 0. J_0 and J_1 are Bessel functions of the radial coordinate. The angular resonant frequency $\omega = 2\pi f$ is given by

$$\omega_{010} = \frac{2.405 c}{R} \quad (3)$$

Note that the resonant frequency, f , is independent of the cavity length.

Assume an electron traveling nearly at the speed of light (c). It enters the cavity at time $t = 0$ and leaves at a time $t = d/c$. To receive the maximum kick from the cavity, the time it takes the particle to traverse the cavity is to equal one half of an RF period, that is,

$$t = \frac{d}{c} = \frac{1}{2} T_{\text{RF}} = \frac{\pi}{\omega} \quad (4)$$

Under this condition, the electron always sees a field pointing in the same direction. The accelerating voltage (V_{acc}) for a cavity is

$$V_{\text{acc}} = \left| \int_{z=0}^{z=d} E_{\text{el}} dz \right| \quad (5)$$

For an electron accelerator with energy > 10 MeV, it is sufficiently accurate to use $v = c$, so that $t(z) = z/c$. Thus

$$V_{\text{acc}} = \left| \int_{z=0}^{z=d} E_z(\rho = 0, z) e^{i\omega z/c} dz \right| \quad (6)$$

$$V_{\text{acc}} = E_0 \left| \int_{z=0}^{z=d} e^{i\omega z/c} dz \right| = dE_0 \frac{\sin\left(\frac{\omega d}{2c}\right)}{\frac{\omega d}{2c}} = dE_0 T \quad (7)$$

Here T is referred to as the “transit time factor.” At 1.5 GHz, we have $d = c\pi/\omega = 10$ cm, and Eq. (7) simplifies to

$$V_{\text{acc}} = 0.064 \text{ m} \cdot E_0$$

The average accelerating electric field (E_{acc}) is given by

$$E_{\text{acc}} = \frac{V_{\text{acc}}}{d} = \frac{2E_0}{\pi} \quad (8)$$

Here E has the dimensions of V/m.

3. PEAK SURFACE FIELDS

To achieve a high accelerating field in a cavity, it is important to minimize the design ratios of the peak fields to the accelerating field. For the TM_{010} mode in a pillbox cavity, we have

$$E_{\text{pk}} = E_0, \quad H_{\text{pk}} = \sqrt{\frac{\epsilon_0}{\mu_0}} J_1(1.841) E_0 = \frac{E_0}{647\Omega} \quad (9)$$

Thus we obtain the following ratios:

$$\begin{aligned} \frac{E_{\text{pk}}}{E_{\text{acc}}} &= \frac{\pi}{2} = 1.6, \\ \frac{H_{\text{pk}}}{E_{\text{acc}}} &= 2430 \frac{\text{A/m}}{\text{MV/m}} = 3.05 \frac{\text{mT}}{\text{MV/m}} \end{aligned} \quad (10)$$

The units for magnetic field used are teslas.

4. POWER DISSIPATION AND Q_0

In order to support the electromagnetic fields, currents flow within a thin surface layer of the cavity walls. If the surface resistance is R_s , the power dissipated/unit area (P_a) due to Joule heating is

$$P_a = \frac{1}{2} R_s H^2 \quad (11)$$

The quality, Q_0 , is related to the power dissipation by the definition of Q_0 :

$$Q_0 = \omega \frac{\text{Energy stored}}{\text{Power dissipated}} = \frac{\omega U}{P_c} \quad (12)$$

where U is the stored energy and P_c is the dissipated power.

The total energy in the cavity and the power dissipated are

$$U = \frac{1}{2} \mu_0 \int_v |H|^2 dv, \quad P_c = \frac{1}{2} R_s \oint_s |H|^2 ds \quad (13)$$

where the integral is taken over the volume of the cavity. Thus

$$Q_0 = \frac{\omega \mu_0 \int_v |H|^2 dv}{R_s \oint_s |H|^2 ds}, \quad Q_0 = \frac{G}{R_s}, \quad (14)$$

$$G = \frac{\omega \mu_0 \int_v |H|^2 dV}{\oint_s |H|^2 ds}$$

Here G is called the *geometry factor*. It only depends on the cavity shape and not on its size. For the TM_{010} mode in a pillbox cavity, we obtain

$$U = \frac{\pi \epsilon_0 E_0^2}{2} J_1^2(2.405) d R^2 \quad (15)$$

$$P_c = \frac{\pi R_s E_0^2 \epsilon_0}{\mu_0} J_1^2(2.405) R[R+d] \quad (16)$$

$$G = \frac{453 R d}{(R^2 + R d)} \Omega \quad (17)$$

Combining Eqs. (3) and (4), we find that in order to obtain the maximum accelerating voltage from the cavity, we require

$$\frac{R}{d} = \frac{2.405}{\pi} \quad (18)$$

so that $G = 257 \Omega$. A typical observed surface resistance for a well-prepared superconducting Nb cavity is $R_s = 20$ n Ω . Thus we have a Q_0 value of

$$Q_0 = \frac{G}{R_s} = 1.3 \times 10^{10} \quad (19)$$

For a typical cavity length of $d = 10$ cm (at 1.5 GHz), we obtain $R = 7.65$ cm. For an accelerating voltage of 1 MV, we obtain the following results:

$$E_{\text{acc}} = \frac{V_{\text{acc}}}{d} = 10 \text{ MV/m}$$

$$E_{\text{pk}} = E_0 = \frac{\pi}{2} E_{\text{acc}} = 15.7 \text{ MV/m}$$

$$H_{\text{pk}} = 2430 \frac{\text{A/m}}{\text{MV/m}} E_{\text{acc}} = 24.3 \text{ kA/m} = 30.5 \text{ mT} \quad (20)$$

$$U = \frac{\pi \epsilon_0 E_0^2}{2} J_1^2(2.405) d R^2 = 0.54 \text{ J}$$

$$P_c = \frac{\omega U}{Q_0} = 0.4 \text{ W}$$

The performance of a superconducting cavity is evaluated by measuring the Q_0 as a function of the cavity field level.

This gives information on the average behavior of the RF surface.

5. THERMOMETRY BASED DIAGNOSTICS

To resolve the local distribution of RF losses from the various mechanisms described above, temperature mapping is used as a diagnostic technique. A chain of rotating carbon thermometers, or an array of fixed thermometers, samples the temperature of the outer wall of the cavity. Temperature mapping with carbon thermometers has played a key role in improving the understanding of mechanisms that lead to residual resistance, multipacting, thermal breakdown, and field emission. Carbon makes a sensitive thermometer at liquid helium temperatures because, as a semiconductor, its resistance increases exponentially with decreasing temperature. Above the superfluid temperature (2.17 K), temperature increments of the cavity wall of a few mK can be easily detected. A single rotating arm bearing 10 to 20 thermometers per cell is appropriate for locating stable field emitters or thermal defects in sizable structures, such as a multicell cavity. For temperature mapping in superfluid helium, thermometers need to be isolated from the superfluid bath so that movable elements do not provide good sensitivity. A large array of fixed thermometers is preferred. These are brought in intimate contact with the cavity wall by the use of spring-loaded contacts. Grease applied between the cavity wall and the thermometer element improves heat transfer and keeps the superfluid away. Due to the large number of thermometers and leads, the fixed method is suitable for investigations with single-cell cavities. An example of a fixed thermometry system is shown in Fig. 3, and a typical temperature map is shown in Fig. 4 [17].

Figure 3. (a) A single-cell niobium cavity surrounded by an array of ≈ 700 carbon thermometers that make close contact with the outer wall of the cavity. (b) There are 19 thermometers placed on each board that is contoured to closely follow the cavity profile. (c) A single thermometer consists of a 100 Ω carbon resistor embedded in an epoxy housing. It is held by a spring-loaded pin inserted into holes in the board. The surface of the thermometer is ground so that the carbon element is exposed and subsequently covered with a thin layer of varnish to provide electrical insulation. The leads are made of a low-thermal-conductivity alloy, such as manganin.

Figure 4. Temperature map at 40 mT of a single-cell 1.5 GHz cavity showing heating at a defect site near the cavity equator (labeled 1) and field emission sites (labeled 2, 3, and 4) near the cavity iris.

6. REFRIGERATOR REQUIREMENTS

Although the power dissipated in the superconducting cavity is very small, the losses will be dissipated in the liquid He bath. Together with the static heat leak to the cryostat, these losses comprise the cryogenic loss. Typically the ac power needed to operate the refrigerator is larger than the dissipated power in 2 K liquid He by a factor of 750. One part of this factor comes from the technical efficiency (η) of the refrigerator, typically $\eta = 0.2$ for a large system, and the other part comes from the Carnot efficiency η_c , which at 2 K is

$$\frac{1}{\eta_c} = \frac{300 - 2}{2} \quad (21)$$

At 10 MV/m, the required refrigerator ac power due to the RF loss would be 300 W for the case of a single-cell 1.5 GHz cavity. For a copper cavity of the same geometry, with a typical $R_s = 3 \text{ m}\Omega$, the RF power dissipation in the cavity would be 60 kW for an accelerating field $E_{\text{acc}} = 10 \text{ MV/m}$. Furthermore, the ac wall power will be a factor of 2 higher because of the typical klystron efficiency. Thus, the ac power cost of running a copper cavity in CW mode would be several hundred times higher than the cost for an Nb cavity.

7. SHUNT IMPEDANCE

An important quantity used to characterize the losses in a cavity at a given accelerating voltage is the shunt impedance (R_a) as typified by a parallel RLC circuit:

$$R_a = \frac{V_{\text{acc}}^2}{P_c} \quad (22)$$

in which case P_c = power dissipated and V_{acc} is the acceleration voltage. Hence the shunt impedance is in ohms.

Ideally the shunt impedance should be large for the accelerating mode so that the dissipated power is small. This is particularly important for copper cavities, where the wall power dissipation is a major issue and we wish to have as large an accelerating field as possible. For the TM_{010} mode pillbox cavity and R_s of 20 n Ω , we have

$$R_a = \frac{4\mu_0 d^2}{\pi^3 R_s \epsilon_0 J_1^2(2.405) R[R+d]} = 2.5 \times 10^{12} \Omega \quad (23)$$

Note that the ratio of R_a/Q is given by

$$\frac{R_a}{Q_0} = \frac{V_{\text{acc}}^2}{\omega U} \quad (24)$$

which is independent of the surface resistance. For the pillbox TM_{010} mode, we have

$$\frac{R_a}{Q_0} = 150 \Omega \frac{d}{R} = 196 \Omega \quad (25)$$

By applying computer codes to determine electromagnetic fields, the computed figures of merit for the Cornell/TJNAF five-cell cavity are given in Table 1. Note that due to the presence of the beam holes, the shunt impedance is reduced and the peak surface fields are enhanced, relative to the pillbox case. For a realistic cavity shape, R/Q_0 is lowered due to the presence of the beam holes, typically by a factor of 2.

Table 1. Figures of Merit for the Cornell/CEBAF Five-Cell Cavity

G	290 Ω
R/Q (per 5-cell cavity)	480 Ω
$E_{\text{pk}}/E_{\text{acc}}$	2.6
$H_{\text{pk}}/E_{\text{acc}}$	4.7 mT/(MV/m)

^aData taken from Ref. 4.

8. RF SURFACE RESISTANCE

Based on the very successful BCS theory [18], expressions for the superconducting surface impedance have been worked out by Mattis and Bardeen [19]. These expressions involve material parameters, such as the London penetration depth λ_L , the coherence distance ξ_0 , the Fermi velocity V_F , and the electron mean free path l . They are in a rather difficult form to obtain general formulas to work with. Computer programs have been written—for example, by Turneaure [20] and Halbritter [21]. Figure 5 gives the results from Halbritter's programs for niobium and lead and Nb_3Sn . Table 2 gives the material parameters used for the calculations. Calculations from the theory agree well with experimentally measured R_s for $T/T_c > 0.3$. At lower temperatures, the residual resistance term dominates.

A simplified form of the temperature dependence of Nb for $T_c/T > 2$ and for frequencies much smaller than $2\Delta/h \approx 10^{12} \text{ Hz}$ is

$$R_s = A(1/TJ)f^2 \exp(-\Delta(T)/k_B T) + R_0 \quad (26)$$

Here k_B is Boltzmann's constant. The second term, R_0 , is called the *residual resistance*. Typical R_0 values for Nb cavities fall in the range from 10^{-7} to $10^{-8} \Omega$. The record for the lowest surface resistance is $1-2 \times 10^{-9} \Omega$ [22]. For comparison, the surface resistance of copper at 1.5 GHz is 3 m Ω .

The operating temperature of a superconducting cavity is usually chosen so that the first term in Eq. (26) is reduced to an economically tolerable value. R_0 , referred to as the *residual resistance*, is influenced by several factors. Some of the sources are extraneous to the superconducting surface—for example, lossy joints between components of the structure. Other factors originate at the superconducting surface. A well-understood and controllable source of residual loss is trapped dc magnetic flux from insufficient shielding of the earth's magnetic field, or other dc magnetic fields in the vicinity of the cavity. To get the highest Q_0 , a superconducting cavity must be well shielded from the earth's field. Typically, at 1 GHz, R_0 is $10 \mu\Omega/\text{mT}$ [23]. Another important residual loss

Figure 5. Theoretical surface resistance at 1.5 GHz of lead, niobium, and Nb_3Sn as calculated from Halbritter's program [20]. The values used for the material parameters are given in Table 2.

Table 2. Material Parameters Used for the Calculations of Fig. 5

Material-Parameter	Pb	Nb	Nb ₃ Sn
T_c [K]	7.19	9.20	18.00
Energy gap, Δ/kT_c	2.10	1.86	2.25
Penetration depth λ [Å]	280.00	360.00	600.00
Coherence length ξ [Å]	1110.00	640.00	60.00
Mean free path ℓ [Å]	10,000.00	500.00	10.00

mechanism arises when the hydrogen dissolved in bulk niobium precipitates as a lossy hydride at the RF surface [24]. This residual loss is a subtle effect that depends on the rate of cooldown and the amount of other interstitial impurities present in niobium. The effect can be severe enough to lower the Q_0 to 10^8 depending on the amount of hydrogen dissolved and the cooldown rate of the cavity. More than 2 ppm wt of hydrogen can be dangerous.

9. CAVITY FABRICATION AND SURFACE PREPARATION

Niobium cavities can be constructed from sheet niobium using the techniques of forming (e.g., deep drawing or spinning) followed by electron beam welding [25]. Another method is to deposit a thin niobium film onto a preformed copper cavity substrate [26]. The copper cavity is made in essentially the same way as the sheet niobium cavity, except for surface preparation before film deposition. If the cavity has more than one cell, the cells need to be tuned relative to each other, by adjusting the dimensions, so that the accelerating field is the same for each cell. Dimensional variations between cells are sufficient to alter the field profile substantially. Typical fabrication tolerances are in the range of a few tenths of a millimeter.

The purity of niobium used is important, both in terms of bulk impurity content and in terms of inclusions from manufacturing steps, such as rolling. Inclusions on the RF surface play the role of normal conducting sites for thermal breakdown. Dissolved impurities serve as scattering sites for the electrons not condensed into Cooper pairs. These impurities lower the thermal conductivity, impede the heat transfer to the helium, and limit the maximum tolerable surface magnetic field before the onset of thermal breakdown. The accompanying decrease in electrical conductivity, or the RRR value, serves as a convenient measure of the purity of the metal. The formal definition of RRR is

$$RRR = \left(\frac{\text{resistivity at 300 K}}{\text{residual resistivity at low temperature (normal state)}} \right) \quad (27)$$

Here low temperature means the temperature at which the dc resistivity in the normal state becomes residual. A convenient relationship between thermal conductivity and RRR for niobium is

$$k \approx 0.25 RRR \left(\frac{\text{W}}{\text{mK}} \right) \quad (28)$$

This relationship can be derived from the Wiedemann-Franz law [27] and from the ratio of the superconducting to

normal conducting state thermal conductivities [28]. To achieve the optimum RF performance, the surface of the cavity must be prepared to approach as close as possible the ideal. Microscopic contaminants can limit the performance, either by thermal breakdown or by field emission [29]. A clean RF surface is achieved by chemically etching away a surface layer, rinsing thoroughly with ultraclean water, and then taking precautions so that no contaminants come in contact with the clean RF surface. The resistivity of the water should be close to theoretically pure (18 MΩ-cm), and the water should be filtered to eliminate particles larger than 1 μm. After etching, water is recirculated for several hours through the cavity in series with the water purification system so as to continuously and thoroughly remove any chemical and particulate residue from the niobium surface. For a review of cavity fabrication and preparation procedures, see Ref. 28.

Many laboratories have found that the RF surface can be made even cleaner if chemistry is followed by high-pressure rinsing (HPR) of the cavity with ultrapure water [30]. At TJNAF, for example, water at a pressure of 70 bar to 80 bar is sprayed through stainless steel nozzles each having a 0.3 mm diameter orifice [31]. The potent jets of water are scanned across all parts of the RF surface to dislodge and sweep away microscopic contaminants that have adhered to the surface.

After rinsing, the cavity is transported into a dust-free clean room where the water is drained. The cavity surface thus only comes in contact with filtered air. The level of cleanliness required is comparable with that in the semiconductor industry where a clean room environment of Class 10–100 is routine. Class 10 refers to the number of particles of size 0.5 μm or larger in 1 ft³ of air. The surface of the cavity must be dried before the cavity is evacuated, placed inside a cryostat, and cooled down for RF tests. During final assembly, the laboratory workers in the vicinity need to wear special particulate-free clothing and follow strict protocols to reduce particulate generation.

During these various stages of cavity production and preparation, there are many opportunities for defects to enter the cavity. Therefore great care must be exercised during the manufacture of sheet metal, deep drawing of cups, electron beam welding, chemical etching, rinsing, drying, and insertion of coupling devices, as well as in the final attachment of the cavity to the vacuum system of the test stand or the accelerator. Two examples of defects that caused thermal breakdown are shown in Fig. 6 [32]. On a statistical basis, we expect that the number of defects increases with cavity surface area.

10. OVERCOMING FIELD EMISSION

The temperature mapping diagnostic technique for superconducting cavities shows that emission arises from particular spots, called “emitters,” located in high electric field regions. The electrons that emerge from the emitters travel in the RF fields of the cavity and impact the surface (Fig. 7). Some electrons may be captured in the axial fields and accelerated along with the beam. These produce unwanted “dark current,” which may spoil the beam quality

Figure 6. Scanning electron microscope (SEM) micrographs of defects that caused thermal breakdown. (a) A chemical or drying stain 440 μm in diameter. The small crystal on the right side contains K, Cl, and P. This defect quenched at $E_{\text{acc}} = 3.4 \text{ MV/m}$. (b) A 50 μm crystal containing S, Ca, Cl, and K. This defect quenched at $E_{\text{acc}} = 10.7 \text{ MV/m}$. These defects were located by temperature maps. (Courtesy of CERN.)

or impact the walls of adjacent cavities. The pattern of temperature rise as a function of position along a given meridian contains implicit information about the location and characteristics of the source. The power deposited by the impacting electrons depends on the trajectory as well as on the intrinsic properties of the emitter.

In their basic theory of field emission [33], Fowler and Nordheim (FN) showed that in the presence of an electric field, electrons tunnel out of the metal into the vacuum because of their quantum wave-like nature. However, a comparison with the observed currents reveals that, at a given field, emission is substantially higher than the FN predictions. Traditionally, the excess has been attributed to a “field enhancement factor,” which is believed to be related to the physical properties of the emitter discussed below. Both RF and dc studies reveal that emitters are micron- to submicron-size contaminant particles [14]. Figure 8 shows an example of a region of emitting particles found in a niobium cavity [34]. The properties of the emitter that lead to enhanced emission are (a) the microgeometry of the particle [35], (b) the nature of condensed gases or adsorbates on the surface of the particle [36], and (c) the interface between the particle and the underlying metal RF surface [37]. Accordingly, a high level of cleanliness is necessary for cavity surface preparation. Field emission-free performance has been achieved with HPR [31]. Recently, many nine-cell 1.3 GHz structures were prepared at DESY by using HPR [38]. A sample of their results is shown in Fig. 11.

Figure 7. Calculated electron trajectories in a three-cell 1.5 GHz cavity operating at $E_{\text{pk}} = 50 \text{ MV/m}$. The emitter is located in the end cell, where the surface electric field is 44 MV/m. Note that a significant number of field-emitted electrons bend back and strike the wall near the emitter. Others are accelerated through the cavity structure and could produce unwanted “dark current” that may be accelerated in adjacent cavities.

When raising the RF electric field in a superconducting cavity for the first time, the field emission often decreases abruptly; the cavity is said to “process” or “condition.” There has been much progress in characterizing processed

(a)

(b)

Figure 8. (a) SEM micrograph of field emitting particles. Note the cluster of small spherical balls that indicate that a part of the site melted. EDX analysis shows that the particles are stainless steel. Note also the jagged microgeometry of the particles believed responsible for field enhancement. (b) The melted cluster is expanded.

Figure 9. SEM pictures of the processed site found at the location predicted via temperature maps. (a) Low magnification; (b) high magnification of crater region within the starburst of (a). The molten splashes in the crater region were found to contain indium, presumably from the indium wire seals used to make vacuum joints.

emitters at a microscopic level using techniques such as SEM, EDX, Auger, and AFM. These studies reveal that emitter processing is an explosive event that accompanies what we usually refer to as a “spark” or a “discharge,” or

the “electrical breakdown” of the insulating vacuum [39]. Figure 9 shows a typical SEM micrograph of an exploded emitting site [40].

To reach the highest accelerating fields, the highest thermal conductivity is essential to avoid thermal breakdown, and a high level of cleanliness is essential to avoid field emission. High-pressure water rinsing is a very successful cleaning technique to avoid field emission. In multicell structures with large surface area, there is always a significant probability that a few emitters will eventually find their way on to the cavity surface. There is also the danger of dust falling into cavities during installation of power coupling devices as well as during installing of the structure into the accelerator.

A technique that eliminates field emitters in situ is high-pulsed power RF processing (HPP) [41]. The essential idea is to raise the surface electric field at the emitter as high as possible, even if for a very short time (\ll milliseconds). As the field rises, the emission current rises exponentially to the level at which melting, evaporation, gas evolution, plasma formation, and ultimately a microdischarge (RF spark) take place. The ensuing explosive event destroys the emitter. An important benefit of HPP is that the technique can be applied to recover cavities after their final installation. It can also be used to recover the performance of cavities, which may be accidentally contaminated, as, for example, in a vacuum mishap. To achieve emission-free performance at a desired E_{acc} , processing must be carried out at $\approx 2 \times E_{acc}$. Figure 10 shows the improvement in performance achieved by HPP [42]. [Recently, many nine-cell 1.3 GHz structures were prepared at DESY by using HPR techniques [38]. A sample of their results is shown in Fig. 11. Occasionally it is possible to achieve field emission-free performance, as shown by the best curve of Fig. 11.]

11. OVERCOMING THERMAL BREAKDOWN

The most effective cure for thermal breakdown caused by millimeter- to submillimeter-size defects is to (a) use better quality material that is free of such defects or (b) to raise the thermal conductivity of the niobium so that remaining defects will be able to tolerate more power before driving the neighboring superconductor into the normal state [43]. A simple analysis of the thermal breakdown shows that the maximum magnetic surface field is

Figure 10. Performance of a five-cell 1.3 GHz niobium cavity improved by HPP. Before HPP, the maximum field was limited by heavy field emission to $E_{acc} = 22$ MV/m. After applying 1 MW of power and reaching $E_{pk} = 90$ MV/m in the pulsed mode, the field emission was processed away and $E_{acc} = 28$ MV/m was possible in the CW mode.

Figure 11. High performance of several nine-cell 1.3 GHz cavities achieved by high-pressure rinsing.

given by

$$H_{\max} = \sqrt{\frac{4k(T_c - T_b)}{aR_n}}, \quad \text{i.e., } H_{\max} \propto \sqrt{k} \propto \sqrt{RRR} \quad (29)$$

Here k is the thermal conductivity, T_c is the superconducting transition temperature, T_b is the bath temperature, a is the radius of the defect, and R_n is the surface resistance of the defect. This dependence on RRR is supported by detailed numerical simulations of thermal breakdown, as well as by experiments on cavities made from Nb of different RRR (Fig. 12).

Figure 13 shows the thermal conductivity of three samples of niobium that have different histories of heat treatment [44]. The common feature of all three curves is the

Figure 13. Thermal conductivity (λ) of niobium with $RRR = 90$ (as received), $RRR = 400$ after postpurification with yttrium, and $RRR = 250$ after annealing the postpurified sample for 6 hours at 1400°C. (Courtesy of Wuppertal.)

sharp drop below $T_c = 9.2$ K, as more and more electrons condense into Cooper pairs. At the higher temperatures ($4\text{K} < T < T_c$), a significant, although small, fraction of electrons is not frozen into Cooper pairs and can carry heat effectively, provided that the electron-impurity scattering is low. As the temperature in the neighborhood of the

Figure 12. A summary of the results of multi-cell cavities [40]–[44] showing the importance of high RRR coupled with emission reduction techniques such as HPP and HPR. The line shows a \sqrt{RRR} dependence expected from the simple theory of thermal breakdown.

Table 3. Expected RRR for 1 ppm wt of Major Impurities^a

Element	RRR
H	2640
N	4230
C	4380
O	5580
Ta (1000 ppm wt)	1140

^aNote that the effect of Ta is given in terms of 1000 ppm wt.

defect is between the bath temperature and T_c , the high-temperature thermal conductivity is the most important and has the strongest effect on thermal breakdown. The higher the RRR , the higher the thermal conductivity in this temperature range.

Below 4 K, as electrons condense into Cooper pair, electron-phonon scattering also decreases. As a result, the thermal conductivity from phonons begins to increase, leading to the phonon peak near 2 K. With decreasing temperature, the number of phonons decreases $\propto T^c$. The value of the phonon conductivity maximum is limited by phonon scattering from lattice imperfections, of which the grain boundary density is the most important. If the crystal grains of niobium are very large (e.g., because of annealing at high temperature), one observes a large phonon peak, as shown in the thermal conductivity behavior of the sample with $RRR = 250$, which was annealed at 1400°C. As the phonon peak is at about 2 K, it does not help to thermally stabilize defects that heat up in the RF field.

The light, interstitially dissolved impurities have the strongest effect on the RRR . Among these, oxygen is dominant. The other interstitials are carbon, nitrogen, and hydrogen. Among the metallic impurities, tantalum is found in the highest concentration (typically 500 ppm by weight) because all naturally occurring ores contain some tantalum. This impurity level is not a problem because tantalum is a substitutional impurity and does not substantially affect the electronic properties. However, Ta can become a problem if clustering occurs. The Nb used to fabricate a cavity has been checked, for example, by an eddy current scanning technique [45] to look for large defects such as Ta clusters. Next in abundance are the higher temperature, refractory elements, such as tungsten, zirconium, hafnium, and titanium, usually found at the level of 10–50 ppm wt. The electron-scattering effectiveness of the various impurities are shown in Table 3 in terms of their effect on the RRR [46].

To obtain the net RRR , one must add the resistance contributions for each impurity element in parallel. The contributions of the phonons is always present, so that the highest theoretical RRR for niobium is 35,000 [47]. Experimentally, the highest RRR ever achieved in a niobium sample was 28,000 [48].

The most convenient method to obtain high-purity niobium for superconducting cavities is to remove the interstitials during the electron-beam melting stages of the ingot. Multiple melts and progressive improvements in the furnace chamber vacuum have led to a steady increase in the RRR of commercial niobium over the last decade from 30, typical of commonly available “reactor grade”

niobium, to 300 [49]. The RRR of commercially available Nb continues to improve. Recently, niobium sheet of $RRR = 500$ –700 became available from a Russian source [50].

If RF surface magnetic fields higher than 50 mT are desired on a consistently reproducible basis, the thermal conductivity of the niobium must be improved to $RRR > 300$. In one method called *postpurification*, the purity of the niobium is increased by solid-state gettering of oxygen using yttrium [51] or titanium [52] at high temperature. The foreign metal is vapor-deposited on the niobium surface. In the same step, the high temperature decreases the diffusion time of the oxygen in niobium. Over a few hours, oxygen is trapped in the deposited getter layer. If yttrium is used, the best temperature is 1200–1250°C because both the vapor pressure of yttrium and the diffusion rate of oxygen in niobium are sufficiently high. If titanium is used, temperatures of 1350–1400°C are required because of the lower vapor pressure of titanium. Typically during postpurification, the RRR improves by a factor of two in a few hours. An important disadvantage of the postpurification is that the yield strength of niobium falls substantially due to the high-temperature treatment. Also, titanium diffusion into the bulk along grain boundaries demands additional etching.

12. Nb/Cu CAVITIES

As we mentioned, thin Nb films on higher thermal conductivity copper is another way to avoid thermal breakdown. The technique of sputter coating niobium has been developed by CERN for 350 MHz structures and applied successfully to hundreds of structures [26]. In the most successful coating method to date, thin film deposition is carried out by cylindrical magnetron sputtering. Before the coating stage, the copper cavity is degreased, chemically polished ($\approx 20 \mu\text{m}$), rinsed with high-purity, dust-free water and alcohol, and dried under clean laminar airflow. After bakeout of the copper cavity to reach a good vacuum, a typical coating time is 4 hours. The coating thickness is a few microns at a substrate temperature of 180–200°C. The RRR of the deposited niobium serves as one of the monitors of film quality. The sputtering rate and substrate temperature are optimized to reach an RRR greater than 20. Note that the low RRR relative to bulk niobium is not a problem because the film is very thin. The rod-like grains of the niobium film are up to 1 μm long and 10–150 nm in diameter. When studied with transmission electron microscopy, the individual grains show a high density of defects, consisting of dislocations and point defect agglomerates [53]. The distance between two defects varies from 2 to 20 nm. The onset T_c of as-deposited films is 9.6 K, but the transition width is larger than for bulk niobium (typically a few tenths of a kelvin). The large transition width (5 K in some cases) is indicative of poor film quality.

Although Q_0 values $\approx 10^{10}$ are obtained at low fields, the RF losses of Nb/Cu cavities increase steadily with field. This effect is attributed to intergrain losses in the niobium films, which become more severe at higher frequency. Recently [54], there is evidence to show that

impurities buried in the films can also account for increased losses at high fields.

13. FUTURE DIRECTIONS, NEW MATERIALS

Based on the fundamental aspects, for a material to be useful in accelerators, the primary requirements are a high transition temperature and a high superheating critical magnetic field. Among the elemental superconductors, niobium has the highest T_c . Although lead, coated on to a copper cavity, has been very useful in early studies and heavy-ion accelerator applications, the higher T_c and H_c has made niobium the more attractive choice. Technical considerations, such as ease of fabrication and the ability to achieve uniformly good material properties over a large surface area, have also proven favorable for niobium. The realm of superconducting compounds has been much less explored because of technical complexities that govern compound formation. In looking at candidates, such as Nb_3Sn , NbN , and the new high-temperature superconductors (HTS), such as $YBa_2Cu_3O_7$, it is important to select a material for which the desired compound phase is stable over a broad composition range. With this criterion, formation of the compound may prove more tolerant to variations in experimental conditions, which in turn would make it possible to achieve the desired single phase over a large surface area. With a T_c of 18 K, Nb_3Sn is the most successful compound explored to date [55]. At low fields, residual resistance values comparable with niobium have been achieved. However, the maximum fields reached to date are far lower than those for sheet niobium cavities. The new HTS are even further from the performance level desired for application to accelerators. Figure 14 compares the measured RF surface resistance at low fields of several superconductors: HTS, Nb_3Sn , and Nb [56]. The surface resistance of Nb at 1.3 K, Nb_3Sn at 4.2 K, and copper at 77 K are included for comparison.

Early enthusiasm over the remarkable strides made in the transition temperature of HTS are now tempered with difficulties in achieving useful properties, such as a high critical current density. The coherence lengths of the cuprates are very short (17 Å within the copper-oxygen planes and 3 Å perpendicular to the planes, respectively). There is also a large anisotropy of the magnetic and electrical properties between the c axis and the ab planes, with superior behavior when the current flow is in the ab plane. To produce good quality HTS films, it is therefore necessary to orient the grains so that the c axis is normal to the RF surface everywhere. This restriction will be a significant challenge for realizing HTS in existing accelerating cavity shapes. It is also essential to have the right stoichiometry and oxygen content. Because of the short coherence length, transport properties are extremely sensitive to minute defects, such as grain boundaries and their associated imperfections. Decoupling of superconducting grains is believed to occur because the coherence lengths approach the scale of the grain boundary thickness, forming only weak links between individual grains. As a result, the intergrain critical current is two to three orders of magnitude lower than intragrain critical current. Even at

Figure 14. Measured surface resistance of HTS compared with the same for Nb (1.3 K) and Nb_3Sn (4.2 K). In the case of HTS, the resistance is quoted at 77 K if it is already residual; if the resistance is still decreasing with temperature, the residual is obtained at 20 K. The solid lines show the calculated surface resistance of copper at 77 K, Nb_3Sn at 4.2 K, and Nb at 1.3 K.

a clean grain boundary, the scale of the disorder that exists from breaking up of a unit cell can exceed the coherence length, especially in the direction of the c axis [57].

14. CONCLUSION

Even at the modest fraction of the ultimate potential, many attractive applications are now in place, and new ones are forthcoming. As our understanding of field limiting mechanisms continues to improve, new techniques emerge to further advance gradients, such as high-purity niobium to raise the thermal conductivity, high-pressure rinsing to provide cleaner, field emission-free surfaces, and high pulsed power processing to destroy residual emitters. The new techniques for bulk niobium cavities have demonstrated that gradients can be improved to between 20 and 30 MV/m in multicell structures. If such gradients can be reliably achieved, exciting new applications are on the horizon, such as the TeV electron-positron linear collider [58] or a multi-TeV muon collider [59].

SUPERCONDUCTING ELECTROMAGNETS

JOHN E.C. WILLIAMS
Massachusetts Institute of
Technology
Cambridge, Massachusetts

The design and construction of superconducting magnets has been made possible by the development of technical superconductors. There are three principal materials: the alloy niobium–titanium (NbTi), the intermetallic compound niobium–tin (Nb₃Sn), and the collective high-temperature superconductors (HTSs) based on copper oxide layers in a perovskite structure. Nb₃Sn and NbTi were developed in the early 1960s. A small solenoid made of Nb₃Sn achieved a field of 10 T in 1963, and the alloy NbTi was also first examined as a wire for a superconducting magnet in that year. In the time that has elapsed since those first steps, superconducting magnets weighing up to many hundreds of tonnes have been built and operated.

Technical superconductors are a class having special properties that allow superconductor operation in high magnetic fields and with useful current densities. Superconductors are of two types; both can support the flow of electrical current without resistance only below a combination of maximum temperature, field, and current density, with critical parameters T_c , B_c , and J_c [1]. For type I superconductors, typical values of T_c and B_c are 9 K and 0.1 T, respectively. Flux is excluded from the bulk of a type I superconductor, and current flows only in a surface layer, about 10^{-4} mm thick. The current is carried by electron pairs of equal and opposite momentum. (This momentum includes terms arising from both velocity and linked flux.) Since flux is excluded from the interior of a type I superconductor, and current flows only on the surface, a useful overall current density can be obtained only in wires of a diameter unacceptably small for magnet construction. Consequently, a type I superconductor cannot be used to construct a useful magnet, even if the critical field were to be higher than 0.1 T. Examples of type I superconductors are lead, indium, mercury, and pure annealed niobium.

By contrast, type II superconductors allow flux to penetrate into the bulk of the lattice in the form of an array of flux quanta. A circulating supercurrent surrounds each flux quantum (2.07×10^{-15} V · s) [2]. If a net transport current flows along a type II superconducting wire, a density gradient of flux quanta exists across the wire. The flux density gradient is given by

$$\frac{dB}{dx} = -\mu_0 J_c \quad (1)$$

where J_c is a bulk critical current density and μ_0 is the permeability of free space.

However, a type II superconductor is not necessarily a technical superconductor. The interaction of the net transport current flow with the flux quanta creates a Lorentz force that causes a migration of the flux across the superconductor. Such a migration appears as a voltage gradient along the superconductor, which causes a dissipation; that is, the superconductor appears to be resistive. For these

reasons pure annealed type II superconductors are resistive with a transport current in the presence of a field. Because of the penetration of flux, the maximum temperatures and fields below which superconductivity arises in them are up to 18 K and 25 T, respectively. The latter is the upper critical field B_{c2} , at which the lattice is fully packed with flux quanta. The penetration of flux into the lattice begins at a lower critical field B_{c1} .

The technical superconductor is a type II superconductor in which this migration of flux quanta is inhibited. This is achieved by the introduction of lattice defects, in the form of crystal boundaries, impurities, vacancies, or dislocations [3]. At these defects flux quanta tend to become pinned against further movement, at least until the Lorentz force increases.

To the extent that mechanical models assist in the understanding of quantum effects, a typical pinning center may be imagined as a long hole through the lattice of the superconductor. If a flux quantum, or an integral number of flux quanta, were located in this hole, the associated circulating current would lie in the material around the hole. If the flux quantum were to move away from the hole, the current would have to become elongated so as to continue to flow in solid material. That would increase the interactive force between flux and current, so tending to force the flux back into the hole. The movement of flux quanta through an array of pinning centers is also influenced by thermal vibration. Since the temperature at which electron pairs can form is low, thermally induced lattice vibration is comparable in energy density with that of the pinning strength of the centers. Thus a flux quantum trapped at a pinning center may be dislodged by a large enough random thermal movement. That flux quantum would then migrate down the Lorentz force gradient to another pinning center. On the macroscopic scale this effect will reduce the flux density gradient and hence the Lorentz force. So, under conditions of constant transport current and external field, the random movement of flux quanta will die away until the current, field, or temperature changes. This process is known as *flux creep*. It is central to the manner in which technical superconductors can be used in magnets [4].

The continuous movement of flux across an annealed type II superconductor appears as a voltage gradient along it. Similarly, the process of flux creep through a field of pinning centers creates a voltage gradient, and through the interaction with the transport current, it gives rise to dissipation. The faster the flux creep, the greater is the local dissipation. Thus with flux creep is associated a local temperature rise. Since the specific heat of materials is small at low temperatures, the dissipation associated with flux creep can cause significant temperature rise. (At room temperature the energy of dissipation through flux creep would generate little temperature rise.) Thus the dissipative effect of flux creep can lead to a runaway flux movement. As the temperature rises, the critical current density decreases. According to Eq. (1), that in turn leads to an increased flux movement and thence to more dissipation. In the extreme case the temperature rises above the critical value, and superconductivity ceases. This process is known as a *flux jump* [5]. In a magnet

wound with superconducting wire, the sudden reversion to the normal state of a small length of the wire will result in the dissipation of the stored magnetic energy at high density in a volume that expands through thermal diffusion. If the stored energy is large enough and the thermal diffusion slow enough, the temperature rise at the point of initiation may exceed the melting point of the wire. The essence of the design of superconducting magnets is the suppression or control of this fundamental thermal instability.

1. TECHNICAL SUPERCONDUCTORS

The major properties of the three technical superconductors are typically as shown in Table 1. T_c is the highest temperature below which superconductivity can exist (electron pairs can form) in zero field and with zero current. B_{c2} is the upper critical field at 0 K at which the lattice is fully packed with flux quanta. $J_{c \text{ typ}}$ is a typical operating current density at useful values of field and temperature. (Below the lower critical field B_{c1} , the technical superconductor behaves as a type I superconductor; that field is typically 0.01 T.) The two leading HTS materials are based on yttrium or on bismuth. The critical parameters refer to typical bismuth-based HTS.

Figure 1 illustrates the typical variation of critical current density with field and temperature for the two low-temperature technical superconductors. Depending on the local values of any two of the parameters, the third has a local critical value. In a magnet conductor, B and J are usually fixed, so T is the critical parameter. The distance between the operating values B , J , and T and the critical surface is the margin. In fact, since current and field are locally fixed, only the temperature can vary. Thus the temperature margin determines the susceptibility of the conductor to disturbance. The higher the margin, the more stable it will be. Since NbTi must operate at the lowest temperatures, it is the least stable. The HTS, by contrast, can operate with such high-temperature margins that they are very stable. However, that also leads to a problem of protection that must be addressed carefully in the future design of large HTS magnets.

Despite its low-temperature margin NbTi is the most widely used technical superconductor. It is a ductile alloy, compatible in metallurgical processing with copper and cupronickel. However, Nb₃Sn must be used in magnets or sections of magnets generating fields above about 12 T. HTS materials are now also beginning to be used in small magnets. Almost all magnets are wound with wire or a large cross-sectional conductor. (In principle, a magnet might be formed from a block of superconductor into

Figure 1. Variation of critical current density of a technical superconductor as a function of field and temperature.

which a field is frozen, e.g., by applying a field and then lowering the temperature. Instability makes that infeasible in low-temperature superconductors, but HTS may make such monolithic magnets possible.)

1.1. Composite Superconductors

The suppression of instability and the protection of the conductor in the event of an instability are the predominant problems in the design of superconducting magnets. If a magnet is to operate reliably, the tendency for a runaway magnetothermal effect to trigger a full transition from the superconductive to the normal conducting state must be suppressed. Two methods have been developed to achieve that: the elimination of flux jumping and the limiting of its consequences through cryogenic stabilization [5].

The essence of the stabilization of a technical superconductor is its subdivision into fine filaments. In the composite conductor, this is achieved by embedding a large number of fine filaments in a matrix. The matrix is usually high-conductivity copper, although aluminum has also been used. The copper serves several functions. It rapidly conducts heat away from the surface of the fine filaments; since its resistivity is much lower than that of the superconductor in its normal state, it allows current to flow with relatively low dissipation when the adjacent superconductor has become normal through an instability.

1.2. Niobium–Titanium

Figure 2 shows a typical cross section through a NbTi composite superconductor. It is manufactured by a co-drawing process [6]. Typical wire diameters lie in the range of 0.1–3 mm with critical currents at 4.2 K and 8 T of between 5 and 500 A. The insulation is typically Formvar (polyvinylformal). The diameter of the superconducting filament is determined largely by stability but also by hysteresis loss. The latter is the integrated effect of dissipation by flux creep during the rise of current and field in a magnet. Hysteresis loss is minimized by decreasing the diameter of the filaments. Typically the number of filaments in a wire may lie between 10 and 100,000.

Table 1. The Critical Properties of the Principal Technical Superconductors

	NbTi	Nb ₃ Sn	HTS
T_c (K)	10	18	90
B_{c2} (T)	13	27	> 100
$J_{c \text{ typ}}$ (A/mm ²)	1000	5000	1000

Figure 2. Cross section of a typical niobium–titanium composite superconductor. (Courtesy of Vacuumschmelze GMBH).

1.3. Niobium–Tin

Nb_3Sn is a brittle compound, and its use in a magnet winding is considerably more complex than NbTi. The predominant method of forming the compound is the diffusion of tin into niobium at a high temperature [6]. The tin is contained either internally within filamentary niobium tubes or in a tin-rich bronze surrounding solid niobium filaments. The niobium has typically up to 5% of tantalum for improved critical current density. The stock wire is unreacted for winding and is insulated with a glass braid, such as silica glass. After winding, the coil is reacted at about 700°C for up to 200 h. During this reaction the tin diffuses into the niobium and forms the compound Nb_3Sn . For adequate diffusion the diameter of the niobium filament must be no greater than 0.005 mm. After reaction the wire is brittle and cannot tolerate bending. Therefore the winding must be consolidated by vacuum impregnation with epoxy resin. Figure 3 shows a typical cross section through a bronze route superconducting wire before reaction.

Figure 3. Cross section of a typical niobium–tin superconductor. (Courtesy of Vacuumschmelze GMBH).

As in the NbTi composite, copper is required as a stabilizer and for protection. In order to preserve the low resistivity of the copper, tin must not be allowed to diffuse into it during the reaction. (That would, in any case, dilute the tin available for diffusion into the niobium.) A barrier is inserted between the bronze and the copper matrix to prevent such unwanted diffusion. This barrier is in the form of a thin wrap of tantalum or niobium.

1.4. High-Current Conductors

To form high-current conductors in either NbTi or Nb_3Sn , cables of small wires are usually embedded in a copper or aluminum matrix. In this way NbTi composite conductors with critical currents of up to 100,000 A can be constructed. Similarly high-current Nb_3Sn composites can be constructed by carefully cabling prereacted wires and soldering the cable into a copper matrix. Handling such pre-reacted Nb_3Sn conductors requires exacting quality control procedures [7].

An important form of high-current conductor is the so-called *cable-in-conduit* (CiC). A cable of composite strands is inserted into a closed sheath, usually of stainless steel. Liquid helium (sometimes in the superfluid state at a temperature below 2.17 K) is circulated through the gaps between the strands of the cable [8]. This arrangement combines good support of the strands against the Lorentz forces with a low shielding loss and high current (see Section 6).

Another development in Nb_3Sn conductors is a pre-reacted cable of very fine wires. The strands are so thin that bending radii appropriate to normal winding techniques can be tolerated [9].

2. HIGH-TEMPERATURE SUPERCONDUCTORS

At present only a very few superconducting magnets use these materials. These superconductors all contain copper oxide layers in a perovskite crystal structure [10]. Two major types are being actively developed for application to magnets: yttrium-based and bismuth-based.

2.1. Yttrium HTS

This material has the chemical composition $\text{YBa}_2\text{Cu}_3\text{O}_7$, abbreviated YBCO. It has a critical temperature of 80 K. Its critical field at 4.2 K has not been directly measured but is believed to be about 100 T. Wire is manufactured in the form of a tape, samples of which have achieved a critical current density of 7000 A/mm^2 at 5 T and 77 K. Lengths of wire suitable for the construction of magnets have not yet been produced. Their manufacture suffers from the disadvantage of a highly anisotropic critical current density; that is, the critical current depends strongly on the orientation of the local field relative to the crystal orientation. Nevertheless, magnets operating at liquid nitrogen temperatures will probably use this material in the near future.

2.2. Bismuth HTS

This material is manufactured in two forms, with chemical compositions of $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_7$, abbreviated 2212, or $(\text{BiPb})_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_7$, abbreviated 2223. Both of these are being manufactured in lengths of up to 1000 m, and small magnets have been wound from them. The 2212 requires lower temperatures for high-field operation than the 2223. However, it is more easily fabricated and coils of the 2212 have been tested in external fields to show that useful currents can be carried at 30 T and 4.2 K. Either of these BSCCO materials may soon be the choice for inserts in very high field solenoids.

3. STABILITY

3.1. Adiabatic Stability

Regrettably, the flux jump is not the only source of heating sufficient to raise the temperature above the local critical value. Movement of a wire under the influence of the Lorentz forces in the body of a winding can generate local frictional heat sufficient to raise the temperature of a wire above the local critical value, especially where the temperature margin is small. A further precaution that must therefore be exercised in a magnet designed to avoid flux jumping is the consolidation of the winding so that no sudden frictional movement can occur to generate heat. This is achieved by impregnating the winding with epoxy resin, or another agent, in order to prevent sudden movement between wires, or between wires and stationary structure such as coil forms. This is the form of winding of the *adiabatic magnet*, which is so termed because no thermal sink exists within the winding.

Despite the use of fine filaments and winding techniques to avoid mechanical disturbances, the adiabatic winding is susceptible to sudden local transition from the superconductive to the normal state, if only through failure of the cryogenic environment. The resulting spreading normal zone is a process known as *quenching*. It may be precipitated by the relief of local stresses, which may merely be the repositioning of a wire, or cracking in a resin impregnant, and it may result in quenching at a current and field below design values. On recooling and recharging, the next premature occurrence of quenching can be at a higher current. This sequential improvement in the operating current is known as *training*. It is a common characteristic of large adiabatic magnets, especially of magnets with complex topology, such as particle-beam-handling magnets.

Despite the disadvantages associated with instability, quenching, and training, adiabatic magnets are the most common embodiment because they achieve the highest overall current densities in the windings. They enable the most compact magnets and the highest fields.

3.2. Cryostability

A second method of stabilization exploits the powerful cooling effect of liquid helium to maintain the temperature of a conductor below the local critical value even in the presence of flux jumping or other severe perturbations.

This is achieved by paralleling the superconductor with sufficient copper or aluminum cooled by liquid helium [11]. Now, even though all the transport current were to flow in the copper, the temperature would be kept below the critical value of the superconductor if sufficient surface were presented to the helium. This is the principle of cryostability. The governing expression for this mode of operation of a superconductor is

$$\frac{I^2 \rho}{A} = hP \quad (2)$$

where ρ is the resistivity of the copper, A is the copper cross section, h is the heat transfer rate, and P is the wetted perimeter of the copper. If the value for h is chosen to be about 1000 W/m^2 , this becomes a conservative stability criterion but leads to a low overall current density in a winding because the cross section of the stabilizing copper is large.

The earliest large magnets (mainly for bubble chambers built in the late 1960s) were designed in accordance with this principle. However, the boiling heat transfer curve for liquid helium has two branches, as shown in Fig. 4: nucleate boiling, line (a), with high heat transfer coefficient and film boiling; line (c) with lower coefficient (1000 W/m^2 is typically the lowest value of heat transfer rate in the film boiling regime). Intermediate between these is a region of unstable boiling, line (b). During an instability some or all of the current may transfer locally from the superconductor to the copper. The local generation of heat in such an extended region is line (f), rising from zero where no current flows in the copper to the full heating where all the current flows in the copper. The areas (d) and (e) then represent respectively regions where more heat is removed than generated and where more heat is generated than removed.

The sharing of current between the superconductor and copper results in the following expression for the local temperature

$$\frac{I(I - I_s)\rho}{A} = q(\theta - \theta_b)P \quad (3)$$

where I is the total current, I_s is the current still in the superconductor, ρ is the resistivity of the copper, and q is the heat transfer coefficient at the temperature difference $\theta - \theta_b$ between the copper and the helium bath. A good approximation for the current in the superconductor at a temperature θ is

$$I_s = \frac{I_c(\theta_c - \theta)}{(\theta_c - \theta_b)} \quad (4)$$

where I_c is the critical current at θ_b , the bath temperature. Equations (2)–(4) are represented together with the boiling heat transfer in Fig. 4. If the cooling exceeds the heating, area (d) greater than area (e), then recovery of superconductivity will occur. The normal region will collapse from the cold ends. This type of stability, called *cold end recovery*, allows higher values of h to be assumed in Eq. (2); 3000 W/m^2 is commonly accepted. This in turn allows a smaller cross section of copper and a more compact winding [12].

Figure 4. Boiling heat transfer curve for liquid helium and the heat generation curve for a composite superconductor.

4. PROTECTION

The other crucial issue in the design of superconducting magnets is protection. In both the adiabatic and cryostable types, the consequences of quenching must be anticipated. The methods by which this is achieved are quite different in the two types.

4.1. Adiabatic Protection

In this winding the conductors are in a compact array without an internal heatsink but with close thermal coupling between conductors. Therefore, when a conductor becomes normal through a perturbation, not only does the normal zone travel along the wire but the local heating rapidly causes adjacent conductors to heat up and become normal. Quenching then expands as a three-dimensional zone of increasing volume and surface area. The volume of normal conductor at any instant is approximated by

$$V_n \propto v_1 v_2 v_3 t^3 \quad (5)$$

where $v_{1,2,3}$ are effective velocities of quench propagation along the wire and transverse to it and t is the elapsed time. Thus the magnetic energy stored in the field is dissipated in a rapidly expanding volume of conductor. The velocities of propagation depend, among other things, on the local temperature margin; the greater the margin, the slower are the velocities. Although not as high as the velocity along the wire, the dominant velocities are those between turns and between layers. Rapid propagation of quenching between turns is desired in order to spread the temperature rise over a large volume. For that reason HTS winding may be more difficult to protect than those with the smaller temperature margins of Nb_3Sn or NbTi .

Two criteria are applied to this process to gauge the vulnerability of the magnet winding to quenching: (1) the final temperature of the wire at the point of initiation of quenching and (2) the voltage appearing between layers or turns of the winding. The latter criterion involves complex computation of the spatial distribution of normal and superconducting regions during the quench. However, the peak temperature generally dominates the criteria. This must clearly neither exceed the allowable temperature for the insulation or impregnant nor produce unacceptable

local stresses due to differential thermal expansion. A rule of thumb for acceptable peak temperature is 100 K. To achieve such limit (and simultaneously limit the voltage), sufficient copper must parallel the superconducting filaments so that the integrated heating in the copper does not exceed the acceptable peak value. Because of the rather complex time dependency of the current in a quenching adiabatic magnet, this criterion is best illustrated by reference to the protection of a cryostable magnet.

4.2. Cryostable Protection

In this type of magnet no propagation of a quench zone occurs between adjacent conductors. Furthermore the one-dimensional propagation of quench along a conductor is slow. If, for example, the level of liquid helium is low so that a length of conductor is exposed to helium vapor and has quenched, no propagation will occur, and the normal zone will be stationary. In such a case protection of the conductor against excessive temperature rise must be by external discharge of the stored magnetic energy. Interturn voltage is hardly ever a dominant effect in the protection of a cryostable magnet. The limiting criterion is therefore the temperature rise of the conductor at the point of quench initiation. Just as for the adiabatic magnet, a generally accepted criterion is a rise of no more than 100 K. The prediction of the temperature rise is now rather simple. If the magnet is discharged exponentially, the governing equation is

$$J_{\text{Cu}}^2 \rho(\theta) dt = c(\theta) d\theta \quad (6)$$

The left-hand side of Eq. (6) represents the heat being generated in the resistance of the copper, and the right-hand side represents the same heat being absorbed by its enthalpy. The quantities $\rho(\theta)$ and $c(\theta)$ are the temperature-dependent resistivity and volumetric specific heat of the copper.

Equation (6) may be rewritten as

$$\int_0^\infty J_{\text{Cu}}^2 dt = \int_{4.2}^{\theta_{\text{max}}} \left\{ \frac{c(\theta)}{\rho(\theta)} \right\} d\theta \quad (7)$$

In this expression the right-hand side is a function of the copper, or some other conducting material, between a low temperature, generally assumed to be that of liquid helium boiling at atmospheric pressure, 4.2 K, and the allowable upper temperature, generally 100 K [13]. (It is sometimes called the “ G function” but not in the original reference.) If the discharge of the magnet is exponential, Eq. (7) becomes

$$\frac{1}{2} J_{0\text{Cu}}^2 \tau = G(\theta_{\text{max}} - 4.2) \quad (8)$$

where $J_{0\text{Cu}}$ is the initial maximum current density in the copper. For copper at 100 K, the value of the G function is typically $6 \cdot 10^{16} \text{ A}^2 \text{ m}^{-4} \text{ s}^{-1}$. In order to achieve the required time constant of discharge, the voltage across the magnet must be as large as the inductance demands. As an example, a large magnet might have a stored energy of

100 MJ, an operating current of 10,000 A, and a copper cross section of 500 mm². The inductance would be 2 henries and $J_{0\text{Cu}}$ would be 2×10^7 A/m². The time constant of discharge would have to be 17.32 s, and the maximum initial discharge voltage 1.154 kV.

4.3. Winding Topology

The design of a winding array is dictated by the desired field properties. The basic expression governing the field produced by a winding is the Biot–Savart law, expressed as

$$dB = \frac{I \cdot dl \sin(\theta)}{r^2} \quad (9)$$

where $I \cdot dl$ is a current element, and θ is the angle between that element and the radius vector r to the field point. The direction of the field vector is perpendicular to both the current element and the radius vector. This expression is integrated in closed form for the fields of solenoids and of long linear windings. The forward computation of field produced by a given current array is straightforward. It can be performed for any configuration of currents, although the closed-form calculation is easy only for circular or straight arrays. The reverse computation, of a current array to produce a given field topology, is possible only for a few simple configurations, specifically for the axially symmetric field of a current ring and the circular field of an infinite straight current. The off-axis fields of a circular current array involve elliptic integrals. Numerical methods for the solution of the off-axis field of a current arc are routinely available as commercial codes. Most field geometries are produced by combinations of straight currents and current arcs. Generally the design problem proceeds by the iterative recomputation of the fields generated by incrementally modified straight or arc current arrays.

5. OPERATION IN TIME-VARYING FIELDS

Although most superconducting magnets constructed to date have been designed for steady-state operation, a few have been constructed for use either under AC conditions or with a rapidly changing field [14]. The design of a conductor for such operation involves the reduction of dissipative mechanisms in the superconductor. One source of dissipation under conditions of changing field has been described, that is, flux creep. That loss is generally called *hysteresis loss* and is approximated per unit volume by the expression

$$Q \approx \frac{1}{4} \Delta B d_w J_c \quad (10)$$

where ΔB is the field change, d_w is the wire diameter, and J_c is the critical current density. It is seen that the dissipation is smallest for thin wires.

Other sources of dissipation are found in composite superconductors. The most important of those is what is called *shielding loss*. It arises as follows. To reduce hysteresis loss and to improve the stability of a supercon-

ductor against flux jumping, the superconductor is finely divided into filaments in a (typically) copper matrix. However, it may be seen that the collection of filaments will still tend to exclude flux unless the filaments are transposed. Full transposition of any but a single layer of filaments is impossible within the matrix. However, a compromise is the twisting of the conductor. A short twist pitch or high resistivity of the matrix will allow flux to penetrate through the layers of filaments [15]. The time constant of penetration is given roughly by

$$\tau = \left(\frac{\mu_0}{2\rho} \right) \left(\frac{L}{2\pi} \right)^2 \quad (11)$$

where ρ is the resistivity of the matrix and L is the twist pitch. External field change will generate dissipation roughly given by

$$Q = \left(\frac{B^2}{2\mu_0} \right) \left(\frac{\tau}{\tau + t} \right) \quad (12)$$

where t is the time constant of the field change B . If the change is very rapid compared with the time constant of penetration of the conductor, the dissipation approaches the energy density of the magnetic field. Some magnets have been made with superconductors that have a matrix of cupronickel. The resistivity of cupronickel is high, which leads to a short time constant for flux penetration. However, the conductor is not well stabilized, and in the event of a quench it is not well protected against local hot spot. The CiC conductor, described above, also minimizes the shielding losses.

6. FORCES AND STRESSES

The force on a conductor in a field is given by the expression

$$F = BI \quad (13)$$

where I is the current in amperes, B is the component of the field in tesla perpendicular to the current vector, and F is the force per unit length in newtons which is directed perpendicular to the current and field vectors. The calculation of stresses in the conductors of a winding can be performed in closed form for only a few simple cases. For an isolated circular loop, the hoop stress averaged over a section of wire (whose cross section may include superconducting filaments, copper, depleted bronze, etc.) is given by

$$\sigma = BJr \quad (14)$$

where B is the average field at the wire perpendicular to the plane of the loop, J is the current density averaged over the wire section, and r is the mean radius of the loop. If J is in A/m², and r is in meters, then σ is in pascals. In a multilayered solenoidal winding the stresses in the wire are influenced by the transmission of radial forces between layers and by axial forces generated by radial components of field at the ends of the solenoid. The analysis of these stresses usually is performed by standard programs.

However, Eqs. (13) and (14) provide a useful rough guide to the stresses that will be encountered in a solenoidal winding.

The forces in long straight windings, such as extended dipoles, may be similarly estimated by the summation of the forces found from Eq. (13). The stresses in solenoidal windings are often supported by the conductor alone. Since the stresses are predominantly tangential, they produce tension in the components of the wires. In NbTi composites the stresses tend to be divided roughly equally between the NbTi superconductor and the copper unless the latter is annealed. In Nb₃Sn conductors most of the tensile load appears in the Nb₃Sn superconductor itself because the Young’s modulus is high, 172 GPa. The other components of a Nb₃Sn composite tend to be annealed by the heat treatment.

6.1. Examples of Superconducting Magnets

Common applications of superconducting magnets include the following: magnetic resonance imaging (MRI), laboratory magnets (for NMR analysis, susceptibility measurement), particle-beam handling, subatomic particle analysis, power conditioning, energy storage, open gradient magnetic separation, and magnetohydrodynamic (MHD) power generation. All superconducting magnets are wound. The most common winding topologies are solenoids and extended linear windings. The latter are in general of the form of armature windings, having straight sections with end turns of complex shape. Solenoids are used in magnets for MRI, most laboratory magnets, particle analysis, and energy storage. Extended linear windings are used in particle-beam-handling magnets, in rotating machines (rotor windings), for particle focusing (quadrupoles, hexapoles), and in MHD power generation. Occasionally a superconducting winding has an associated ferromagnetic flux path. (In such so-called superferric magnets, the iron is usually included in the magnet’s cryogenic environment, to avoid the transmission of high forces between low temperature and room temperature.)

Although most superconducting magnets are solenoids or extended dipoles and multipoles, a few magnets of more complex shape have been manufactured. These include

Table 2. Major Characteristics of a 750-MHz NMR Solenoid

Type	Solenoid
Materials	NbTi and Nb ₃ Sn
Energy	15 MJ
Center field	17.6 T
Bore at 4.2 K	74 mm
Typical weight	250 kg

very large “ying–yang” coils for the mirror fusion test facility (MFTF) [16], saddle coils for experiments on magnetohydrodynamic (MHD) power generation [17] and toroidally shaped coils for several Tokamak fusion experiments [18]. (Toroidal field magnets for fusion devices are D-shaped coils that are arrayed around a circular plasma path; in the absence of orthogonal—poloidal—fields, the conductors of these coils experience pure tension as in a solenoid.)

All are large magnets, storing energy in the range of 100 MJ. The stored magnetic energy is a rough classification of the size and cost of a magnet, and not necessarily of the difficulty of design and construction. Very high-field, compact magnets present more difficulty because of small operating margins, high stresses, and high-energy densities during quenching.

One of the largest superconducting magnets under construction is the model central solenoid for the International Thermonuclear Experimental Reactor (ITER). It stores 650 MJ and weighs 100 tonnes [19]. The most precisely engineered have been the high-field NMR magnets. They now have reached fields of 18.8 T with homogeneity of 10^{−9} in a 10 mm spherical volume.

NMR and MRI magnets operate in persistent mode. After energizing, a superconducting switch is closed across the winding so that the current continues to flow in an essentially resistanceless circuit. These are the most commonly produced commercial magnets [20].

Superconducting particle-beam-handling magnets have made possible the very high-energy accelerators in operation at BNL, CERN, DESY, and the Fermi Laboratory. Superconducting dipole magnets are typically 10 m

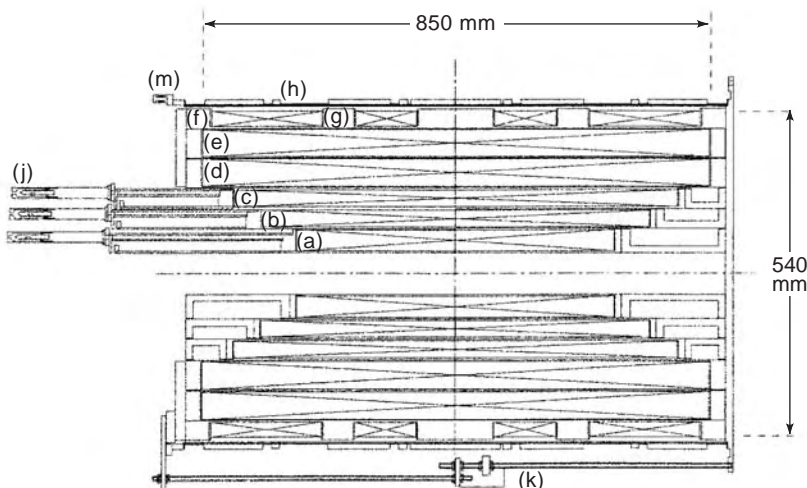

Figure 5. The winding profile of a typical commercial NMR magnet. (Courtesy of Magnex Scientific PLC.)

Figure 6. An illustrative view of the LHC dipole construction, showing the windings and the structural yokes. (Courtesy of CERN.)

long or greater, generating transverse fields of up to 8 T to provide the deflection required to bend the particle beam to a circular orbit. The requirement for uniformity of field is about 10^{-4} over 25 mm width. Superconducting quadrupole magnets are used for focusing of the particle beam and typically provide field gradients of up to 25 T/m.

6.2. Specific Examples

6.2.1. NMR Magnet for 750 MHz Proton Frequency [21]. Superconducting magnets for NMR and MRI are described separately within this encyclopedia. However, as they typify solenoidal magnets, the 750 MHz magnet is described here in outline. Figure 5 gives the profile of the windings of

a commercial magnet along with some of the structural details. The global characteristics are listed in Table 2.

In the figure the windings are labeled (a) through (g). Windings (a), (b), and (c) are of Nb_3Sn . The wire size is largest in section (a), where the field is highest and the critical current density lowest. In fact, section (a) consists of three grades of wire in order to maximize the local winding current density. Sections (d) and (e) are the main NbTi winding, again graded to maximize overall current density. Sections (f) and (g) compensate the axial gradients introduced by the full-length sections. All magnets used for NMR are operated in persistent mode. The windings are connected in series through superconducting joints. After energizing, the windings are closed through a superconducting switch (k). The joints (j) between the Nb_3Sn sections provide the best performance (highest critical current) in low field. Therefore they are mounted away from the windings on posts that rigidly support the brittle conductor. Surrounding the windings is an array of shim coils (h) that provides for fine adjustments. Each shim set has its own switch (m).

6.2.2. Particle Accelerators. The Fermilab energy doubler/saver is typical of the use of superconducting beam-bending magnets used in particle accelerators [22,23]. The field generated by the magnet is oriented vertically and extends over a length of 6 m. High-energy protons are slightly deflected by the field-length product of the magnet. The transverse force on the particle beam is as predicted by the Lorentz equation [13]. A large number of these dipoles (774), quadrupoles (216), and sextupoles are arranged to produce a total deflection of 360° . In the Fermilab energy doubler each dipole magnet produces a mere 0.47° deflection at maximum beam energy.

JAERI	NbTi PB	2.00	8.81	10.22	198
CH	NbTi FF	1.00	7.86	13.00	123

A more recent project involving superconducting beam-handling magnets is the Large Hadron Collider (LHC) at CERN. This also uses a sequence of long dipoles, quadrupoles, and sextupoles in two adjacent rings in which protons, or other heavy particles, will circulate in opposite directions to collide at energies up to 14 TeV. The cross section of the winding and associated structure is shown in Fig. 6. The conductors are located so as to approximate a cosine distribution of current density. That arrangement generates a field uniform throughout the center region of each beam. The outward forces on the conductors are constrained by a stainless-steel collar. This cold assembly is supported within an iron yoke that provides a return path for the flux. The yoke is assembled from transformer iron laminations, welded in a set of long steel girders.

6.2.3. Large Coil Task [24]. Six coils were built, one each by the following groups: EURATOM (EU), The Swiss Institute for Nuclear Science (CH), The Japanese Atomic Energy Research Institute (JAERI), Westinghouse Electric (WH), General Dynamics (GD), and General Electric/Oak Ridge National Laboratory (GE/ORNL). Each coil was a constant tension dee coil [18], but each used a different form of conductor. The Westinghouse coil alone used Nb₃Sn, in a CiC configuration; all the others used NbTi in a cryostable (helium-cooled) configuration. The cooling method was either forced-flow (FF) or pool-boiling (PB). The purpose of the program was to demonstrate stability of the coils under conditions of combined toroidal and pulsed poloidal fields. This international program has resulted in the construction of a model toroidal coil array as shown in Fig. 7. The main specifications were as listed in Table 3.

The advent of high-temperature superconducting (HTS) materials has enabled a number of applications in passive microwave electronics. Superconductors exhibit very low losses at microwave frequencies and, although finite, at the practical operating temperature of 77 K (boiling point of nitrogen), these losses are more than two orders of

magnitude lower than normal conductors at frequencies of 10 GHz and below. This has allowed the possibility for high-performance planar microwave components because high-quality epitaxial films can be deposited on both sides of low microwave loss, single-crystal substrates allowing the fabrication of components in planar configurations such as microstrip, stripline, and coplanar waveguide. These configurations are widely used throughout the microwave community in a variety of technologies ranging from GaAs microwave monolithic integrated circuits (MMIC) to integrated circuits using ceramic and laminated substrates. Figure 1 shows a schematic cross section of all three most common planar microwave structures. The use of HTS in these circuit configurations results in passive devices such as resonators, filters, and delay lines with performance far superior to conventional planar technology and with the attractive feature that many well-established design techniques can be used for HTS circuits as well.

The discussion in this article will focus mostly on HTS microwave planar filters, because they are the majority of microwave HTS devices built nowadays. They are also representative of other devices like duplexers and multiplexers, which may contain several filters to separate signals at different frequencies.

Microwave filters are made of several coupled resonators. This article will describe the details of resonators currently used in HTS microwave filters. There are other applications that also use HTS resonators to take advantage of the unique features of HTS materials, for example, in the frequency stabilization of microwave oscillators. These applications will not be described in detail. The interested reader is referred to the reading list for further details.

Planar microwave circuits with HTS materials are also used for some applications that do not involve the use of resonators. Of particular significance are the devices that include planar delay lines. A short overview of these devices is given in this article. Further details can be found in the reading list and in the references therein.

The HTS microwave technology is discussed in this article with the understanding that conventional low-temperature superconductors (LTS), for example, Nb or NbN, can also be used in the same fashion. Practical LTS materials operate typically at 4.2 K, the boiling temperature of liquid He. Furthermore, it should be kept in mind that a larger variety of substrates can be used in LTS technology because it does not require single-crystal epitaxial films. For example, Nb microwave and digital circuits have been demonstrated on Si and single-crystal sapphire substrates [1].

1. HIGH-TEMPERATURE SUPERCONDUCTING FILM PROCESSING TECHNOLOGY

The basic elements of HTS thin film technology from the point of view of microwave applications will be discussed here briefly. Only epitaxial thin films will be addressed because, to date, significantly better properties can be obtained from epitaxial material than from polycrystalline,

Figure 1. HTS technology lends itself to the fabrication of microwave planar devices such as those schematically depicted here in cross section. One advantage of coplanar waveguide (and its variant slotline, not shown) is that only one patterned HTS film is needed. One disadvantage of stripline is that it is difficult to package. HTS devices have been demonstrated in all three structures.

nonepitaxial techniques. Most, if not all, of the developments covered in this article, however, are valid for the case of polycrystalline materials. The main advantage of these materials is cost and coating of nonplanar surfaces like the inside of a cylinder to form a high-Q cavity resonator [2].

Among the various high-temperature superconductors, there are two that have achieved a level of maturity and acceptance in the industry: (1) $\text{YBa}_2\text{Cu}_3\text{O}_7$, usually referred to as YBCO, and (2) $\text{Tl}_2\text{Ba}_2\text{CaCu}_2\text{O}_8$ or TBCCO. High-quality epitaxial thin films of these materials can be deposited on both sides of a variety of low microwave loss, single-crystal substrates by several deposition techniques. Evaporation is the dominant technique for production of large-area YBCO films [3,4], whereas sputtering [5], laser ablation [6], and metal-organic chemical vapor deposition (MOCVD) [7] are used in some YBCO processes and, as detailed below, as a part of most TBCCO processes.

YBCO is typically grown in situ as an epitaxial single-crystal film with thickness ranging from 300 nm to 700 nm. This means that the desired crystalline phase of the material is formed as the film grows because the growth conditions can be adjusted to obtain such results. In contrast, TBCCO films have to be grown in two steps because of the high volatility of thallium. In a first step, a thallium-free epitaxial film containing barium, calcium, copper, and oxygen is formed following the deposition techniques mentioned above. Then, the film is annealed in a thallium atmosphere to form the TBCCO film with the adequate composition and crystalline structure [8].

Despite the complications in the fabrication of TBCCO films, they have the advantage of a higher critical temperature (Table 1) and are typically grown with thickness close to 1 μm . These are advantages because practical devices must be made with thicknesses two or three times greater than the London penetration depth (200 nm to 300 nm) at 77 K (see Section 2.1.). TBCCO films thus offer a greater operating margin than YBCO films.

1.1. Substrates

To date, the two most common substrates used to grow HTS films on are LaAlO_3 (LAO) and MgO. Circuits on sapphire have been demonstrated, but they are much more difficult to make with a YBCO thickness of at least 500 nm. YBCO films thicker than 300 nm tend to crack because of the difference in the coefficients of thermal ex-

pansion of the YBCO and the sapphire substrate. Both LAO and MgO substrates are available commercially from a variety of suppliers around the world and can be readily obtained in circular wafers up to 7.6 cm in diameter and 250 μm to 700 μm in thickness. At 77 K and for frequencies between 1 GHz and 10 GHz, the loss factor ($\tan \delta$) of LAO and MgO is, at most, on the order of 10^{-5} , which is 10 to 100 times smaller than most practical microwave substrates and is compatible with the low conductor loss of HTS.

These two preferred substrates for HTS planar devices have significant differences among them. LAO has a cubic crystal structure above about 450°C. Below that temperature it transitions to a rhombohedral structure, which is only a slight distortion from the cubic structure consisting of a very small stretching of the cubic unit cell along its diagonal. In order to release stress, the crystal will form twin structures, symmetrically related regions oriented in different directions. Noncubic crystals are anisotropic and, as a result of this twinning, the LAO substrate is made up of slightly anisotropic regions randomly distributed throughout the substrate [9]. The net result is an average dielectric constant with a uniformity of approximately 1%

Table 1. Basic Characteristics of the Most Used Thin Films and Dielectric Substrates for Microwave Applications

HTS Films	YBCO	TBCCO
Critical Temperature (T_c)	90 K	110 K
Surface resistance (R_s) at 77 K and 10 GHz (f^2 dependence)	0.2–0.5 m Ω	0.2–0.5 m Ω
Film thickness	300–700 nm	800–1000 nm
Critical dc current density (J_c) at 77 K	2 MA/cm ²	1 MA/cm ²
Penetration depth (nm)	200 nm	200 nm
Substrates	(LaAlO ₃) LAO	MgO
Relative dielectric constant (ϵ_r) at 77 K	23.6	9.7
Dissipation factor ($\tan \delta$) at 77 K	10^{-5}	$<10^{-6}$
Typical dimensions	5, 7.5, 10 cm diameter 250 and 500 μm thick	5 and 7.5 cm diameter 250 and 500 μm thick

Note: Both types of HTS films can be grown in either substrate.

that, among other effects, may provoke unacceptably large tolerances in the resonant frequencies of the resonators that make up a planar filter. In contrast, MgO, which is cubic, has a dielectric constant uniformity of 0.1% [10].

The relative dielectric constant of LAO is $\epsilon_r = 23.4$ at 77 K. This is a higher value than most common microwave substrates whose dielectric constants usually do not exceed 10 ($\epsilon_r = 9.7$ for MgO). This high permittivity makes invalid some of the models that are used in standard planar microwave circuit design, like, for example, the models of quarter-wave-coupled microstrip sections, which are not valid for $\epsilon_r > 18$.

The most important characteristics of these two HTS materials and their substrates are given in Table 1. The properties listed are those a microwave designer would want to know if engaged in an HTS device design project.

1.2. Device Processing

Fabrication of microwave devices using either YBCO and TBCCO follows relatively straightforward photolithographic techniques. Patterning of the superconducting layer is typically accomplished by Ar-ion milling. The processing may include the deposition and patterning of low-resistivity contacts for interfacing with other devices or instrumentation. These are typically made by depositing a thin (200 nm to 300 nm) layer of gold or silver through a shadow mask on the contact areas [11]. Another possibility is to deposit a layer of gold or silver over the whole HTS film and then selectively remove the metal in the photolithographic process. The latter option allows for an in situ deposition of the metal in the same chamber where the HTS film is grown, without breaking vacuum, favoring a low-resistance contact between the HTS and the metal. Interfacing with other devices via coaxial connectors or directly to other substrates, superconducting or otherwise, can be accomplished using gold wire or ribbon attached to the low-resistivity contacts by ultrasonic thermal compression bonding or gap-welding (ribbons). Fabrication details of filters and delay lines made at Northrop Grumman can be found in Ref. 12. Other institutions follow similar procedures.

1.3. Microwave Packaging of High-Temperature Superconducting Devices

Proper packaging of cryogenic microwave devices is critical to the success of the technology. In general, planar microwave devices are made up of a dielectric or semi-insulating substrate, typically mounted on a metallic package or carrier by means of conducting epoxy or soldering. The mounted device then interfaces with other devices or measurement instrumentation most commonly via coaxial connections. In this case, the metallic carrier forms part of the ground terminal by connecting to both the outer jacket of the coaxial interconnection and the ground plane defined on the substrate. This means that microwave currents flow into the planar device through the center conductor of the coaxial interface and back out through the ground plane on the substrate, the metallic carrier, and its connection to the coaxial connector outer jacket. This current flow into the packaging assembly must occur without appreciable impedance mismatch or discontinuity. Figure 2 illustrates these points schematically with an example for a microstrip device.

The criticality of these connections among substrate, carrier, and connectors is exacerbated when cryogenic cooling of the microwave package is required because a large thermal mismatch between the various components may cause cracking of the substrate or degradation of the interface between substrate and carrier or connector. Furthermore, the quality of the interface between the cryoelectronic substrate and the outside world must be preserved through many temperature cycles between ambient and cryogenic temperature to allow for repeated testing of the device and an operational environment, which may require that the device warm up to room temperature while not in use. Suitable microwave package designs must therefore include one or more of the following elements: (1) the use of thermally matched materials, (2) adhesives that remain sufficiently pliable at cryogenic temperatures, and (3) configurations that allow the various parts of the package to contract and expand freely while maintaining good electrical contact.

When considering materials that are thermally matched to HTS substrates, the important parameter is the total contraction between room temperature and the

Figure 2. Microwave packaging of HTS devices is challenging because mechanical and electrical integrity must be maintained when the device is cycled from ambient to cryogenic temperatures. Special attention must be paid to the ground-current return path so as not to introduce parasitic reactances that could severely affect the performance.

Figure 3. Measured relative thermal contraction of several materials of interest in HTS technology, including Si and GaAs. These or similar data should be used in the selection of carrier materials and the packaging of hybrid HTS-semiconductor components. If a good thermal match between parts that must remain in intimate mechanical and electrical contact cannot be obtained, sufficiently pliable conductive adhesives may be adequate for some applications, particularly if the mismatched parts are small.

operating temperature, for example, 77 K, and not the thermal coefficient of expansion. Figure 3 shows the relative thermal contraction for several materials, including LAO and MgO, in $\mu\text{m}/\text{cm}$ (i.e., at a given temperature, a 1 cm-long piece of material shrinks so many microns from its length at 300 K). As can be seen, the slope of this curve, that is, the thermal coefficient of expansion, varies greatly with temperature over the range of interest, making it a practically useless parameter for the selection of appropriate materials. Although there are some differences in the rate of contraction as the materials shrink from room temperature, the key parameter is the total contraction at 77 K. For example, Nb and LAO are fairly well matched at 77 K, even though their rate of contraction as a function of temperature is slightly different. This is borne out by extensive experimentation [12]. Other substrate/carrier material pairs have been successfully used as well.

2. MICROWAVE PROPERTIES OF SUPERCONDUCTORS—DYNAMIC RANGE BENEFITS

The key reason for developing a microwave HTS technology is the exploitation of the low loss afforded by HTS compared with conventional metals like gold and copper. High-performance, low-loss devices using conventional materials can generally be made at the expense of high volume, usually in the form of hollow or partially dielectric-filled waveguide components. The potential of HTS is to enable components with the same or better performance in a much reduced volume that must include the cryocooler. Figure 4 shows a comparison between calculated losses in several common types of transmission line, including HTS microstrip on LAO, for the parameters listed in Table 1. For calibration, included in this comparison is Au microstrip at 77 K, also on LAO. For the microstrip cases, only the conductor and dielectric losses were calculated; radiation losses or coupling to spurious surface modes were ignored. Also included are the losses in X-

Figure 4. Calculated attenuation comparison for various transmission-line types including HTS and gold microstrip on 500 mm-thick LAO substrates. The line impedance for each line was $50\ \Omega$. All microstrip substrates were assumed to be $500\ \mu\text{m}$ thick. Notice that X-band waveguide has lower loss than HTS microstrip (for the parameters chosen). However, HTS microstrip has broader bandwidth and the potential for smaller volume because it facilitates the integration of several microwave components.

Band waveguide, which are lower than HTS for the parameters chosen, although HTS microstrip offers the advantage of much wider bandwidth and ready integration of several components into a small volume. Notice that the useful frequency range for X-band waveguide is typically only 8 GHz to 12 GHz. Integration capability combined with low loss are key elements of HTS technology because most systems insertion opportunities will develop for applications offering significant size advantages with respect to conventional approaches.

A different and useful way of getting insight into the advantages of HTS planar circuits is from the point of view of resonant structures, which form the basic building block of passband filters. This can best be discussed in terms of quality factor, Q , which is the ratio between stored and dissipated energy, represented as

$$Q = \frac{\text{Stored energy}}{\text{Dissipated energy}} \quad (1)$$

For empty electromagnetic cavity-type resonators, this is, in essence, a figure-of-merit measuring the degree of compromise between volume (stored energy) and surface area (microwave losses on the conducting surfaces). In general, both stored and dissipated energy depend on the dielectric constant and the geometric configuration used, the dissipated energy also depends on the surface resistance of the (super) conducting surfaces and the losses in the dielectric. In practice, there could be other types of losses such as radiation, which, for simplicity, will be neglected in this discussion. In principle, the performance of any passive device can be projected from the Q of the type of structure used to make up the device. For example, a resonator made up of a section of microstrip line can be calculated from well-known expressions [13]. The insertion loss of a

filter can, in turn, be estimated from the Q of the resonators that make up the filter [14].

Figure 5 is a plot comparing the Q and volume, as a function of frequency, of resonators made up of a microstrip line section and an empty metallic cube, respectively. As the dimensions of the resonator are specified at each frequency, the volume calculated is that of the smallest cube capable of resonating at a given frequency. The microstrip HTS resonator volume was calculated assuming it is in an enclosure with cross section as shown in the

Figure 5. Calculated comparison of quality factor (Q) and volume for two types of resonators: 50 Ω HTS microstrip on 500 μm -thick LAO and a metallic cube. The Q of a gold-on-LAO microstrip at 77 K was also calculated as a reference. The metallic cube is representative of a simple cavity resonator and was chosen because its Q is easy to calculate [15]. The volume for the microstrip was chosen as a device with the cross section shown in the figure with $a/h = 10$, $d/h = 20$, and a length of $(l/2 + 4h)$. This assumed cross section is independent of wavelength and loses its meaning at the higher frequencies plotted, where the substrate would, in practice, be thinner, making the microstrip always smaller than the waveguide.

figure, where the walls and the lid are sufficiently far away from the superconducting strip that their contribution to the loss is negligible. The Q of HTS microstrip, although higher, is within the same order of magnitude as the Q of the cube resonator. However, the estimated volume can be two or more orders of magnitude smaller, especially at the lower microwave frequencies.

Although to first order the main feature distinguishing HTS from conventional planar microwave passive devices is low loss, other important differences exist and are discussed in the following sections.

2.1. Surface Impedance and Penetration Depth

The surface impedance of a conductor is the characteristic impedance seen by a plane-wave incident perpendicularly on a planar (super)conducting surface. For both normal (e.g., copper, gold) conductors and superconductors, the surface impedance is given by [9,15]

$$Z_S = R_S + jX_S = \sqrt{\frac{j\omega\mu}{\sigma}} \quad (2)$$

where ω is the angular frequency, μ is the permeability, and σ is the conductivity, which is real for normal conductors but is complex for superconductors. In both cases, the RF fields decay exponentially inside the material, defining a field penetration depth. In the case of superconductors, however, this parameter—called the London penetration depth—is independent of frequency and is orders of magnitude smaller than the normal conductor penetration depth (usually referred to as the skin depth). The reasons are derived from the perfect diamagnetism of superconductors, the so-called Meissner effect, and are explained by the Gorter–Casimir and London two-fluid model of superconductivity [9,16].

Table 2 summarizes the differences between normal and superconductors from the point of view of their microwave surface impedance. Notice that the surface resistance of superconductors, R_s , has a frequency-squared (f^2) dependence. In contrast, normal conductors depend on the square root of frequency (\sqrt{f}). Figure 6 shows the difference between copper at 300 K and 77 K, and HTS at 77 K. This must be taken into consideration, especially when designing wideband components. The figure also highlights the large difference between copper and HTS at frequencies below 1 GHz.

As with planar microwave devices using normal conductors, best performance control is obtained when the geometric inductance of the circuit dominates the internal inductance of the superconductor. That is, from a practical point of view, the thickness of the superconductor must be at least two to three times larger than the penetration depth at the temperature of operation. The London penetration depth is a strong function of temperature, and for HTS, it is given approximately by [9,16]

$$\lambda_L = \frac{\lambda_L(0)}{\sqrt{1 - \left(\frac{T}{T_c}\right)^4}} \quad (3)$$

Table 2. Microwave Surface Impedance Comparison Between Normal Conductors and Superconductors

Normal Conductors	Superconductors
$\sigma = \text{Real}$	$\sigma = \text{Complex}$
Penetration (skin) depth: $\delta = \sqrt{\frac{1}{\pi f \mu \sigma}}$	Penetration depth: $\lambda_L(T) = \frac{\lambda_L(0)}{\sqrt{1 - \left(\frac{T}{T_C}\right)^2}}$
$R_S = X_S = \frac{1}{\sigma \delta} \propto \sqrt{f}$	$\lambda_L(0) \cong 150 \text{ nm}$ for YBCO $R_S \propto f^2$ $X_S \cong 2\pi f \mu \lambda_L$
Copper at 300 K: $\delta = \frac{2.1}{\sqrt{f}} \mu\text{m}$ $R_S = 8.24 \sqrt{f} \text{ m}\Omega$	YBCO at 77 K: $\lambda_L(77) \cong 0.2 \mu\text{m}$ $R_S = 5f^2 \mu\Omega$
Copper at 77 K: $\delta = \frac{0.9}{\sqrt{f}} \mu\text{m}$ $R_S = 3.4 \sqrt{f} \text{ m}\Omega$	

Note: The frequency f is in GHz in the numerical equations for δ and R_S above.

where $\lambda_L(0)$, the penetration depth at 0 K, is a fundamental parameter of the material, T is the temperature, and T_C is the critical temperature. For YBCO, $\lambda_L(0) \cong 150 \text{ nm}$, which results in $\lambda_L(77 \text{ K}) \cong 214 \text{ nm}$. The HTS film must be at least 500 nm to 600 nm thick for operation at 77 K, in order for the kinetic inductance effects to be negligible with respect to the total inductance of the circuit.

For practical microwave design purposes, this allows treating the superconductor as a normal conductor with a surface resistance that can be obtained from measured values and a frequency-squared scale factor. It has become customary for workers in the field to normalize the surface resistance to 10 GHz and 77 K, although measured data may have been taken at a different frequency. Devices where the kinetic inductance is allowed to dominate have been demonstrated [17]. However, they are lossy, difficult to fabricate, and quite dependent on temperature because

Figure 6. Surface resistance of HTS at 77 K and copper at 77 K and 300 K as a function of frequency. The surface resistance of copper scales with frequency as $f^{1/2}$; for HTS, it scales as f^2 .

of the strong temperature dependence of the penetration depth.

2.2. Nonlinear Effects

A fundamental characterization of the nonlinear behavior and power handling in HTS materials is through the surface impedance and its dependence on the RF magnetic field H_{RF} [18–23].

$$Z_S(H_{RF}) = R_S(H_{RF}) + jX_S(H_{RF}) \quad (4)$$

The essence of the nonlinear dependence of the surface impedance on signal power level or, equivalently, H_{RF} is intuitively grasped by observing the response of a microstrip resonator, shown in Figure 7. As the input power is increased, the resonator Q degrades (R_S dependence on H_{RF}) and the resonance shifts to lower frequencies (X_S dependence on H_{RF}). Several regimes have been identified in the study of nonlinear phenomena in HTS [20]. A linear region at sufficiently low power levels, a weakly nonlinear region where nonlinear behavior is dominated by grain-boundary weak links (Josephson-junction-like defects in the crystalline make-up of the HTS film) and a strongly nonlinear region dominated by hysteretic vortex penetration. Above this regime, breakdown of the superconducting state occurs, with the surface resistance increasing abruptly because of heating and the formation of normal-state domains [20].

If the magnetic field exceeds its critical value, the material becomes a normal conductor and dissipates heat that must be removed by the cryocooler in the system and can even damage the device. The device ceases to operate as a superconducting device and, if no damage has occurred, must recover after the high-power source has been removed. The related topic of intentionally provoking a superconducting-to-normal transition as a switching mechanism has been studied extensively [24–26].

2.3. Dynamic Range Considerations: Noise Figure

An important consideration for any electronic device is its dynamic range, or range of signal power levels over which the device will operate properly. In the case of passive HTS devices, they are expected to be linear over a certain dynamic range, limited below by noise and above by the onset of nonlinear behavior.

Starting at the lower end, the noise generated in a passive device will generally be of a thermal nature. A measure of how much noise any device generates is given by the noise figure [27], which is, by definition, related to the excess noise generated in the device when a matched resistor at 290 K (ambient temperature) is placed at the input. Thus the noise figure would be equal to 1 (or, equivalently, 0 dB) if the device were perfectly noiseless or if it were an ideally lossless passive device. The accepted noise figure definition as a function of device temperature is [27]

$$F_{dB} = 10 \cdot \log \left[1 + (L - 1) \cdot \frac{T}{290} \right] \quad (5)$$

Figure 7. Effects of increasing the input power level on a superconducting microstrip resonator. This measurement (courtesy of Dr. M. Golosovsky, Hebrew University of Jerusalem) captures the essence of the nonlinear RF power dependence of the surface impedance $Z_s = R_s + jX_s$. As power level increases, so does R_s , and the resonance Q decreases. On the other hand, the effect of increased power level on X_s manifests itself on a shift of the resonance toward lower frequencies [20].

Here, L is the insertion loss of the device as a number greater than or equal to 1 (i.e., $10 \log(L) \geq 0$ dB), and T is the temperature in degrees Kelvin. For a passive, lossy device at 290 K, the noise figure turns out to be equal to its insertion loss, a rule that system designers commonly use when dealing with passive components such as filters or lengths of transmission line. HTS devices, however, because they operate at cryogenic temperatures (77 K, typically), will have a lower noise figure, according to the accepted definition [27]. Figure 8 shows this expression graphically as a function of the insertion loss of the device for 77 K and 290 K (ambient temperature). Thus, in considering the dynamic range of HTS devices, the lower end of the range will tend to be lower than for conventional devices, not only because of their inherent low loss, but also because they operate at cryogenic temperatures. Measurements reported in the literature [28] confirm, to first order at least, that the noise in HTS passive devices is indeed thermal in nature.

Figure 8. Noise figure of a cryogenically cooled passive device as a function of insertion loss. Notice that the noise figure equals the loss at 290 K (by definition), but it is lower for devices operating at a lower temperature.

2.4. Dynamic Range Consideration: Nonlinearity and Power Handling

The upper limit of the dynamic range of HTS passive devices is limited by nonlinearities in the superconductor. This is in contrast to conventional technology, for which this upper limit could be orders of magnitude higher, generally limited by such phenomena as the voltage breakdown of air or the dielectric used, or melting of the metallic pattern because of high currents. HTS, on the other hand, is fundamentally limited by the dependence of its surface impedance on the magnetic field shown in Eq. (4). In a linear media, there is no dependence between surface impedance and magnetic field, so Eq. (4) implies that the fields at the surface of the HTS film will have distortions with respect to the ones in a linear material.

Of particular importance is the intermodulation distortion (IMD), whose most distinctive feature is the generation of third-order mixing products at frequencies $2f_1 - f_2$ and $2f_2 - f_1$ when a device is driven by two harmonic signals at f_1 and f_2 . The upper end of the dynamic range is then reached when the power level of the applied signals is such that the third-order products rise above the noise floor and can be mistaken and processed by the system as real signals.

Nonlinear effects are exacerbated in HTS devices where the microwave fields are nonuniformly distributed. For example, an HTS microstrip line has much higher current density (and magnetic field) near the edges of the line than along the center. Thus, as the signal power level is increased, the current density at the line edges will generate nonlinearities and increased losses, degrading the performance of the device. As a result, the linearity condition, which may be a relatively minor issue with conventional filter technology, is, in contrast, very key in HTS filter technology.

A system dynamic range can, in turn, be determined from that of its components. An important example is that

of a microwave receiver front-end, usually consisting of a low-noise amplifier (LNA) placed after the antenna, which is then followed by one or more downconversion stages. The dynamic range of the receiver is greatly determined by the noise figure, gain, and IMD of the LNA, with the components that follow having much less influence. Many applications demand a preselector filter between the antenna and the LNA to reject strong interfering signals that could generate unwanted mixing products because of the nonlinearity of the LNA [28]. The preselector filter must not significantly degrade the receiver dynamic range, and so it must have low insertion loss (i.e., low noise figure) and an IMD sufficiently lower than the LNA's with respect to both in-band signals and the rejected out-of-band interfering signals. This is an important example because HTS filter technology is a strong candidate for this type of preselector in some applications like wireless communications base-station receivers [29].

Nonlinear properties of HTS bandpass filters are strongly dependent on frequency. This is because of the frequency dependence of current and field amplitudes on the resonators that form the filter, which, on some of the resonators, have sharp peaks at the frequencies close to the edge of the passband [30]. As a result, the nonlinear properties of HTS filters are normally set by these resonators, and the frequencies close to the edge of the passband are typically the ones where IMD and other nonlinear effects are more prominent (see Figure 9). This is an important consideration in HTS preselector filters, which may be subject to strong out-of-band interfering signals.

Although IMD is normally tested with two tones to check for the generation of mixing products, the signals applied to HTS filters are often not sinusoidal, and it may be difficult to predict the nonlinear effects from the

Figure 10. Simulated WCDMA spectrum before (black) and after (grey) an HTS filter showing the effect of the nonlinearities in the regrowth of the spectrum outside the passband.

two-tone characterization. This happens, for example, when HTS filters are driven with spread-spectrum signals, like those used in CDMA- or WCDMA-based communication systems. The IMD in this case causes a broadening of the band-limited spectrum, which may mask the signals in adjacent channels (see Figure 10). Prediction of this type of effects requires using nonlinear numerical techniques [31].

3. HIGH-TEMPERATURE SUPERCONDUCTING FILTERS

One of the most important applications of HTS microwave technology are high-performance passband filters because they can be made in planar configurations. Filters are often the dominant contributor to system volume, in particular when banks of low-loss filters are required. As discussed earlier, high-Q structures can be obtained at the expense of high volume. HTS planar configurations like microstrip or coplanar waveguide have Q comparable with cavities at a much smaller volume (see Figure 5), and so HTS is an attractive approach to reducing the volume of high-performance filters.

3.1. Insertion Loss and Q

A straightforward way of thinking of bandpass filters is as coupled resonators. The performance of a resonator is characterized by its quality factor Q , defined in Eq. (1). When the resonator forms part of an electrical circuit, the circuit delivers and takes back energy from the resonator, affecting its characteristics. The unloaded Q of a resonator, Q_u , is its intrinsic quality factor, without the effects of an external circuit. A first-order filter consists of a single resonator. Its bandwidth can be adjusted by the degree of coupling into the resonator by the external circuit. In a lightly coupled resonator, little disturbance is introduced by the input and output circuits, and its resonant conditions and bandwidth are close to those of an ideal, unloaded resonator. When coupling into the resonator is strong, the disturbance is large and the Q is now dominated by

Figure 9. Frequency response and intermodulation distortion in a 8-pole quasielliptic planar HTS filter subject to two tones spaced by 100 KHz. The power of the fundamental signals (upper trace) follows the transfer response of the filter, whereas the intermodulation products (lower trace) peak at the edges of the passband. The figure also compares measurements (dots) with simulations (lines) made with nonlinear numerical techniques [31].

both the resonator and the external circuit, making the total or loaded Q lower than the ideal, unloaded Q, and therefore the filter bandwidth is now wider. For a higher order filter made up of various resonators coupled together, the idea is the same. Narrow-band filters require that the resonators be loosely coupled to each other, and the minimum bandwidth is limited by the unloaded Q of the resonators. Wider bandwidth filters will have tighter coupling among resonators. Clearly, then, narrow-band filters are a desirable application for HTS because its inherent high Q enables narrow bandpass filters with low loss and small volume. This was illustrated in Fig. 5, which helps to convey the significance of the loss-volume tradeoff from the point of view of using HTS and metallic cavity resonators to make filters. There is also a tradeoff between bandwidth, filter order (number of resonators), and insertion loss. The following is an approximate expression for the mid-band insertion loss of a filter [14], in dB, which reflects this tradeoff in Chebychev filters as

$$L_{dB,n} \cong \frac{4.34}{B} \cdot \sum_{k=1}^n \frac{g_k}{Q_{uk}} \quad (6)$$

Here, n is the filter order, g_k is the normalized series inductance and shunt capacitance values of the low-pass prototype filter [14], B is the filter bandwidth as a fraction of the center frequency, and Q_{uk} is the unloaded Q of the k th resonator. For the purposes of estimation, it is reasonable to assume that all the resonators in the filter will have the same Q_u . Figure 11 illustrates the tradeoff between insertion loss, bandwidth, and filter order as a function of resonator Q. It shows how Eq. (6) can be used to estimate the potential of a certain filter technology, in this

Figure 11. Estimated insertion loss of fourth- and fifth-order Chebychev passband filters of 1% and 0.1% fractional bandwidths as a function of the unloaded Q of the resonators that make up the filter. It was assumed that all the resonators have the same Q. The chart shows the increase in insertion loss caused by increasing the filter order by one and reducing the fractional bandwidth by a factor of ten.

case HTS, and understand its limitations. The insertion loss was estimated for Chebychev-type filters [14] of the fourth and fifth orders, respectively, and for 1% and 0.1% fractional bandwidths. The purpose of this chart is to point out the difference in loss caused by increasing the filter order by one and by increasing the fractional bandwidth by a factor of ten. Figure 11 complements Fig. 5 by helping to make a connection between the insertion loss of a filter of a given order and bandwidth and a specific structure and its volume. The information provided by these two figures can readily be extended to cover other structures and technologies.

3.2. Selectivity and Q—Types of HTS Filter Designs

Besides having an effect on the insertion loss, the quality factor of the resonators that form a filter also affect the steepness of the frequency response at edges of the passband. Steep filter skirts demand high Q_u in the resonators and make possible a sharp transition between the stopband (where an insertion loss L_s is guaranteed) and the passband (where a return loss L_r is guaranteed). The width of this transmission band δf is limited by the Q_u of the resonators in the filter. For the particular case where $L_s = L_r = -23\text{ dB}$ and a maximum of 20% of the incident power is allowed to be dissipated in the filter (i.e., maximum insertion loss caused by dissipation is about 1 dB), the minimum width of the transition band δf is given by [30]

$$\delta f \leq 8\pi\beta_0 \frac{f_0}{Q_u} \quad (7)$$

where f_0 is the center frequency of the filter and $\beta_0 \approx 0.75$ for Chebychev filters and 0.25 for elliptic filters [30].

From Equation (7), it is clear that the width of the transition band also depends on the type of filter design through the coefficient β_0 , with Chebychev filters providing wider transition bands than elliptic filters.

Most modern HTS filters use couplings between non-adjacent resonators to produce elliptic or quasielliptic responses having transmission zeros close to the edge of the passband. This type of coupling is not used in Chebychev filters, which do not have transmission zeros in their frequency response. Elliptic filters, on the other hand, need the highest number of nonadjacent interresonator couplings, but require fewer resonators than Chebychev filters for a given ratio between the bandwidth and the width of the transmission region. For example [30], a filter with a center frequency of 2 GHz, 20 MHz bandwidth, 400 KHz transition width, requiring a 20 dB return loss in the passband, and 85 dB of insertion loss in the stopband, would need 48 resonators in a Chebychev design and 15 in an elliptic design. The elliptic design would have 14 transmission zeros in the stopband.

Chebychev and elliptic designs represent extreme cases of filter design, where either full advantage is taken from nonadjacent interresonator couplings (elliptic filters), or this type of coupling is not used at all (Chebychev). There is a wide range of intermediate designs (quasielliptic filters) depending on how many interresonator couplings are used and how many transmission zeros are synthesized.

Many HTS filters use at least a single pair of transmission zeros at the edge of the passband.

3.3. Planar Resonator Designs

There are four main features that HTS filter designers seek in a planar resonator:

1. Miniaturization
2. Low interresonator coupling vs. distance
3. High power handling
4. High Q

Obviously, a single resonator design will not optimize all these four features. Rather, a certain resonator shape represents a compromise between several of them. For example, miniaturized resonators tend to have large current densities, and this tends to degrade their quality factor and power handling. In the paragraphs below, we will discuss each of these features and give some examples of representative HTS resonator designs.

Miniaturization of the size of the planar resonators has been a trend in HTS filter design since shortly after its beginning. The high Q of HTS resonators allows the design of filters with many resonators without significant degradation of the insertion loss. This, together with substrate cost and the limitations in the substrate size, has motivated filter designers to try to fit as many resonators as possible on a given substrate area. Early HTS filters were made with straight microstrip transmission line resonators, and the need for miniaturization has motivated the use of other types of resonators that use less real state. One possibility is the use of quasilumped elements as in Figure 12. Other possibilities include several ways of folding the transmission line in forms of loops, hairpins, spirals, or even fractal shapes. Some of these geometries will be discussed below.

Miniaturization of the space that the resonators take is not the only requisite to have small HTS planar filters. One also needs to have resonators that can be placed close to each other while keeping a low degree of coupling among them. Low coupling is necessary to make narrow-band filters, and traditional layouts need high interresonator spacings to achieve this. To avoid the use of large

Figure 12. Example of a quasilumped resonator having an inductor and an interdigital capacitor (US patent 6,438,394). Courtesy of Superconductor Technologies Inc.

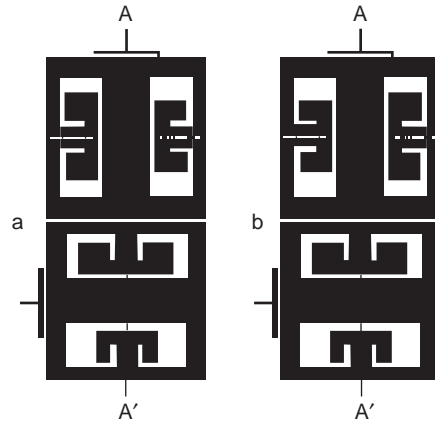

Figure 13. Example of resonators with low interresonator coupling. In this design, perfectly symmetrical resonators would be uncoupled. The degree of coupling is set by small disturbances in the resonators that break the symmetry [37] © 1999 IEEE.

areas of substrate, some resonators are designed to have low interresonator coupling, and make it little sensitive with interresonator spacing. An example of such type of resonators is shown in Figure 13.

Resonators with high Q and high power handling have a common requirement: low current densities in the HTS. As explained earlier, current crowding along the edges of typical planar transmission lines (e.g., microstrip, stripline, and coplanar waveguide) ultimately limits the maximum power level that can be handled. Improved filter designs are based on planar structures that avoid the effects of significant current crowding at the edges, as is the case of low-impedance microstrip lines [32].

Another approach involves the use of resonators with parallel segments of microstrip transmission lines having symmetrical currents, so the fields between transmission line segments tend to cancel (see inset in Figure 14). This reduces the current-crowding effects at the adjacent edges of the transmission line segments. The resonator layout is then based on folding a line in several segments, and having the segment with the strongest current density surrounded by adjacent segments with symmetrical currents. This is achieved at the even resonances of the spiral-in spiral-out resonators of Figure 14 [33].

Another significant type of HTS resonators with high power handling are the structures based on the circular TM_{010} mode [34–36]. The most salient features of this approach are shown in Figures 15(a) and (b), which show the electromagnetic fields and current profile in a microstrip and a disk resonator, respectively. In the latter, the RF magnetic fields do not close above the substrate but within it, under the disk. Thus the current density does not peak at the edges of the resonator and its distribution is more uniform. The only possible drawback of this approach is that the fields are more confined to the disk resonator, and intercoupling between resonators to form a filter may be more difficult, perhaps requiring three-dimensional structures for proper control of the coupling. This would eliminate some of the planar integration advantages. Fully planar filters using this concept, however, have been successfully demonstrated [34].

Figure 14. Layout of a spiral-in spiral-out resonator. Symmetrical currents in the various segments of the transmission line (and particularly on those with strongest currents at resonance) reduce current crowding effects, enhancing the quality factor and the power handling of the resonator [33]. Inset: detail on how symmetric currents reduce the fields between the strips. Similarly, antisymmetric currents would enhance the fields in the region between strips and increase the current densities at the adjacent edges of the strips. Courtesy of Superconductor Technologies Inc.

Obtaining high Q planar HTS resonators involves using HTS materials with low surface resistance and keeping current densities low. Both of these aspects have been discussed previously. A third requirement to obtain high Q in these resonators is to avoid package losses. These losses are usually because of the currents on the metallic walls of the package induced by the currents in the resonator. To prevent them, it is important to avoid resonator shapes that, at resonance, would launch propagating modes that would propagate in the direction perpendicular to the substrate, and generate high currents on the metal lid [37].

3.4. Examples: Filters for Base Stations of Wireless Communication Systems

There are many examples of planar filters that can be found in the literature and on the world wide web [38,39]. As an example of the performance achievable with this technology, Figure 16 shows the response of a 17-pole filter made by Cryoelectra GmbH, and Figure 17 shows a front end including several filters and low-noise amplifiers for base stations of third-generation wireless communication systems.

Example 1. Four-Channel Passband Multiplexer. Figure 18 shows a diagram of a multiplexer architecture [12,40]. It can accommodate as many channels as the bandwidth of the 90° hybrid coupler covers. Input microwave energy is equally split at the first coupler. If the frequency is within the passband of the two identical filters connected to the coupler, it passes through the filters and adds in-phase at the output port of the output hybrid coupler for Channel 1. If the frequency is not within the passband of the Channel 1 filters, the signal is reflected back to the input coupler where it recombines such that it is out-of-phase at the input port and in-phase at the input of the second channel hybrid coupler. The process then repeats itself until the signal exits the device through the appropriate channel port. Figure 19 presents details of one implementation of this device [12,41] showing one input, four outputs, and a through port terminated in an external (coaxial) load. Additional channels could be connected to this port provided they are still within the bandwidth (about 10%) of the hybrid coupler used in this demonstration. Figure 19 also shows a detail of the assembly, which includes the internal HTS interconnections between filters and the integrated thin film resistive terminations at the out-of-phase port of the output hybrid in each channel.

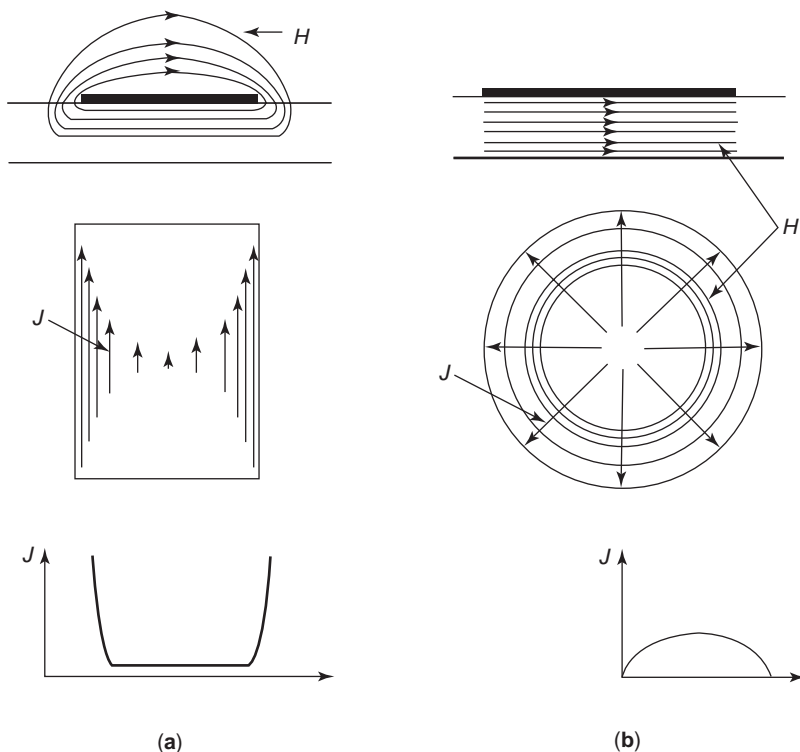

Figure 15. Diagram (courtesy of Dr. Z-Y Shen, E.I. du Pont de Nemours and Co.) [34], showing the magnetic field and current distribution in a $\lambda/2$ microstrip resonator (a) and a TM_{010} printed disk resonator (b). In the disk, the magnetic field lines are circular and remain on the plane of the disk, so the current is not highly nonuniform, as is the case of the rectangular microstrip resonator. The advantage of the disk is that it can handle much higher power levels [34–36].

Figure 16. Frequency response of a 17-pole elliptic filter for UMTS applications [50].

The HTS material used for this work was YBCO thin film deposited on 500 μm -thick LAO substrates. The package included an Aluminum frame holding the external coaxial connectors and niobium carriers onto which the LAO substrate pieces were mounted. Niobium has a good thermal expansion match to LAO, so the electrical and mechanical integrity of the device was preserved when cycling from ambient temperature to near 77 K. The substrate-carrier assemblies were mounted on the Aluminum frame using a beryllium-copper spring arrangement. Figure 20 shows the measured performance. The

low-frequency skirts of Channels 2, 3, and 4 show some level of interaction between channels that can be eliminated using a wider guardband between channels. Refs. 12 and 41 include a full discussion of the design, fabrication, and measurements on this device.

This unit was one of a series of demonstration devices delivered to the U.S. Navy's High-Temperature Superconductivity Experiment II program by several contractors for inclusion into the space package [42].

Figure 17. Picture of a front end with six highly selective HTS filters and LNAs (three on each side of the ring) developed within the ACTS project SUCOMS.

Figure 18. Multiplexer architecture used to demonstrate a four-channel HTS microstrip device. This configuration has the advantage of allowing as many channels as the bandwidth covered by the 90° hybrid. Each filter is terminated in $50\ \Omega$ and is essentially isolated from the others. Other schemes require that the impedance terminations in each filter be adjusted to account for the presence of all the filters in the multiplexer, practically limiting the maximum number of filters to ten or twelve.

Figure 19. Photo montage of a four-channel YBCO-on-LAO microstrip multiplexer demonstrated under the U.S. Navy's High Temperature Superconductivity Space Experiment II (HTSSE-II). Details of the design, fabrication, and assembly of this device can be found in Refs. 12 and 41.

4. HIGH-TEMPERATURE SUPERCONDUCTING DELAY LINES

Work on superconducting delay lines started at Lincoln Laboratory well before the advent of high-temperature superconductivity, and concentrated mostly on linearly dispersive delay lines for analog signal processing. Linearly dispersive delay lines have delay characteristics that vary linearly with frequency over a certain operating bandwidth and can be used to perform pulse compression, a technique to process and detect small signals that may be below the receiver noise floor [1]. The pioneering work at Lincoln Laboratory in this area using LTS and, more recently, HTS thin film technologies has been extensively documented in the literature [1,43].

Nondispersive delay lines have a constant delay-versus-frequency characteristic and are typically used as

analog memory elements that can store a signal for, say, up to a few hundred nanoseconds while the system is engaged in other processing steps. Work on HTS nondispersive delay lines has also been significant [44–47], including two instantaneous frequency measurement subsystems based on banks of delay lines [44–47]. Clearly, the advantages of superconductivity are that a long length of line can be fabricated in a small volume by defining a long, planar transmission line on a wafer. Reference [46] compares conventional nondispersive delay lines, which require amplifiers between sections of transmission line (e.g., coaxial), with HTS delay lines using projections based on measurements made on relatively short (22 ns) delay lines. Key delay-line parameters are delay, bandwidth, insertion loss, and third-order intercept point. Conventional delay lines that must resort to amplification to boost the signal are limited in dynamic range by the amplifiers.

Figure 20. Measured response of the four-channel HTS multiplexer. Further details can be found in Refs. 12 and 41.

5. CRYOCOOLERS AND CRYOGENIC PACKAGING

Key to the insertion of superconducting microwave circuits into electronic systems is the integration of the HTS components with a cryogenic refrigerator and its associated control electronics. Clearly, for HTS technology to be ultimately successful, the user must be rendered able to ignore the fact that cryogenics are used at all, by providing long-lifetime cryocoolers and optimally small cryogenic packages with standard envelop characteristics and interfaces (e.g., 19 inch rack mounts and backplane blind-mate connectors).

Many important considerations enter into the design of a cryogenic package suitable for a microwave HTS subsystem. Figure 21 is a schematic representation of this package, showing its main elements and the various heat inputs that must be considered for an appropriate thermal

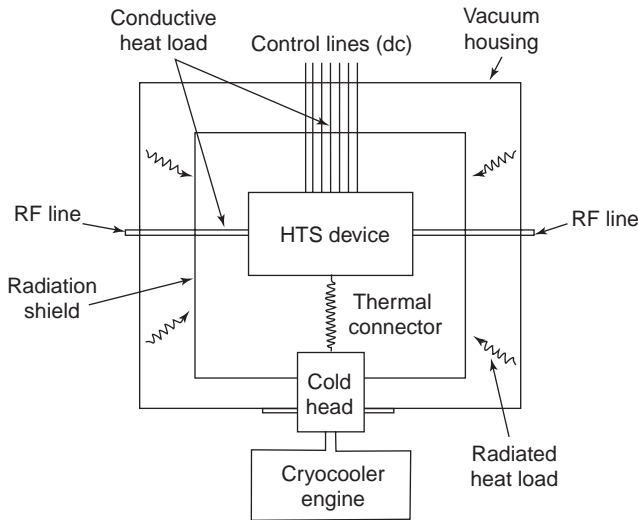

Figure 21. Schematic diagram of the cryogenic package for a hypothetical HTS device showing conducted heat inputs through input/output RF and control lines and the mechanical support of the cold head, as well as the radiated heat input from the (warm) wall of the vacuum housing. The purpose of this diagram is to show the main elements that affect the design of the cryogenic package.

design. References 48,49 provide specific details on the cryogenic aspects of a communications filter subsystem, including packaging.

Cryogenic receiver front ends, including HTS filters, have pushed the development of cryocoolers. The use of

Table 3. Sample Requirements That Will Affect the Choice of Cooler and Cryogenic Packaging Approach

Requirement	Comments
Size and weight	Stringent in almost all applications
Cool-down time	Some applications may require very fast turn-on time (e.g., a few minutes). They would be a driver toward higher cooler power and lower HTS device thermal mass
Vibration	For example, a minute amount of mechanical distortion on a circuit caused by vibration from the cooler may generate a phase modulation that degrades the circuit performance
Power consumption and power supply type	E.g., 120 Vac
Mode of operation	E.g., continuous, intermittent, short missions and then mostly idle, etc.
Temperature stability and control	While any fine temperature feedback control loop ($< \pm 0.01$ K) tends to be done using heater and a temperature sensor, some applications may require a certain degree of cooling engine control ($< \pm 0.5$ K)
Unattended lifetime	Some applications (e.g., space) may require a lifetime on the order of 10 years or more
Vacuum lifetime	All-welded construction; use of getters in a clean, well-conditioned (baked) system

these front ends in communications ground stations at remote locations operating unattended for a long time requires cryocoolers with high reliability and low power consumption. Nowadays, most cryocoolers deployed in base stations of wireless communication systems use the Stirling-cycle [48]. However, when HTS was discovered, the applications of this type of cryocooler were mostly limited to airborne military applications requiring the use of a small cooler, and communications ground stations required a larger, more reliable refrigerator using the Gifford–McMahon cycle.

The choice of a cryocooler will depend on the system and the cooling requirements imposed by the component or subsystem to be cooled, which determines the amount of cooling power required at the operating temperature. Typical sample system and cooling requirements and some comments as to their significance are given in Tables 3 and 4, respectively.

Table 4. Cooling Requirements That Will Influence the Cooling Power (Heat Lift) Required for a Given Application

Requirement	Comments
Power dissipated in the device	A filter with a 0.5 dB insertion loss that must pass a 20 W signal will dissipate 2 W of heat that must be removed by the cryocooler. Also, semiconductor devices such as low-noise amplifiers, which improve in noise and gain performance when cooled, always dissipate a certain amount of heat which must be taken into consideration
Number of microwave and dc control leads	These are the electrical interface between the cryocooled device and the outside world. For example, a filter might require two microwave leads (input and output) and two pairs of dc control lines for the heat sensor and a small heater to keep the temperature constant. These conductors represent a heat loss that the cooler must overcome because they connect the outside ambient temperature with the cold device. While the dc control lines are typically made of thin low-thermal-conductivity, high-resistivity wire (e.g., gauge 32 manganin), the microwave leads must achieve a compromise between insertion and thermal loss
Surface area	Radiation loss is another form of heat loss that the cooler must overcome and therefore must be minimized. The total surface area and their infrared radiation emissivity are important design parameters. Low emissivity radiation shields are typically used between the warm vacuum vessel wall and the cold device
Thermal mass	For those applications that have a cool-down time requirement, the thermal mass of the device to be cooled is important and will be affected by the microwave packaging material and its shape

Table 5. Some Cryogenic Refrigerator Types Suitable for HTS Technology

Cooler Type	Heat-Lift Range Available at 80 K	Comments
Split Stirling	0.5–3 W	Available from many manufacturers, used primarily in the tactical military infrared industry. Has a cold head Separated from a compressor by a metallic transfer line up to 15 cm long
Integral Stirling	0.5–5 W	Also used in infrared detectors. Several versions are being used in HTS front-ends for wireless communications base stations. The compressor and cold finger are integrated in a single unit.
Gifford–McMahon	2–>200 W	Widely used in the support of vacuum systems for semiconductor industry; highly reliable and versatile. The compressor and cold head are separate units connected by fluid lines that can be several meters long
Throttle-cycle	~ 4 W	Reliable and low cost. The compressor and cold heat are separate units connected by fluid lines that can be several meters long
Jule–Thomson	0.5–2 W	Generally used as an open-cycle cooling system for short tactical missile IR detector applications
Pulse tube	0.5–2 W	Emerging technology. It avoids moving parts on the cold part of the cooler, avoiding vibrations and increasing reliability. It has been used in a number of prototypes of HTS front-ends for wireless communications base stations

Cryocoolers suitable for microwave HTS technology will typically have from 3 W to 10 W of cooling capacity [49]. A primary concern systems designers have is the reliability of cryogenic refrigerators, which varies greatly depending on their type and size. Leveraging developments in other fields, such as infrared detectors, the reliability of small, military tactical cryocoolers has steadily increased in recent years, with some manufacturers claiming up to 40,000 h of mean-time to failure (MTTF). On the other hand, larger laboratory or industrial units and specialized coolers for aerospace applications operate for 5 years to 10 years and require minimal servicing. Table 5 lists some of the cryocooler types of interest. The intent here is not to be all-inclusive but to provide a basic reference to the type of coolers most likely to be employed in HTS microwave technology. Reference [49] is a good source of the latest developments in cryocooler technology. Figure 22 is a photograph of a commercial HTS filter

subsystem, showing the cryocooler and associated electronics in their open package.

6. CONCLUSION

High-temperature superconductor microwave technology offers unique advantages derived from the low microwave loss of HTS materials and the inherent low thermal noise in cryogenically cooled components. The main applications to date are related to increased microwave receiver sensitivity, and this is most likely to have an impact on wireless military and commercial communications systems. The reason is that receiver sensitivity and dynamic range must be preserved in the presence of a large number of spurious signals that, if unfiltered, degrade receiver performance. Generation of clean transmitted signals requires filtering in the transmitter, which, coupled with

Figure 22. Photograph of an HTS filter assembly for commercial wireless applications (courtesy of Superconductor Technologies, Inc.).

the need to reject unwanted high-power signals at the receiver, has spurred work on high power handling in HTS filters. Interest in the United States and abroad exists in the wireless commercial communications market, and several companies are testing and deploying base station receiver front ends consisting of cryogenically cooled filter-LNA subassemblies.

HTS microwave filters are therefore a promising technology, especially at frequencies below 3 GHz where the loss in conventional microwave materials force high-performance filters to be very large in order to achieve the required low insertion losses and selectivity. Leveraging developments in infrared imaging detector technology and perhaps new developments of cooled semiconductor components for fast computer workstations, cryocooler technology is progressing to the point where long lifetimes and small-size, low-weight coolers are now widely available.

SUPERCONDUCTING MICROWAVE TECHNOLOGY

DURGA P. CHOUDHURY
S. SRIDHAR
Northeastern University

Superconductivity is a remarkable state of matter in which electric current can flow inside materials without any detectable resistance. This phenomenon was discovered by the Dutch physicist H. K. Onnes in 1911. While studying the temperature dependence of the electric resistance of mercury in his newly invented helium liquefier, Onnes found that below a temperature of about 4 K, the resistance abruptly fell to below measurable limits.

In a superconductor, perfect electric conductivity or zero resistivity occurs only below a “critical temperature” T_C . This happens because the electric current, instead of being carried by single electrons, is carried by pairs of electrons called Cooper pairs, which have the ability to conserve energy because of quantum mechanical reasons. A direct current induced in a superconducting ring has been shown to persist for over 2 years without any measurable decay. From this type of experiment, the upper limit on resistivity ρ is $\sim 10^{-25} \Omega \cdot \text{m}$. As ρ for copper is $\sim 10^{-8} \Omega \cdot \text{m}$, a factor of 10^{17} larger, it is believed that the electric resistance of a superconductor is truly zero.

Another important characteristic of superconductors was the discovery by W. Meissner and R. Ochsenfeld in 1933 that a superconductor expels all magnetic flux from its interior; that is, a superconductor is also a perfect diamagnet. This phenomenon is known as the Meissner effect.

A key area of technological applications of superconductors is in high-frequency devices, particularly at frequencies in the radiowave, microwave, and millimeter-wave spectral ranges. Broadly speaking, two principal areas of high-frequency applications can be identified:

- *Passive devices*, typically using resonant and transmission line structures, exploiting the low-loss properties of superconductors.
- *Active elements*, such as oscillators, mixers, logic elements, and other similar devices, which exploit a macroscopic quantum coherence property of the charge carriers, called the Josephson effect.

The price to pay to achieve the superior performance is the need to cool the superconducting device to temperatures well below room temperature. This means the use of cryogenic fluids like liquid nitrogen or liquid helium, or a mechanical cryocooler. Despite the need for a cryogenic environment, there are many applications where the superior performance of superconductors prevails over conventional devices.

1. SUPERCONDUCTING MATERIALS

Superconductivity has been observed in diverse types of materials including pure metals, alloys, semimetals,

organic materials, semiconductors, polymers, and even elemental insulators. Presently, at least 26 of the naturally occurring elements are known to be superconducting at sufficiently low temperatures at ambient pressure, and the number of alloys and intermetallic compounds are well above 1000.

A significant advancement in understanding superconductivity was the theory of Bardeen, Cooper, and Schrieffer in 1957. This theory successfully described the microscopic mechanism of superconductivity and explained the properties of most superconductors for nearly 30 years.

Then came the era of high-temperature superconductivity, with the groundbreaking discovery by Bednorz and Müller in 1986 of superconductivity in a Ba—La—Cu—O compound with T_C around 30 K, which subsequently earned them a Nobel Prize. This discovery rekindled the interest in superconductivity and spurred the hopes of finding new technological applications. The efforts led to the discovery of other copperoxide-based superconductors that have critical temperatures well in excess of the boiling point of nitrogen (77 K), an easily available and cheap cryogenic fluid usable for commercial applications. Presently the highest critical temperature is about 150 K at high pressures in $\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_8$.

Superconductors fall in two broad categories, namely, “high critical temperature” (or “high- T_C ”) and “low critical temperature” (or “low- T_C ”) materials. (There are many other ways of classifying them, such as Type I and Type II superconductors, heavy fermion, and conventional superconductors.) Some examples of low- T_C superconductors, particularly relevant to commercial applications, are niobium and its alloys, such as NbN and Nb_3Ge . These have critical temperatures in the region of 10 K to 20 K. The high- T_C superconductors that are most commonly used include $\text{YBa}_2\text{Cu}_3\text{O}_7$ (commonly referred to as YBCO or Y-123, $T_C \sim 93$ K), $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8$ (commonly referred to as BSCCO or Bi-2212, $T_C \sim 90$ K), and $\text{Tl}_2\text{Ba}_2\text{Ca}_2\text{Cu}_3\text{O}_{10}$ (TBCCO or Tl-2223, $T_C \sim 125$ K).

Besides the critical temperature, some other relevant physical parameters that characterize a superconductor are as follows:

- *The London penetration depth* (λ_L): The depth to which an applied direct current (dc) magnetic field is confined because of the Meissner effect.

- *The coherence length* (ξ): The length scale over which the two electrons forming the Cooper pairs are separated.
- *The (thermodynamic) critical field* (H_C): The magnetic field whose associated free energy is equal to the free energy change in the superconducting transition. A “Type I” superconductor will completely expel the applied field below H_C and will become normal abruptly as the applied field exceeds this magnitude, assuming no demagnetization effects. For “Type II” superconductors (which includes practically all of the superconductors of technological interest), the field starts to penetrate in the form of vortices at a “lower critical field” H_{C1} ($< H_C$), but superconductivity is not quenched until the applied field exceeds the “upper critical field” H_{C2} ($> H_C$).

Some superconductors of relevance to microwave applications are described in Table 1 along with their relevant properties (λ_L , ξ , H_{C1} , and H_{C2} quoted are extrapolated to $T = 0$ K).

1.1. Substrates for Thin-Film Superconductors

For most electronic applications, including microwave devices, superconductors are necessarily used in the form of thin films. This requires the use of a foreign material for a substrate. Some of the popular substrates include sapphire ($\alpha\text{-Al}_2\text{O}_3$), lanthanum aluminate (LaAlO_3), and magnesium oxide (MgO). Ferroelectric substrates like strontium titanate (SrTiO_3) and $\text{KTa}_{1-x}\text{Nb}_x\text{O}_3$ are also used to achieve tunability at the expense of additional dielectric loss.

The electrical parameters that characterize the properties of a substrate material are its dielectric constant ϵ and its loss tangent $\tan \delta$. (The loss tangent of a substrate is defined as $\tan \delta = \sigma/\omega\epsilon$, where σ is the conductivity.) Other factors such as environmental stability, mechanical strength, chemical inertness, and absence of magnetic moment are also important. Close lattice match between the deposited film and the substrate is essential to achieve good epitaxial growth. These parameters have been measured and investigated by various researchers using different techniques for most substrate materials.

In general, the dielectric constant would be more or less frequency independent unless the frequency is close to a

Table 1. Some Commercially Used Superconducting Materials and Their Physical Properties

Material	T_C (K)	λ_L (nm)	ξ (nm)	H_{C1} (Oe)	H_{C2} (Oe)	Crystal Structure
Pb	7.2	37	83.00	803	803	Face-centered cubic
Nb	9.2	32	39.00	~ 1600	~ 3200	Body-centered cubic
NbN	16.0	50	4.00	300		BI

BSCCO ^b	~ 90.0	500	0.16			Tetragonal

^aAt 4.2 K.

^bYBCO, TBCCO, BSCCO, and most other high- T_C superconductors are highly anisotropic. The values given are for microwave current flowing in the ab -plane, which is often the plane of epitaxial growth and the desired geometry in most technological applications.

^cAverage of ab -plane and c -axis value.

Table 2. Some Commonly Used Substrate Materials for Superconducting Thin-Film Devices

Material	Dielectric Constant	Loss Tangent	Crystal Structure	Growth Surface	Remarks
LaAlO ₃	25.00	5×10^{-6}	Rhombohedral	(110)	Usually twinned
YAlO ₃	16.00	10^{-5}	Orthorhombic	(110)	
MgO	9.65	6.2×10^{-6}	Cubic	(100)	Good lattice match
Sapphire	8.60	3.8×10^{-8}	Hexagonal	(11 02)	Very low loss
NdGaO ₃	23.00	3.2×10^{-4}	Orthorhombic	(110)	Good for multilayer circuits
SrTiO ₃	300.00	3×10^{-4}	Cubic	(100)	Good for tunable device applications
YSZ	27.00	7.4×10^{-4}	Cubic	(100)	

resonance frequency of the material. The dielectric constant is also expected to have a weak temperature dependence for nonferroelectric substances. The loss tangent is expected to increase with temperature. Table 2 provides the most commonly accepted values of these material parameters for some of the substrates, measured at 10 GHz and 77 K unless otherwise stated.

Most of these materials have high ϵ ; this imposes certain restrictions, especially for high-frequency applications. A high ϵ reduces the dimension of the device and thus imposes stringent dimensional tolerance, especially in the millimeter-wave region. But consideration of dielectric constant has to be sacrificed for some even more important parameters, namely, a lattice match between the substrate and the film, and not widely different thermal expansivity from the superconductor. A lattice mismatch would create atomic level strain and leads to poor superconducting properties. Another criterion is that losses in the substrate must be negligible compared with the losses in the superconductor. Heavy twinning in materials like LaAlO₃ creates problems in multilayer films. When the substrate is reheated for the deposition of a new layer, the thermally induced movement of the twin boundaries strain the previously deposited layers.

There are numerous methods of depositing superconducting films on substrates, the most common being pulsed laser deposition (PLD), coevaporation, and off-axis sputtering or physical vapor deposition (PVD). Each of these methods has its pros and cons. For example, PLD produces high-quality films at a fast rate (a few angstroms per second) but only over relatively small areas, typically less than 2 in. diameter. The PVD method is useful for producing larger area films, but the deposition rate is only a fraction of an angstrom per second. Another method of film deposition, namely, metal-organic chemical vapor deposition (MOCVD), popular in the semiconductor industry, has also been tried for high- T_C superconductors, although somewhat less successfully owing to the chemical and structural complexity of the high- T_C materials. We refer the reader interested in deposition technique to some useful resources (see, for example, Ref. 1).

The “quality” of a deposited superconducting film is characterized by several parameters, such as the critical temperature T_C , the transition width ΔT_C , and the critical current density J_C , which is the maximum lossless current per unit cross-sectional area that the film can carry. The higher the T_C and J_C and the lower the ΔT_C , the better the film.

2. THE SUPERCONDUCTOR–MICROWAVE INTERACTION

A superconductor has zero electrical resistance only at zero frequency (dc). At any finite frequency, it exhibits losses that increase with frequency. A superconductor can be regarded as being composed of two types of charge carriers, one consisting of the lossless Cooper pairs and the other being lossy “quasiparticles.” Such a description is known as the “two-fluid model” and is applied to all known superconductors.

The finite frequency [alternating current (ac)] response of a superconductor is characterized in terms of a generalization of Ohm’s law: $\mathbf{J} = \sigma_s \mathbf{E}$, where \mathbf{E} is the applied electric field and $\sigma_s = \sigma_1 - i\sigma_2$ is the complex conductivity. The normal part σ_1 comes from the motion of the quasiparticles, and the imaginary part σ_2 comes from that of the Cooper pairs. For most superconductors well below the transition temperature, $\sigma_2 \gg \sigma_1$. The frequency ω , wave vector \mathbf{k} , temperature T , and current density \mathbf{J} dependence of σ_s contains all the information about the electrical properties of the superconductor. For a normal metal, $\sigma_s = \sigma_n$ is purely real.

Figure 1 shows a lumped circuit equivalent of a superconductor. The large inductive element L_{sc} represents the lossless carriers, and the parallel branch with a series combination of a resistor R_n and an inductance L_n represents the quasiparticles. At dc, the large inductor shorts out the resistive branch, leading to zero resistance, whereas at finite frequencies, there is always dissipation.

As the excitation frequency increases, the impressed electromagnetic field is confined closer to the surface. In a normal metal, this is known as the skin effect and the

**Figure 1.** Two-fluid model equivalent circuit of a superconductor.

characteristic length of confinement (the “skin depth”) is given by $\delta_n = (2/\mu\omega\sigma_n)^{1/2}$, where σ_n is the (normal) conductivity. δ_n for Copper at 10 GHz and 77 K is 0.55 μm . In a superconductor at temperature $T \ll T_c$, the skin depth is replaced by the “London penetration depth” $\lambda_L = 1/(\mu\omega\sigma_2)^{1/2}$. The penetration depth is typically independent of frequency from dc to microwave frequencies and is comparable with the London penetration depth in Table 1.

The interaction of a time-varying electromagnetic field and a metal (normal or superconducting) at microwave frequencies is best described in terms of the surface impedance defined as $Z_s = R_s + iX_s = (i\mu\omega/2\sigma)^{1/2}$. R_s and X_s are the surface resistance and reactance, respectively. As can be seen, R_s and $X_s \propto \omega^{1/2}$ in a normal metal, where $\sigma = \sigma_n$. On the other hand, $R_s \propto \omega^2$ and $X_s \propto \omega$ in an “ideal” superconductor. This can be easily verified by assuming σ_1 and λ_L to be frequency independent and $\sigma_2 \gg \sigma_1$.

The property that makes superconductors attractive for passive microwave circuits is that their surface resistance is orders of magnitude lower than that of normal metals. For example, thin-film YBCO has a surface resistance of <0.1 m Ω at 77 K and 10 GHz compared to 8.7 m Ω of copper under identical conditions, and this difference is even higher at lower temperatures. Figure 2 shows the measured frequency and temperature dependence of R_s of some of the most common superconducting and nonsuperconducting materials [3].

2.1. Nonlinearity in High- T_c Superconductors

For most superconductors, particularly the high- T_c superconductors, the surface impedance increases with applied microwave power, even for moderate power levels (<0.1 W). In other words (unlike normal metals), they act as nonlinear circuit elements. This nonlinear response often poses serious constraints on the utility of superconductors in practical devices. Some specific examples of such limitations are as follows:

- Degradation of insertion loss with increasing power.
- Generation of harmonic frequencies: For an applied signal at frequency f , most of the harmonic power is generated at a frequency of $3f$. Given today’s tight use of the electromagnetic spectrum, practically all frequency ranges have been preassigned by the appropriate authorities (e.g., the Federal Communication Commission in the United States) with just the required amount of bandwidths. Thus, radiation by a device at frequencies far outside the designated frequency of operation is unacceptable.
- Frequency mixing, leading to intermodulation products (intermods): For two nearby frequencies f_1 and f_2 , the strongest intermods are produced at $2f_1 - f_2$ and $2f_2 - f_1$. The result is that spurious frequencies are produced in devices.

Figure 3 shows the effect of nonlinearity on a suspended line resonator with a resonance frequency of 3.73 GHz [4]. At low power levels, the response in the frequency domain is close to a Lorentzian. As the input power is

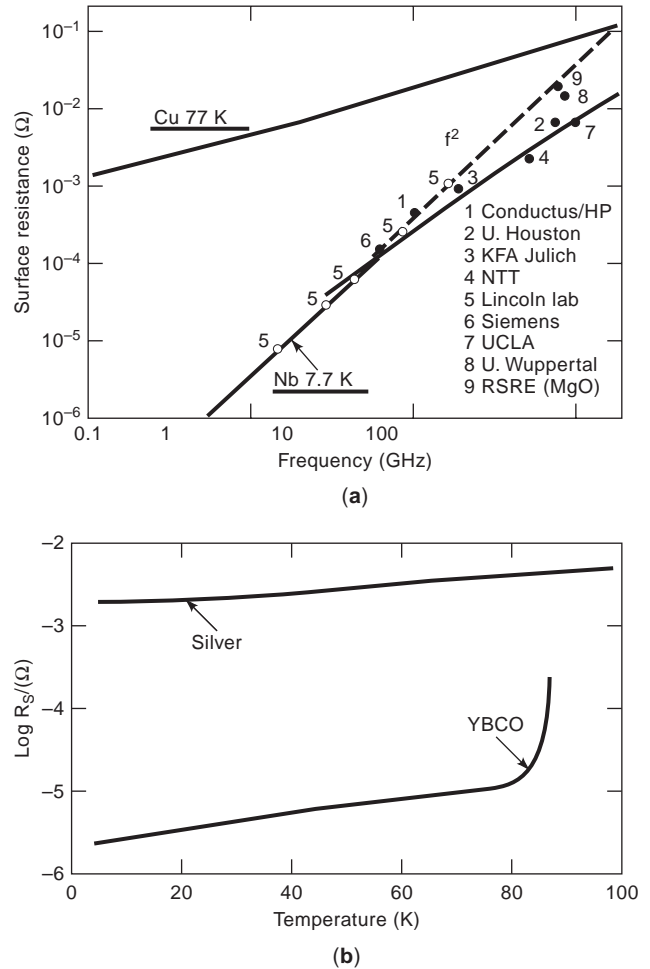

Figure 2. (a) Comparison of the surface resistance of YBCO at 77 K with other superconducting materials. The horizontal bands represent YBCO. (From Ref. 3, with permission.) (b) Temperature dependence of the surface resistance of YBCO grown by several techniques compared with niobium and niobium-tin superconductors at the same reduced temperature. The scale on the upper axis refers to the reduced temperature for the Nb₃Sn and Nb, whereas the lower scale refers to the actual temperature of the YBCO films. The T_c of the three materials coincides. $f = 8$ GHz.

increased, the shape begins to distort, and the Q and the resonance frequency go down. This also highlights the point that at high power levels, the Q of a superconducting resonator cannot be defined in terms of a “3 dB bandwidth.” A quantitative measure of the nonlinearity of a device is specified in terms of its third-order intercept (TOI), defined as the input power at which power output at the fundamental and the third harmonic equal each other. Single-tone TOI for most commercially used HTSC materials is at least 70 dBm (10 kW).

These effects together limit the maximum power that a passive superconducting circuit can handle, and raising the power handling capacity has been one of the prime concerns of material scientists and engineers alike. Much of the nonlinearity of the high- T_c materials is ascribed to material properties (e.g., granularity and “flux pinning”) and is expected to improve with synthesis and deposition

Figure 3. (Left) Frequency-domain response of a suspended resonator. Notice the deviation from a Gaussian shape as the input power increases. (Right) The R_s of a similar resonator against applied power at different temperatures. (From Ref. 4, with permission.)

techniques. From a design point of view, nonlinearities can be suppressed by increasing the surface area of the device, leading to lower current densities and avoiding current crowding at the edges. Thus, a planar filter can handle significantly higher power than a stripline, and a cavity resonator has Q value orders of magnitude higher than one built out of a transmission line, even factoring out the losses in the substrate. However, higher dimensional circuits are not always practical for many applications because they take up more space and often have the problem of mode degeneracy (i.e., more than one mode of oscillation at the same frequency). The latter problem can often be solved by making the circuit slightly asymmetrical, but then modeling them with a computer becomes more cumbersome.

3. PASSIVE MICROWAVE CIRCUITS

Passive microwave circuits are some of the most promising applications of superconductors to date. In the following we shall focus on the advantages of high-temperature superconductors (HTS) materials and the special considerations that applies to them. General ideas about passive microwave devices are available in the literature. For a good review of the current state of the art, see Ref. 5. For a more elementary introduction, see Ref. 6.

Superconductors are an attractive alternative to “conventional” materials for three principal reasons:

1. *Very low surface resistance* compared with normal metals: For example, insertion loss of a superconducting filter (~ 0.1 dB) is usually at least 3 dB lower than one made out of high-quality metal (e.g., oxygen-free high-purity copper) under equivalent conditions. Thus in applications where the signal strength is low, superconductors are the material of choice.
2. *A frequency-independent penetration depth.* In normal metals, the skin depth is proportional to the inverse square root of the frequency of the signal, giving rise to strong dispersion of a wideband signal,

unacceptable in many applications. In superconductors, the penetration of electromagnetic field is dominated by the “London penetration depth,” which is independent of frequency, giving rise to phase dispersion-free propagation in the transverse electromagnetic (TEM) mode.

3. *The ability to be fabricated in extremely compact geometries,* arising from the low loss mentioned above. Thus, a several-meter-long coaxial delay line made out of a normal conductor can be replaced with a superconducting one that is only a few square centimeters in area, and bulky dielectric resonator filters can be replaced by compact planar superconducting filters.

3.1. Transmission Line

A microwave transmission line can be constructed in several geometries, each having its pros and cons. The most common geometries are microstrip, stripline, and coplanar. Many other novel geometries such as the suspended line and coplanar strips are also used for special-purpose applications. The basic concepts behind transmission line and distributed circuits is the same whether or not they are made out of superconductors, and the interested reader can find them elsewhere (see, for example, Ref. 7). Here we will briefly discuss only those issues that are specific to superconducting transmission lines.

The two major distinctions between superconducting and nonsuperconducting transmission lines stem from the temperature and frequency dependence of the characteristic impedance of the line, defined as $Z_0 = (L/C)^{1/2}$ where L and C are the equivalent lumped inductance and capacitance, respectively. In addition to the usual geometric inductance, superconductors have temperature-dependent kinetic inductance because of the presence of the Cooper pairs. Also, for sufficiently low temperatures ($T \ll T_C$, or more pertinently, $\lambda_L \ll \delta$), the penetration depth is independent of the frequency, giving rise to a phase dispersion-free propagation for the TEM mode. Nonlinear effects are another major complication in dealing with superconducting transmission lines, as has been discussed. The

nonlinear effects are particularly worse in the edges of the line where the current density is maximum. Therefore, a good design for a passive superconducting circuit tends to avoid sharp edges as much as possible. Owing to these, full-wave analysis of superconducting transmission lines is quite a daunting task that cannot be done satisfactorily using most commercially available CAD programs and often must be carried out for individual needs.

One of the most promising applications of superconducting transmission lines is in the form of hybrid interconnects between components, both semiconducting and superconducting and both analog and digital.

3.2. Resonators

The “quality factor” (Q) of a resonator is defined to be $Q = U/f_0/P$, where U is the total energy stored in the oscillator, f_0 is the resonance frequency, and P is the power dissipated per cycle. As $P = \int R_s H^2 dA$, where the integral is over the surface of the material comprising the resonator walls, the Q can then be written as $Q = \Gamma/R_s$, where Γ is a geometric factor, for a resonator entirely comprising a single material.

The advantage of a superconducting resonator over a normal metal one is the very high Q owing to the much smaller surface resistance of the former. At 10 GHz, Q as high as 10^{11} can be achieved (using niobium cavities in TE₀₁₁ mode), compared with a maximum Q of around 10^4 using copper. Superconducting cavities are typically operated in the TE₀₁₁ mode because this has no electric fields on the cavity walls. Cavities have been made out of both low-temperature and high-temperature superconductors [8], although the latter is a lot harder to make owing to the ceramic nature of the material. Superconducting cavities such as these play an important role as a research tool for precision measurements of surface impedance of superconductors and other materials. Figure 4 shows a picture

of a niobium cavity that was fabricated at Northeastern University and is used to measure the surface impedance of other crystalline superconductors using the cavity perturbation technique [9].

A major application of superconducting cavities is in providing large high-frequency electric fields for accelerating subatomic and atomic particles. The fields in a cavity resonator are given by $E_{\max} = \gamma(QP_{\text{abs}})^{1/2}$ so that significantly larger fields can be achieved with high Q cavities for much lower absorbed powers P_{abs} . A notable example is the continuous electron beam accelerator facility (CEBAF) for heavy ions, which uses superconducting niobium cavities operating at megahertz frequencies.

Superconducting microwave cavity resonators are among the most stable frequency standards available today owing to their very high Q values. One of the applications of such high-stability frequency standards is in satellite and deep-space communications, where it is important to maintain precise clocks on board the satellite to improve synchronization between the ground-based clock and the satellite or space vehicle’s on-board clock.

Another potential application is in the master oscillator of a Doppler radar. A Doppler radar identifies the target velocity by measuring the frequency shift of the reflected beam. Clearly, for the measurement to be reliable, the frequency of the source has to be highly stable. This is especially important for detecting targets flying close to the ground (e.g., a cruise missile), because reflections from the ground (the “ground noise”) can completely mask the signal.

3.3. Filters

A filter is realized by a set of coupled resonators with closely spaced resonance frequencies. The response of each resonator is represented as a pole in the frequency domain. Thus a filter with n resonating elements is called

Figure 4. A superconducting niobium cavity used for surface resistance measurement. The specimen under test is thermally insulated from the cavity using a sapphire rod, allowing it to be probed up to nearly room temperature while the cavity is still superconducting. (Right) The disassembled cavity showing the sapphire sample mount. (Left) The packaged structure. Q values of $\sim 10^7$ to 10^8 at 4.2 K are routinely obtained in this setup. (Courtesy of Z. Zhai and H. Srikanth.)

Figure 5. A four-pole superconducting filter and its measured performance. (Courtesy of Dr. Daniel Oates, MIT Lincoln Laboratory.)

an n -pole filter. The resonators can be lumped (e.g., tank LC oscillators) or distributed (e.g., half-wave transmission lines.) Clearly, the greater the number of poles in a filter, the greater the bandwidth that can be achieved for a pre-set filter skirt and band ripple, or the steeper the filter skirt and smaller the band ripple for a given bandwidth. Both are desirable. However, increasing the number of elements increases the insertion loss proportionally. Thus, many applications that require *both* a small insertion loss and steep filter skirt with low band ripple cannot be realized using conventional materials such as high-purity copper.

Alternative technologies such as surface acoustic wave (SAW) devices do produce better results, but are still too lossy (typically 2 dB to 4 dB). Dielectric resonator based filters have low loss, but are too bulky for many lucrative applications. This is precisely why superconductors are the material of choice for making high-performance filters. The extremely low surface resistance allows a designer to use a lot more elements for a given amount of insertion loss.

Figure 5 shows a four-pole microstrip Chebyshev filter fabricated at the MIT Lincoln Laboratory with a 4.8 GHz center frequency and 100 MHz bandwidth patterned on an LaAlO_3 substrate with YBCO film. The filter uses a “hair pin try”; that is, the resonators are bent with a U-turn to save wafer space. The right-hand side of Fig. 4 shows the measured insertion loss (S_{21}) of the filter at 77 K temperature. Also shown for reference is the performance of equivalent elements made out of silver (Ag) at 77 K and gold (Au) at room temperature (300 K). The advantages of high- T_C superconducting filters are quite obvious.

One of the problems in working with HTS material is the lack of availability of large wafers of acceptable quality. The maximum size of high-quality HTS films are presently limited to about 5 cm, compared with 30 cm wafers of semiconductors. This poses a problem in two cases: (1) where the center frequency is low, requiring the length of the transmission lines of a distributed filter to be long, and (2) where the bandwidth is tight (a fraction of 1%), requiring very weak coupling, and hence large separation between elements. The first problem calls for miniaturization of the device, and there are several means of accomplishing this, including the use of lumped resonators [10] and high-dielectric-constant substrates. The second problem is usually solved by a technique called staggering.

Figure 6 shows a photograph of a high-performance lumped-element nine-pole Chebyshev filter.

3.3.1. Frequency Agile Devices. A filter is much more useful if it can be tuned. Several innovative approaches to tune a passive filter have been tried. One method consists of changing the resonance frequency of the individual resonators (due to change in the kinetic inductance) with temperature. The desired variation in temperature is achieved by a control line in the form of a heating element placed close to the resonators. A better method is to build the filter on a ferroelectric substrate with a low Curie temperature such as $\text{KTa}_{1-x}\text{Nb}_x\text{O}_3$ and $\text{Sr}_{1-x}\text{Pb}_x\text{TiO}_3$ [11]. The permittivity of the substrate can be changed by applying a bias voltage, thus providing the necessary tuning. The optimal temperature of operation is slightly above the Curie temperature of the substrate to avoid hysteresis and to produce maximum tunability for a given bias voltage. Impedance matching of the input and output is done with a set of ferroelectric transformers. As these techniques essentially manipulate the electrical length of the filter elements, the same methods can also be used to tune the parameters of other passive structures.

Another important type of filter is a “chirp” filter. A “chirp” is essentially a frequency-modulated signal whose frequency increases (“upchirped”) or decreases (“downchirped”) with time. One of the applications of chirp signals is in Doppler radars to optimize power output and bandwidth, both of which are desirable. Using a simple sinusoidal signal, however, both cannot be achieved

Figure 6. A nine-pole lumped Chebyshev filter from Superconductor Technologies Inc. (Courtesy of Dr. Balam Willemsen, Superconductor Technologies, Inc.)

simultaneously. A higher bandwidth means a shorter pulsewidth, which limits the maximum power transmitted per pulse and vice versa. A chirped waveform gets around this limitation. Another application is to compensate the distortion of a wave packet after passing through a dispersive transmission line. The principal advantage of constructing a chirp filter out of superconducting material is low dispersiveness.

A superconducting chirp filter in microstrip geometry consists of a series of quarter-wave forward-coupled transmission lines that are deliberately decoupled for a specified length between the couplings. The transmission line is wound in the form of a spiral to optimally use the film surface. As a pulse is applied to the input, the individual frequency components couple to the output line that corresponds to their resonance frequencies. Depending on whether the resonators are increasing or decreasing in length down the line, a downchirped or upchirped signal is obtained at the output.

3.4. Antenna

Using superconducting antennas can improve efficiency enormously because of their lower loss (for a general discussion of antennas, see Ref. 12). In particular, there are three situations when a superconducting antenna can outperform one made out of a normal metal sufficiently to merit its use:

1. *Electrically Short Antennas.* A dipole antenna has maximum radiation efficiency when its characteristic length is an integral multiple of the wavelength being radiated. For low-frequency applications (such as underwater communication, which involves frequencies of the order of 15 kHz), this length can be unrealistically large, and hence a shorter antenna has to be deployed. The radiated power P is proportional to $(l/\lambda)^2$ for a linear (electric dipole) antenna and $P \propto (D/\lambda)^4$ for a circular loop (magnetic dipole) antenna, where l is the length of the linear antenna, D is the diameter of the loop antenna, and λ is the radiated wavelength. For $l, D \ll \lambda$, the impedance of the antenna is mostly reactive and most of the power

is dissipated as ohmic losses in the antenna and the feed network. Therefore, introduction of superconducting radiating elements and feed networks can dramatically improve the radiation efficiency at low-frequency regions.

2. *Superdirective Antennas.* A superdirective antenna [13] has directional gain much larger than a conventional one. This can be of advantage in radio beacons and radar transmitters. A superdirective antenna is realized in practice by an array of closely spaced (separation \ll wavelength) dipole elements that are excited approximately 180° out of phase with respect to their neighbor. Such a structure has a low efficiency when built out of normal metal because ohmic losses in each individual element add up. In addition, these antennas have inherently low radiation efficiency because of cancellation of the radiation field, and use of HTS material can enhance efficiency.
3. *Millimeter-Wave Antennas and Feed Networks.* Superconducting antennas also improve the performance of antenna arrays and other distributed feed systems, where the power gain because of the distributed structure has to compete with the loss in an increasing number of elements. In a copper microstrip antenna, the overall gain begins to decrease beyond about 40 elements, whereas the same antenna employing superconducting elements shows an increase in gain up to about 400 elements. This increase in gain can be crucial in mission critical applications such as military target tracking systems.

Figure 7 is a photograph of a 16-element phased-array antenna that was developed at the U.S. Air Force Rome Laboratory.

3.5. Delay Lines

Requirements for a good delay line are low loss, low dispersion, and large delay for unit size/weight of the material. Superconducting delay lines are far superior to normal metal ones in satisfying these requirements, so

Figure 7. A 16-element superconducting phase array antenna and the feed network. An LaAlO_3 substrate is holding the HTS film. To the right of it is a 1 mm quartz plate holding the corresponding copper patches that provides an electromagnetic coupling to room temperature environment. A 0.5 mm vacuum between the two and low thermal conductivity spacers provide the required thermal isolation. The quartz plate has the necessary mechanical strength to withstand the atmospheric pressure and also serves as a radome. The antenna operates at 20 GHz. (Courtesy of Dr. Jeffrey Herd, U.S. Air Force Research Laboratory.)

much so that superconducting delay lines were in application even before the advent of high- T_C superconductivity [14]. Delays of the order of 20 ns can be routinely achieved with HTS materials on a substrate with an area of a few square inches, with good possibilities of achieving more than 100 ns in the near future. A copper coaxial line has to be several meters long for producing the same amount of time delay and would have a high insertion loss.

A novel application of a delay line is the measurement of instantaneous frequency of a nonperiodic signal [15]. This is achieved by splitting the input signal power equally between a series of n phase discriminating units, where n is the number of bit of frequency resolution desired. Each phase discriminating unit consists of a mixer, one port of which is fed by the signal directly and the other one by the same signal delayed.

4. ACTIVE MICROWAVE CIRCUITS

In 1962 B. D. Josephson predicted that when two superconductors are separated by a thin layer of metal or an insulator, a lossless current can flow up to a certain critical value I_C before a voltage appears across the junction. This is the manifestation of the phenomena that the Cooper pairs that carry lossless electric current can tunnel through the potential barrier represented by the junction material. Josephson’s remarkable prediction was verified experimentally the following year and is known as the Josephson effect. The Josephson effect opened the way for several new applications of superconductors, which

exploit the fact that superconductivity is actually an amazing manifestation of quantum mechanics on a macroscopic scale. The most noteworthy of these is the superconducting quantum interference device (SQUID) magnetometer. With sensitivities approaching 10^{-15} T/Hz^{1/2} values, SQUIDS can measure magnetic field with precision that is unimaginable with any conventional techniques. The interested reader is referred to some useful reference for further details (see, for example, Ref. 16). In the following, we shall describe some of the microwave applications of the Josephson effect that have the potential to radically alter the future of microelectronics.

The Josephson current I is related to the phase difference θ between the Cooper pair on the two sides of the junction as $I = I_C \sin \theta$. When current across the junction exceeds the critical value, a voltage V appears across it that is related to time rate of change of θ as $\partial\theta/\partial t = 4\pi eV/h$ (i.e., the phases of Cooper pairs on the two sides of the junction begin to “slip” relative to each other.) Figure 8(a) shows a lumped circuit equivalent of a Josephson junction (JJ), called a resistively shunted junction (RSJ model). The conductance and the capacitance represent the resistive and displacement current flow across the junction. The static characteristics of the circuit is given in terms of Stewart–McCumber parameter [17,18] $\beta = 4\pi eI_C C/hg^2$.

Elementary mathematical analysis of Fig. 8(b) shows that the time-domain response of the circuit can be written as $I/I_C = \beta d^2\theta/d\phi^2 + d\theta/d\phi + \sin \theta$, where $\phi = 4\pi eI_C t/hg$, t being time. This is equivalent to the equation describing the motion of a simple pendulum in a gravitational field. Thus the Josephson current behaves like a

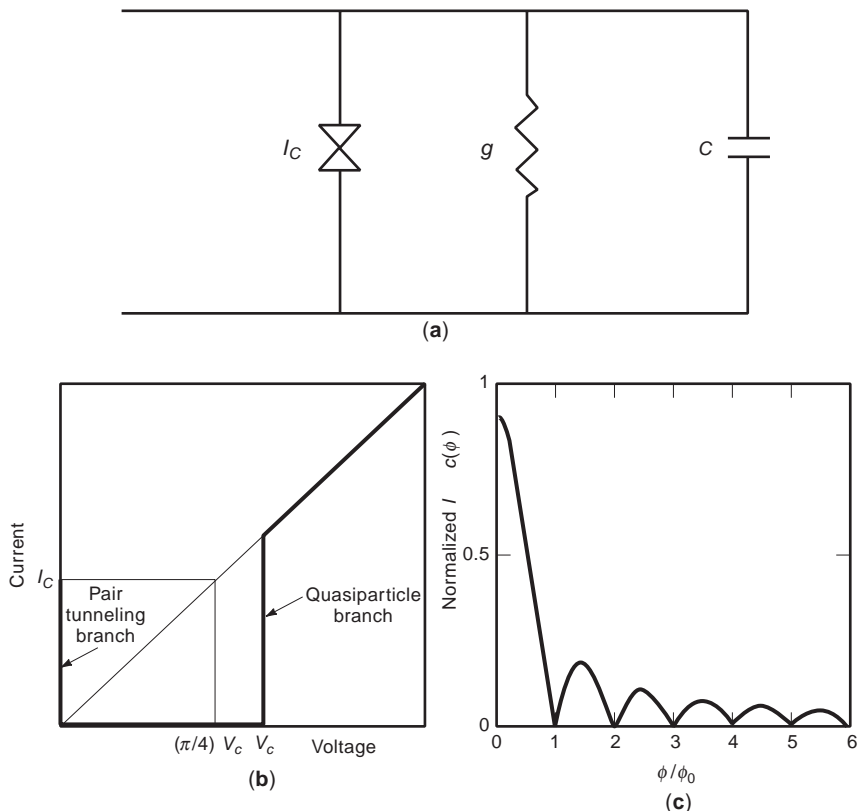

Figure 8. (a) Lumped equivalent of a superconductor-insulator-superconductor (SIS) Josephson junction. (b) I - V characteristics of an SIS Josephson junction. (c) Dependence of junction critical current on the threaded flux.

damped harmonic oscillator for small currents, which is underdamped for $\beta < 1/4$ and overdamped for $\beta > 1/4$. This also implies a hysteretic $I-V$ behavior in the a region $I_{\min} < I < I_C$, and the value of I_{\min} must be obtained by solving the above equation. The value of I_{\min} decreases monotonically with increasing β . Another useful property of a JJ is the flux dependence of the critical current. If the JJ has a flux Φ threaded to it, then the critical current is given by $I_{C\Phi} = I_C \sin(\pi\Phi/\Phi_0)/(\pi\Phi/\Phi_0)$, where $\Phi_0 = h/2e = 2 \times 10^{-15}$ Wb is the “flux quantum.” (The flux threaded through any superconducting ring must be an integral multiple of Φ_0 .) This is shown in Fig. 8(c).

To date, the most promising applications of superconducting active devices have been demonstrated only in low-temperature superconductors, most notably lead, niobium, and niobium nitride with aluminum oxide (AlO_x), magnesium oxide (MgO), and lead oxide (PbO) as the insulating barriers. For a Cooper pair to tunnel coherently across a junction, its thickness must be comparable with the coherence length of the material, which is extremely small for high- T_C superconductors (see Table 1). The critical current in these materials is also rather high (of the order of milliamperes), which is required for the Josephson coupling energy $\hbar I_C/4\pi e$ to overcome the thermal energy $k_B T$, but it produces excessive Joule heating in the resistive shunts and high voltages across inductances. There are additional factors arising out of complex crystal structure and presence of “weak links” (i.e., small angle grain boundaries) that make fabrication of JJs difficult in these materials. There are several possible analog and digital applications of the Josephson effect in microwave frequency regime, some of which are outlined in the following.

4.1. Superconducting Digital Logic Circuits

From the early days of its discovery, the JJ has been eyed as a potential replacement of semiconducting logic gates (a detailed review is provided by Ref. 19). Josephson junctions are inherently bistable (with zero and finite resistivity). However, the real driving force behind a “superconducting supercomputer” comes from three different sources:

- Josephson junctions can be switched *much* faster than a CMOS logic gate, where the parasitic and junction capacitance limits the minimum switching time. For a JJ, however, the theoretical limit on switching time is $\hbar/2\pi\Delta$, where \hbar is Planck’s constant and Δ is the superconducting energy gap. For niobium, this corresponds to 0.22 ps, and practical circuits with switching times of 1.5 ps have been fabricated. The large difference between the theoretical upper limit in switching speed and those practically achieved stems from parasitic capacitance in the junction. However, there are no space-charge effects in a JJ, and hence these capacitances are much smaller compared with semiconductor circuits.
- Average power dissipation per gate in a JJ is at least two orders of magnitude lower than equivalent semiconductor gates. This means that the gates can be

packed closer together, thereby reducing the propagation delay of the signal, another constraint in high-speed digital circuits. As an example, a four-bit microcontroller fabricated out of JJ and clocked at 770 MHz dissipated 5 mW, in contrast to a replica made out of gallium arsenide (GaAs) and clocked at 72 MHz that dissipated 2.2 W.

- Digital circuits operating over ~ 100 GHz must use superconducting interconnects, because the inherent dispersion and loss in metal interconnects will degrade the signal sufficiently to make the circuit inoperable.

Owing to the hysteretic $I-V$ characteristics of the JJ, switching between zero resistance and finite resistance states (logic 0 and logic 1 in our convention) cannot be achieved as fast as it would be in a nonhysteretic device. If the current is reduced slightly below the value at which a logic 0 to logic 1 switching takes place, the circuit will remain in logic 1 state. Owing to this property, such circuits are called “latching circuits.” The maximum clocking speed of these circuits cannot exceed a few gigahertz. To solve this problem, JJs are shunted with resistors that make them nonhysteretic. These circuits, called rapid single flux quantum (RSFQ) devices, are the basic building block of superconducting logic circuits. They differ from “conventional” logic in a fundamental way: The logic state is not decided by the voltage level of the gate but by the presence or absence of voltage pulse generated by the motion of single fluxons. Practical superconducting digital circuits with significantly higher performance have been demonstrated. Using niobium technology, a 4 bit microprocessor has been fabricated by Fujitsu and a 1 kbit random access memory (RAM) chip has been made by NEC (for a good review of recent progress in Josephson IC fabrication, see Ref. 20). Many other leading manufacturers are also pursuing this technology [21].

There are a few rather unusual problems in the practical realization of a superconducting computing device. It is impractical to realize a high-speed computer in a Von Neumann-type architecture that involves massive data transfer between a central processor and the memory, which are physically separated over a relatively long distance. An order-of-magnitude estimate of the maximum allowable data path (assuming microstrip interconnects on a substrate with dielectric constant ~ 20) of a computer operating at 300 GHz is ~ 0.3 mm. Clearly, this is very difficult to realize on a circuit board. However, applications such as dedicated digital signal processor with on-board cache memory and multichip modules can have phenomenal speed and performance increase if built using RSFQ logic.

4.2. Detectors and Mixers

The nonlinearity of a Josephson junction can be exploited to make a mixing device. In addition to the low noise and high efficiency that these devices offer, they can easily be integrated to an all-superconductor radiofrequency (RF) receiver front end.

The general principles of mixing due to photon-assisted tunneling was derived and applied to superconductor-insulator-superconductor (SIS) junctions by Tucker [22,23]. There can be two types of mixers using Josephson junctions: those using Cooper pair tunneling operating near zero bias voltage and those using quasiparticle tunneling operating near gap voltage. Quasiparticle mixers are usually preferable over Cooper pair mixers for several reasons. For one, the junction capacitance has to be small so that most of the current comes from Cooper pair tunneling and not displacement electric field. This means the use of point contact junctions that are difficult to fabricate reproducibly. Second, they are noisy because of harmonic mixing of all frequencies up to the gap frequency. According to the quantum theory of mixing, strong nonlinearity in I - V characteristics (more precisely, when $I_{dc}(V_{dc} + hv/e) - I(V_{dc}) \gg I_{dc}(V_{dc}) - I_{dc}(V_{dc} - hv/e)$) can result in conversion gain exceeding unity and conversion efficiency approaching the quantum limit even in a purely resistive mixer. Third, the shot noise in a quasiparticle mixer is lower than that in Cooper pair tunneling mixers. SIS quasiparticle mixers have been used in radio astronomy for quite a while.

4.3. Analog-to-Digital Converters

Analog-to-digital converters (ADCs) are another type of circuit where phenomenal performance improvement has been demonstrated using superconducting circuitry. While superconducting ADCs can be and have been fabricated in most architectures and have the usual advantage of a large bandwidth because of their fast switching capability, there is the additional advantage that when exploiting the multithreshold characteristics of a JJ [see Fig. 8(c)], an n -bit flash ADC requires only n comparators as opposed to $2^n - 1$ that would be normally required [24]. This allows high-bandwidth and high-resolution ADCs to be fabricated reliably and compactly.

4.4. Precision Voltage and Frequency Sources

The Josephson relation $\partial\theta/\partial t = 4\pi eV/h$ can be used both as a source of high-frequency radiation and as a dc voltage standard. The power radiated by the oscillating Josephson current in response to a small dc bias (483.5 GHz/mV) is usually too very small (a few nanowatts) to be of much practical use, but coherent Josephson arrays have been fabricated that can output as much as a few microwatts, and power levels of up to 1W have been predicted. On the other hand, when irradiated with microwaves, a JJ develops a dc voltage across it. As frequency of such radiation can be accurately controlled and measured, such devices are one of the accepted precision voltage standards today.

4.4.1. The Future of Superconducting Microwave Electronics. How are these myriad of possible superconducting circuits realized in practice? Just like any other microelectronic circuit, they are lithographically patterned on a substrate through a similar sequence of steps in a semiconductor [25]. Thus, the vast assortment of techniques developed during the last several decades for and by the

semiconductor industry can be ported into commercialization of superconducting electronics. For a complete self-contained system, many of the subsystems have to be built out of semiconductor devices [e.g., the (IF) amplifiers for an RF transceiver]. An efficient way of manufacturing these systems is to mix HTS and high electron mobility transistor (HEMT) semiconductor circuits on the same substrate as a multichip module (MCM) [26]. Typically the HTS film is grown on a GaAs substrate with a thin buffer layer for better lattice match. Semiconductor devices perform better at lower temperatures because of enhanced carrier mobility, so the overall performance increases. Decrease of thermal noise is another desirable byproduct. Also, with the increase in the packing density of the semiconductor circuitry, a decrease in operating temperature, and the advent of high-temperature superconductors, the disparity between the operating voltage levels associated with the two types of circuits is going down, minimizing the possibility of ground loops between these two types of elements. Any large-scale commercial application of HTS microwave circuit will rely on the ability to integrate them, either as a hybrid component or as a monolithic component, with active semiconductor components.

There are many hurdles in the road to success of superconducting devices. The absence of a room-temperature superconductor, essential for consumer market, is one of them. Even if there was a room-temperature superconductor, the vast amount of techniques developed by the semiconductor industry for precise and predictable control of material properties are unavailable in the superconductor industry. The reason for this is obvious: The whole phenomenon of high-temperature superconductivity is only understood phenomenologically at best. There is no equivalent of "bandgap engineering" for superconductors. If we knew the material to dope to change the superconducting bandgap, we could then produce a room-temperature superconductor!

However, consumer electronics, although a large share of the market, still is not all of the market. There are niche markets, mostly in the defense sector and commercial/military wireless communication, who would pay the extra dollar to have the advantages of superconducting electronics (see, for example, Ref. 27). For example, the low insertion loss and steep skirt of a superconducting filter makes it cost effective in a cellular base station where the receiving/transmitting antenna must operate within tight bandwidth tolerance and divide up the available bandwidths among as many customers as possible. Such filters are available from many vendors, and several are being field-tested by cellular service providers. One example of a large-scale attempt to use HTSC microwave circuits in communication application is the U.S. Naval Research Laboratory's "High Temperature Superconductivity Space Experiments" (HTSSE) [28]. The U.S. Air Force is another major player in this field and expects to use low-loss superconducting antennas in the next-generation radar systems. System integration is a crucial aspect toward commercialization, and significant progress has been made to this end. Integration of individual superconducting microwave components to produce a complete

self-contained RF receiver/transmitter front end has been successfully demonstrated by many researchers. Integration of superconducting and semiconducting electronics on the same device has also been carried out.

At the present rate of progress, we can safely say that the growth of superconducting electronics will steadily increase with time. Whether it would radically alter the present state of the art, similar to the effect the advent of solid-state circuits had over the vacuum tube technology, will be seen in the years to come.

Acknowledgments

SURFACE ACOUSTIC WAVE APPLICATIONS

DONALD C. MALOCHA
University of Central Florida

Since the introduction of the surface acoustic wave (SAW) interdigital transducer in the late 1960s, SAW devices have tremendously affected a broad range of systems. The key to this technology is the ability to sense or tap a traveling electroacoustic wave on a piezoelectric substrate whose velocity is 10^5 times slower than an electromagnetic wave. The velocity and photolithographic line resolution determine the practical SAW operating frequency range from approximately 30 MHz to 3 GHz. Typical devices are manufactured in volumes from a few cubic millimeters at high frequencies to a few cubic inches at lower frequencies. Typically, the high-frequency devices have a small volume and low cost. Using various SAW components depending on the required specifications, it is possible to provide precise frequency filtering, frequency resonance, time-pulse shaping, and signal processing. The passive, solid-state SAW devices provide very high performance relative to their volume, weight, and cost, which is the reason for their widespread use. The highest cost precision devices are typically used for military and satellite systems, which have the most demanding specifications; the intermediate cost devices are used in modest volume military man packs, military base stations, and commercial base stations; and the lowest cost devices are used in a broad range of commercial and consumer applications.

During the 1970s and early 1980s, military applications guided the development of the technology providing the ability to implement new and, up to that time, unachievable systems. A broad range of applications included dispersive devices and filter banks for radars, filters, and resonators for conventional communication systems, delay lines for systems and weapons, and coded devices, encoded modulator devices, and convolvers for spread-spectrum systems requiring secure communications. These systems encouraged the development of most of the components still in use by SAW devices today. The advent of enormous commercial opportunities in mobile and wireless systems in the 1990s ushered in a renaissance in SAW technology and has spawned technological innovation in devices and systems.

In addition to device technological innovation, research and development on other propagating Rayleigh-like modes, called pseudo-SAW, and new substrate materials, such as lithium tetraborate and langasite, have provided lower loss, higher frequency, and wider bandwidth devices. These material and device enhancements allow SAW devices to compete for insertion in the RF, IF, and processing sections of modern communication systems. Commercial and consumer applications include cellular and mobile phones, car and garage door openers, VCRs, CATV, fiber optic repeaters, spread-spectrum systems, sensors, identification tags, satellite communication systems, and many more [1-4].

1. SAW TVIF FILTER

The SAW TVIF filter stands alone as the first significant commercial application of SAW devices for the television intermediate-frequency (TVIF) filter and deserves a highlighted discussion. Development began in the 1970s when SAW technology was just emerging. Design, analysis, fabrication, and packaging were all extremely challenging for SAW devices at that time. However, it was recognized that a significant technological advance would be achieved if a single, solid-state component could replace the bulky, multiple LC tank circuits in the IE, which were both expensive to build and insert into the chassis. In addition, the LC sections drifted with temperature and aged with time producing a profoundly negative effect on video reception. The SAW TVIF filters were first introduced to the market in the late 1970s and demonstrated that high-volume manufacturing of the devices was feasible. Today, every TV manufactured has a SAW TVIF filter.

Figure 1 compares the SAW versus LC implementation of filtering in a TVIF section [5]. The SAW TVIF filter is interesting because it demonstrates that the SAW transversal filter can meet a demanding design and cost specification. The TV system requirements have been in place since TV's inception and vary by country around the world. The U.S. system requirement is typical and is used as the example. The video and audio transmission format have remained the same for compatibility over the years and were determined from the original transmission specifications. These specifications required a nonsymmetrical template for the magnitude of the TVIF filter response and a precise dispersive group-delay response. The nonsymmetrical magnitude response sets the relative video and audio carrier levels and shapes the chroma response. The group delay must vary precisely with frequency to reproduce a sharp image and accurate colors. Early SAW TVIF filter insertion losses were greater than 20 dB, which reduced the internal SAW device triple transit echo (TTE) to approximately 46 dB. A TTE greater than -40 dB produces a noticeable ghost picture that would be unacceptable to the consumer. Lower loss devices using new transducer and

Figure 1. Early comparison of the SAW TVIF filter and the LC equivalent circuits used in U.S. television sets. (Reproduced with permission of the IEEE, *Proceedings of the IEEE*, 64(5):672 (1976).)

device embodiments reduce the loss below 20 dB while maintaining the specifications and costs required in the TV.

SAW devices are manufactured by using many of the previously developed integrated circuit techniques. Multiple devices on a single crystal substrate using aluminum electrodes fabricated by conventional photolithographic techniques is very attractive. Similar to silicon technology, high-volume manufacturing provided the vehicle for advancing the technology so that costs were reduced. Costs for SAW TVIF filters dropped from several dollars per device in the 1980s to under \$0.50 for current devices and are currently manufactured in volumes of millions per month. The SAW technology and device embodiments have been changed and refined to provide better performance at a lower cost [4]. As the first high-volume commercial SAW application, the TVIF filter can be credited for the confidence that companies had when developing the current wide range of high-performance, low-cost commercial SAW products.

2. TYPICAL WIRELESS COMMUNICATION SYSTEM

There are tremendous numbers of different wireless communication systems for audio, video, and data transmis-

sion. Rather than attempting to focus on any one system that has its own specific characteristics, a more generic approach is taken. Figure 2 shows a schematic for a typical transmitter and receiver system. The radiofrequency (RF) section eliminates spurious responses and establishes the noise figure for the system, and the intermediate frequency (IF) sections provide the channel selectivity and limit the noise bandwidth. To reduce cost, the second IF section is eliminated when possible. The oscillator/synthesizer is used for channel selection and may be used as the system clock. The postprocessing of the signal may also contain SAW devices in many coded and secure communication systems. The gray blocks represent elements in which SAW devices may be inserted, depending on specifications.

2.1. RF SAW Devices

The receivers of interest operate in the frequency range between approximately 30 MHz and 3 GHz where typical SAW devices find application. The RF section center frequency and bandwidth are consistent with the channel requirements, and fractional bandwidths can be from fractions of a percent to tenths of a percent. The RF section consists of one or two RF filters and a low-noise amplifier

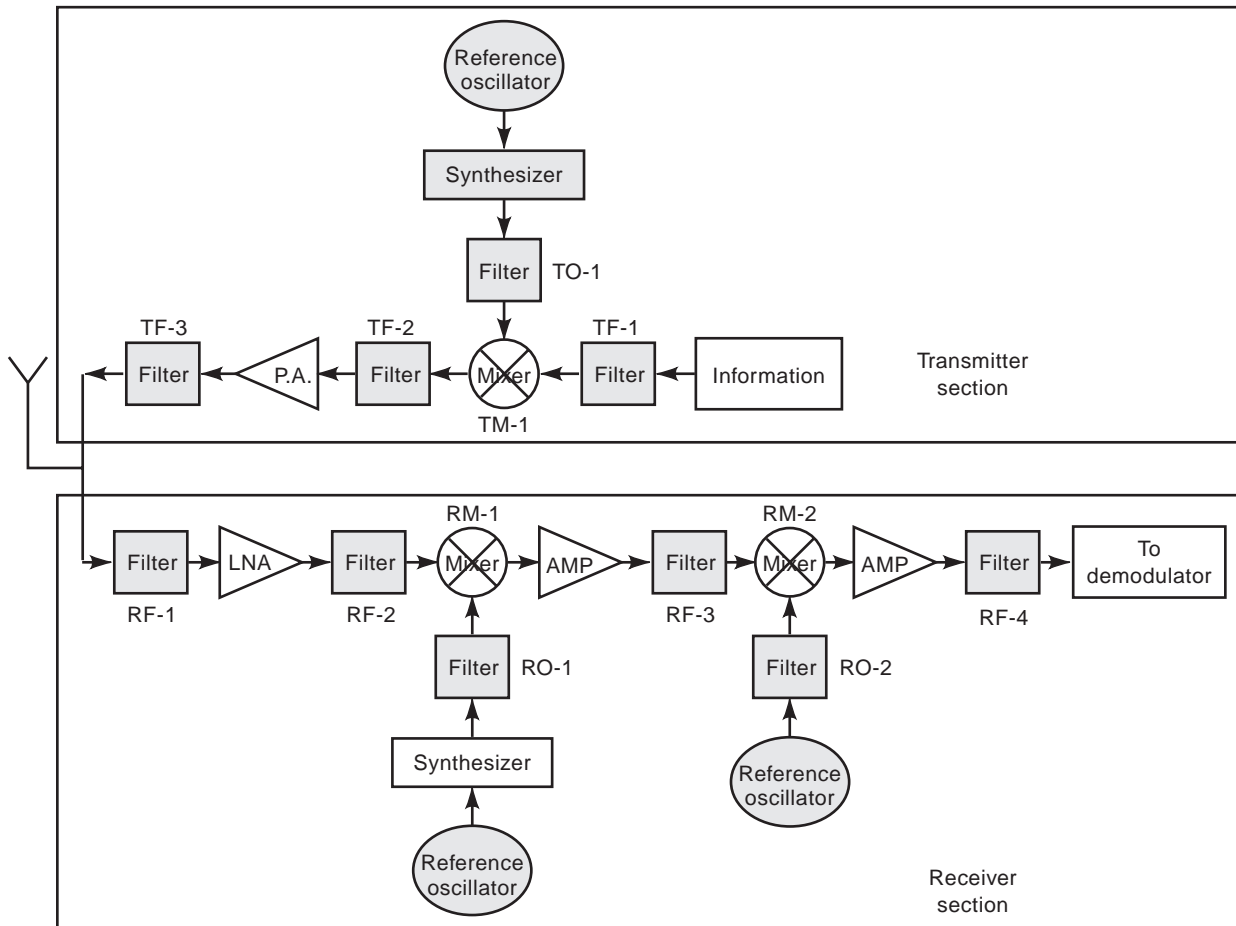

Figure 2. Schematic diagram of a generic transmitter/receiver (transceiver) system. The transceiver has a common antenna. The system can be separated into a transmitter and receiver by eliminating the common antenna. The gray blocks represent possible SAW elements within the RF and IF transceiver sections.

Figure 3. An 870 MHz SAW filter with a 3% fractional bandwidth and 2.0 dB insertion loss. This filter uses a multiresonator approach in a ladder-type network. This filter is used as the front-end RF filter in the Advanced Mobile Phone System (AMPS). (Reproduced with permission of the IEEE, J. Machui et al., 1995 *IEEE Ultrasonics Symposium Proceedings*, pp. 121–130.)

(LNA). As an example, a typical mobile telephone system's center frequencies vary from approximately 450 MHz to more than 2 GHz with fractional bandwidths of 1% to 5%. One RF filter that has very low loss and good selectivity is desired. However, two filters may be necessary, the first with very low loss and marginal selectivity and a second filter with a higher loss and better selectivity. Any loss before the LNA is a direct reduction in signal-to-noise ratio. Therefore, RF filters require extremely low loss, typically between 1 dB and 3 dB. Figure 3 shows a typical SAW front-end RF filter for a mobile phone application at 870 MHz with an insertion loss of approximately 2.0 dB and a 25 MHz bandwidth [6]. Typically nulls are designed at the adjacent transmit/receive frequencies for a transceiver, and sidelobe rejection depends on the design approach. The second RF filter can have a relaxed insertion loss specification but typically has greater out-of-band spurious suppression. Figure 4 shows a SAW interstage filter at 950 MHz with approximately 3 dB insertion loss implemented by using a transversely coupled resonator approach [6]. SAW filter design techniques for RF filters

Figure 4. A 950 MHz SAW filter with an approximate 3% fractional bandwidth and 3 dB insertion loss. This filter uses a transversely coupled resonator filter, which provides a two-pole response and good ultimate sidelobe rejection. This filter is used in the Global System for Mobile communication (GSM). (Reproduced with permission of the IEEE, J. Machui et al., 1995 *IEEE Ultrasonics Symposium Proceedings*, pp. 121–130.)

include two-transducer low-loss designs, interdigitated interdigital transducers, single and multitrack resonant structures, and ladder/lattice impedance filters. For cellular applications, the antenna is common to both the transmitter and receiver, and it may be necessary for the RF receiver filter to accept large input power at the transmission frequencies. SAW ladder/lattice filters are currently of great interest because they handle high power and provide low loss and acceptable selectivity. Other important considerations are the temperature coefficient of frequency and the material coupling coefficient. The bandwidth must be increased to accommodate operation over the required temperature range, and the coupling coefficient determines the maximum achievable bandwidth for a given insertion loss.

2.2. IF SAW Devices

The IF filter typically has greater selectivity and higher insertion loss than the RF filter. The IF center frequency is chosen for good image rejection and adjacent channel selectivity and is lower than the transceiver operating frequency, typically from tens to hundreds of megahertz. The IF filter must have a narrow transition band and low sidelobe levels to limit the noise within the system and may also have specific traps to reduce adjacent channels, intermodulation, or other spurious carrier responses. The insertion loss is usually not as stringent a requirement as in the RF filter because the signal-to-noise ratio is set before this stage and amplification is typically low cost and available. IF stage insertion loss can range from several decibels to as much as 50 dB depending on the fractional bandwidth and system requirements. Figure 5 shows a typical SAW IF bandpass filter at 70 MHz, insertion loss of 22 dB, 8 MHz bandwidth, and group-delay variation of approximately 40 ns. The filter is a conventional two-transducer, SAW transversal implementation that demonstrates the excellent passband shaping, extremely sharp skirts, and near-constant group-delay response.

2.3. SAW Resonator Oscillator Applications

The oscillator/synthesizer often uses a SAW resonator for the frequency-control element having a center frequency

Figure 5. A typical 70 MHz IF filter having a typical insertion loss of 22 dB, 3 dB bandwidth of 8 MHz, and sidelobe rejection of greater than 55 dB. The passband has less than 0.25 dB ripple and group-delay variation of approximately 40 ns. The passband ripple and group-delay variation are primarily caused by TTE. The 70 MHz IF frequency is popular for military applications. (Reproduced with permission from Sawtek, Inc.)

such that, when mixed with the incoming carrier, it results in a signal at the IF center frequency. The oscillator frequency is chosen on the basis of a wealth of system considerations including the reception frequency, single versus double conversion, inter- and cross-modulation products, and other specifications. It is desired that the resonator be high *Q*, low loss, and have excellent temperature stability versus frequency. As an example, Fig. 6 shows a 199 MHz, quartz, two-port SAW resonator response. The peak to spurious level typically needs to be greater than 10 dB to ensure that any excessive loop gain in the oscillator does not result in oscillator instability. SAW resonator *Q*'s are typically several thousand and can be designed to tens of thousands. SAW oscillators often compete with bulk acoustic wave (BAW) devices that typically operate at much lower frequencies and use multipliers to obtain the frequencies of interest. Both SAW and BAW-based oscillators are often called crystal oscillators (XO). Oscillators have frequency drift primarily caused by the crystal temperature coefficient of frequency (TCF) and often have sophisticated electronics and temperature control to achieve long-term and short-term stabilities. Various configurations include the voltage-controlled (VCXO), temperature-controlled (TCXO), oven-controlled (OCXO), and microprocessor-controlled (MCXO) crystal oscillators.

Using a narrowband SAW resonator, it is also possible to produce a notch filter [7]. Notch filters are used to eliminate a narrow carrier that is produced within a radio, such as in the oscillator, or they are used to eliminate an external signal, such as an adjacent channel carrier frequency. Various circuit configurations are used with resonators to produce a notch. The notch filter should have good temperature stability and a notch bandwidth adequate to track over the required operating temperature range. Multiple coupled resonators are used to obtain a larger notch bandwidth than are the conventional single-pole resonators.

3. SIGNAL PROCESSING APPLICATIONS

3.1. Coded and Quadrature Modulators

3.1.1. PSK SAW Filter. Because each tap in a SAW device is independently controlled, it is very easy to implement simple-phase, shift-keying (PSK) biphasic coding into a device. A schematic of a typical PSK-coded SAW used for coding the data in a spread-spectrum system is shown in Fig. 7. A digital datastream is converted into a series of impulses whose polarity corresponds to the sign of each data bit. The input transducer launches the wave whose phase depends on the sign of the input pulse and which is then convolved with the coded transducer. The SAW-coded transducer is composed of a series of time chips. The sign of each chip is implemented by properly connecting of each electrode to the appropriate busbar. The overall SAW impulse-response length is equal to the data bit length. The output from the SAW-coded transducer can be further modulated for transmission. A similar SAW filter can be used as the matched filter at the receiver where a compressed pulse is achieved whose phase is a function of the original data stream. The frequency bandwidth is determined by the chip impulse-response length, and the processing gain is a function of the number of chips per bit. Figure 8 shows the measured time response of a 128 chip PSK correlator, which exhibits a peak-to-sidelobe ratio of approximately 21 dB, as expected.

Figure 7. Schematic diagram of a typical SAW PSK-type coded filter. The input data are converted into a series of phase-modulated impulses that then produce the SAW output-coded waveform.

Figure 8. Measured time-domain response of a 128 chip PSK SAW correlator. (Reproduced with permission from Sawtek, Inc.)

3.2. Continuous-Phase Frequency-Modulation Devices

SAW devices are designed in both the time and frequency domains. The ability to pulse shape allows developing and implementing precise modulation schemes that are very difficult to implement with other technologies. Quadrature modulation techniques are very popular for transmission, they include quadrature-phase shift keying (QPSK), minimum shift keying (MSK), and others. The MSK waveform, along with many others, forms a class of continuous-phase frequency modulation (CPFM), encodes the information in the phase and frequency of each chip or bit, and has a uniform amplitude envelope. The phase continuity and uniform amplitude provide minimum distortion when transmitting through power amplifiers, which are often nonlinear. These advantages are obtained at the expense of a wider chip null bandwidth, which reduces data rates. A schematic of a simple way to implement a CPFM system is shown in Fig. 9 where the SAW device provides pulse shaping when excited by an impulse. For MSK, the pulse envelope shape is a simple one-half cycle cosine whose length is equal to the required bit length. The data bit length is one half the MSK impulse-response length, and therefore, the device impulse response from a given data bit impulse overlaps adjacent data bits to form a nearly continuous, flat-envelope code stream. The predicted and measured SAW MSK waveforms are shown in Fig. 10.

Figure 10. Predicted and measured time-domain response of a SAW MSK system at 300 MHz and a 92.5 MHz data rate. The predicted response has approximately 4% amplitude modulation compared with the 7% measured. The main cause for amplitude modulation is hardware system implementation.

3.3. Synchronous Optical Network

The synchronous optical network (SONET) has critical and demanding timing for data transmission. When transmitting over long distances, such as transoceanic, it is necessary to recover the clock from the actual nonreturn-to-zero (NRZ) datastream to retime the data at intermediate points along the network. One popular method is to use a SAW filter within the clock-recovery circuit, as shown in Fig. 11. Figure 12 shows a high *Q*, 622 MHz, quartz, SAW filter used in a SONET clock-recovery system. The device has a typical insertion loss of 16 dB, and a quartz substrate is used to minimize temperature drift

Figure 9. Schematic diagram of a typical SAW MSK-type coded filter. The input data are converted into a series of phase-modulated impulses, which then produce the SAW output-coded waveform.

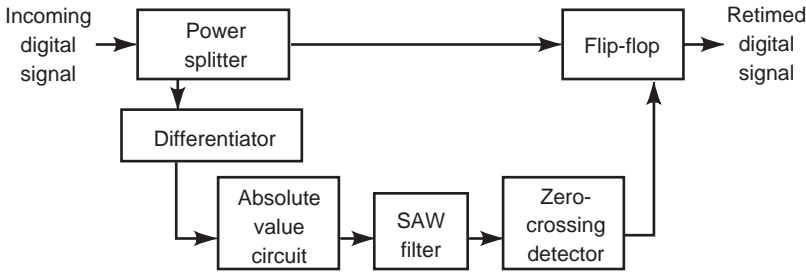

Figure 11. A simple schematic diagram of a SONET clock-recovery circuit using a SAW filter.

effects. In addition to the clock recovery, SAW devices may be used in SONET as delay elements for timing or for data pulse shaping to minimize intersymbol interference and reduce the probability of error in data recovery.

3.4. Channelizers

In wideband communication systems that have multiple channels, it is often required to break the receiving bandwidth into adjacent channels. Sometimes these channels are processed independently, or there are times when multiple channels may be combined into a wider band channel. This requires a sophisticated system that has well-matched individual channels and an electronic system that provides the required switching network. SAW channelized receivers have met this demanding requirement for both military and commercial applications. A complete integrated SAW channelizer system allows dynamic, active switching in or out of one or more channels. The superimposed frequency response from a seven-channel, 330 MHz SAW filter bank is shown in Fig. 13. The uniformity of amplitude and out-of-band rejection (approximately 50 dB) between channels require precise filter design and system integration.

3.5. Dispersive Devices

3.5.1. Radar. One of the earliest and technologically important applications of SAW devices was in radar systems. The simplest radar in concept is the pulse radar. To obtain the greatest accuracy in determining an object's distance from a source, it is desirable to transmit a very narrow pulse from the source, which is subsequently reflected from an object and received. The delay corresponds to the round-trip distance difference. The maximum

Figure 12. Frequency response of a 622.08 MHz SAW filter used in a SONET clock-recovery circuit. The device has a typical insertion loss of 16 dB, a 3 dB bandwidth of 0.93 MHz, a delay of 700 ns, and is fabricated on quartz. (Reproduced with permission from Sawtek, Inc.)

viewing distance is limited by the path loss and the minimum detectable signal-to-noise ratio. Therefore, it is desirable to transmit very narrow, high-amplitude pulses or to extend the pulsewidth. The former approach requires a very low duty factor and high-power transmitters, whereas the latter lengthens the pulse, which limits distance accuracy. The solution to these two conflicting requirements is to use a dispersive transmit pulse that changes the instantaneous carrier frequency with time. A chirp radar uses a SAW dispersive (or chirp) filter to transmit a long dispersive pulse that has significantly more energy than a simple, single-carrier frequency pulse [8]. Then the return signal is sent to a matched SAW chirp filter that compresses the pulse. The SAW input/output devices are a matched set whose transmit filter is an upchirp and receive filter is a downchirp. Figure 14 shows a schematic representation of an upchirp and downchirp SAW filter. For a linear chirp, the frequency changes at a given chirp rate (Hz/s) from some minimum to some maximum value across the device. The processing gain, which is approximately given by ratio of the output compressed pulsewidth to the transducer impulse response length, is a direct function of the device's time-bandwidth product. Devices can be produced using simple dispersive transducers or by using long reflector structures called reflective array correlators (RAC) [8]. Time-bandwidth products from several hundred to tens of thousands have been achieved. The time-domain responses of the transmitted or received chirps may be weighted to produce a more optimum

Figure 13. The superimposed frequency response of all channels of a seven-channel SAW filter bank at a center frequency of 330 MHz. (Reproduced with permission from Sawtek, Inc.)

Figure 14. (a) Schematic of an upchirp SAW filter. (b) Schematic of a downchirp SAW filter.

time-domain pulse-compression response at the receiver. Figure 15 shows the frequency responses of an expander/compressor matched pair at a center frequency of 1 GHz having a bandwidth of 450 MHz, a dispersive delay of 0.45 μs, and a time-delay slope of 1000 MHz/μs. The compressed-time matched-correlator response has a compressed pulsewidth inversely proportional to the bandwidth (2.22 ns as compared with 2.9 ns measured) and a typical peak-to-sidelobe ratio of approximately 10 × log (time-bandwidth product), which is 23 dB.

3.5.2. SAW Chirp Fourier Transformer. Another application of SAW dispersive devices is in a chirp Fourier trans-

form system that performs a real-time Fourier transform of a given input signal, which is confined to the system bandwidth. Given a function $f(t)$ that has a Fourier transform, $F(\omega)$, the frequency domain function is written as

$$F(2\pi\mu t) = \int_{-\infty}^{\infty} f(\tau)e^{-j2\pi\mu t\tau} d\tau$$

where $\omega = 2\pi\mu t$.

Using the identity $2t\tau = t^2 + \tau^2 - (t - \tau)^2$, the equation is rewritten as

$$F(2\pi\mu t) = e^{-j\pi\mu t^2} \int_{-\infty}^{\infty} f(\tau)e^{-j\pi\mu\tau^2} e^{j\pi\mu(t-\tau)^2} d\tau$$

Figure 15. A dispersive SAW expander and compressor matched filter pair. The center frequency is 1.0 GHz, a 450 MHz bandwidth, 0.45 μs delay, and 1000 MHz/μs dispersion. (a) Expander and (b) weighted compressor. (Reproduced with permission from Sawtek, Inc.)

Figure 16. Schematic diagram of a SAW chirp Fourier transform system.

This is the equation form of the chirp Fourier transform that is a time function multiplied by a complex chirp, convolved with a second chirp, and then multiplied by a third chirp. A typical SAW implementation of a multiply-convolve-multiply (MCM) chirp transform system is shown in schematic form in Fig. 16. The convolve chirp is usually twice the length of the multiply chirps. The first multiply chirp conditions the input signal by adding the dispersive delay, and then the second chirp sorts the input signal frequencies in the time domain through the convolution process, providing the amplitude-frequency response curve. The final chirp multiply is necessary only if the phase information is desired and does not affect the amplitude response. Figure 17 shows a schematic representation of the system output for an input signal composed of three different frequencies. The convolve chirp is an up-chirp that sorts the frequencies from low with the smallest delay to high with the longest delay. The output signals have a finite time length due to the limited bandwidth of the SAW chirp system. The SAW implementation of the chirp transform system is not an exact implementation of the chirp Fourier transform because it is limited in both time length and frequency bandwidth. However, it works

Figure 17. Schematic representation of the output waveform of a SAW chirp system given the sum of three tones having equal amplitude as the input waveform.

well for bandlimited and multitone input waveforms used in radar and other military systems.

3.5.3. SAW Elastic Convolver. Spread-spectrum systems need some type of matched filter, correlator, or convolver to extract the transmitted signal from noise and interfering sources. SAW elastic convolvers were studied in the 1970s for use in militarily secure, spread-spectrum communication systems [8,9]. The SAW convolver is a three-port device that uses the nonlinear portion of the crystal constants to perform a real-time convolution on any two arbitrary input signals within the operating bandwidth and time length of the device. The device is shown schematically in Fig. 18. The device consists of two input interdigital transducers (IDT), two beam compressors, and a long output plate between the two beam compressors. The input IDT provides the input signal from the receiver, and the reference IDT provides the known reference code signal. To enhance the nonlinear effect within the crystal, the power density is increased by compressing the SAW beam to only a few wavelengths. The beam compressors are usually either multistrip couplers, a horn-type waveguide, or self-focusing IDTs with typical compression ratios of 5 to 20. The two counterpropagating waves are compressed and then trapped under the electrode waveguide, which is only a few wavelengths wide, where they eventually slide by each other. The nonlinear crystal parameters provide point-source multiplication, and the long solid electrode provides the summing bus that is proportional to the integration time. The output signal is the convolution of the two SAW input waveforms at twice the carrier frequency of the inputs. The processing gain of the system is given by the device's time-bandwidth product. Typical devices have time lengths of several microseconds and bandwidths of tens to hundreds of megahertz. A convolver with a 10 microsecond integration length and a 100 MHz bandwidth has a processing gain of 30 dB. Typical convolver efficiency is between -50 dBm to -75 dBm, which depends on the substrate material, bandwidth, integration time, and device design. Figure 19 shows the predicted and measured results of a $22 \mu\text{s}$ long, real-time SAW convolution of a coded MSK signal. The agreement between measurements and the theory of the compressed pulse are excellent.

4. SAW REMOTE SIGNALING AND SENSORS

4.1. Identification Tags

SAW devices are used in the passive mode as identification tags or in remote sensing. A schematic of a pulse-excited, time-reflective type of a coded SAW tag is shown in Fig. 20. The tag is composed of an antenna, a transducer, and a series of partial reflectors. A remote transmitter sends an interrogation pulse that is received by the antenna and excites the SAW transducer, which launches a wave. The SAW is partially reflected at each reflector and is sent back to the SAW transducer where it is retransmitted back to the interrogator. The center position of the reflector provides a series of delayed pulses that provide the unique code for identification. The device is totally passive, and the antenna and SAW chip are integrated into a single,

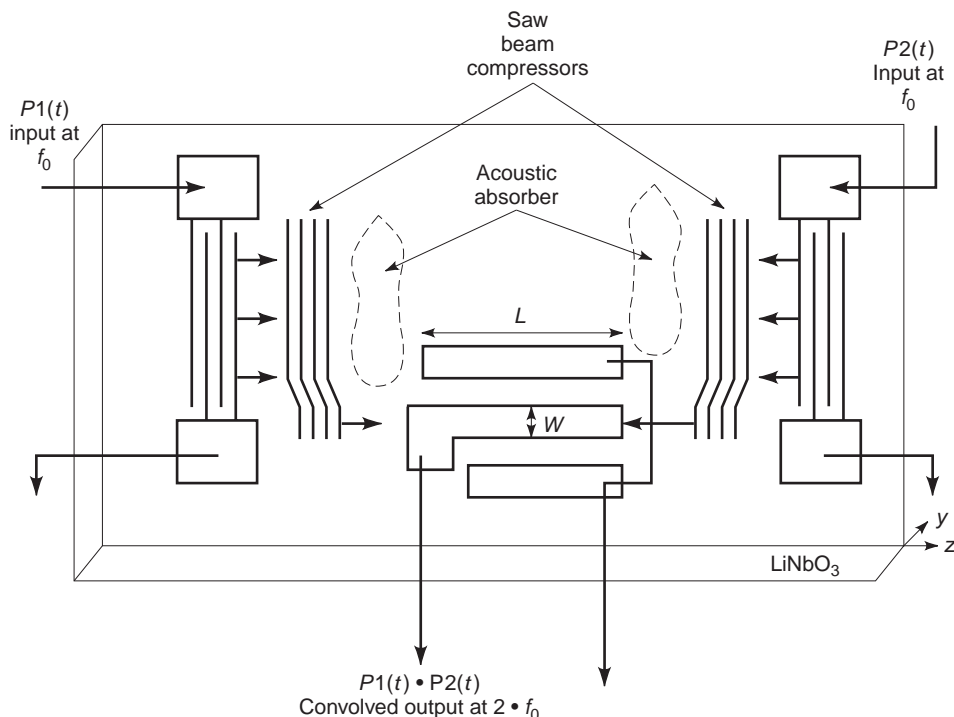

Figure 18. Schematic view of a SAW beamwidth compression elastic convolver.

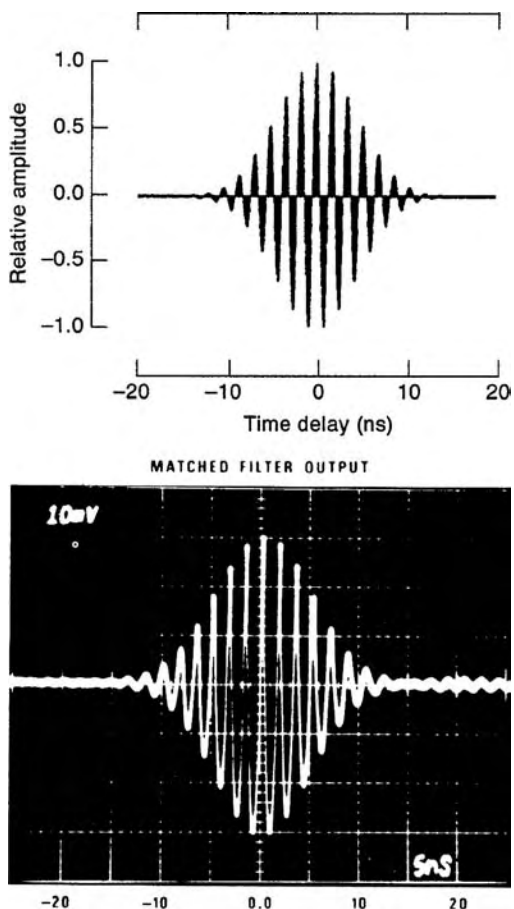

Figure 19. Correlation of a compressed-pulse time-response of a SAW elastic convolver.

low-cost package. Figure 21 shows the measured time-domain results for a reflective, coded, passive SAW tag. The time pulses are relatively uniform and discrete, which makes demodulation of the tag information easy and accurate.

4.2. Remote Signaling

Remote signaling has become very desirable and accepted by consumers and industry. Examples include remote car door openers, car accessory operation, garage door openers, remote lights, power utility meters, and others. It makes some very simple operations even simpler and faster, increases industrial productivity, and is used in inaccessible places and environments for control and sensing. The acceptance of such systems is based on the relatively small size and cost. As an example, a transmitter for a keyless automobile entry is embedded on the actual key with minimal increase in size. A simple system used for a keyless entry system is shown in Fig. 22 [9]. The system consists of two SAW filters, an amplifier, an integrated circuit for the code generator, and a battery. The two SAW filters and amplifier are placed in a single package, and a custom ASIC is designed and programmed for the specific code generator. The integrated circuit provides the code data, and the data format is simple on-off shift keying (OOSK). One SAW is used in the oscillator as the frequency-control element, and the second SAW filter is used to remove unwanted harmonics and spurious responses from the oscillator.

4.3. Sensors

Sensing the external environment using SAW technology is a relatively new and growing market. The different

Figure 20. A schematic of pulse-excited, time-reflective type of a coded SAW tag. The device consists of a transmit/receive antenna, a dual-purpose input/output transducer, and a series of reflectors that have centers of reflection corresponding to a pulse position code.

number and types of SAW sensor devices and systems cannot be adequately presented here [10]. SAW sensors are under investigation to sense gases, temperature, acceleration, pressure, and other parameters. The two critical issues are to find a sensitive sensing mechanism for the parameter of interest while eliminating or compensating for all other environmental elements, thereby isolating the measurement to only a single environmental element (gas, temperature, etc.). One popular method for measuring gases is to use a SAW delay line having a gas sensitive film in an oscillator circuit on the substrate surface. As the gas absorbs and desorbs, there is a change in the film's

Figure 22. Schematic of a simple, low-cost SAW-based remote keyless entry system using on-off shift keying. (From RF Monolithics data sheet, HX1000.)

elastic properties that creates a change in acoustic velocity, delay, and insertion loss. This is translated into a frequency shift in the oscillator. The change in frequency versus gas absorption is often determined in parts per

Figure 23. A schematic of a simple SAW sensor composed of a two-transducer-delay line with a selective absorbing film, which changes the amplitude, phase, and/or insertion loss of the delay line.

million for a well-calibrated system. A schematic of a simple SAW sensor is shown in Fig. 23. Sensing is developing into a very large market. Combining sensing with wireless transmission results in remote sensing applicable to a huge number of applications in transportation, medical, environmental, manufacturing, and many other fields.

1. INTRODUCTION TO SAW TECHNOLOGY

1.1. SAW Devices

Surface acoustic waves (SAWs) are mechanical waves whose associated particle displacements are bounded to the surface [1]. The typical penetration into the volume is in the order of one acoustical wavelength λ . Figure 1 shows a finite-element analysis of the particle displacement caused by a special surface acoustic wave, the so-called Rayleigh wave. The particle displacement in Fig. 1, however, is enlarged to make the displacement (or strain) visible. The actual displacements are in the order of some angstroms.

Figure 1. Finite-element analysis of the particle displacement caused by a surface acoustic wave.

On piezoelectric substrates SAWs can easily be generated by using so-called interdigital transducers (IDTs) shown in the left part of Fig. 2 [2]. A SAW device consists of metallic structures on top of a highly polished piezoelectric substrate, such as one or several of these IDTs and reflection or coupling gratings. Typically aluminum is used for the metallization. For an IDT, the widths and spacings of the electrodes and strips determine together with the phase velocity v the operating frequency f . The sum of the electrode width and spacing gives the geometric period p (pitch) of the IDT. In the plainest transducer, the pitch p is constant over the entire IDT. The resonance condition is given by a SAW wavelength λ of

$$\lambda = 2p \quad (1)$$

The operating frequency f of the IDT is thereby given by

$$f = \frac{v}{\lambda} = \frac{v}{2p} \quad (2)$$

The number of pitches N of the transducer gives its length in the time domain, which determines the bandwidth B of operation by

$$B = \frac{v}{2Np} \quad (3)$$

The input and output IDTs are electrically connected, for example, via bond wires to the pins of a hermetically sealed package (see Fig. 3). Triggered by the piezoelectric effect, an electrical microwave input signal at the transmitting IDT stimulates a microacoustic wave that propagates along the surface of the elastic solid body. In

Figure 2. Schematic of an interdigital transducer with pitch p and associated P -matrix model, where u and i are respectively the electrical voltage and current and a and b denote the incident and outgoing acoustic waves respectively.

Figure 3. Schematic drawing of a SAW filter.

contrast, a SAW propagating through an IDT generates an electric charge distribution at the receiving IDT, causing a microwave electrical output signal [3–10]. To suppress unwanted reflections from the edges absorbers become fixed to the ends of the chips.

The main advantages of the SAW technology are the low velocity of the acoustic waves, which allows the implementation of a large number of wavelengths or significant delay times within a small chip, and the high quality factor of the materials, which results in low attenuation factors. Both factors together allow for filters with relative bandwidths from 0.1% up to almost 100% with flat pass-band response, steep skirts, high selectivity, and precise phase characteristics.

Since the early 1990s, driven by the booming wireless technology business, great and important progress in SAW device performance has been made and a variety of innovative applications developed. Most telecommunication systems, in particular mobile radio and satellite systems, depend on extremely high-performance SAW filters. Large and, to an increasing extent, smaller radar systems have utilized pulse compression SAW filters. High-frequency SAW-based oscillators replace the low-frequency quartz crystal sources and the required frequency multiplier chains in many electronic systems. All modern television and televisionlike receivers contain SAW filters for Nyquist IF filtering.

Many digital spread-spectrum systems use SAW band-pass filters in the IF and RF stage up to 2.5 GHz [11]. Up to now wideband spread-spectrum systems were used mainly in military applications. Digital technology, however, allows the realization of spread-spectrum systems only with low bandwidths and long integration times. Therefore, most commercial systems are based on this technology. For digital CDMA systems, however, analog IF antialiasing filters are required; therefore SAW filters offering steep passband skirts, flat amplitude response, and linear phase are used. For indoor applications with strong interference a bandwidth higher than the coherence bandwidth is needed [12]. In spread-spectrum systems with high bandwidths SAW devices are the only choice for real-time signal processing such as correlation and spectrum shaping. Fixed-code matched filters have opened up a wide range of signal processing capabilities. SAW-based chirp spread-spectrum wireless system applications with extremely high data

rates have been demonstrated very successfully and are now in the pioneering stage on the market. Today digital signal processors (DSPs) can handle some 10 MHz bandwidth, while SAW devices can deal easily with some hundreds of megahertz of bandwidth. This advantage of SAW devices over DSPs will become smaller one day with progress in the development of digital circuits.

SAW sensors for many physical (electrical, mechanical, thermal, etc.), chemical, and biological quantities as measurands are now becoming mature and commercially feasible. Radio SAW sensing is under investigation at many laboratories, and a few new products are on the market. Wireless identification tagging and reading based on passive SAW interrogator labels (SAW tags) have recently been introduced to the market.

SAW technology has evolved since the mid-1970s and now allows the routine design of filters in the range from 20 MHz to 3 GHz [13]. This frequency band is used in many new wireless communication systems and for sensor applications, especially within the ISM frequency at 2.5 GHz, which is also used for the intermediate frequency for broadband systems operating at higher frequencies [14]. Currently, the submicrometer manufacturing and material techniques are improving greatly and are encompassing even higher frequencies of ≤ 10 GHz. Delay-time lengths are limited by the size of standard wafer dimensions to 16 μ s. Precise simulation tools for SAW devices are available. Thus it is possible to optimize the SAW devices on a computer before fabrication of the first samples. Very accurate SAW devices performing complex signal processing in communication systems may be designed.

1.2. Materials and IDTs

The invention of the IDT in 1965 [2] as a most efficient technique for the generation and detection of SAWs on a piezoelectric substrate immediately paved the way to two major microwave engineering product design directions, with quite different thrusts. At one end of the scale, in the high-volume, low-cost-component market, the challenge was related to whether mass-produced SAW filters and resonators could be competitive in price and performance with established technologies. At the opposite end, the focus was on low-volume, high-cost components for radar signal processing and maximum emphasis was given to the efficient implementation of SAW pulse compression filters with very large compression gains. Between these two extremes, a wide range of other SAW device configurations and applications began to receive intensive research scrutiny.

SAW devices are based on excitation, propagating, reflection, and detection of microacoustic waves. On the basis of a variety of physical principles, methods and techniques have been developed for the microwave–microacoustic transduction, for reflecting, guiding, focusing, and amplifying the waves, and for introducing controlled dispersion. The use of transduction and reflection, which are the basic mechanisms in most SAW devices, is discussed by way of a two-port resonator illustrated in Fig. 4. Both the IDTs and the reflectors are distributed elements, consisting of an array of metallic electrodes or strips. The

Figure 4. Schematic layout of a two-port SAW resonator. Two IDTs (input and output) are backed by several reflector strips forming a cavity.

(active) IDTs exploit piezoelectricity to launch and detect the SAW waves. The (passive) reflector gratings, usually a set of metal strips that can be short- or open-circuited, act within their stopband as a mirror reflecting the incident waves, thus forming a cavity. Elements combining transduction and reflection with a predefined phase relation (Fig. 5) are in use for advanced SAW IF filters. They enable single-phase unidirectional transducers (SPUDTs) and contribute to the size reduction of IF filters by using resonances within the transducers.

For an arrangement of strips with a width of $\lambda/4$ and a pitch of $\lambda/2$, reflections add up constructively. Therefore a sequence of alternatively polarized type 1 structures will result in both strong transduction and reflection. On the other hand, using an arrangement of strips with a width of $\lambda/8$ and a pitch of $\lambda/4$ (split finger), (e.g., type 2, 3, or 4), reflections add up destructively. Cell types 2 and 4 will launch a transduction with opposite sign, while a type 3 cell will introduce no transduction and reflection.

The first basic design parameter is the phase velocity v , because according to Eqs. (2) and (3) it determines the spacing and number of pitches of a transducer for a given operating frequency f and bandwidth B . The second basic design parameter is the electromechanical coupling coefficient k^2 , which is a measure of the efficiency in converting an applied microwave signal into mechanical energy associated with the microacoustic wave. It also determines the minimum insertion attenuation of a SAW device for a given relative bandwidth. Because of the piezoelectric effect, the SAW velocity differs little between free or metallized

Figure 5. Basic cells for building a generalized SPUDT.

Table 1. Properties of Frequently Used SAW Substrate materials

Material	Orientation ^a		v (m/s)	k^2 (%)	TCD (ppm/K)
	Cut	Prop			
Quartz	ST	X	3158	0.1	0
	37°rotY	90°rotX	5094	0.1	0
LiNbO ₃	Y	Z	3488	4.1	94
	41°rotY	X	4750	15.8	69
	128°rotY	X	3980	5.5	75
LiTaO ₃	36°rotY	X	4220	6.6	30

^a“Orientation cut” denotes the crystalline orientation of the substrate surface normal; “orientation prop” gives the orientation of the wave propagation direction.

surface, or within an IDT. Again, k^2 gives the relative difference between the velocities with electrically open/short-circuited surface. Both v and k^2 depend on the material tensor elements of elasticity, piezoelectricity and dielectric permittivity, and on the mass density (among others).

A wide variety of single-crystalline substrates such as quartz (SiO₂), lithium tantalate (LiTaO₃), and lithium niobate (LiNbO₃) are commonly used for SAW devices. The wave types propagating on these substrate materials show velocities v between 3000 and 5000 m/s, which is slower by a factor of 10^5 compared to that of guided electromagnetic waves, such as waves guided by microstrip transmission lines. Thus, devices operating in the VHF/UHF frequency region can be fabricated with linewidths in the order of micrometers or below, which can be produced very accurately and reproducibly using optical projection printing techniques.

Table 1 gives an overview on the fundamental SAW properties of some of the most frequently used cuts. Quartz crystal cuts show excellent temperature stability, which is given by the temperature coefficient of delay, (TCD). The coupling coefficient k^2 , however, is low, which limits the relative bandwidth that can be electrically matched without losses to some percent. Therefore, quartz crystal cuts are used mainly for narrowband devices down to 0.1% relative bandwidth, or when steep skirts in the transfer function are specified. SAW devices on quartz are used in the IF stages of mobile phones, for resonators or delay lines used in local oscillators, and for dispersive delay lines used in radar applications. The coupling coefficient k^2 of LiNbO₃ is much larger than that of quartz, allowing medium-loss devices for wideband applications with relative bandwidths up to $\sim 10\%$. SAW devices on LiNbO₃ are used for IF filtering in TV or satellite receiver sets, for example. Some special cuts, like the 41°rotY cut of LiNbO₃ or the 36°rotY cut of LiTaO₃ show extreme high coupling coefficients, which makes these cuts highly suited for low-loss and wideband applications needed in the RF stages of mobile phones.

1.3. SAW Design

The design of SAW devices is based mainly on signal theory. Signal theory algorithms such as impulse response modeling [15] allows for a first-order design because the impulse response $h(t)$ of the IDT is—with the help of the

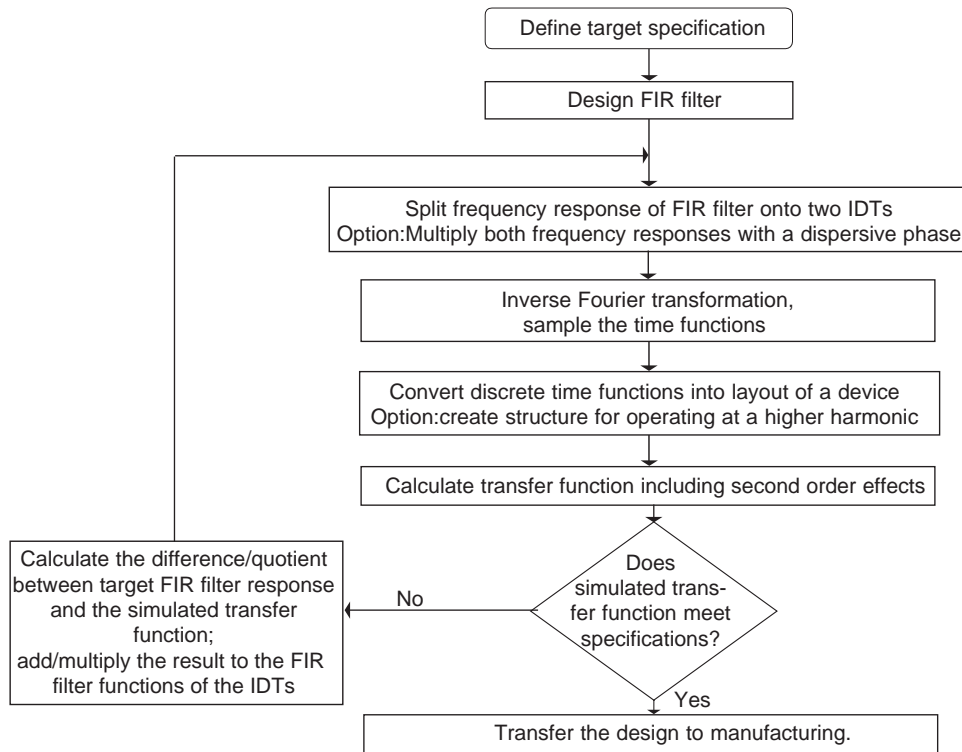

Figure 6. Flowchart for the design algorithm of a SAW delay line.

SAW velocity v —directly related to the overlap and spacing of the electrodes if reflections are not dominant. The frequency response $H(f)$, which is the Fourier transform of $h(t)$, therefore can be computed quite straightforwardly from the electrode pattern. This procedure can also be reversed and used for filter synthesis. To achieve a given transfer function for a transducer, for example, the overlaps can be weighted (apodized) according to the corresponding impulse response. Figure 6 is a flowchart for a typical design algorithm of a SAW delay line.

SAW tapped, reflective, or transducer-coded delay lines are specified mainly in the time domain. SAW linear, pulseshaping, and nonlinear phase delay lines, on the other hand, are specified mainly in the frequency domain. To start the design, these specifications must be transferred into a finite impulse response [15–19].

In the next step, the target frequency response has to be split up onto two IDTs, which can be achieved by using one apodized and one uniform transducer, with one or both transducers being dispersive, or by using two dispersive and amplitude weighted transducers. If an uniform IDT is chosen, the frequency response of the weighted transducer is given by the overall frequency response $H(f)$ divided by the frequency response of the uniform IDT. When using two weighted IDTs, the frequency response can be split using the square-root method [19]. If dispersive transducers are chosen, their appropriate phase or chirp functions have to be multiplied additionally by the frequency response of each individual transducer. The chirp functions can be adapted to improve the matching conditions for the IDTs. After transforming the frequency response of each individual transducer into the time

domain, a linear or a nonlinear sampling method is applied to both time functions, which allows a synthesis of an initial guesses for the two IDTs of the delay line [19]. To transfer this sampled IDT into a geometric layout, the SAW velocity within the transducer v_{IDT} has to be determined quite accurately. The group delay time specification of the device can be achieved by a proper shift of these building blocks by using the SAW velocity on free space v .

Filters operating at the third harmonic can be designed at their nominal frequencies and, instead of taking every tap, only every third active tap is realized. For IDTs operating at even higher harmonics, every fifth, seventh, and higher active tap may be selected.

Signal theory guidelines, however, are not adequate for accounting for microwave and microacoustic effects. These so-called second-order effects include the acoustic reflections at strips and electrodes, effects due to the charge distribution on electrodes; mechanical loading effects such as mass loading, stress loading, and topographical loading at strip edges; the microacoustic attenuation and dispersion; the diffraction and refraction of the waves, beamsteering due to anisotropy of the substrate; the generation of spurious bulk acoustic waves (BAWs) in the IDTs and/or the conversion of SAWs into BAWs, ohmic losses of the strips; and electromagnetic feedthrough between IDTs. This second-order effects can be treated only by using network theory or field theory algorithms.

The quantitative characterization of the second-order effects is solved by field theory approaches [20], by test chip measurements, and by a combination of both [21]. In order to store the results in databases, they are fitted to simple, mostly analytic expressions depending on

Figure 7. Basic cells for the *P*-matrix model. The transversal finger structure is divided into several substructures, which can be simulated in a straightforward manner. P_d , for instance, gives the *P* matrix of a “down” step, P_f of a free surface, P_u of a “up step,” P_m of metallized surface, P_e of an electrical charge, and so on; *o* is the symbol for the *P*-matrix cascading algorithm.

frequency, geometric parameters (e.g., metallization height, metallization ratios), and material parameters (e.g., coupling coefficient or mass density). Bond wires, chip layout effects, and package parasitics are accounted for using adequate lumped-element models.

For a SAW analysis, the SAW structures are subdivided into substructures that are further subdivided into basic two-port (with two acoustic ports) or three-port cells (with two acoustic and one electric port), as depicted in Fig. 7. A typical basic cell, for example, may be a single electrode as well as a detail of an electrode. This may be necessary when the charge distribution on the electrodes (depicted in Fig. 8) or edge effects are modeled. The electrical and acoustical descriptions of the substructures are then

Figure 8. Electrical charge distribution on the electrodes in a section of an IDT.

cascaded using network theory algorithms. Popular techniques include various lumped-element methods such as equivalent-circuit modeling techniques, matrix manipulation techniques such as *P*-matrix formalisms (Figs. 2 and 7), or coupling-of-modes (CoM) techniques [22]. By cascading all the subcells, and by including the microwave parasitics and electrical matching structures, the electrical terminal behavior of the microacoustic device, which gives the simulated transfer function, can be analyzed. To simulate diffraction effects, an extended angular spectrum of the straight-crested waves model can be used [23,24].

The deviations of the simulated transfer function from the target frequency response can be used in an optimization process to modify the two frequency responses defining both IDTs. This gives two new IDT functions, which build the starting point of the next synthesis, the next simulation, and, if necessary, the next optimization. The number of necessary iterations of this optimization process depends on the specifications of the delay line, but typically 5–10 iterations are sufficient. If the simulated transfer function of the final optimization run comes close enough to the specified target frequency response, the geometry of this design is transferred to the technology for manufacturing.

1.4. Manufacturing

SAW manufacturing is based on the technology of integrated circuits [13]. The basic prerequisite for the reproducible manufacturing of SAW components is that the wafer material be as perfect as possible. Only a defect-free monocrystal and a good standard of surface polish will ensure constant propagation velocity and low damping of the waves. In contrast to the semiconductor process, only one single metallization layer has to be manufactured, but with a much higher demand with respect to geometric precision of the linewidth and thickness uniformity. For instance, projection printing using a wafer stepper is a reliable fabrication technique that provides the required high resolution and positional accuracy as well as a low defect density. In conjunction with a single-level liftoff or etching process (see Fig. 9), this provides the best dimensional stability and reproducibility of the aluminum structure, together with the smooth finger edges that are particularly important for the propagation properties of the acoustic waves. Small variations of the electrical performance are introduced by misalignments of the orientation of the wafers, variations of the metallization height, and deviations from the desired mark:pitch ratio.

The pattern of small SAW devices is repeated several times on the mask so that a large number of devices can be exposed simultaneously. For larger SAW devices, such as long delay lines, tapped delay lines, chirp filters, and convolvers, the devices have to be composed on the wave using a programmable wafer stepper. Wafers with diameters of ≤ 5 in. are used in today’s high volume fabrication. For special applications crystal substrates with lengths of ≤ 25 cm are available, which, in principle, enables SAW devices having delays times up to $40 \mu\text{s}$.

The maximum operation frequency is given by the minimum linewidth. Very fine lines can be obtained by X-ray

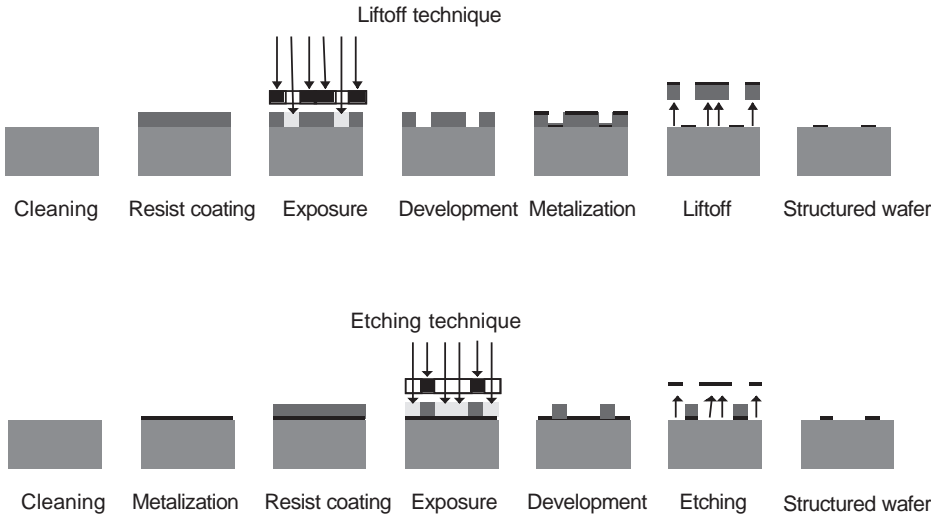

Figure 9. Process flow of SAW device fabrication (*top*—liftoff technology; *bottom*—etching technology).

[25] or electron-beam exposure [26], deep UV, or ion projection [27], which allow linewidths down to $0.1\ \mu\text{m}$ and fundamental frequency responses up to 10 GHz. However, those techniques are still, in the experimental stage. SAW companies often use optical lithography, which allows a patterning down to $0.3\ \mu\text{m}$ with a high precision of linewidth [28]. As is seen from Fig. 10, high resolution and good edge quality are achieved. Using this process, the fabrication of SAW devices operating up to 2.45 GHz in the fundamental mode has been demonstrated.

From the packaging point of view the most commercial challenge today is the miniaturisation of SAW filters and their integration into front-end modules [29]. Epcos, for instance, has developed a highly miniaturised chip-size package technology (see Fig. 11). The SAW chip is flip-chip mounted onto a chip carrier serving as the bottom part of the package. The electrical connections to the chip are bonded with solder bumps. An underfiller attaches the SAW chip solidly to the chip carrier. Thus, the backside of the chip can also serve as part of the package. To protect the surface of the acoustically active area of the SAW chip, a cavity is built on the wafer with photolithographic process in two steps. First, a closed polymeric wall is placed

around the active filter structure. Using the same process, this wall is then covered with a roof. Using this technology, Epcos could introduce SAW filters for 2 GHz applications, such as personal communication networks and systems and UMTS (Universal Mobile Telephone System) devices available in a $2 \times 2 \times 0.8\text{-mm}^3$ -chip package technology. The technology, moreover, allows for a further miniaturisation of SAW filters beyond a $1\ \text{mm}^2$ footprint area.

2. TWO-PORT DEVICES

The two-port devices of the SAW delay lines can be subdivided into linear phase, dispersive, and tapped delay lines. This devices are mainly used for expanding, compressing, or pulshaping in the IF part of radar or spread-spectrum communication systems. Additional applications for linear phase delay lines are in the feedback loop of an oscillator or for the signal delay necessary in military surveillance systems or in calibration routines for radar systems.

2.1. Linear Phase Delay Lines

Linear phase delay lines with long delay times are needed mainly for military surveillance systems [16] and for the

Figure 10. SEM photograph of part of an IDT with $0.6\ \mu\text{m}$ periodicity and $0.4\ \mu\text{m}$ linewidth.

Figure 11. Chip-size package technology (© Epcos, Munich, Germany).

Figure 12. Normalized measured transfer function of a delay line operating at a center frequency of 384 MHz with a relative bandwidth of more than 50%.

linearization of radar systems [28,30]. For both systems large absolute bandwidths are requested. A special application of linear phase delay lines are spectrum-shaping filters like PSK to MSK conversion filters.

Figure 12 shows an example for a typical transfer function (normalized) of a linear phase delay line [31] achievable in SAW technique operating at a centre frequency of 380 MHz and covering a relative bandwidth of 52%. The insertion attenuation is approximately 25 dB. The delay time is $0.75 \mu\text{s}$. The amplitude deviations within the pass-band are less than $\pm 0.5 \text{ dB}$. The ripple on the group delay response is caused by acoustic reflections. If these reflections are gated in the time domain, group delay errors are within $\pm 1 \text{ ns}$.

For SAW devices with large absolute bandwidths, a high center frequency, which lowers the required relative bandwidth, is of advantage. Furthermore, a great variety of amplifiers and other circuitries are available for the ISM band from 2.4 to 2.5 GHz. Therefore, nowadays many commercial radar systems use this frequency band for IF operation. Figure 13 presents the layout of a linear phase SAW delay line incorporating a shielding pad between

Figure 13. Typical layout of a linear phase delay line for a center frequency of 2.45 GHz.

both IDTs (dark gray area) to lower electromagnetic feedthrough. The bulky black hexagonal areas are the bonding pads. The center frequency of this delay line is 2.45 GHz, and group delay times of 1.0, 1.5, and $2.0 \mu\text{s}$ have been realized. The area of an IDT directly scales with the acoustic wavelength and thus shrinks when increasing the center frequency. For the bonding pads, on the other hand, a minimum area is needed for a safe bonding process. Thus, for high frequencies the bonding pads become larger than the acoustically active area of the IDT. The filter has been designed for operation bandwidths of 400, 600, and 800 MHz, respectively. The devices exhibit excellent passband characteristics and low group delay distortions similar to those shown in Fig. 12. The insertion attenuation is approximately 25 dB. Stopband attenuation is better than 30 dB close-in.

2.2. Pulseshaping Linear Phase Delay Lines

The amplitude and phase of the transfer function of a SAW delay line filter can be designed independent of each other, as pointed out in Section 1. Thus signals, which are limited in both the time and frequency domains, can be shaped by SAW delay-line filters. For example, it is possible to design SAW delay lines having a rectangular impulse response with constant phase, which results in a sinc transfer characteristic and linear phase in the frequency domain.

Phase-shift-keyed (PSK) signals are quite easily generated digitally. A PSK signal consists of a sequence of contiguous chips of duration T_c and uses two signal phases: -0° and 180° . If the state of two consecutive chips remains the same, then the phase of the signal does not change. If the chip state changes (from 0 to 1, or 1 to 0), the phase of the signal changes by 180° . A MSK signal also consists of a sequence of contiguous chips of duration T_c , but there are no phase shifts at the transitions between adjacent chips. Instead, the instantaneous frequency of the carrier takes on a value f_1 in some of the chips and a value of f_2 in others, again in a pseudorandom sequence. The phase of a MSK signal is everywhere continuous, and so is its first time derivative since the transitions between f_1 and f_2 occur at the peaks of the waveform. Because of this “smoother” nature of the waveform, the amplitude of the spectral sidelobes falls more rapidly with the distance from the center frequency confining 99.5% spectral energy within its mainlobe, compared to 92% of a PSK signal. Also, MSK signals show a 33% higher spectrum efficiency when compared to PSK signals and thus allow higher bit rates or lower bit error rates (BER) for the same given bandwidth.

In contrast to PSK signals, minimum-shift-keyed (MSK) signals are more difficult to generate. In order to convert a PSK signal into a MSK signal, the convolution with a rectangular time function has to be performed [6,32]. The length of the rectangular time function must be one chip length of the PSK signal. This can be done easily with a SAW delay line. This spectrum-shaping feature can also be implemented in the SAW IF filter of a superheterodyne receiver, and it can be included in a SAW tapped delay line, as shown in Section 2.4.

Figure 14. SAW-based PSK-to-MSK conversion filter [6, p. 191].

Figure 14 [6, p. 291] shows a sketch of this PSK-to-MSK signal conversion with the help of a SAW conversion filter. A PSK waveform at an angular frequency f_1 and a chip length T_c is fed to the SAW conversion filter with an impulse response of a time length of T_c at an angular frequency f_2 . The output signal then is a MSK waveform whereby the code is represented by the two angular frequencies f_1 and f_2 . An almost rectangular impulse response is generated using one very short IDT and one with a length vT_c . The two angular frequencies f_1 and f_2 are chosen to satisfy the condition

$$(f_2 - f_1) T_c = \frac{1}{2} \tag{4}$$

This means that a f_2 chip contains an extra one-half cycle of carrier as compared to a f_1 chip.

In Fig. 15 the measured frequency and impulse responses of a PSK-to-MSK conversion filter for a system using a chip rate of 60 ns are shown. Deviations in the upper frequency band are caused by electrical feed-through. Spurious signals in the time domain are below 30 dB.

2.3. Nonlinear Phase Delay Lines

First applications of nonlinear phase (sometimes called *dispersive*) SAW filters were in radar systems for pulse expansion and pulse compression [33–35]. Typical characteristics of these filters were bandwidths of a few percent and integration times up to 20 μ s. The nonlinear phase function in the frequency domain of an expander and the appropriate compressor filter have to cancel each other to

result in an overall linear phase function of the system. In subsequent systems the expanded signals were generated digitally and SAW filters were used only for compression of the expanded signals.

SAW dispersive delay lines were also used as spreading and despreading filters in spread-spectrum transmission systems, and for very fast broadband channel sounding [36,37]. The spreading/despreading function can be implemented as a special feature in the SAW IF filters of the transmitter and receiver. Thereby, no further components or wiring is needed to upgrade a conventional transceiver to a spread-spectrum system. For this application, SAW dispersive filters and SAW tapped delay lines (see Section 2.4) are used. Dispersive filters generate compressed impulses with a much lower sidelobe level. However, in contrast to tapped delay lines, only two (almost) orthogonal codes can be implemented using SAW dispersive delay lines, an “up” chirp and a “down” chirp.

Two different filter techniques were used for the building of a dispersive delay line; in the first, the input and output transducers are arranged in parallel acoustic tracks and the signal is shaped by chevron-type reflectors, which connect the input and output transducers acoustically. These devices are called *reflective array compressors* (RACs) [38–40]. As the length of the crystal chip is used twice, the integration time can be extended up to 40 μ s for standard 3-in SAW wafers. The second configuration consists of two inline transducers, and the weighting function is implemented in both transducers [17,19,41].

As an example, a pulse compression filter covering a long chirp time of 12 μ s over a bandwidth of approximately 6 MHz is shown in Fig. 16. The main second-order effect of

Figure 15. Normalized measured frequency and impulse responses of a PSK-to-MSK conversion filter for a system using a 60 ns chip rate.

Figure 16. Impulse response of a dispersive delay line with a chirp time of $12\ \mu\text{s}$ and a bandwidth of 6 MHz. The filter is used as compressor in a pulse compression system. Therefore, the amplitude of the filter is weighted according to a Hamming function.

a SAW device of such specification is due to diffraction effects caused by the long delay time. By compensating these diffraction effects, the suppression of close-in spurious signals of the compressed impulse can be improved significantly, as demonstrated in Fig. 17.

The software for the design of chirped SAW devices for pulse expansion and compression has been improved continuously. In the 1980s it was necessary to utilize the principle of stationary phase to compensate second-order effects. Starting from the 1990s, it became possible to design pulse compression filters even with a low time-bandwidth product using optimization techniques [19]. As an example, two dispersive filters (expander and compressor) are shown in Fig. 18. These filters were designed using optimization techniques.

2.4. Tapped Delay Lines

One of the key technologies of modern RF consumer communications is the spread spectrum technique [12]

Figure 17. Compressed pulse using the compressor of Fig. 16 (solid line—final design including compensation of diffraction; broken line—first design).

which originated in the military arena with a flurry of developments during and following World War II. Spread-spectrum communication became the standard for military signaling since it reduces the friendly communicator's detectability and combats the enemy-introduced interference.

Because of its inherent wideband transmission and the occurring processing gain, spread-spectrum communication also shows excellent performance in preventing multipath phenomena and allows to transmission of signals over noisy channels with a high degree of signal security.

Driven by the immense progress of communication systems, in the mid-1980s research groups began to develop wireless spread-spectrum demonstrators, shifting spread-spectrum from military to commercial applications. The radio channel of modern portable cordless telephone systems, for example, in indoor cells such as business and public administration buildings, shows a large coherence bandwidth and small delay spread (typically 30 MHz and 100 ns). These channel properties are optimally exploited by a spread-spectrum system using a higher bandwidth than the coherence bandwidth. Therefore, throughout the world, civil spread-spectrum systems are now in practical use, such as in wireless LAN products. The ongoing trend toward spread-spectrum communication is due to its excellent robustness in indoor radio channels, the demand for user privacy, with low-power, unlicensed communication devices, and also low cost of systems.

Modern commercial spread-spectrum systems use a frequency hopping (FH) or the direct-sequence code-division multiple access (DS CDMA) system, both combined with time-division multiple access (TDMA). Most modern DS CDMA systems use pseudonoise (PN) codes for channel separation. The RF energy, thereby, is spread across a wide frequency band by replacing each data bit by a number of chips, namely, multiple subbits, which occupy the same time interval. The more the signal is spread, the lower is the interference threat to or from other systems using the same frequency band. For that reason, in most countries regulatory bodies insist on a minimum processing gain of 10 dB. The upper limit of processing gain is determined mainly by the available RF bandwidth. Some new concepts, however, use a chirp function instead of the pseudonoise codes, resulting in a chirp spread-spectrum system (see Section 2.2). In a CDMA or chirp system the correlation of the received signal with a given time function (code or chirp function) has to be performed in the receiver.

Among the encoding and decoding techniques necessary in all spread-spectrum systems [12], analogue SAW matched delay lines can be used for code generation and as matched filtering to despread the received information signal [31,42]. Using SAW matched delay lines [43,44], the correlation can be carried out asynchronously, and the front-end hardware can be implemented simply and compactly. SAW matched delay lines easily exhibit moderate correlation gain values in the order of 20–30 dB, which cannot be met by digital matched filter implementations. For many systems a fixed-code SAW tapped delay line (TDL) is feasible as a matched filter.

Figure 18. Geometry of the expander (top) and compressor (bottom) filter. The meander line through the active taps is depicted.

In SAW dispersive matched delay lines, different phase (and eventually amplitude) spread-spectrum modulation schemes can be implemented. Two, three, or more phase states for the code chips extend the variety of signals with good correlation properties and high resistance against interference in buildings. Exclusively binary signals do not offer this variety, and their detection after hardlimiter sampling is very sensitive to sinusoidal interference [36,37].

The desired correlation function can be realized in the SAW delay line and defines the impulse response of the delay line. In addition, an optional frequency limitation may be built in. A schematic layout of a PSK tapped delay line is depicted in Fig. 19. Additional weighting functions necessary to convert the PSK signal to an MSK signal can be implemented easily.

A SAW tapped delay line basically is a transversal SAW filter incorporating an input interdigital transducer (IDT) and an output IDT, one of which is phase-coded like the one shown in Fig. 19 for binary phase shift keying (BPSK) modulation. The chip-defining reversal of the waveform cycles is simply achieved by an appropriate polarity reversal of the IDT fingers.

Instead of BPSK modulation, which gives a theoretical sidelobe suppression of 13 dB, a MSK modulation scheme can also be applied. This can be achieved, for instance, by using an input IDT according to Fig. 19, having a time length of one chip. Thereby, this IDT will perform an additional convolution with a rectangular time function of one chip length to PSK transfer function. The impulse response of a MSK tapped delay line is depicted in Fig. 20. The instantaneous frequency is directly related to the code, here a PN code sequence with a length of 128 chips. The time sequence of the two different frequencies of the MSK modulation scheme can easily be seen.

Figure 21 gives the power spectrum of the MSK-modulated tapped delay line. In comparison to BPSK, a MSK modulation results in a 10 dB additional sidelobe suppression and a falloff increased by 6 dB. The insertion attenuation of this delay line is approximately 18 dB. The binary pattern of the tapped delay line cannot be seen in the frequency domain, but the bandlimitation of the

output IDT is obvious. Additional weighting of the spectrum for generating a Gaussian MSK is possible.

The performance of a tapped delay line is characterised by the correlation response. The correlation gain obtainable depends on the choice and length of the binary code. In our example the length of the code is 128 chips, the correlation gain is 21 dB, and the peak:sidelobe ratio is approximately 15 dB, as shown in Fig. 22.

3. ONE-PORT DEVICES

The one-port devices of SAW delay lines are mainly wired to antennas and used for passive marks in identification or sensor systems.

3.1. Operating Principle of a SAW-Based Wireless Passive ID or Sensor System

SAW devices can be used as identification and sensor elements not requiring a power supply for measuring wirelessly physical, chemical, and biological quantities such as temperature, pressure, torque, acceleration, and humidity [14,45,46]. These applications are based mainly on the invention and implementation of SAW identification (ID) tags and their combination with traditional SAW sensor techniques.

The operating principle of such a system is schematically depicted in Fig. 23. A radiofrequency electromagnetic (RF) readout signal is transmitted by the reader unit, which contains a radar transceiver. A small portion of this signal is picked up by the antenna of the passive SAW transponder, where an IDT, connected to the antenna, converts the received signal into a SAW.

The microacoustic wave is stored for a certain time in the SAW device and coded according to the code number or the sensor variable of interest. This storing of the acoustic

Figure 19. Schematic layout of a PSK tapped delay line.

Figure 20. Impulse response and instantaneous frequency of a tapped delay line applying a MSK modulation scheme.

Figure 21. Normalized frequency response of the MSK-modulated tapped delay line.

energy can be done using either a delay-line configuration or a resonator. If the storing is done using a delay-line configuration, the information is encoded in the number, the time positions, and the phases of the response pulses. This coding can be achieved by using either a coded transducer, as depicted in Fig. 25, or reflector array, as shown in both Figs. 23 and 26. If resonant structures are used for storing, the information is encoded by the center frequencies and the respective phases. The temporarily stored and coded microacoustic signal is reconverted into electrical signals by the IDT and retransmitted to the radar transceiver unit via the transponder antenna.

Because of the low velocity of SAWs, long delay times in the range of some microseconds can be achieved using rather small SAW chips. Therefore, at VHF/UHF frequencies, environmental echoes caused by electromagnetic multipath propagation phenomena are already safely faded out when the sensor response arrives at the radar transceiver (see Fig. 24). Hence, the response signal of the SAW ID tag or sensor can easily be separated from environmental echoes in the time domain.

The response signal of the SAW ID tag or sensor contains all information about the number and geometries of the coding structures as well as the propagation and

Figure 22. Autocorrelation function of the tapped delay line shown in Figs. 20 and 21.

Figure 23. Schematic of a SAW-based radiolink system that uses a reflective delay line.

reflection properties of the SAW. Its evaluation in the radar unit may allow for the extraction of the desired information, which may include the sensor effect to a certain measurand or a specific ID number. As the distance between the radar transceiver and the SAW transponder is unknown or may even vary, differential evaluation of the signals are usually employed and differences in amplitudes, phases, frequencies, and propagation time delays are evaluated.

SAW transponders are passive components without any active logic on chip. Therefore, they cannot be addressed individually. To access more than one transponder, a frequency-division multiple access (FDMA), time-division multiple access (TDMA), code-division multiple access (CDMA), space-division multiple access (SDMA), or any combination of these must be realized. For FDMA orthogonal frequency bands or subbands must be used for each individual transponder. This technique is feasible for several resonant transponders [47,48]. When implementing a TDMA scheme, different time positions for each reflected signal must be chosen for minimising intersymbol interference. Typical 10 TDMA reflective SAW delay lines, each with three or four reflectors, can be realized. Using CDMA and the corresponding signal processing, again approximately 10 transponders having orthogonal codes can be addressed [49,50]. For SDMA techniques a space separation of the transponders has to be ensured. Because of the field attenuation of Rx (receiver) power with r^4 , the near-far problem limits the multiple access of passive radio transponders.

Figure 24. Response signal of a SAW ID tag or wireless sensor.

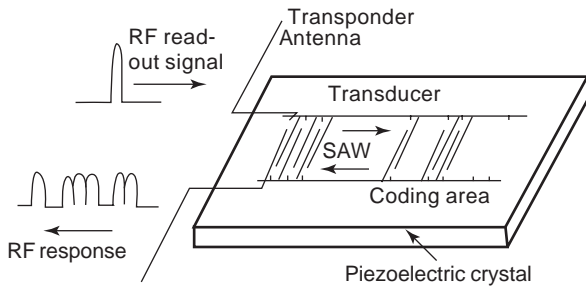

Figure 25. Schematic layout of a SAW ID tag with several coding transducers electrically connected to a common busbar.

Dipole, patch, slot, or loop antennas are used for passive SAW transponders. In the VHF/UHF frequency range, the insertion attenuation of SAW transponders is in the order of 20–60 dB [14,45,46], depending on the operating frequency, the substrate material, and the number of reflectors. The achievable access rate is up to 10^5 per second. The latter fact allows for communication with fast-moving objects or vehicles.

The reader units for SAW ID tags or wireless sensor system applications [14,46] resemble those used in traditional radar systems. For fast-moving or fast-changing measuring conditions, pulse radar or pulse compression radar systems have been used; in cost-sensitive applications, FMCW (frequency-modulated carrier wave) or stepped-frequency systems are used.

In Europe, only two frequency bands suitable for SAW ID tags and/or wireless sensor applications are allocated for unlicensed low-power devices (LPDs) such as industrial, scientific, or medical (ISM) apparatus: 433.07–434.77 MHz and 2.4–2.4835 GHz. The allowed equivalent isotropically radiated power (EIRP) in these bands is $P_0 = 25$ mW. Applying this power level, the typical readout distance for a SAW ID tag or wireless sensor is in the order of several meters. Table 2 summarizes typical resolution values that can be achieved using passive SAW sensors read out wirelessly by a radar transceiver [14].

3.2. Identification Tags

For ID tags, a great amount of individual coding is required. A SAW ID tag usually incorporates a coupling IDT and a coding area [51–54]. There are two ways of designing the coding area—either reflectors are used (see

Figure 26. Schematic layout of a reflective delay line.

Fig. 26) or, alternatively, several coding transducers are wired together by a common busbar (see Fig. 25). The layout of a delay line with several coding transducers is similar to that of a tapped delay line, whereby the tapped transducers are connected by a long busbar to the coupling transducer to build up a one-port device. On high-coupling materials with a high dielectric constant, there might already arise some electrical phase shifts on this busbar, deteriorating the overall performance. In principle, the coded transducers could also be electrically connected to the coupling transducer and the antenna via a circulator, a phase combining network, or bonding wires.

Most SAW ID tags and passive sensors are designed using a reflective delay line, like the one sketched in Fig. 26. The surface acoustic wave in a reflective delay line propagates toward reflectors distributed in a characteristic barodelike pattern and is partially reflected at each reflector. Using reflectors reduces the chip length by a factor 2 compared to the nonreflective arrangement shown in Fig. 25. Furthermore, the electrical impedance of the transducers remains unaffected by the actual code.

The coding of a SAW ID tag depends on the applied modulation technique. In the simplest case, this coding is done by a binary amplitude shift keying ASK (ON/OFF); each predetermined possible symbol position is occupied either by a transducer or reflector (ON bit) or not (OFF bit). Figure 27 shows a measurement of an ID tag using a reflective delay line structure and an ASK modulation scheme. Using 32 symbol positions, 2^{32} different tags can be coded. ID tags with ASK modulation are already in use, such as in German subway systems operating at 2.45 GHz [45].

The ASK ON/OFF keying is outperformed by other modulation techniques such as phase shift keying (PSK). A binary PSK (BPSK) modulation obtains the same bit error rate at a 6 dB lower signal-to-noise ratio compared to an ASK modulation, thus enhancing the maximum readout distance by a factor of approximately 40%. Higher-order PSK-like quadrature PSK (QPSK) use fewer symbols (reflectors) and therefore need less chip size and result in a lower insertion attenuation, but a higher signal-to-noise ratio is needed for the detection.

The requirements for a SAW transponder used in a phase modulation system, however, become more stringent, because all influences that change the delay time of a signal, such as SAW velocity variations or the accuracy of the fabrication process, must be controlled within a small fraction of one SAW wavelength.

A good choice for the modulation technique used in SAW ID tags might be a pulse position modulation (PPM) (see Fig. 28), which achieves the code density of a higher phase modulation scheme but avoids their stringent sensitivity on small inaccuracies during the fabrication process [54]. In a pulse position modulation scheme the symbol occupies one of several possible timeslots. In most radar systems, the accuracy in the time resolution for one target is much higher than the time separation needed to resolve two targets. Therefore, using a PPM modulation the timeslots can be arranged much more densely, compared to the symbol separation in a ASK modulation.

Table 2. Typical Resolution of Wireless SAW Sensor Systems

Measured Quantity	Measurement Result	Resolution
Identification number	Change of signal pattern	32 bits
Temperature	Variation of SAW velocity	0.1 K
Mechanical quantities such as pressure, force, torque, acceleration, friction	Variation of elastic constants	1% of full scale
Impedance sensors	Variation of amplitude and phase of reflected signal	5% of full scale
Distance	Change of signal delay	20 cm
Relative position	Change of Doppler phase	2 cm
Angular position	Change Doppler phase	3°

3.3. Delay-Line Sensors

For a wireless SAW sensor, fewer symbols or reflectors are required compared than for an ID tag [14,46,56]. In most cases four to five symbols and/or reflectors are sufficient for one transponder. Figure 29 is a photo of a SAW reflective delay line for temperature sensing mounted in a surface mount device (SMD) package. The tag works in the 2.45-GHz ISM band. On the left side the IDT can be seen, and to the right there are four reflectors placed on the chip.

For sensing purposes, the delay time between the symbols and the respective phase differences have to be examined very accurately. Figure 30 shows the impulse response of the signal received from a SAW sensor incorporating five reflectors. The corresponding baseband signal is depicted in a polar diagram to show the phase relations between the symbols. Symbols R1, R2, R3, R4, and R5 denote the signals reflected from reflectors 1, 2, 3, 4, and 5, respectively. φ_{2-1} gives the phase difference between signals 1 and 2. Because the delay time between signals 4 and 5 is short, there is a slight intersymbol interference (ISI) between these two signals.

The evaluation of the carrier phase differences results in a huge enhancement in resolution, when compared to the evaluation of the delay-time differences. The enhancement is in the order of f_0/B , whereby f_0 gives the center frequency and B the bandwidth of the system. The resolution is comparable to a GPS (global positioning system), in which the evaluation of the carrier phase results in a

Figure 27. Measurement of the SAW ID tag with 8 ON/8 OFF/8 ON/8 OFF symbols, and 1 ON symbol.

resolution of parts of a millimeter, whereby the evaluation of the delay times gives an accuracy of some meters only.

The evaluation of the phase differences, however, induces an ambiguity when the phase shift exceeds 360° . This ambiguity of the phase evaluation can be overcome by using a precise evaluation of the delay times. Figure 31 gives the continuous phase difference φ_{3-1} of a wireless SAW reflective delay line as a function of temperature.

Lithium niobate, LiNbO_3 , is an ideal material for temperature sensors, because of its large temperature coefficient of delay TCD between approximately -70 and -85 ppm/ $^\circ\text{C}$, depending on the cut angle, and its high electroacoustic coupling factor [14,57,58]; for instance, SAW radio-requestable temperature sensors have been used to monitor the temperature of high-voltage surge arresters [59]. Also, the feasibility has been shown to monitor the temperature of a brake disk of a railcar during train braking [60] or the rotor temperature of an asynchronous motor during rotation [59]. The typical temperature resolution is in the order of 0.2°C . Up to about 200°C , standard assembly, interconnect, and packaging techniques can be used. Using special materials, such as lanthanite, and titanium for electrode material, operation up to temperatures as high as 1000°C have been demonstrated [58].

Using reflective delay lines for measuring mechanical parameters, such as pressure [61], force, strain, or acceleration, an adapted mounting and packaging technique is required. Wireless SAW pressure sensors are formed using a quartz diaphragm that bends under hydrostatic pressure. Figure 32 shows a schematic layout [62]. An “all-quartz package,” consisting of the SAW delay-line chip

Figure 28. Schematic of a SAW ID tag applying a pulse position coding scheme [55].

Figure 29. Photo of an assembled SAW reflective delay-line sensor for temperature sensing.

together with a cover and a lid formed of the same material, results in minimal thermal stresses and therefore minimizes cross-sensitivity to temperature. Using this all-quartz package, one obtains a pressure resolution of about 1% of the full range.

Adding an inertial mass in an appropriate way, a radio-readable SAW accelerometer can be built up [63]. With the help of a SAW reflective delay line, monitoring of the friction coefficient between a car tire and the road surface, a key parameter when stabilizing a vehicle in critical situations, has been demonstrated [64]. The friction coefficient can be determined by evaluating the mechanical strain in the tire-road contact area by utilising the deformation of a tread element.

As is demonstrated with a torque sensor, a high sensitivity can be attained even if the temperature effects superpose the sensor signal [45]. The SAW reflective delay lines measure, comparable to resistive strain gauges, the torque indirectly by detecting the strain or stress distribution generated by a torque acting on the shaft. The fact

Figure 30. Polar map of the SAW impulse response of a reflective delay line in the base band.

Figure 31. Variation of the continuous phase difference ϕ_{3-1} between the first and third responses of a reflective delay line as a function of temperature.

that the strain has an opposite sign in $\pm 45^\circ$ orientation relative to the shaft axis can be used for temperature compensation. The potential use of quartz and LiNbO₃ as substrate materials has been investigated [65,66].

3.4. Chirped Delay-Line Sensors

The sensitivity with respect to the delay time of a SAW delay-line transponder can be enhanced by using chirped reflectors and/or transducers [45,67,68]. In a dispersive device, the delay time τ of a transmitted signal depends on the frequency f . For a linear dispersion with bandwidth B , dispersion time T , and center frequency f , we can calculate for all frequencies within the passband, with

$$\tau(f) = \tau_0 \pm \frac{T}{B} f \tag{5}$$

where the plus/minus (\pm) sign represents an up/down-chirp law. A variation Δv of the SAW velocity v now affects both the time τ_0 and the synchronous frequency f , and both result in a change of the delay time τ . Therefore, we get in first order a shift and in addition a small tilt of the chirp function $f(t)$. This feature is similar to the impact of a Doppler shift to a FMCW radar system.

Neglecting the small tilt, we obtain the following equation in first order:

$$\frac{\Delta\tau}{\tau_0} = \left[1 \mp \frac{T}{B} \frac{f_0}{\tau_0} \right] \frac{\Delta v}{v} \tag{6}$$

Figure 32. Schematic drawing of a pressure sensor based on a SAW reflective delay line assembled in an all-quartz package.

Figure 33. Illustration of the amplification effect for the sensitivity of the delay time using dispersive delay lines.

The expression in the brackets of this equation can be interpreted as an amplification factor for the sensitivity of the group delay, due to the usage of chirped devices. Figure 33 illustrates this amplification effect for the sensitivity of the delay time. The horizontal arrow gives the shift of the delay time of the area of the synchronous frequency and the vertical arrow, the shift in the synchronous frequency by a variation of the SAW velocity. The delay time to the new area with the correct synchronous frequency results from both effects and the chirp rate.

An increase by a factor of 10–100 is possible; even a change in the sign is possible. Figure 34 shows measurements of dispersive SAW sensors, and the amplification effect can be seen. This amplification, however, is effective only in the group delay time. In the phase variation, we get the same dependence as we would obtain by using a nonchirped device.

3.5. Combination with External Sensors

It is possible to wirelessly read out signals of arbitrary sensors, that is, of non-SAW sensors, as long as these sensors operate as impedance sensors [53,69,70]. In that case, a second IDT deposited on the SAW transponder can be

Figure 34. Measurement of the amplification effect for the sensitivity of the delay time by using dispersive delay lines.

Figure 35. Schematic layout of a passive SAW reflective delay-line device combined with an external sensor.

electrically loaded by the external sensor, which changes the IDT’s microacoustic reflectivity (see Fig. 35).

The reflectivity of an interdigital transducer as a function of a complex termination impedance Z_{load} at its electrical port is given in the well-known P -matrix formalism with P_{11} :

$$P_{11}(Z_{load}) = P_{11}^{sc} + \frac{P_{13}^2}{P_{33} + \frac{1}{Z_{load}}} \quad (7)$$

The measuring signal changes the value of the load impedance, thus changing the reflection characteristics of the IDT and thereby the time function of the retransmitted signal of the transponder. To enhance the sensor effect, a substrate with a high coupling coefficient, resulting in a high P_{13} and a low P_{33} , should be used. Figures 36 and 37 show the acoustic reflectivity of a split-finger ($\lambda/8$) IDT on $LiNbO_3$ as a function of its electrical load.

Using this technique, for instance, the remote measurement of high electrical currents or of the water content of soil has been demonstrated [45,71,72]. In 2001, a SAW-based tire pressure measuring system designed for commercial vehicular applications has been introduced [73]. This novel system shows an accuracy of ± 15 kPa within a pressure range of 100–400 kPa, an excess pressure stability of 600 kPa, and a high heat stability up to 130°C.

3.6. Resonant Delay-Line Sensors

The required delay time required to overcome environmental echoes can also be obtained by using one-port SAW resonator configurations [47,48]. An RF burst impulse

Figure 36. Acoustic reflection factor P_{11} of a split-finger IDT on $LiNbO_3$ as function of the complex reflection coefficient of its load impedance Z_L (Smith chart representation). The diagram shows lines of constant acoustic reflection. For line n , $|P_{11}|$ is $n(-5$ dB).

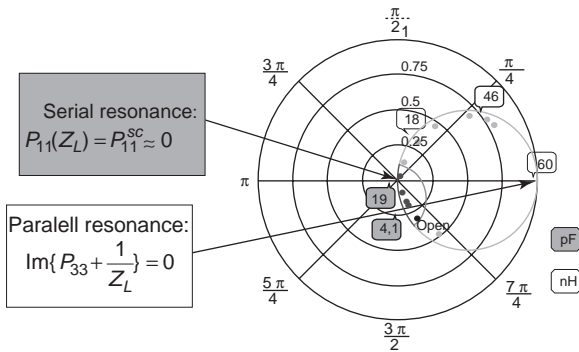

Figure 37. Measured amplitude and phase of the acoustic reflection factor P_{11} (polar chart representation) of a split-finger IDT with capacitive and inductive load impedance Z_L .

excites a high- Q resonator. The retransmitted RF burst of this resonator can still be seen even when all multipath echoes have faded. The sensitivity of these resonator-type transponders is comparable to that of a reflective delay-line transponder, however, with a significant reduction in SAW chip size. The combination of resonant SAW transponders with an external sensor as a variable load can also be used for pulling the resonator frequency. This is similar to the combination of a reflective delay line and external sensors.

4. CONCLUSION

Surface acoustic wave linear and nonlinear phased delay lines play a key role in the radiofrequency (RF) and intermediate-frequency (IF) stages of wideband radar systems. Pulse shaping filters allow a simple generation of complex signals used in modern digital telecommunication systems. Chirped and tapped delay lines enable wideband spread-spectrum systems, much broader than what can be obtained by using modern digital circuitry. Reflective delay lines and transducer-connected delay lines allow the construction of identification and sensor systems using passive transponders that can be wirelessly addressed using a radiolink.

Acknowledgment

Many of the results reported in this contribution were obtained by a common effort of all of our former colleagues and students in the department ZT MS 1 of Siemens AG. The authors want to especially acknowledge the contributions of W. E. Bulst, K. Wagner, G. Scholl, F. Schmidt, T. Ostertag, and Dr. W. Ruile. We also gratefully acknowledge the contributions of Prof. Franz Seifert and A. Pohl from the University of Technology in Vienna and Prof. R. Weigel from the University of Erlangen, Prof. E. Schrüfer from the Technical University of Munich, and their students.

1. INTRODUCTION

Surface acoustic wave (SAW) devices were first considered for electronics in the 1960s, and since then a vast array of devices has emerged, with wide-ranging applications. Like

other acoustic waves, SAWs have the advantage of a low velocity, around 3500 m/s, so that large delays are obtainable in a small space, and in suitable materials they can give very low propagation loss. A familiar device exploiting these properties is the quartz crystal oscillator, found almost everywhere in clocks and wristwatches as well as in many professional systems. The oscillator relies on propagation of a bulk acoustic wave in a quartz crystal, with reflections from the two major parallel faces so that a resonant cavity is formed. Surface wave devices exploit the same two advantages, low velocity and low loss, but with an additional feature. Because the wave travels along a surface it is accessible throughout its propagation path to components for generation, reflection, waveguiding, and so on, so that substantial versatility is obtained. The versatility is well illustrated by the enormous range of devices developed since the inception of the subject.

This subject developed initially in response to a demand for dispersive delay lines (chirp filters) for pulse compression radar. In this application the SAW filters perform a signal processing function, giving an improvement in signal-to-noise ratio and increasing the range capability of the radar. Other devices perform a similar function for spread-spectrum signals in communication systems. Another type of device is the bandpass filter, initially developed for I.F. filtering in domestic TV receivers. This has been an outstanding success for SAW, with practically all TV sets now having a SAW filter. The bandpass filter has also been widely used in professional systems such as radar, and more recently the demand for filters has increased greatly with the growth of wireless telecommunications, particularly mobile telephones. Many different types of SAW bandpass filter, suitable for different applications, have been developed, and a typical present-day mobile phone handset will contain 6–10 SAW filters. Another type of SAW device is the oscillator, in which a SAW delay line or resonator is used as a feedback element to control the frequency of an oscillating circuit. Compared with a bulk-wave oscillator, the SAW device can operate at higher frequencies, up to 500 MHz, though its stability is not quite as good. The popularity of SAW devices, particularly for wireless communications, is demonstrated by the worldwide production quantities of around 3 billion devices annually.

1.1. Nature of Surface Waves

In a solid material, acoustic waves (or “elastic” waves) are associated with distortions of the material, such that distances between particular atoms are changed. These distortions, formally expressed as “strains,” are accompanied by internal forces known as “stresses.” In an acoustic wave, energy is continuously exchanged between elastic and kinetic forms. An infinite material can support propagation of a bulk wave, that is, a freely propagating wave unaffected by boundaries. Bulk acoustic waves are of two basic types: (a) *longitudinal waves*, in which the particle motion is along the wavevector, and (b) *transverse* (or shear) *waves*, with particle motion normal to the wavevector. Typical velocities are 6000 m/s for longitudinal waves and 3000 m/s for transverse waves.

1. INTRODUCTION

Surface acoustic wave (SAW) devices were first considered for electronics in the 1960s, and since then a vast array of devices has emerged, with wide-ranging applications. Like

other acoustic waves, SAWs have the advantage of a low velocity, around 3500 m/s, so that large delays are obtainable in a small space, and in suitable materials they can give very low propagation loss. A familiar device exploiting these properties is the quartz crystal oscillator, found almost everywhere in clocks and wristwatches as well as in many professional systems. The oscillator relies on propagation of a bulk acoustic wave in a quartz crystal, with reflections from the two major parallel faces so that a resonant cavity is formed. Surface wave devices exploit the same two advantages, low velocity and low loss, but with an additional feature. Because the wave travels along a surface it is accessible throughout its propagation path to components for generation, reflection, waveguiding, and so on, so that substantial versatility is obtained. The versatility is well illustrated by the enormous range of devices developed since the inception of the subject.

This subject developed initially in response to a demand for dispersive delay lines (chirp filters) for pulse compression radar. In this application the SAW filters perform a signal processing function, giving an improvement in signal-to-noise ratio and increasing the range capability of the radar. Other devices perform a similar function for spread-spectrum signals in communication systems. Another type of device is the bandpass filter, initially developed for I.F. filtering in domestic TV receivers. This has been an outstanding success for SAW, with practically all TV sets now having a SAW filter. The bandpass filter has also been widely used in professional systems such as radar, and more recently the demand for filters has increased greatly with the growth of wireless telecommunications, particularly mobile telephones. Many different types of SAW bandpass filter, suitable for different applications, have been developed, and a typical present-day mobile phone handset will contain 6–10 SAW filters. Another type of SAW device is the oscillator, in which a SAW delay line or resonator is used as a feedback element to control the frequency of an oscillating circuit. Compared with a bulk-wave oscillator, the SAW device can operate at higher frequencies, up to 500 MHz, though its stability is not quite as good. The popularity of SAW devices, particularly for wireless communications, is demonstrated by the worldwide production quantities of around 3 billion devices annually.

1.1. Nature of Surface Waves

In a solid material, acoustic waves (or “elastic” waves) are associated with distortions of the material, such that distances between particular atoms are changed. These distortions, formally expressed as “strains,” are accompanied by internal forces known as “stresses.” In an acoustic wave, energy is continuously exchanged between elastic and kinetic forms. An infinite material can support propagation of a bulk wave, that is, a freely propagating wave unaffected by boundaries. Bulk acoustic waves are of two basic types: (a) *longitudinal waves*, in which the particle motion is along the wavevector, and (b) *transverse* (or shear) *waves*, with particle motion normal to the wavevector. Typical velocities are 6000 m/s for longitudinal waves and 3000 m/s for transverse waves.

The surface-wave solution in an isotropic material was found by Lord Rayleigh in 1885 [1], and is often called a *Rayleigh wave*. Here, the material is assumed to have a planar surface, free of mechanical forces. Rayleigh found a propagating-wave solution, essentially a sum of longitudinal and transverse components, with amplitude decaying exponentially away from the surface. Typically, most of the energy is within a depth equal to one wavelength. The wave is of seismological interest because it explains a component of the signal detected by a seismograph following a ground shock. It travels somewhat more slowly than transverse bulk waves and is nondispersive, with velocity independent of frequency. The motion of the material is in the *sagittal plane*: the plane containing the surface normal and the propagation direction.

1.2. Piezoelectric Materials

As will become clear later, SAW devices always use piezoelectric materials. The meaning of this term is that stresses and strains within the material are accompanied by electric fields, which arise from fundamental interactions at the atomic level. The electric fields are central to the operation of the majority of SAW components, particularly transducers for generation and detection of the waves. The presence of piezoelectricity complicates the nature of the wave, which is now (in most cases) accompanied by an electric field. But there is another complication in that to be piezoelectric a material has to be anisotropic, so that its macroscopic properties depend on the orientation of the internal structure. Usually crystalline materials are chosen because they can give low losses. The wave properties depend on the orientation of the crystal lattice relative to the macroscopic object. In contrast to the isotropic case considered by Rayleigh, anisotropy and piezoelectricity introduce immense complications when investigating properties of SAWs. As a consequence, the search for materials and orientations suitable for SAW devices has been an ongoing activity throughout the development of SAW.

In general, a numerical investigation of a piezoelectric crystal usually yields surface-wave solutions similar to the isotropic case except for the associated electric field. This is often called a *piezoelectric Rayleigh wave*. Various properties relevant to SAW usage are considered, in order to find a suitable orientation. As a result, a variety of “standard” materials and orientations have been established. In particular, crystals of quartz, lithium niobate, and lithium tantalate are used. Owing to anisotropy, it is essential to quote the orientation when specifying a SAW material.

In some cases other types of wave are found, in particular various types of “leaky wave.” Some of these can be used for SAW-type devices, although their behavior is somewhat different. In this article, the “wave” is assumed to be a piezoelectric Rayleigh wave unless otherwise stated; other types of wave are considered later.

1.3. Basic SAW Device

Piezoelectricity enables SAWs to be generated conveniently by *interdigital transducers* (IDTs) placed on the surface of the material, which is often called the *substrate* (Fig. 1). The IDT consists of a set of interleaved metal electrodes,

alternately connected to two bus bars. When a voltage is applied, this sets up a spatially alternating electric field at the surface, coupled to acoustic stresses by the piezoelectric effect. A surface wave is generated if the frequency is such that the SAW wavelength is similar to the transducer periodicity. The IDT is most effective for a frequency such that its periodicity equals the SAW wavelength. At other frequencies the waves generated in different regions of the transducer are subject to progressive phase differences, so that the total wave amplitude is smaller. The IDT is therefore frequency-selective. A similar IDT can be used to detect an incident SAW, producing an electrical output signal. Thus, the device has electrical input and output signals, with electroacoustic conversion at both transducers.

The wave propagation inside the device is almost ideal in that propagation loss is low, diffraction effects are small (because the beam of surface waves is typically more than 20 wavelengths wide), and dispersion is negligible. For typical power levels the material behaves linearly, so that harmonic generation and intermodulation products are negligible. Hence for many purposes second-order effects such as these can be ignored. However, they do need to be considered, and sometimes compensated for, when an exacting specification is to be satisfied.

Because of the selectivity of the IDTs, this device can be regarded as a bandpass filter. It can also be regarded as a delay line, with delay determined by the velocity and the distance between transducer centres, typically $3\ \mu\text{s}/\text{cm}$. As a delay line, it is suitable for signals whose spectrum is within the frequency band of the transducers. The input transducer generates SAWs traveling in both directions, and it is often necessary to add absorbing material to suppress reflections of waves from the ends of the substrate. The basic design is capable of a huge range of variations for special purposes. In particular, bandpass filters employ modifications to ensure good suppression in the stopband, a flat response in the passband, narrow skirts separating these regions, and minimal group delay variation within the passband.

1.4. Fabrication and Performance

The device basically consists of a piezoelectric substrate with a specially shaped metal film (usually of aluminium) on the surface. This structure is well suited to fabrication by established photolithographic techniques, similar to those used in semiconductor device processing. Many patterns can be made simultaneously by exposing a layer of photoresist on a large circular wafer (or “slice”), followed by development and chemical etching. The patterns are separated by cutting them into the individual devices, then known as “chips,” which are sealed into hermetic packages to protect them from moisture and contamination. This process is well established in the semiconductor industry and well suited to production of large quantities of devices, thus giving economy of scale. For large quantities, costs can be less than U.S. \$1.00 per device. Moreover, the method is very versatile since almost arbitrary geometries can be produced.

The fabrication process sets some limits on device performance. The linewidth of the basic IDT (Fig. 1) is a

Figure 1. Basic SAW delay line.

quarter of the center-frequency wavelength, and the minimum linewidth usable in commercial production is around $0.4\ \mu\text{m}$. For a typical SAW velocity of $3500\ \text{m/s}$, this sets the maximum center frequency at about $2\ \text{GHz}$, although special techniques can increase this number a little. The minimum frequency is in the region of $10\ \text{MHz}$, simply because in this region the devices become rather clumsy and expensive. The velocity determines the delay for a given length. A device $2\ \text{cm}$ long gives about $6\ \mu\text{s}$ delay, and lengths of $15\ \text{cm}$ are quite feasible but become expensive because they are not suited for large-quantity production. Bandwidths range substantially, from 0.1% to 50% of the center frequency.

Generally, internal losses in the device are small, so one might expect a small insertion loss to be obtainable. However, in practice this is limited by distortion arising from multiple SAW transits. To give low loss, the device of Fig. 1 would need good electrical matching between the transducers and the source and load, normally involving inductors to tune out the transducer capacitances. For this case, the acoustoelectric conversion loss is ideally $3\ \text{dB}$ (because half of the energy applied to a transducer emerges as a wave generated in the unwanted direction). Hence a device insertion loss of $6\ \text{dB}$ is expected. This is indeed close to reality, but unfortunately there is also an unwanted signal because the transducers reflect the waves. This signal, called the *triple transit signal*, occurs after three transits of the device, involving a reflection from each transducer. When electrically matched, the transducer reflection coefficient is $-6\ \text{dB}$, and hence the triple-transit signal is $12\ \text{dB}$ below the main signal. This level is quite unacceptable for most applications, and often it is reduced by deliberately mismatching the transducers (e.g., omitting the inductors). For this reason, early types of SAW device often have relatively high insertion losses, $15\text{--}30\ \text{dB}$. However, a wide range of techniques have been applied to this problem, yielding a variety of low-loss types of bandpass filter.

Some general accounts of the subject will be found in Refs. 2–6.

2. INTERDIGITAL TRANSDUCERS

The *interdigital transducer* (IDT) is a basic component in all SAW devices. As explained earlier, a simple IDT

consists of a set of electrodes alternately connected to two busbars, as shown in Fig. 2a. The electrodes are regular, that is, they have constant width a and pitch p .

The operation of the IDT can be described approximately by a simple delta-function model [7]. Suppose initially that a voltage V is applied to only one electrode, with the others grounded. Surface waves will be generated with amplitude proportional to an element factor denoted by $E(\omega)$. The SAW amplitude is expressed in terms of the associated surface potential $\phi_s(x)$, which is thus given by $V E(\omega) \exp[\pm jk(x - x_n)]$, where k is SAW wavenumber and x_n is the location of the electrode center. Here k is related to the velocity v by $k = \omega/v$. In Fig. 2a we take the lower busbar to be grounded and apply the preceding formula to each live electrode, adding the waves generated. We define a polarity \hat{P}_n for electrode n , such that $\hat{P}_n = 1$ or zero for a live or grounded electrode, respectively. The potential of the wave emerging at the left is thus

$$\phi_s(\omega) = VE(\omega) e^{jkx} \sum_{n=1}^N \hat{P}_n \exp(-jkx_n) = VE(\omega) e^{jkx} A(\omega) \quad (1)$$

where N is the number of electrodes centred at x_n . The summation is denoted by $A(\omega)$, which is known as the *array factor*. Usually the array factor varies with ω much faster than the element factor $E(\omega)$, so the array factor is essentially the frequency response. Fourier transformation of $A(\omega)$ into the time domain gives the function $a(t) = \sum_{n=1}^N \hat{P}_n \delta(t - x_n/v)$, which is a series of delta functions at times corresponding to the centers of the live electrodes.

For the transducer of Fig. 2a the electrode positions are regular, and we can take $x_n = np$, where p is the electrode pitch. Also, the polarity sequence is $\hat{P}_n = 1, 0, 1, 0, \dots$, since the electrode voltages alternate between V and 0 . Substituting these, $A(\omega)$ becomes a simple geometrical progression that is easily summed. Its magnitude is

$$|A(\omega)| = \left| \frac{\sin(N_p \theta/2)}{\sin(\theta/2)} \right| \quad (2)$$

where $\theta = 2kp$ and N_p is the number of live electrodes (equal to the number of transducer periods). This equation predicts a series of peaks. The fundamental response, at which the transducer pitch equals the SAW wavelength,

Figure 2. Transducer types: (a) single-electrode configuration; (b) double-electrode configuration.

occurs for $\theta = 2\pi$. The formula remains unchanged if we replace θ by $\phi = \theta - 2\pi$. In the region of the fundamental passband, ϕ is small and the function becomes $|A(\omega)| \approx N_p |\sin(X)/X|$, with $X = N_p \phi/2$; and X can be written as $X = \pi N_p (f/f_0 - 1)$, where $f_0 = v/(2p)$ is the center frequency. From this it follows that the 4-dB points are approximately at $\phi = \pm \pi/N_p$, giving a fractional bandwidth of $\Delta f/f_0 = 1/N_p$. The bandwidth is $\Delta f = 1/T$, where $T = 2pN_p/v$ is the transducer length in time units.

This delta-function model is applicable because in practice the wave propagation is almost ideal. Provided suitable materials are chosen for the substrate and the electrodes (usually aluminium), the waves propagate with very little loss or dispersion. Also, diffraction effects are usually small, although this often needs consideration, and we return to it in later.

In addition, we have assumed that the electrodes don't affect the waves, in particular, that they don't reflect the waves. This assumption is usually invalid for the transducer of Fig. 2a. Individual electrodes have a small reflection coefficient, typically 1 or 2%. However, the reflections add coherently at the center frequency, because the electrode pitch is $\lambda_0/2$ (where λ_0 is the centre-frequency wavelength). This problem can be avoided by using a *double-electrode transducer*, as in Fig. 2b, where each electrode is split into two. The electrode spacing is now $\lambda_0/4$, so reflections from adjacent electrodes are cancelled at f_0 . The main penalty is that the electrode width is $\lambda_0/8$ instead of $\lambda_0/4$, so that fabrication becomes more difficult. The original transducer of Fig. 2a is, in contrast, called a *single-electrode transducer*. The analysis in Eq. (1) applies for both types of transducer; it is necessary to change only the polarity sequence \hat{P}_n .

The transducer admittance Y_t , defined assuming that no waves are incident, is important when electrical matching is considered. Often the admittance is dominated by a capacitance C_t , so this is usually written explicitly. Y_t can be written as $Y_t = G_a(\omega) + jB_a(\omega) + j\omega C_t$, where G_a and B_a are the acoustic conductance and susceptance, due to the excitation of surface waves. For a uniform transducer such as those in Fig. 2, these terms have the approximate forms

$$\begin{aligned} G_a(\omega) &\approx G_a(\omega_0) \left[\frac{\sin X}{X} \right]^2; \\ B_a(\omega) &\approx G_a(\omega_0) \frac{\sin(2X) - 2X}{2X^2} \end{aligned} \quad (3)$$

These formulas assume that electrode reflections are not significant. The formula for B_a is deduced from G_a by using causality. This implies that B_a must be the Hilbert transform of G_a for any transducer.

For a two-transducer device, such as that in Fig. 1, the terminal admittances Y_{11} and Y_{22} are just the transducer admittances Y_t . This follows because Y_{11} is the admittance seen at one transducer when the other is shorted, and we have assumed that a short-circuited transducer does not reflect SAWs. Also, the transadmittance Y_{12} can be shown to have magnitude given by $|Y_{12}| = G_{a1}G_{a2}$, where G_{a1} and G_{a2} are the two transducer conductances.

As noted above, electrode reflections are eliminated by using a double-electrode transducer. However, these transducers still have a finite SAW reflection coefficient when connected to finite electrical loads, thus giving rise to the unwanted triple-transit signal. Special methods can be applied to deal with this, notably the use of specially designed internal reflections in SPUDTs, described later.

3. PROPAGATION EFFECTS

The choice of suitable materials for SAW devices is intimately concerned with a variety of propagation effects, particularly piezoelectric coupling, diffraction, and temperature effects. The choice of material is a vital part of the design procedure because the material properties have a strong bearing on the performance obtainable.

3.1. SAW Solutions and Velocities

Many of the required SAW properties of a material can be deduced from the SAW velocity, and the velocity itself is important, of course. The SAW solution is found starting from the bulk-material constants: the stiffness c_{ijkl} , piezoelectric d_{ijk} and dielectric ϵ_{ij} constants, together with the mass density ρ . The values originate from bulk measurements on the crystals, and large amounts of data are given by Slobodnik et al. [8] and Gualtieri et al. [9]. Kovacs et al. [10] give values for lithium niobate and tantalate.

The calculation of SAW solutions in an anisotropic piezoelectric material is a complex numerical process [11] that will not be described in detail here. Because of the anisotropy, the assessment of a material for SAW applications involves calculation of its SAW properties for all possible orientations, and since the orientation is governed by

Figure 3. SAW velocities on Y-cut lithium niobate, as functions of propagation direction.

three angles, this task is very extensive. The substantial literature on these topics includes Slobodnik’s handbook [8] and a review [12].

The SAW solution for a free surface has velocity denoted here by v_f . It is also common to examine a “metallized” surface, meaning that an idealised metal film is assumed to be on the surface, short-circuiting the parallel electric field but thin enough to have no mechanical effect. In this case the velocity is v_m . The fractional difference between the two velocities is defined as

$$\frac{\Delta v}{v} \equiv \frac{v_f - v_m}{v_f} \quad (4)$$

and this indicates the strength of electrical coupling to the SAW. The element factor $E(\omega)$ mentioned earlier is proportional to $\Delta v/v$, so this governs the conversion efficiency of an IDT. Figure 3 shows velocities for Y-cut lithium niobate, as functions of propagation direction. The coupling is strongest for propagation in the Z direction and this orientation, known as “Y-Z lithium niobate,” is a popular choice. For this case, a 100-MHz wave on a free surface, with power density of 1 mW/mm, gives a surface potential of about 0.8 V. The particle displacements at the surface are about 0.08 nm (0.8 Å), which is comparable with interatomic distances and far less than the SAW wavelength of 35 μm . It is also common to define a coupling constant $k^2 = 2 \Delta v/v$.

3.2. Diffraction

SAW diffraction can be analyzed by a method similar to that often used in optics, using a scalar to represent the wave amplitude [12]. Perturbations due to components such as transducers and gratings are ignored in this method. Except for the most sophisticated devices, these approximations are usually adequate. The analysis may then be done on the basis of data for the SAW velocity. As in conventional optics, SAW diffraction gives a near-field (Fresnel) region, in which the amplitude distribution is similar to that of the source, and a far-field (Fraunhofer) region, where the amplitude corresponds to the Fourier transform of the source. Several complications occur, how-

ever, because of the anisotropy of the substrate material. In summary:

1. *Beamsteering.* In beamsteering, the energy flow direction \mathbf{E} in a wide beam of SAWs is not parallel to the wave vector \mathbf{k} . The angle γ between \mathbf{E} and \mathbf{k} is the beamsteering angle (or “power flow angle”), given by $\tan \gamma = (1/v) dv/d\theta$, where $v(\theta)$ is the SAW velocity at an angle θ . Usually the substrate is chosen such that $\gamma = 0$, but the effect can still occur as a result of misalignment.
2. *Minimal-Diffraction Orientations.* For some substrates, notably Y-Z lithium niobate, the anisotropy is such that diffraction spreading is substantially reduced. This occurs when $d\gamma/d\theta \approx -1$. This condition can be very helpful when designing high-performance devices, because it eliminates the need to compensate for diffraction.
3. *Parabolic Approximation and Scaling.* In many cases the SAW velocity variation $v(\theta)$ can be approximated by writing k_x as a quadratic function of k_y (where x is the principal propagation direction). Assuming no beamsteering, we can write $k_x(k_y) = k_x(0) - 0.5bk_y^2/k_x(0)$. The constant b is unity for an isotropic material and zero for a minimal-diffraction orientation and is given by $b = 1 + d\gamma/d\theta$. If the approximation is valid, the wave amplitude distribution is simply scaled in the x direction. Specifically, if $\psi_i(x,y)$ is the distribution for the isotropic case, the anisotropic case gives a distribution $\psi(x,y) = \psi_i(bx,y) \exp[j(b-1)xk_x(0)]$.

As in optics, the amplitude distribution for the isotropic case is given by formulas involving Fresnel integrals. When the parabolic approximation is invalid, it is necessary to use a more fundamental approach, commonly the angular spectrum of plane waves (ASoPW) method. For this method, the source is represented as a sum of plane-wave elements, with distribution determined by a Fourier transform. Each plane wave propagates according to the known velocity $v(\theta)$. The statements given above can all be deduced from the ASoPW formulation.

In SAW devices, diffraction is usually a second-order effect; that is, the receiving transducer is in the near-field region of the transmitter. However, in an apodized band-pass filter, described below, diffraction can cause some unacceptable signals in the stopband above the passband. These can be reduced by sophisticated design techniques that compensate for the diffraction.

3.3. Temperature Effects

Temperature stability is usually of vital interest when designing a SAW device. Temperature changes cause SAW velocity changes and also thermal expansion, and both these factors affect the delay given by a device. The velocity variation can be calculated using the temperature coefficients of the bulk piezoelectric constants, and with the expansion coefficient this gives the temperature coefficient of delay (TCD). In most cases the delay varies approximately linearly with temperature. However, for some

cases the velocity and expansion effects cancel, at one temperature. The delay $T(\theta)$ then has the quadratic form $T(\theta) = T(\theta_0)[1 + c(\theta - \theta_0)^2]$, where θ is the temperature and θ_0 is the “turn-over temperature,” at which the TCD is zero. In particular, for ST-X quartz, $\theta_0 = 21^\circ\text{C}$ and $c = 32 \times 10^{-9} (\text{C}^\circ)^{-2}$. This orientation is a rotated Y cut, with propagation along the crystal X axis and a rotation angle of 42.75° . It is commonly used for temperature-stable devices, although the rotation angle is usually reduced a little, increasing θ_0 . This is done because the center of the operational temperature range is usually higher than 21°C . It also compensates for a reduction of θ_0 associated with the crystal mounting and the presence of transducers.

The effect of a temperature change is to scale the device impulse response $h(t)$, which changes to $h'(t) = h[t/(1 + \varepsilon)]$, where ε is a small quantity. Correspondingly, the frequency response changes from $H(\omega)$ to $H'(\omega) = H[(1 + \varepsilon)\omega]$. Hence the center frequency is scaled by a factor $\Delta f_0/f_0 = -\Delta T/T = -\varepsilon$, and the bandwidth is also scaled by the same factor.

3.4. Other Propagation Effects

For standard SAW materials, propagation loss is usually small provided the crystals are well polished. For example, at 1 GHz the loss for a free surface is about 1 dB/ μs for Y-Z lithium niobate, and 3 dB/ μs for ST-X quartz [12]. These figures are approximately proportional to f^2 , and they are increased a little when transducers are present. Nonlinear effects are usually negligible in practical devices. Theoretically a free surface gives no dispersion, but in practice there is a little dispersion due to transducers and gratings. However, these effects are not usually of practical significance.

A more significant effect is waveguiding, which can occur because the SAW velocity in components such as transducers is slightly lower than the free-surface velocity outside. In relatively long devices the waves propagate as a series of modes, with some dispersion. For moderate apertures there is often a dominant fundamental mode plus some unwanted higher modes. The unwanted modes cause small perturbations, usually at frequencies somewhat higher than the center frequency. These distortions are seldom significant in devices with wide apertures, greater than typically 20 wavelengths.

4. MATERIALS

A considerable variety of suitable materials has been established, bearing in mind the above propagation effects and the strength of piezoelectric coupling ($\Delta v/v$). The orientation is often specified by two axes. For example, Y-Z lithium niobate indicates a Y-cut crystal with SAW propagation along the crystal X axis. An example of a rotated Y-cut crystal is ST-X quartz, which can be written as 42.75°Y-X quartz. This has propagation along the crystal X axis (in the surface). Looking down the X axis, toward the origin, the crystal Y axis is rotated by 42.74° clockwise from the surface normal.

For more general cases, it is common to use Euler angles, λ , μ , and θ . We define X, Y and Z as crystal axes

and x , y , and z as device axes, with x as the SAW propagation direction and z as the outward-directed normal to the surface. Initially the angles are zero and x,y,z are the same as X,Y,Z. There are three rotations, as follows:

1. Rotate the x , y , and z axes anticlockwise about z through an angle λ (as seen by an observer looking down the z axis toward the origin). Call the new axes x_1, y_1, z_1 .
2. Rotate the x_1, y_1, z_1 axes anticlockwise about x_1 through an angle μ . Call the new axes x_2, y_2, z_2 .
3. Rotate the x_2, y_2, z_2 axes anticlockwise about z_2 through an angle θ . Call the new axes x_3, y_3, z_3 .

In the final orientation, z_3 is the surface normal and x_3 is the propagation direction. For a rotated Y-cut crystal, with cut angle ψ , we have $\lambda = \theta = 0$ and $\mu = \psi - 90^\circ$.

Table 1 gives data for some common SAW materials. Y-Z lithium niobate (LiNbO₃) has strong piezoelectric coupling and minimal-diffraction properties, advantageous for wideband and low-loss devices, but its temperature stability is poor. This material generates unwanted bulk waves rather strongly. The 128° rotated cut minimizes bulk-wave generation, but this is not a minimal-diffraction orientation. ST-X quartz (SiO₂) has weak piezoelectric coupling and is generally limited to narrowband devices, but its good temperature stability is attractive for narrowband filters and resonators. X-112°Y lithium tantalate (LiTaO₃) is an intermediate case, as is lithium tetraborate (Li₂B₄O₇). Zinc oxide (ZnO) films on glass substrates have been used for TV IF filters, for reasons of economy. This film has also been used on sapphire substrates to give a high-velocity combination, and 1.5-GHz filters have been produced [13]. Langasite (La₃Ga₅SiO₁₄) has recently become available for SAW applications, giving properties quite similar to quartz but with stronger piezoelectric coupling [14]. A variety of other new crystals with similar properties, including langatate and langatite, are also becoming available.

The leaky SAW and STW cases will be described later.

Table 1. Data for Common Materials

Material	v_f (m/s)	$\Delta v/v$ (%)	$\varepsilon_\infty/\varepsilon_0$	TCD (ppm/°C)
Y-Z LiNbO ₃	3488	2.4	46	94
128°Y-X LiNbO ₃	3979	2.7	56	75
ST-X quartz	3159	0.06	5.6	0
X-112°Y LiTaO ₃	3300	0.35	48	18
45°X-Z Li ₂ B ₄ O ₇	3350	0.45	11	0
La ₃ Ga ₅ SiO ₁₄ ^a	2747	0.18	—	−1
ZnO on glass ^b				
(fundamental mode)	2576	0.7	—	11
36°Y-X LiTaO ₃ (LSAW) ^c	4212	2.4	50	32
64°Y-X LiNbO ₃ (LSAW)	4742	5.5	52	80
Quartz, $36^\circ\text{Y-X} + 90^\circ$ (STW)	5100	—	5.6	0

^aLangasite data are for Euler angles 0, 140, 25.5° . This is a minimal-diffraction orientation.

^bData depend on film thickness; typical data are shown.

5. BASIC SAW DEVICES

5.1. Bandpass Filtering

This is one of the commonest applications of SAW devices, and apodization is a fundamental method of achieving this.

5.1.1. Apodized Transducers. *Apodization*, that is, variation of the electrode lengths, is a common method for weighting SAW IDTs. The principle is illustrated in Fig. 4, which shows a device with two transducers, one apodized and the other unapodized. In the apodized transducer, at each x_n there are electrodes extending from both busbars, with a small break at a position that determines the apodization. The SAW sources can be taken to be the live electrodes, or alternatively the gaps between electrodes with different voltages. The figure shows single-electrode transducers for clarity, although in practice they are more commonly the double-electrode type to avoid the electrode reflection problem described above.

To appreciate the operation, it is first necessary to consider reception of waves by the unapodized transducer at the left. For the moment, we will simply state that the frequency response, for waves incident from the right, is essentially the same as the response when the transducer generates waves to the right. This is a result of reciprocity, considered later. For a transducer receiving SAWs, the response is defined by assuming the transducer to be short-circuited, and considering the current I_{sc} in the short circuit when a wave with specified potential ϕ_s is incident. The ratio I_{sc}/ϕ_s is almost the same as Eq. (1), except that a slightly different element factor is used.

The argument presented above applies if the surface-wave beamwidth is the same as the transducer aperture. When dealing with an apodized launching transducer, this is no longer true. To simplify, consider a voltage applied to only one electrode of the apodized transducer. The electrode extends a distance u_n , say, from the live busbar. Now, the short-circuit current induced in the left transducer will be proportional to u_n . To see this, note that apodization has not affected the amplitude of the wave or the charge density that the wave induces on the receiving transducer. However, the charges exist only within the SAW beamwidth, and this width is u_n . Hence, when integrated to obtain the short-circuit current, the result will

be proportional to u_n . The response of the apodized transducer is thus similar to an unapodized one [Eq. (1)], except that the source strength is proportional to u_n . To maintain the units, we use u_n/W , where W is the total aperture, so the response has the form

$$H_{ap}(\omega) = E(\omega) \sum_{n=1}^N \frac{u_n}{W} \exp(-jkx_n) \quad (5)$$

The device response is basically $H_{ap}(\omega)H_{un}(\omega)$, where $H_{un}(\omega)$ is the response of the unapodized transducer Eq. (1). To be more specific, this gives the transadmittance Y_{12} , which is the current obtained when the output transducer is short-circuited and unit voltage is applied to the input transducer. This formulation is valid only if one of the two transducers is unapodized. If we ignore the slow frequency variation of $E(\omega)$, the Fourier transform of Eq. (5) gives a series of impulses with amplitude proportional to u_n . Hence the *time-domain* response is directly related to the *spatial* variation of the electrode lengths, that is, by the apodization.

In practice the observed response is affected by the electrical source and load impedances, and to allow for these we also need the remaining Y -matrix components Y_{11} and Y_{22} . Since electrode reflections are assumed here to be negligible, these Y components are just the transducer admittances.

A general technique for analyzing an apodized device is to divide it into imaginary parallel “channels,” extending in the x direction [7]. Each channel can be regarded as an unapodized device, connected electrically in parallel with the others. However, provided there are no electrode reflections, the analysis can be done without channeling.

5.1.2. Transversal Filtering. If we ignore the slowly varying function $E(\omega)$, Eq. (5) has the form

$$H(\omega) = \sum_{n=1}^N A_n \exp(-j\omega n\tau) \quad (6)$$

where A_n are real constants and $\tau = p/v$ is the electrode spacing in time units. This is the response of a *transversal filter*, which can be thought of as a tapped delay line with taps spaced in time by τ and connected to an output via

Figure 4. Transversal bandpass filter using an apodized transducer.

circuits with amplitude response A_n . The response could have been arrived at by considering a continuous waveform and then sampling it with a sampling frequency $f_s = 1/\tau$. In this context we can apply the sampling theorem, which states that any bandlimited waveform can be reproduced by sampling at a sufficiently high rate, and then filtering to eliminate some high-frequency components introduced by the sampling process. Hence, *any* required frequency response can be synthesized by appropriate choice of the real constants A_n , provided (1) f_s is high enough, (2) the original time-domain waveform is of finite length, and (3) technological constraints are satisfied (maximum frequency, device length etc.). It is a property of transversal filters that the amplitude response is symmetric about frequency $f_s/2$, and this is the center frequency of a single-electrode transducer. Hence, for the general case we need more than two electrodes per center-frequency wavelength; four is quite common. This actually provides a benefit in that electrode reflections are minimized, as discussed earlier.

Another realisation of the transversal filter is the digital finite impulse response (FIR) filter. This comparison is of great value because the design of FIR filters has been considered in great detail. A simple design method is to Fourier-transform the required frequency response to the time domain and then, in order to obtain finite length, multiply by a finite-length window function such as the Hamming function or the Kaiser function [3]. A very effective design method is provided by the Remez algorithm, which can be used to design a filter with an amplitude response of arbitrary shape, subject to a tolerance expressed as an arbitrary function of frequency [15]. Alternatively, linear programming can be used [16].

In practice, the design procedure needs to compensate for a variety of second-order effects, particularly distortion associated with the terminating impedances (the “circuit effect”) and diffraction. These can be compensated by recursive methods; it is even possible to compensate for distortions of unknown physical origin, provided experimental results are sufficiently repeatable.

Sometimes a transversal filter will incorporate a *multistrip coupler* (MSC). This consists of a sequence of disconnected metal strips perpendicular to the SAW wavevector and spanning two SAW tracks. The MSC can couple SAWs from one track to the other with high efficiency and with wide bandwidth. In the transversal bandpass filter, it has been widely used in order to minimize interference from unwanted bulk waves. The MSC is often used when the substrate is Y-Z lithium niobate;

this material gives significant bulk-wave generation but is otherwise attractive because it minimizes diffraction effects. The coupler also enables two apodized transducers to be used, giving improved flexibility. The number of strips needed for a full transfer of the SAWs is in the region of $2.5/(\Delta v/v)$. This prohibits use of the coupler on weakly piezoelectric substrates such as quartz, since the number of strips would be unrealistic.

5.1.3. Withdrawal Weighting. In this technique, selected SAW sources are withdrawn from a uniform transducer, in such a way that the density of remaining sources mimics the amplitude variation of an apodized transducer [17]. This is shown in Fig. 5. Withdrawal-weighted transducers are suitable for filters with small bandwidths, less than, say, 5%, and they have the merit of being insensitive to diffraction effects. The electrodes can still be regular, so the response is still governed by the simple delta-function analysis described earlier.

The two weighted transducers shown in Figs. 4 and 5 have rather different impulse responses, since the withdrawal-weighted transducer response has a sequence of steps. However, the latter can easily be designed such that the *integral* of its impulse response is similar to the *integral* of the impulse response of the apodized transducer. When this is done, the frequency responses of the two transducers will be similar. The main difference is that the stepped nature of the withdrawal-weighted transducer introduces unwanted sidelobes at some distance from the passband of the filter. For this reason, the technique is applicable only for narrowband devices.

5.1.4. Performance of Transversal Bandpass Filters. Filters of the types described here can give excellent performance because their behavior is well understood and the devices are very reproducible, so that small errors can be corrected by redesigning. The main limitation is that insertion losses must be high in order to minimize the triple-transit signal. For the best results, single-electrode transducers are avoided and great care is taken in the design—errors due to the circuit effect, diffraction, and other second-order effects are compensated for [18]. The apodization pattern is often “sloped,” because the presence of several sidelobes in line causes distortion in the conductance G_a and hence in the device response. Special techniques are used to minimize reflections from the ends of the transducers. Filters for vestigial sideband (VSB) applications in TV are made with 6 MHz bandwidth

Figure 5. Transversal filter using a withdrawal-weighted transducer.

centred at 40 MHz, in-band variations of only ± 0.2 dB in amplitude and ± 20 ns in delay, and skirt width 500 kHz. Ganss-Puchstein et al. [19] developed filters for digital radio with 64-QAM (quadrature amplitude modulation), with 20 MHz bandwidth and an amplitude ripple of only ± 0.05 dB. Peach [16] shows filters at 160 MHz, with a shape factor (ratio of 40 and 3 dB bandwidths) of 1.04, and with an in-band ripple of ± 0.15 dB.

5.2. Correlation

In the context of SAW devices, “correlation” refers to the process of applying a complex waveform to a linear device whose impulse response is the time reverse of the input waveform. The device is known as a “matched filter.” The output waveform has a prominent peak called the *correlation peak*. If the input waveform is accompanied by noise, as is always the case for a radio receiver, the correlation process increases the signal-to-noise ratio (SNR), giving the maximum SNR obtainable by linear signal processing. Several types of SAW device have been developed for this purpose.

5.2.1. Pulse Compression. This technique, used in radar systems, increases the maximum range at which a target can be detected without needing an increase in the peak transmitted power. In principle any type of complex waveform is applicable, provided the time–bandwidth product (TB) is large, where T is the waveform duration and B is its bandwidth. The matched filter increases the signal-to-noise power ratio by a factor TB, equivalent to increasing the transmitted peak power by this factor. For radar systems, TB is typically 50–500.

In practice the transmitted waveform is usually a chirp, that is, a waveform whose frequency varies monotonically with time. The echo due to a point target has the same form. The matched filter needs to have its impulse response as the time reverse of this, another chirp, and this can be regarded as a dispersive delay line. In essence, the filter applies a delay dependent on frequency, such that all frequency components arrive at the output at the same time. Figure 6 shows a typical arrangement, where the right transducer has graded periodicity. For a single-frequency SAW, the transducer responds most strongly where its pitch corresponds to the SAW wavelength, so that different delays are obtained for different frequencies.

The left transducer can be uniform, as shown, or it could be another graded-periodicity transducer.

In the radar receiver, the device usually has one transducer apodized in order to give the impulse response a humped envelope. This reduces the sidelobes of the output signal, which need to be small so that they are not falsely interpreted as extra targets. The sidelobes can be 35 dB below the main peak. Typically, bandwidths are in the region 10–100 MHz and durations (T) are 5–20 μ s. For the longer devices quartz is the preferred material because temperature stability is needed, while shorter devices use strong piezoelectrics (lithium niobate or tantalate) to obtain acceptable losses.

Interdigital devices generally give larger insertion losses as the TB product is increased. This limitation is overcome in the reflective array compressor (RAC), which has two arrays of inclined grooves, each reflecting the waves through 90° . The groove arrays reflect strongly when the pitch corresponds to the wavelength, and the RAC has graded pitch so that different frequencies are subject to different pathlengths and hence delays. With this technique, devices with TB products up to 16,000 have been produced [20].

5.2.2. PSK Filters. While chirp waveforms are common in radar systems, communication systems often use phase-shift-keyed (PSK) waveforms, or other related waveforms. A PSK waveform consists of a sequence of contiguous pulses of carrier, with relative phase 0 or 180° . In spread-spectrum communications, each bit of data can be represented by a sequence of this type, and correlation is needed to optimise the SNR. This can be achieved using a SAW tapped delay line, with taps corresponding to the pulses; the taps are connected in a polarity sequence corresponding to the coding.

5.2.3. Convolver. Another type of correlator is the nonlinear convolver, shown in Fig. 7. In this device, RF signals are introduced at both ends of a lithium niobate substrate, so that they propagate towards each other. Where they overlap, a weak nonlinear mechanism causes mixing and a sum-frequency signal is produced, with amplitude proportional to the product of the input wave amplitudes. The non-linearity is an intrinsic property of the material. The product signal appears as an electric field which can be sensed by a uniform metal electrode (the

Figure 6. Interdigital pulse compression filter.

Figure 7. SAW convolver.

parametric electrode) extending over most of the area between the input transducers.

If the input waveforms are $f_1(t)$ and $f_2(t)$, the wave amplitudes within the device have the forms $f_1(t - x/v)$ and $f_2(t + x/v)$ (ignoring some delays). The output waveform $g(t)$ is proportional to the integrated product of these, so that

$$g(t) \propto \int f_1\left(t - \frac{x}{v}\right) f_2\left(t + \frac{x}{v}\right) dx = \frac{1}{v} \int f_1(2t - \tau) f_2(\tau) d\tau \tag{7}$$

where $\tau = t + x/v$. It is assumed here that the traveling SAW signals have finite length and that they overlap only under the parametric electrode. With this assumption, the integrals in Eq. (7) can have limits $\pm \infty$. The second form in Eq. (7) is a standard convolution integral, except that t is replaced by $2t$ because of the relative motion of the two waveforms—and, as is well known from systems theory, convolution describes mathematically the process performed by any linear device. Hence the convolver acts as a *linear* filter, but with one of the input waveforms acting as the impulse response. In particular, it can correlate any type of coded waveform, including the chirp and PSK waveforms considered above, and the coding can be changed instantaneously.

For the configuration of Fig. 7 the device produces a very weak output signal. To improve the efficiency, convolvers have been developed with the SAW beam compressed to a narrow width, typically 3 wavelengths, thus increasing the power density. Typically, the output power for CW signals is $P_O = P_1 + P_2 - 70$ dBm, where P_1 and P_2 are input powers and all powers are measured in dBm (decibels referenced to 1 mW). Although input signal levels of 25 dBm are feasible, the interaction is obviously very weak; nevertheless it is strong enough for practical signal processing. Practical devices can have parametric lengths of 20 μ s and bandwidths of 100 MHz. Interactions in semiconductors have also been used to improve the efficiency.

The convolver shows exceptional versatility. However, it is limited by the need to provide an input “reference” waveform to act as the impulse response, and it has not found widespread application.

5.3. Resonators

As for microwave devices, SAW resonators can be used either for stabilization of oscillators or as the basis for low-loss bandpass filters. A basic difference is that in SAW there is no effective localized reflection mechanism—a single strip, for example, gives mode conversion as well as reflection and is therefore unsuitable for a resonator. However, strong reflectivity can be obtained from a grating consisting of an array of strips, with period equal to $\lambda/2$ at the center frequency. Typically, each strip has a reflection coefficient in the region of 1%, and there may be, say, 200 strips. The strips are commonly short-circuited metal electrodes, although grooves are often used for oscillators because they give lower losses. The grating may be analyzed using the CoM equations given later.

As shown in Fig. 8, a resonant cavity can be formed by two reflecting gratings [21]. The waves penetrate some distance into the gratings, so that the cavity length is effectively larger than the separation of the gratings. Consequently, the frequency spacing of the resonances can be

Figure 8. One-port resonator and its equivalent circuit.

Figure 9. Two-port resonator and its equivalent circuit.

quite small, for example, 1% of the center frequency. The gratings reflect strongly only over a narrow bandwidth, and the device can be designed such that only one resonance appears.

The addition of one or two transducers between the gratings provides coupling to one electrical port (Fig. 8) or two electrical ports (Fig. 9). The transducers are often designed to have negligible electrode reflections. In high- Q devices for oscillator applications, this condition can be obtained by recessing the electrodes into grooves on the surface. Alternatively, it is possible to use double-electrode transducers. Such transducers have little effect on the cavity resonances. The substrate is usually ST-X quartz, because the high Q value implies that temperature stability is important. Experimental Q factors can be up to 10^5 at 100 MHz, or 10^4 at 1000 MHz [21].

Properly designed resonators behave approximately as the equivalent circuits shown in Figs. 8 and 9, with a series resonant branch connected to capacitances equal to the transducer capacitances C_t . The one-port device has a resonance frequency $\omega_r = [L_m C_m]^{-1/2}$, at which the admittance is maximized. There is also an antiresonance frequency ω_a at which the admittance is zero, related to the capacitance ratio by $(\omega_a - \omega_r)/\omega_r \approx 0.5 C_m/C_t$.

An alternative type of two-port resonator uses single-electrode transducers with the electrode pattern made as an extension of the adjacent grating pattern. In this case the device can be made entirely from a single metal film, and it is not necessary to recess the electrodes. This “synchronous” resonator is much easier to make, especially at high frequencies, and Q values of 2250 have been obtained at 2.6 GHz [22].

5.4. Oscillators

A two-port resonator can be used to realize an oscillator by connecting one port to the other via an amplifying feedback circuit, with the amplifier gain exceeding the resonator loss [21]. Alternatively, a SAW delay line can be used [23]. The delay line is designed with one or both transducers long enough to enable it to oscillate at only one frequency. It is also possible to use a one-port resonator, with a special type of circuit [21].

The frequency stability of the oscillator is a crucial issue. Short-term stability relates to fluctuations associated with noise in the loop, causing the output signal to have a spectrum of finite width. Lewis’ analysis [23] showed that for a delay line, the 3 dB width of the spectrum is $\Delta\omega \approx 4k\theta (\text{NF}) G^2 \omega_0^2 / [Q^2 P_0]$, where k = Boltzmann’s constant, θ = absolute temperature, and $Q = \omega_0 \tau$ is the Q factor of the delay line, with delay τ ; G , P_0 , and NF are respectively the amplitude gain, output power, and noise figure of the amplifier, when saturated as in the oscillation condition. This formula also applies for a resonator, although it does not include flicker noise. A delay line needs to be physically much larger than a resonator to obtain the same Q . On the other hand, the maximum input power for a resonator is less than that of a delay line because of the magnification associated with the resonance.

Medium-term stability is associated with the temperature stability of the quartz, discussed elsewhere. Long-term stability refers to frequency drift over periods of months or years, and the mechanisms determining this are not clear. However, Parker and Montress [21] have shown that use of a package made of quartz can enable the ageing rate to be 0.1 ppm per year or less.

Improved results are obtainable using the surface transverse wave (STW) on quartz. This orientation gives high velocity, which is attractive for high-frequency devices, and can tolerate higher power levels than ST-X quartz, leading to better short-term stability [24].

5.5. Wireless Interrogation: Sensors and Tags

The temperature sensitivity of SAW devices is usually seen as a limitation. However, it can be exploited to measure temperature. Many other quantities can also be measured, and related devices are used as identification tags. A typical device is shown in Fig. 10 [25]. An interdigital transducer is connected directly to an antenna, generating SAWs when a RF pulse signal is received. A series of reflectors, usually short gratings, generates a characteristic pattern of reflected waves, and these are received by the transducer and radiated by the antenna. Typically, the 2.4-GHz ISM band is used. The delay in the SAW device helps to distinguish the return signal from the transmitted signal.

The return signal generated by this device is dependent on environmental factors such as temperature or stress, so these can be measured. It is also characteristic of the device design, and can therefore be used for identification. Identity tags can be made by using a sequence of reflectors

Figure 10. Reflective delay line for wireless tag or sensor.

coded in some way. For example, they might be in a regular sequence except that selected reflectors are omitted. Such devices potentially have wide-ranging applications. The number of possible codes is envisaged to be up to 10^{19} [26].

Temperature can be measured by comparing the phases of waves from individual reflectors. Strain can also be measured, and with the device mounted on a sealed cavity this can also indicate pressure. Chemicals can be detected by coating the device with a film that absorbs the target chemical, causing a change of density and hence SAW velocity. As an alternative to the delay line of Fig. 10, one-port resonators can be used.

6. LOW-LOSS BANDPASS FILTERS

Since the early 1980s, the rapid expansion of wireless systems, particularly mobile telephony, has led to a strong demand for bandpass filters with low insertion losses. Losses often need to be less than 10 dB for IF filters, and 2 dB for RF filters. As discussed above, this requirement cannot be met using traditional transversal filters because of the triple-transit problem, and consequently a variety of new devices have been developed. There are many approaches for this problem [27], but here we consider only the main ones. They can be classified as follows:

1. Use a unidirectional transducer, which generates waves more strongly in one direction than the other. With this feature, triple-transit signals can be reduced while still maintaining low losses. It can be shown that the transducer must have internal reflectivity to satisfy this condition.
2. Develop filters based on SAW resonators, analogous to microwave resonator filters. In effect, an infinity of multiple-transit signals are used here.

6.1. Single-Phase Unidirectional Transducers (SPUDTs)

This term describes a class of unidirectional transducers; the term “single-phase” distinguishes them from some earlier types that are of little interest now. The dominant type of SPUDT is known as the *distributed-array reflective*

Figure 11. Structure of DART transducer.

transducer (DART), illustrated in Fig. 11. Each cell of this transducer has two narrow electrodes of width $\lambda_0/8$ and a wide electrode of width $3\lambda_0/8$, and the interelectrode gaps are all $\lambda_0/8$. Here λ_0 is the cell length, equal to the center-frequency wavelength. Reflections from the narrow electrodes are negligible because they occur in pairs with spacing $\lambda_0/4$, so that reflections cancel at the center frequency. Hence, in effect, only the wide electrodes act as SAW reflectors. The waves are effectively generated at the centers of the live electrodes. In general, it can be shown that for best directivity the distance between a generation center and a reflection center needs to be $(n/2 \pm 1/8)\lambda_0$, where the factor $1/8$ appears because the reflection coefficient is known to be imaginary. In the DART, the distance between the two centres is $3\lambda_0/8$ and therefore satisfies this requirement [28].

Like any other transducer, a SPUDT gives optimum acoustoelectric conversion if it is electrically matched. If it has enough directivity, it can be shown that this is also close to the condition that minimizes the acoustic reflection. Thus, low loss and good triple-transit suppression are obtained simultaneously. In practical DARTs it is common to have a directivity of 6 dB or more, and this is sufficient for these purposes. However, this is limited by the electrode reflectivity obtainable, and for this reason the DART needs to be fairly long, $100\lambda_0$ or more. Hence the bandwidth is quite small, and the substrate is a temperature-stable material such as quartz.

Weighting can be applied to modify the response. The transduction in one cell can be removed by connecting the second electrode to the ground bus instead of the live one. Reflection can be removed by replacing the wide electrode by two narrow ones (each $\lambda_0/8$ wide, with a $\lambda_0/8$ space). Moreover, the transduction and reflection can be regarded as smooth functions of position, using withdrawal weighting to obtain the actual designs for individual cells. In this way, the design can satisfy performance criteria such as bandwidth, ripple, skirt width, and stopband rejection. A considerable advance was made when it was realized that the reflection and transduction functions can also change sign; these changes are realized by displacing the corresponding electrodes. The use of differently signed reflectors is equivalent to incorporation of resonators into the structure, so the transducer became known as a *resonant SPUDT* (R-SPUDT) [28]. The resonances enable the device length to be substantially reduced, for a given specification. A further reduction was obtained by using a two-track arrangement, in which each track consists of two R-SPUDTs connected in parallel with the R-SPUDTs in the other track [29]. These size reductions have been very significant in the main application area, which is for IF filtering in CDMA mobile phones, with bandwidth around 1 MHz. The design process is an extremely sophisticated “global” optimization procedure, taking account of the amplitude and phase ripple requirements as well as the amplitude response and tolerances. These devices can actually exploit the triple-transit effect, using it to reduce the skirt widths; in the passband, the triple transit is usually minimized. This represents a considerable extension of the initial objective of the SPUDT, which was simply to reduce the triple-transit level.

6.2. Resonator Filters

As in microwave technology, SAW resonators can be coupled in order to realize a bandpass function. However, a SAW device behaves as a resonator only within the reflection band of the gratings. The width of this band is approximately $\Delta f/f \approx 2|r_s|/\pi$. Here $|r_s|$ is the strip reflection coefficient, typically a few percent, so the filter bandwidth obtainable is quite small.

An example is the *longitudinally coupled resonator* (LCR) filter, also called the *dual-mode SAW* (DMS) filter [30]. As shown in Fig. 12, this has three transducers between two reflecting gratings, with the outer two transducers connected together. In effect, each outer transducer plus its adjacent grating serves to act as a SPUDT, launching SAWs toward the center of the device when a voltage is applied. The device as a whole behaves as a cavity with two resonances. This arrangement is often used for RF filters, with center frequency 900 MHz or more, in which case the transducers are usually the single-electrode type. The response is typical of a two-pole filter, giving a flat passband with low loss when electrically matched. It is common to cascade two devices electrically in order to improve the stopband rejection. The device can give low loss and good stopband rejection, but the skirt width is relatively wide because of complications arising from reflections within the device.

Another resonator filter is known as the *impedance element filter* (IEF). This consists of a sequence of SAW resonators connected as an electrical circuit, without any acoustic coupling between them. Resonant behavior can be obtained simply by using long single-electrode transducers. It is known that, for a sufficiently large number of electrodes, the reflections can cause the transducer to behave as a resonator, with equivalent circuit approximately as in Fig. 8 [31]. Usually, reflecting gratings are also added at the ends to increase the Q factor. The IEF uses a sequence of series and parallel resonators (Fig. 13), where the former have higher resonant frequencies. The filter center frequency is at the antiresonance of the parallel resonator (where $Y \rightarrow 0$) and at the resonance of the series resonator (where $Z \rightarrow 0$), so that the signal is transmitted with little attenuation. Outside the passband there are deep nulls due to the resonance of the parallel resonator and the antiresonance of the series one. Beyond that are the stopbands where there is little acoustic activity, and here the response is determined mainly by the static capacitances and the electrical loading.

Figure 12. Longitudinally coupled resonator (LCR) filter. Bus-bars shown without connections are grounded.

Figure 13. Typical configuration for impedance element filter (IEF). Usually each resonator is a single-electrode transducer with a grating on each side.

Like the LCR filter, the IEF can provide very low loss (1 dB) at RF frequencies (900 MHz and above) [32]. Its stopband rejection is not so good, but the skirts can be narrower. There is also the key advantage that quite high power levels can be tolerated, around 2 W. This ability is essential for some mobile phone transmitter filters. Many systems use a duplexer consisting of two IEFs, both connected to the antenna. One of these IEFs is at the transmitter output, and the other is at the receiver input. These devices normally use leaky waves on lithium tantalate, a subject described later.

The transverse-coupled resonator (TCR) filter is another resonant device, although it operates on entirely different principles [33]. As shown in Fig. 14, it has two identical tracks, each containing a single-electrode transducer with a grating on either side. Coupling between the tracks occurs because the device behaves as a waveguide that supports two waveguide modes, one symmetric and one antisymmetric. This behavior is associated with the narrow width, typically 6λ . Excitation of one transducer causes generation of both modes, and because of the different mode velocities, a signal appears in the other track. For each mode the device behaves as a conventional resonator. The presence of two modes gives the device a two-pole response. The pole frequencies correspond to the wave velocities of the modes, and because these are very close together, the fractional bandwidth of the filter is very small, typically 0.1%. Using a ST-X quartz substrate, this filter has been widely used in the IF circuit of GSM mobile phone handsets, with typically 200 kHz bandwidth and 200 MHz center frequency.

6.3. Capabilities of Bandpass Filters

Table 2 summarizes the capabilities of the various types of filter. When considering a particular requirement, the

Figure 14. Transverse-coupled resonator (TCR) filter.

Table 2. Typical Performance for Main Types of Bandpass Filter

Type	Transversal	DART	LCR	IEF	TCR
Substrate	Various	ST-X quartz	42°Y-X LiTaO ₃	42°Y-X LiTaO ₃	ST-X quartz
Center frequency (MHz)	50–500	80–500	500–2000	600–3000	50–200
Bandwidth (%)	1–50	1–3	1–3	1–4	0.05–0.15
Insertion loss (dB)	15–40	6–10	1–3	1–3	5–7
Maximum rejection (dB)	60	45	55	45	50
Minimum shape factor ^a	1.1	1.5	3.0	1.5	2.0

^aShape factor = ratio of 40-dB and 3-dB bandwidths.

different capabilities of the various devices need to be considered, including the temperature stability. A variety of packages are used, including metal and surface-mount ceramic types. Flip-chip mounting is often used to minimize the size, which may be as small as $2 \times 2 \text{ mm}^2$ for GHz-range devices. The frequency response depends on the external terminating impedances, often specified as 50Ω , and often the transducer capacitances need to be tuned out using inductors. It is also common to use two-component circuits to transform the impedances. Other factors, especially important at high frequencies, are stray capacitance or inductance, and electromagnetic feedthrough.

Many filters can be arranged in a balanced form, that is, at each port there are two live terminals designed to accept voltages with opposite polarities. This is needed for operation with some modern communication circuitry. It is also possible to have one port balanced and the other unbalanced, so that the device acts as a balun transformer in addition to its filtering function.

7. LEAKY SURFACE WAVES

In addition to the Rayleigh-type surface wave described earlier, some devices use alternative wave types that behave in a somewhat similar manner. A particular case occurs on 36°Y-X lithium tantalate. The wave is rather like a Rayleigh wave, but the particle displacement is approximately in the transverse direction (parallel to the surface) instead of being in or near the sagittal plane. This wave is not a true surface wave, as shown by the fact that it can radiate some energy into the bulk of the material. Hence the wave is called a “leaky wave”. It is related to a bulk shear wave. A numerical search for wave solutions gives a wavenumber with a small imaginary part, and hence there is some attenuation. The attenuation depends on rotation angle, and becomes small, negligible for practical purposes, at an angle of 36° . For this angle, devices analogous to SAW devices behave in a similar manner. There are significant differences, however, notably that the leaky-wave material gives rise to substantial bulk-wave generation at frequencies above the passband.

This leaky wave has the advantage that, compared with SAWs on lithium tantalate, it gives stronger piezoelectric coupling without an increased TCD (in contrast, the SAW on Y-Z lithium niobate gives stronger coupling but the TCD is larger). In addition, the leaky wave can tolerate higher power levels, because the wave penetrates more deeply in to the substrate. It also has a higher velocity, increasing the electrode widths needed for a

specified frequency. All these features are attractive for low-loss RF filters, and hence IEF and LCR filters for these applications often use this wave. A modified orientation of 42° is now preferred because it is found to give less loss when in the presence of transducers and gratings.

A similar case occurs in 36°Y-cut quartz, with propagation normal to X. Again, this is related to a bulk shear wave, giving a high velocity with some attenuation. This was originally known as a *surface-skimming bulk wave* (SSBW). In practical applications the wave is trapped at the surface by transducers and gratings, and it is then known as a *surface transverse wave* (STW). The high velocity (5000 m/s) is attractive for high-frequency devices and losses can be small, as shown by high-Q resonators at 1 GHz [24].

Leaky waves have been found in a substantial variety of materials, often giving elevated piezoelectric coupling [34]. In addition to waves related to shear waves, as in the abovementioned cases, there are also wave related to longitudinal waves. These give even higher velocities. For example, in $47^\circ\text{Y-X} + 90^\circ$ lithium tetraborate, the longitudinal leaky wave has velocity 7000 m/s and $\Delta v/v = 0.7\%$.

8. ANALYSIS METHODS

Analysis techniques for SAW devices vary greatly in sophistication. The simple delta-function model is very effective for illustrating some basic features, and it can provide the basis for optimized design methods such as the Remez algorithm. At the other extreme, numerical techniques can take account of complicated wave behavior, together with effects due to the mechanical vibration of the electrodes. Such methods can simulate very complex second-order effects and can be beneficial when demanding requirements are to be met, even though the analysis may take many hours on a modern computer. The following presents some notes on methods for unapodized devices, omitting derivations.

8.1. SAW Analysis for Thin Films: Effective Permittivity

The electrodes in a SAW device perturb the waves as a result of electrical and mechanical effects. For practical purposes, electrical effects are independent of the film thickness. Mechanical effects do depend on thickness, causing reflections of the waves. However, these are not important if the film is thin enough, or if electrode reflections are canceled as in the double-electrode transducer.

Assuming initially that mechanical effects can be ignored, an excellent basis for analysis is provided by the effective permittivity $\varepsilon_s(\beta)$. We define this by assuming a surface potential of the form $\bar{\phi}(\beta)\exp(j\beta x)$ and a charge density of the form $\bar{\sigma}(\beta)\exp(j\beta x)$. A factor $\exp(j\omega t)$ is omitted from the equations. We then write

$$\bar{\sigma}(\beta) = \varepsilon_s(\beta)|\beta|\bar{\phi}(\beta) \quad (8)$$

It can be shown that $\varepsilon_s(\beta)$ is actually a function of the slowness β/ω . It can be calculated numerically using the electromechanical constants of the material and its orientation. Applying appropriate boundary conditions, this leads to an analysis allowing for electrode reflections and different wave modes (including bulk waves, e.g.) [35]. However, for many cases it is adequate to ignore bulk-wave generation. Noting that $\varepsilon_s(\beta)$ must be zero for a free surface and infinite for a metallized surface, we can approximate it by using first-order Taylor expansions, leading to Ingebrigtsen's form

$$\varepsilon_s(\beta) \approx \varepsilon_\infty \frac{\beta^2 - k_f^2}{\beta^2 - k_m^2} \quad (9)$$

where $k_f = \omega/v_f$ and $k_m = \omega/v_m$ are respectively the wavenumbers for a free surface and a metallized surface. Also, ε_∞ is an abbreviation for $\varepsilon_s(\infty)$. This formulation can also be written in terms of a Green function $G(x)$, relating potential $\phi(x)$ to charge density $\sigma(x)$, such that

$$\phi(x) = G(x) * \sigma(x) = \int_{-\infty}^{\infty} G(x-x')\sigma(x')dx' \quad (10)$$

where the asterisk indicates convolution. It can be shown that the Green function is the sum of an electrostatic term $G_e(x) = -\ln|x|/[\pi\varepsilon_\infty]$ and a surface-wave term $G_s(x) = j\Gamma_s \exp(-j k_f|x|)$, so that $G(x) \approx G_e(x) + G_s(x)$. Here Γ_s is given by

$$\Gamma_s \approx \frac{(v_f - v_m)/v_f}{\varepsilon_\infty} = \frac{\Delta v/v}{\varepsilon_\infty} \quad (11)$$

When a voltage is applied to a transducer, the surface wave generated in the $-x$ direction has surface potential $\phi_s(x) = j\Gamma_s \bar{\sigma}(k_f) \exp(jk_f x)$, where $\bar{\sigma}(\beta)$ is the Fourier transform of the charge density $\sigma(x)$. This arises from the SAW Green function $G_s(x)$. For the same transducer receiving SAWs, with potential ϕ_i , the short-circuit current is given by the reciprocity relation

$$\left[\frac{I_{sc}}{\phi_i} \right]_{\text{receive}} = - \left(\frac{\omega W}{\Gamma_s} \right) \left[\frac{\phi_s}{V} \right]_{\text{launch}} \quad (12)$$

provided the two potentials are evaluated at the same location. Here W is the beamwidth.

8.1.1. Quasistatic Solution. The formulation above leads to complex solutions because it includes the effects of electrode reflections. However, it can be shown that these reflections can be eliminated from the analysis if the

charge density $\sigma(x)$ is replaced by the electrostatic charge density $\sigma_e(x)$, that is, the charge density for the non-piezoelectric case $\Gamma_s = 0$. The SAW potential generated is then $\phi_s(x) = j\Gamma_s \bar{\sigma}_e(k_f) \exp(jk_f x)$. This is a much simpler formulation because $\sigma_e(x)$ is independent of frequency. Integration of $\sigma_e(x)$ over individual electrodes also gives the transducer capacitance C_t . Established numerical techniques [36] can be used to calculate this function.

In many transducers (including withdrawal-weighted transducers) the electrodes are regular, that is, they have constant width and spacing. In this case there is a simple algebraic method. First, imagine an infinite array of electrodes with width a and pitch p , and suppose that unit voltage is applied to one electrode, centered at $x=0$, with all other electrodes grounded. The electrostatic charge density for this case is denoted by $\rho_f(x)$ (which is finite on all electrodes). The total charge density on a transducer can be obtained simply by superposition, using $\rho_f(x)$ for each live electrode. The potential of the SAW generated is simply $\phi_s = j\Gamma_s \sum_n \bar{\rho}_f(k_f) \exp[jk_f(x-x_n)]$, where the sum is over the live electrodes, which are centered at x_n . Here $\bar{\rho}_f(\beta)$ is the Fourier transform of $\rho_f(x)$, given by the formula

$$\bar{\rho}_f(\beta) = \frac{2\varepsilon_\infty \sin(\pi s) P_m(\cos \Delta)}{P_{-s}(-\cos \Delta)} \quad \text{for } 0 < s < 1 \quad (13)$$

where $\Delta = \pi a/p$, $s = \beta p/(2\pi) - m$, and the integer m is chosen such that $0 < s < 1$. $P_\mu(x)$ is a Legendre function given by $P_\mu(x) = \sum_{n=0}^{\infty} a_n$, with $a_0 = 1$ and

$$\frac{a_n}{a_{n-1}} = \frac{(n-1-\mu)(n+\mu)(1-x)}{2n^2} \quad (14)$$

When μ is an integer, the Legendre function becomes a polynomial. This formulation provides a simple way of analyzing electrostatic phenomena, including the effect of the electrode width a on the fundamental and harmonic responses. For example, it shows that the third harmonic of a single-electrode transducer vanishes when $a/p = 0.5$.

The capacitance of the transducer is obtained by integrating the electrostatic charges on the live electrodes. To facilitate this, we define Q_n as the integral of $\rho_f(x)$ over electrode n . Generally, this requires a numerical integration, but for the special case $a/p = 0.5$, it is found that $Q_n = 4\varepsilon_\infty/[\pi(1-4n^2)]$. With this formula, the transducer capacitance is easily calculated using $C_t = W \sum_n \sum_m \hat{P}_n \hat{P}_m Q_{m-n}$, where \hat{P}_n are electrode polarities, equal to 1 for a live electrode and 0 for a grounded electrode. We find $C_t = \alpha \varepsilon_\infty W N_p$, where W is the aperture, N_p is the number of periods, and $\alpha = 1$ for a single-electrode transducer and 1.414 for a double-electrode transducer.

8.1.2. Electrode Reflections in Regular Arrays. Reflections are particularly relevant in reflective gratings and single-electrode transducers. They arise from electrical and mechanical loading of the surface, and to first order these effects can be analyzed separately and then added. Electrical loading is usually negligible in weakly piezoelectric materials such as quartz.

Electrical reflections can be deduced from Eq. (10) [2], giving a formula involving Legendre functions. For $a/p = 0.5$ and a frequency such that $\lambda = 2p$, the reflection coefficient of one electrode is $r_e \approx \pm 0.72j (\Delta v/v)$. Here the $+$ ($-$) sign is used for open-circuit (short-circuited) electrodes. This takes account of the influence of neighboring electrodes. The phase of r_e is defined by referring it to the center of the electrode. The fact that r_e is imaginary is a consequence of power conservation.

For mechanical loading, a first-order analysis based on perturbation theory [2] gives $r_e = jCh/(2p)$ for $a/p = 0.5$, where h = film thickness. The constant C is typically in the range -0.5 to -0.3 for common SAW materials, although for 128°Y-X lithium niobate $C = +0.8$. For grooves on Y-Z lithium niobate or ST-X quartz, $C \approx +0.6$.

For transducer analysis including electrode reflections, the quasistatic method described above can be adapted, giving the *reflective array model* (RAM) [37]. Alternatively, the CoM equations below can be used.

8.1.3. P-Matrix Description. For general purposes it is common to specify a transducer behavior in terms of a matrix P_{ij} , defined by

$$[A_{t1}, A_{t2}, I]^T = [P][A_{i1}, A_{i2}, V]^T \quad (15)$$

where superscript T indicates a transpose. Here I and V are the transducer current and voltage, respectively. The A s are SAW amplitudes, with subscript $i(t)$ indicating waves incident on (leaving) the transducer. These have additional subscripts 1 or 2 to indicate the acoustic port. The ports are imaginary lines near the edges of the transducer, and their precise location is unimportant. The amplitudes are defined such that $|A|^2/2$ equals the power of the surface wave, and the phase of A is the same as that of the surface potential ϕ_s . This requires the relation $A = \phi_s [\omega W/(2\Gamma_s)]^{1/2}$. Reciprocity leads to the relations $P_{21} = P_{12}$, $P_{31} = -2P_{13}$, and $P_{32} = -2P_{23}$. For a grating, the P_{ij} with i or $j = 3$ are not used.

The P matrix can be applied quite generally, although it is not valid if more than one type of wave is present. For example, it cannot be applied to a SAW device that is also generating bulk waves. However, it is very useful for analysing devices with several components, such as two-port resonators. Simple formulas [38] can be applied to cascade components together, leading to a device Y matrix.

8.1.4. Coupled-Mode Equations. These equations, also called *coupling-of-modes* (CoM) equations, are often used for unapodized components with internal electrode reflections. They are written in the form [38,39]

$$\begin{aligned} \frac{dC(x)}{dx} &= -j\delta C(x) + c_{12}B(x) + \alpha_1 V \\ \frac{dB(x)}{dx} &= j\delta B(x) + c_{12}^*C(x) + \alpha_1^* V \\ \frac{dI(x)}{dx} &= 2\alpha_1^*C(x) - 2\alpha_1 B(x) + j\omega C_t \end{aligned} \quad (16)$$

where $\delta = k - k_0$ and k_0 is the wavenumber at the Bragg frequency, determined by the structure. For example, at the first stopband of a grating with electrode pitch p we have $k_0 = \pi/p$. $C(x)$ and $B(x)$ are slowly varying wave amplitudes defined such that the “real” amplitudes are $c(x) = C(x) \exp(-jk_0x)$ and $b(x) = B(x) \exp(jk_0x)$. The parameters c_{12} and α_1 give the reflection and transduction per unit length, and their presence in different places is needed to satisfy reciprocity. $I(x)$ is the busbar current, which needs to be integrated to obtain the transducer current. C_t is the capacitance per unit length.

For a single-electrode transducer, the parameters are given by

$$c_{12} = \frac{-r_s^*}{p}; \quad \alpha_1 = \frac{j\bar{\rho}_t(k)[2\omega W\Gamma_s]^{1/2}}{4p} \quad (17)$$

assuming that the acoustic ports are taken at the center of the end electrodes. Here c_{12} and α_1 are independent of x , and the CoM equations have an algebraic solution. We first consider the case $V = 0$, which applies for a grating or a short-circuited transducer. We look for a “grating mode,” in which $C(x)$ and $B(x)$ are both proportional to $\exp(-jsx)$. Equations (16) give

$$s^2 = \delta^2 - |c_{12}|^2 \quad (18)$$

When there are no losses, δ is real. Then s is also real, except for a stopband with edges at $\delta = \pm |c_{12}|$. The stopband has a fractional width $\Delta f/f = 2|r_s|/\pi$. Equations (16) can also be solved to find the P matrix of a uniform transducer, assumed to extend from $x = 0$ to L . Defining $D = s \cos(sL) + j\delta \sin(sL)$, this is found to be

$$P_{11} = \frac{-c_{12}^* \sin(sL)}{D}$$

$$P_{12} = P_{21} = \frac{s \exp(-jk_0L)}{D}$$

$$P_{22} = \frac{c_{12} \sin(sL) \exp(-2jk_0L)}{D}$$

$$DP_{31} = 2\alpha_1^* \sin(sL) - 2sK_2[\cos(sL) - 1]$$

$$DP_{32} = \{-2\alpha_1 \sin(sL) + 2sK_1[1 - \cos(sL)]\} \exp(-jk_0L)$$

$$P_{33} = -K_1P_{31} - K_2P_{32} \exp(jk_0L) + 2(\alpha_1^*K_1 - \alpha_1K_2)L + j\omega C_t \quad (19)$$

where C_t is the transducer capacitance, $K_1 = (\alpha_1^*c_{12} - j\delta\alpha_1)/s^2$, and $K_2 = (\alpha_1c_{12}^* + j\delta\alpha_1^*)/s^2$. In Eqs. (19), the first three equations apply for a grating as well as a transducer. We also find $P_{13} = -P_{31}/2$ and $P_{23} = -P_{32}/2$, as required by reciprocity.

To use the CoM equations, c_{12} and α_1 must be known. Equation (17) gives approximate formulas for a single-electrode transducer, but it is also common to use values derived from more accurate analysis, or from experimental measurements. The equations are valid for a wide variety of devices. For example, they can also be used for

SPUDTs, with appropriate values for c_{12} and α_1 . For DARTs, approximate formulas are available [37].

The CoM equations can predict directivity (i.e., $|P_{23}| \neq |P_{13}|$), depending on the phases θ of c_{12} and ϕ of α_1 . Maximum directivity occurs when $2\theta - \phi = n\pi$. The transducer is bidirectional ($|P_{23}| = |P_{13}|$) if $2\theta - \phi = (2n + 1)\pi/2$. Usually the transducer geometry is designed to give directivity if needed, as in the DART. However, a symmetric transducer, which may be the single-electrode type, can give directivity because of asymmetry in the substrate properties. This is known as the *natural SPUDT effect*. It occurs in many materials to some extent, but for common SAW materials and orientations it is absent or negligible.

8.1.5. Accurate Analysis Methods. Although the methods described above are often adequate, many situations call for more detailed techniques. This is the case when better accuracy is needed, such as when the electrodes are relatively thick or have nonuniform geometry as in the DART. For such cases, numerical methods based on finite-element (FEM) or boundary-element (BEM) methods have been developed [40–43]. For long transducers, such methods can be very time-consuming. In this case, a possible approach is to use an accurate analysis for a short transducer and use it to deduce the CoM parameters; the latter can then be used to analyze a long transducer. Another approach is to use FEM to analyze infinite gratings corresponding to the transducer under short-circuit and open-circuit conditions. From the stopband edge frequencies, the CoM parameters c_{12} and α_1 can be deduced [44,45].

Accurate analysis of leaky-wave and STW devices call for different approaches, because these waves are fundamentally different from Rayleigh SAWs. The waves are substantially affected by surface gratings and transducers. For example, a grating can serve to trap the wave at the surface, thus reducing the attenuation. However, at frequencies above the stopband it can cause bulk-wave radiation and thus have the opposite effect. In transducers, the coupling parameter α_1 is known to increase with the film thickness of the electrodes. For these reasons, analysis of these waves is best done with the grating included a priori. Because of these complications, analysis of these waves has been confined mostly to uniform transducers and gratings. For leaky waves, center-frequency CoM parameters (dependent on film thickness) have been deduced from FEM analysis of gratings [44]. Hashimoto and Yamaguchi [46] analyzed a metal grating starting from the effective permittivity and adding mechanical loading using FEM analysis. The numerical results were fitted to an empirical formula due to Plessky [47]. This enabled frequency-dependent CoM parameters to be deduced, including the simulation of loss due to bulk-wave generation. This approach was used for leaky waves on 36°Y-X lithium tantalate [48] and STWs on quartz [49].

SURFACE ACOUSTIC WAVE FILTERS

KEN-YA HASHIMOTO
MASATSUNE YAMAGUCHI
Chiba University
Chiba, Japan

1. SAW TRANSVERSAL FILTERS

In 1965, White and Voltmer showed that surface acoustic waves (SAWs) are excited and detected efficiently by an interdigital transducer (IDT) placed on a piezoelectric substrate [1]. Since precise and fine IDT patterns can be generated by means of photolithography, the IDT invention stimulated worldwide research in the development of various SAW-based signal processing devices in VHF-UHF ranges.

One typical device configuration is the so-called SAW transversal filter shown in Fig. 1. If an impulse signal is

Figure 1. Basic configuration of SAW transversal filter.

applied to one IDT, SAWs are excited through piezoelectricity, and detected by another IDT, on the electrodes of which electrical charges are induced.

Since the delay time is determined simply by the propagation pathlength, the spatial distribution of the excited SAW amplitude determines the impulse response of the device output (see Fig. 1). This suggests that specified impulse responses could be synthesized by designing the IDT pattern; the excitation profile can be controlled by the electrode overlap length [2].

It is clear that the SAW response becomes strong when the SAW wavelength λ is close to the periodicity p_1 of IDT electrodes; that is, the SAW synchronous frequency ω_r is given by V_S/p_1 , where V_S is the SAW velocity.

Denoting the envelope of the weighting function for an IDT by $W(x)$, one obtains the transfer function $H(\Delta\omega)$ of this filter as

$$H(\Delta\omega) \propto \int_{-\infty}^{+\infty} W(x) \exp(+j\Delta\beta x) dx \quad (1)$$

as a function of the deviation $\Delta\omega$ of the frequency ω from ω_r , where $\Delta\beta = \Delta\omega/V_S$. Equation (1) indicates that $H(\Delta\omega)$ is proportional to the Fourier transform of $W(x)$; when $W(x)$ is uniform, $H(\Delta\omega) \propto \text{sinc}(\Delta\beta L_1/2)$, where L_1 is the IDT acoustic length (IDT length in the SAW propagation direction). If a rectangular passband is specified, $W(x)$ should be of the shape of $\text{sinc}(ax)$.

This operation is equivalent to that of finite impulse response (FIR) filters in the digital signal processing. The FIR filter is known to be flexible for designing both amplitude and phase responses, and various design techniques developed for them [3,4] could be adopted. For these reasons, the SAW transversal filters have been widely used in various communication systems and consumer products such as mobile phones, TV sets, and VCRs [4].

It may be understood from the discussion above that IDTs excite SAWs toward both left- and right-hand directions with equal amplitude, which is referred to as *bidirectionality*. Hence, the 3 dB power loss, which is usually called the *bidirectional loss*, is always unavoidable; half of the SAW power launched from the left-hand IDT never reaches the right-hand IDT. At the right-hand (receiving) IDT, the bidirectionality again causes the 3 dB bidirectional loss due to SAW regeneration (reflection) associated with detection. Adding to this bidirectional loss of 6 dB, the impedance mismatching with peripheral circuits should also be taken into account for the evaluation of the total device insertion loss.

In IDTs with the minimized mismatching loss, significant SAW reflection simultaneously occurs as a result of SAW regeneration. This means that multiple echoes are superimposed on the output of the original signal, which result in strong ripples in both amplitude and phase responses in the output signal. One possible and pessimistic countermeasure for suppressing the multiple echoes is to increase the device insertion loss. For this reason, conventional SAW transversal filters exhibit relatively large insertion loss (i.e. ≥ 10 dB). Detailed discussions on the IDT design can be seen in the article SURFACE ACOUSTIC WAVE DEVICES.

Figure 2. Typical configuration of SAW transversal filter.

Figure 2 shows a typical layout of an SAW transversal filter. A shield is placed between the input and output IDTs, earthing the static capacitance between the two IDTs. SAW reflection within the IDTs is suppressed by employing a double-electrode-type IDT (four electrodes per wavelength). The effect of SAW reflection at the IDT edges is minimized by placing grounded electrodes at both sides of the IDTs and cutting them obliquely. Acoustic absorbers are also placed to suppress SAW reflection from the substrate edges as shown in the figure.

Figure 3 shows, as an example, the frequency response of a TV-IF filter prepared on a X-112°Y-LiTaO₃ substrate for Japanese NTSC TV systems (Fujitsu FAR-F4SA-58M750-A008). It is seen that a very complex amplitude response is skillfully synthesized. With a moderate insertion loss of 16 dB, a superior out-of-band rejection of 45 dB and small group delay deviation of 25 ns (typical) are simultaneously realized.

Figure 4 shows the frequency response of an IF filter prepared on a 128°Y-X-LiNbO₃ substrate for U.S. CATV (cable TV) (Fujitsu SBF0406TPL). It is seen that very flat amplitude and group delay responses are obtained throughout the passband of 6 MHz width. The parameters are as follows: insertion loss of 15 dB, amplitude ripple of 0.3 dB, out-of-band rejection of 45 dB, and group delay deviation of 35 ns (typical).

It may be of interest to note that electrode periodicities as well as overlap lengths do not have to be uniform in transversal filters. An interesting application of this is SAW dispersive delay lines for the pulse compression in

Figure 3. Frequency response of TV-IF filter for Japanese NTSC TV systems. (Courtesy of Fujitsu Media Devices, Ltd.)

Figure 4. Frequency response of IF filter for U.S. CATV. (Courtesy of Fujitsu Media Devices, Ltd.)

radar systems [5]. Figure 5 shows the typical configuration.

In the structure shown in Fig. 5, the electrode periodicity gradually changes within each IDT, although all the electrodes are aligned in parallel; the inner electrodes possess larger periodicity, whereas outer ones have smaller periodicity. This means that the inner electrodes are responsible for signal transmission at lower frequencies, and outer ones become active at higher frequencies. As can be seen, due to the difference in the pathlength, the signal delay at lower frequencies is smaller than that at higher frequencies.

Consider an RF burst signal, called the “downchirp signal,” where the instantaneous frequency decreases

Figure 5. Typical configuration of SAW dispersive delay line.

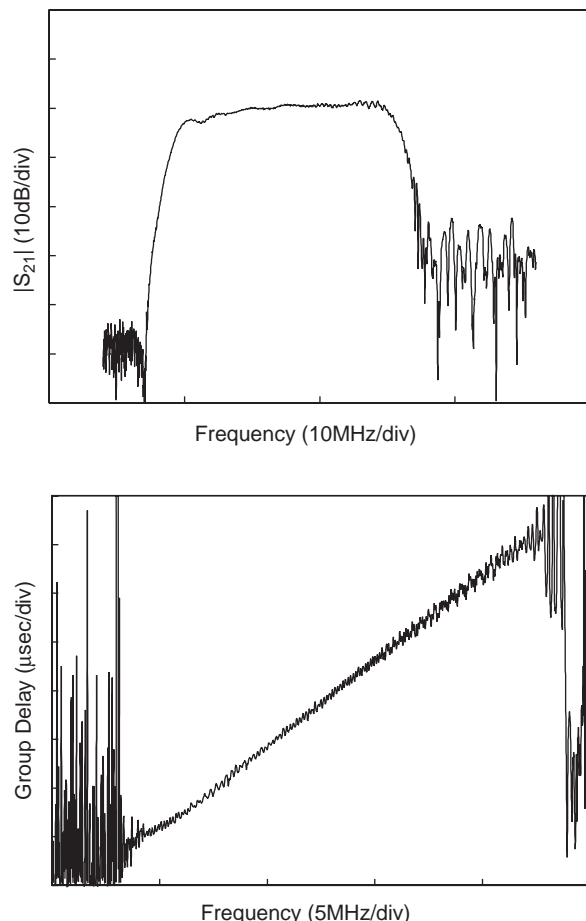

Figure 6. Frequency response of SAW dispersive delay line. (Courtesy of Mitsubishi Electric Co. Ltd.)

linearly with time, while the amplitude is almost constant. When this downchirp signal is applied to the delay line, the signal is compressed and an impulselike signal is obtained as the output.

This function is categorized by the matched filter whose impulse response is the time reversal of the specified input signal. Detailed discussion on this function is given in the article entitled SURFACE ACOUSTIC WAVE DELAY LINES.

In Fig. 5, the IDT electrodes are displaced laterally by an angle θ to reduce SAW internal reflection, and the metal edges are cut obliquely by an angle ϕ , by which the deflection caused at the boundaries between IDT electrode and uniformly-metallised regions is well compensated.

Figure 6 shows the frequency response of a typical SAW dispersive delay line on a YZ-LiNbO₃ substrate with $\theta = 5^\circ$

and $\phi = 22.9^\circ$ [6]. It is seen that the amplitude response is flat throughout the passband of 15 MHz width. The group delay changes linearly with frequency and its variation within the passband is $5 \mu\text{s}$.

2. SELECTION OF SUBSTRATE MATERIALS

Selection of substrate materials determines upper bounds of achievable SAW device performance. Since piezoelectric materials are inherently anisotropic, their properties depend on both crystal-cut angles and SAW propagation directions. In addition, anisotropic materials occasionally support unusual SAWs exhibiting interesting features. Since new substrate materials, waves, structures, and/or crystal cuts may expand the range of SAW device application, investigation of these agents has been one of the most important research topics for more than three decades.

Several important properties are listed here, and their impacts on SAW device performances are described:

1. *SAW Velocity.* The SAW velocity determines the center frequency of devices. Hence, for a given available photolithographic resolution, materials with high SAW velocities can be used to produce appropriately high-frequency devices. On the other hand, materials with low SAW velocities are needed to reduce the size of devices.

2. *Electromechanical Coupling Factor.* The maximum fractional bandwidth of devices is practically limited by the electromechanical coupling factor K^2 . If wideband SAW filters are designed using a substrate material with small K^2 , the electrical mismatching loss is unavoidable and the device insertion loss increases. Conversely, if one attempts to cancel the mismatching loss by peripheral circuits, this results in the reduction of passband width of devices because of large circuit Q .

3. *Temperature Stability.* The SAW characteristics are required to be invariant against temperature variation. The temperature dependence of the resonance frequency f_r is called the *temperature coefficient of frequency* (TCF), which can be estimated by

$$\text{TCF} = \text{TCV} - \alpha \quad (2)$$

where α is the thermal expansion coefficient in the SAW propagation direction and TCV is the temperature coefficient of the SAW velocity. The temperature coefficient of delay (TCD) is also often used and is defined by $-\text{TCF}$. It may be true that materials with large K^2 usually possess poor TCF; large K^2 implies that mechanical properties are very sensitive to perturbations.

4. *Propagation Loss.* Materials with small propagation loss are desirable because propagation loss is directly reflected in increased insertion loss of devices. An intrinsic loss of the order of $10^{-4} \text{ dB}/\lambda$ always exists as a result of thermal lattice vibration, surface roughness, SAW leakage into air, and other factors. Roughly speaking, materials with higher SAW velocities usually possess propagation loss smaller than that of materials having

Table 1. SAW Substrate Materials in Practical Use

Material	K^2	TCF	Notes
YZ-LiNbO ₃ [7]	○	×	Small diffraction
ST-cut Quartz [8]	×	⊙	
128° YX-LiNbO ₃ [9]	○	×	Weak spurious
X-112° Y-LiTaO ₃ [10]	◦	◦	Weak spurious
45° XZ-Li ₂ B ₄ O ₇ [11]	◦	○	
64(41)° YX-LiNbO ₃ [12]	⊙	×	Leaky
42(36)° YX-LiTaO ₃ [13,14]	○	◦	Leaky but low loss
ZnO/Glass [15]	◦	◦	Low cost
ZnO/Quartz [16]	◦	⊙	Weak spurious
ZnO/Sapphire [17]	○	◦	High velocity
SiO ₂ /ZnO/Diamond [18]	◦	⊙	Very high velocity

smaller SAW velocities. Leaky SAWs possess additional propagation loss due to coupling with bulk waves. Should materials, crystal cuts, and/or SAW propagation direction with very small coupling be found, however, the propagation loss becomes negligible.

5. *Spurious Responses.* Unwanted modes launched from IDTs, such as bulk waves propagating along the surface, deteriorate the frequency response of devices. One of the most practical countermeasures is to choose substrates from materials exciting very small spurious (unwanted) modes.

For resonators that will be described in Section 4, the effect of bulk waves is not significant because they do not strongly resonate.

Table 1 shows SAW substrate materials currently used for mass production of SAW devices.

3. ADVANCED SAW TRANSVERSAL FILTERS

3.1. IIDT Filters

It was pointed out in Section 1 that one of the most significant drawbacks of SAW transversal filters is their relatively large insertion loss originating in the bidirectionality of IDTs. A simple countermeasure is to increase the number of IDTs [19,20].

Figure 7 shows an example employing three IDTs [19], two of which have the identical patterns on both sides, and the middle IDT is symmetric with respect to the geometric center. If the middle IDT is impedance-matched with the load, it can receive all the SAW power launched from the

Figure 7. SAW transversal filter using three IDTs.

Figure 8. IIDT-type SAW filter.

two outer IDTs and propagated toward the middle IDT. Therefore, SAW reflection does not occur and the multiple echoes are suppressed. Since all the IDTs can be impedance-matched, low-loss filters are realized with suppressed multiple-echo responses. However, it should be noted that the SAW power launched from the two outer IDTs and propagated toward the outside are useless, which still results in the bidirectional loss of 3 dB.

If the number of IDTs is increased as shown in Fig. 8, the bidirectional loss can be decreased further. This structure is called an *interdigitated interdigital transducer* (IIDT) [20]. With an increase in the number of IDTs, the mutual interaction among the IDTs becomes strong and the device behaves like a resonator filter rather than a transversal filter.

Figure 9 shows the frequency response of an IIDT filter employing leaky SAWs on 36°YX-LiTaO₃ (Fujitsu FAR-F5CB-836M50-G201) [21]. When impedance-matched, the device performance achieved an insertion loss of 2.8 dB, a -3 dB bandwidth at 37 MHz, and an out-of-band rejection of 30 dB.

3.2. Filters Employing Unidirectional IDTs

Another simple solution to avoid the bidirectionality problem is to use unidirectional transducers (UDTs). Various UDTs have been proposed and are categorized into two groups.

The first type employs multiphase electrical input and/or output [22]. Although obtainable performance is ideal, interconnection among electrodes is troublesome in device

Figure 9. Frequency response of IIDT filter on 36°YX-LiTaO₃. (Courtesy of Fujitsu Media Devices, Ltd.)

fabrication. Although all the electrodes themselves are fabricated by a single-step photolithography, their series connection or an airgap structure is needed for the interconnection with the third electrodes. The former results in an increased ohmic loss, while the latter needs complicated fabrication processes.

Another type of UDT employs asymmetric electrode geometries that create the directionality even when the single-phase input and/or output are applied. This type of UDT is called the *single-phase unidirectional transducer* (SPUDT) [23]. Figure 10 shows the distributed acoustic reflection transducer (DART) [24]. For SAW propagation, the structure is symmetric with respect to the center of the wide electrode. This position is referred to as the *reflection center* C_r . On the other hand, when SAW reflection is ignored, SAWs are regarded as being excited from the center of the electrode connected to the upper busbar. This equivalent excitation point is called the excitation center C_e . It is seen, therefore, that the excitation center is displaced by $3p_1/8$ from the reflection center to the right.

Let the distance between C_e and C_r be Δ . SAWs excited at C_e toward $-x$ are reflected at C_r and return to C_e . Throughout the propagation, SAWs experience a phase shift of $\angle\Gamma - 2\beta_s\Delta$ (Γ is the reflectivity) and interfere with those excited directly toward $+x$. Similarly, SAWs excited toward $+x$ are reflected at C_r and return to C_e . For this case, the phase shift is $\angle\Gamma - 2\beta_s(p_1 - \Delta)$.

Since the structure is symmetric with respect to C_r , the phase of Γ is $\pm\pi/2$. So, if $\Delta = \pm 3\lambda/8$ and $\angle\Gamma = -\pi/2$, two SAWs propagating toward $\pm x$ are in phase and added up, whereas SAWs propagating toward $\mp x$ are antiphase and cancel out each other. When $\Delta = \pm\lambda/8$ or $\angle\Gamma = +\pi/2$, the situation is opposite.

Due to the periodicity of the structure, effects of the addition and cancellation are magnified when $\lambda \cong p_1$; the directivity is the function of frequency, and perfect unidirectionality is obtained when $\Delta = \pm\lambda(2n + 1)/8$.

The DART structure shown in Fig. 10 is almost optimal in this sense near the SAW resonance frequency. When this condition is not fulfilled, its performance is limited.

The unidirectionality is also realized by placing a reflector at either side of a bidirectional IDT. Although the structure is very simple, the bandwidth becomes much narrower than that of the IDT itself.

Figure 10. DART structure.

Figure 11. Frequency response of transversal SAW filter employing SPUDTs of DART structure. (Courtesy of Fujitsu Media Devices, Ltd.)

Figure 11 shows the frequency response of a transversal filter employing two SPUDTs of DART structure (Fujitsu SBF1301AC6) on a ST-cut quartz substrate for CDMA IF applications. At the center frequency of 128 MHz, a minimum insertion loss of 13 dB is achieved. By using SPUDTs with a long acoustic length, very flat and steep passband shape is achieved with superior out-of-band rejection of about 40 dB. However, the size of the device considerably increases ($19 \times 6.5 \text{ mm}^2$).

3.3. Resonant SPUDT Filters

For the SPUDT filters discussed above, mechanical reflection is used to cancel electrical regeneration [25]. This means that the frequency response is almost governed by the excitation profile of the SPUDT, and that the length of the impulse response is approximately determined by the physical size of the SPUDT.

Ventura et al. reported that if the directivity is partially reversed within an SPUDT, this causes a local resonance due to the internal multiple reflection, which results in expansion of the impulse response length [26]. This suggests that when both excitation and reflection profiles are properly designed, miniaturized low-loss filters can be realized with little deterioration of phase linearity. This configuration is called the *resonant SPUDT* (R-SPUDT). Although its design is not straightforward and computer aided optimization is essential, current computers are powerful enough for the purpose [28].

Figure 12 shows the frequency response of a 157-MHz R-SPUDT filter (Fujitsu SRF157WAC10) for U.S. TDMA IF applications [27]. Sharp passband shape and small insertion loss of 4.5 dB are simultaneously realized in spite of the limited package size of $5 \times 7 \text{ mm}^2$. As a substrate, $45^\circ\text{XZ-Li}_2\text{B}_4\text{O}_7$ was employed. Bulk-wave spurious responses inherent to this substrate are suppressed skillfully by the device design [27], and an out-of-band rejection of more than 50 dB is achieved at 185–500 MHz.

Figure 12. Frequency response of R-SPUDT filter. (Courtesy of Fujitsu Media Devices, Ltd.)

3.4. Z-Path Filters

Figure 13 shows a filter consisting of two oblique reflectors and two SPUDTs, which is called the *Z-path filter* [29]. It is clear that the folded structure offers substantial reduction in the size of devices without reducing IDT acoustic length. The idea of the R-SPUDT is also applicable to this configuration, and its modification has resulted in further reduction in the size of devices [30].

Figure 14 shows the frequency response of Z-path filter for the CDMA handsets in 1900-MHz band. Quartz was employed as a substrate. It is seen that very sharp passband shape is obtained in spite of the limited package size ($5 \times 5 \text{ mm}^2$), and the shape factor and out-of-band rejection obtained are 1.4 (5–30 dB) and 39 dB (typical), respectively. Because of the suppressed multiple echoes, the amplitude ripple of 0.6 dB (typical) is realized within $f_0 \pm 0.3 \text{ MHz}$. Associated with this, the phase ripple is low and its value is 2.3° RMS (typical) within $f_0 \pm 0.63 \text{ MHz}$.

3.5. Dual-Track Filters

A properly designed SPUDT acts as a perfect reflector when the electrical port is short-circuited.

Let us consider parallel-connected transversal filters, called the *dual-track filter* [31], where a reflector is sandwiched between two SPUDTs (see Fig. 15) and the upper

Figure 13. Configuration of Z-path filter.

Figure 14. Frequency response of Z-path filter for CDMA. Solid line—experiment; and broken line—simulation. The minimum insertion loss is 8.2 dB. (Courtesy of EPCOS AG.)

track has $2 \times \lambda/4$ shorter propagation path than that in the lower track.

Now consider SAWs that are excited by the SPUDT and directly propagated toward the detecting SPUDTs without being reflected by the reflectors. Due to the $2 \times \lambda/4$ difference in the propagation pathlength, the outputs of the detecting SPUDTs cancel each other; the net output is unavailable and all the received SAW power is regenerated or reflected. On the other hand, SAWs arriving at the detecting SPUDTs and being reflected m times (where m is the odd number) by the reflector are in phase, and the net SAW power appears as the output. Since the frequency response is governed by the product of the excitation and the reflection characteristics of the input and output SPUDTs and of the reflector, this configuration offers a steeper response in transition bands with reasonable physical device size.

In addition, the device performances can be improved by designing each track with a different configuration. Furthermore, the idea of the R-SPUDT is also applicable to this configuration. This approach is useful in designing filters with wide fractional bandwidth, where simple R-SPUDT filters are not practical [28].

Figure 16 shows the frequency response of a dual-track R-SPUDT filter for CDMA IF at 183.6 MHz, which was installed in a $9.1 \times 4.8 \text{ mm}^2$ SMT package. The achieved performances are an insertion loss of 8.9 dB, amplitude ripples of less than 0.5 dB_{pp} (decibel peak to peak),

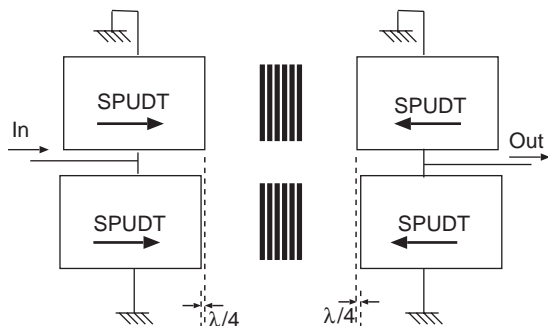

Figure 15. Configuration of dual-track filter.

Figure 16. Frequency response of 183.6 MHz dual-track R-SPUDT filter. (Courtesy of Temex.)

phase ripple of 1.5° RMS, and out-of-band rejection of $> 35 \text{ dB}$.

3.6. Filters Using Tapered IDTs

For wideband IF filters with small shape factors, the fan-shaped (or tapered) IDTs shown in Fig. 17 are effective. In Fig. 17, the structure is subdivided into a number of tracks, where each track has the different center frequency and all the tracks are connected electrically in parallel.

Figure 17. Transversal SAW filter employing fan-shaped (or tapered) IDTs.

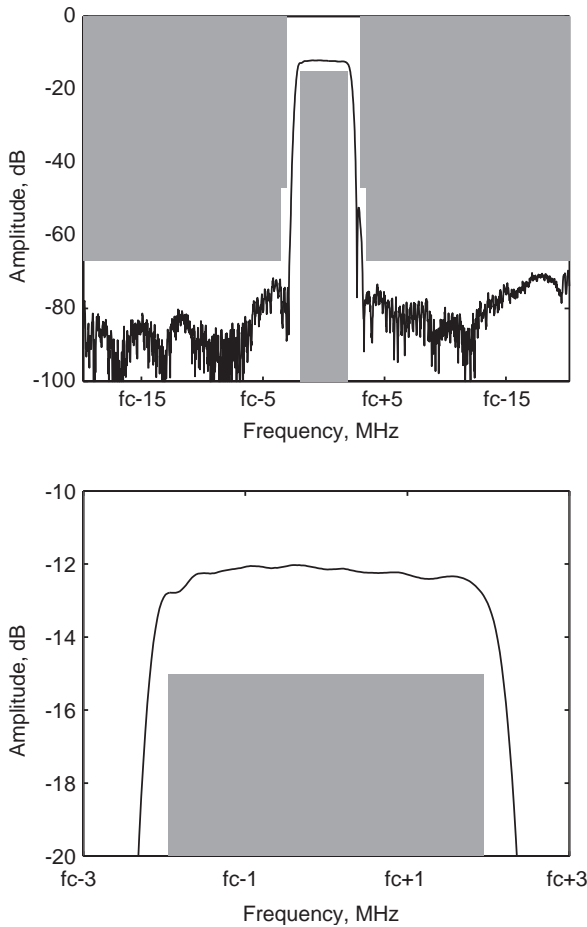

Figure 18. Frequency response of tapered SPUDT filter for 3G base station. (Courtesy of SAWTEK Inc.)

Since each track is equivalent to a very thin but a laterally long nonweighted transversal filter, its individual passband width is very narrow. Hence, as a sum of all the individual responses, the entire structure exhibits a very flat and wide passband with steep shoulder characteristics.

Giving the unidirectionality is also useful for the tapered IDTs to reduce insertion loss avoiding the multiple echo problem. Figure 18 shows the frequency response of an IF filter employing the tapered SPUDTs [32] for a third-generation (3G) base station, where a zero TCF cut of langasite [33] was used as a substrate. The filter exhibits a very flat passband and excellent shape factor around the center frequency about 400 MHz.

Figure 19. Basic configuration of SAW resonator: (a) one- and (b) two-port SAW resonators.

4. SAW RESONATOR FILTERS

4.1. SAW Resonators

In 1970, Ash suggested that SAW resonators could be realized by the configuration shown in Fig. 19, where IDT(s) are sandwiched by grating reflectors [34]. Although multiple resonant modes may exist as a result of a relatively long acoustic path, the number of possible resonant modes is limited by the frequency selectivity of the grating reflectors.

Similar to the invention of IDTs in 1965, the idea of SAW resonators again opened new applications to sophisticated signal processing devices at high frequencies.

Since the basic properties of SAW resonators are very similar to those of quartz bulk-wave resonators, their equivalent circuit shown in Fig. 20 is often used for one-port SAW resonators.

This circuit shows that the one-port SAW resonator exhibits the series resonance at frequency ω_r , where the conductance takes the maximum value. Just above this, the parallel resonance occurs at the (antiresonance) frequency ω_a , where the resistance takes the maximum value. From the equivalent circuit, these frequencies are given by

$$\omega_r = \frac{1}{\sqrt{L_m C_m}} \tag{3}$$

and

$$\omega_a = \frac{1}{\sqrt{L_m (C_m^{-1} + C_0^{-1})^{-1}}} \tag{4}$$

respectively. The capacitance ratio γ is frequently used as a measure of the resonator performance and given by

$$\gamma = \frac{C_0}{C_m} = \frac{1}{(\omega_a/\omega_r)^2 - 1} \tag{5}$$

which corresponds to the inverse of the effective electro-mechanical coupling factor.

The quality factor Q at $\omega = \omega_r$ is called the resonance Q and is denoted by Q_r . This is also an important measure, which is given by

$$Q_r = \frac{\omega_r L_m}{R_m} = \frac{1}{\omega_r C_m R_m} \tag{6}$$

Roughly speaking, the obtainable passband width and insertion loss of filters based on SAW resonators are limited by $1/\gamma$ and Q/γ , respectively.

Figure 20. Equivalent circuit for one-port SAW resonator.

Figure 21. Equivalent circuit for two-port SAW resonator.

Figure 21 shows the equivalent circuit for two-port SAW resonators, where the resonance circuit is involved as a shunt element between two IDTs. This is because the structure is equivalent to a one-port SAW resonator and a simple capacitor if two IDTs are driven in phase and antiphase. This circuit shows that the two-port SAW resonator possesses a strong peak in the transmission response at $\omega \cong \omega_r$.

Figure 22 shows the frequency response of a two-port SAW resonator for the retiming filter in the OC-96 system [35]. A very sharp resonance peak is observed at 4.978 GHz. Thanks to very high SAW velocity ($\cong 10,000$ m/s) on an SiO₂/ZnO/diamond structure, the line resolution of 0.5 μ m is sufficient for the IDT patterning. The following parameters are obtained: an insertion loss of 13 dB, $Q_r = 650$, and a temperature deviation of 150 ppm from -40 to $+85^\circ\text{C}$.

By the way, it has been known that SAWs only with shear horizontal (SH) wave motion raise the total reflection at straight edges. This may be successfully employed to realize ultraminiaturized SAW resonators without grating reflectors [36] (see Fig. 23). However, this idea has not been applied to mass production for various reasons, including (1) difficulties in fabricating precise and fine straight edges, and (2) spurious resonances due to lack of frequency selectivity of the straight-edge reflectors.

Figure 22. A 5-GHz retiming SAW filter on SiO₂/ZnO/diamond structure. (Courtesy of Sumitomo Electric industries, Inc.)

Figure 23. Device configuration of edge-reflection-type SAW resonator.

Kadota et al. showed that the precise and fine straight edges can be realized by using sophisticated dicing saw machines, and very compact SAW resonators were developed and mass-produced based on SH-type SAWs on a laterally polarized piezoelectric ceramic (PZT) substrate [37]. They also showed that various problems such as spurious resonance can be solved by proper device design, and that acoustically coupled resonators, discussed in Section 4.2, are realizable [38].

Figure 24 shows the frequency response of a first IF filter based on this technology for wideband CDMA (Rx) [38]. The filter consists of cascaded-connected two resonator filters, each of which employs a 36°YX-LiTaO₃ substrate and the longitudinally coupled configuration. The filter was specifically designed to attenuate the signal transmission at 190 ± 5 MHz. The filter parameters are as follows: an insertion loss of 4.7 dB, 3 dB bandwidth at 4.1 MHz, attenuation of > 50 dB at 185 MHz and 195 MHz, and group delay deviation of ≤ 50 ns. The chip size and package dimensions are only 0.9×1.7 mm² and $3 \times 3 \times 1.03$ mm³, respectively.

4.2. Double-Mode Filter

Figure 25 shows a configuration called the transversely coupled SAW resonator filter [39], where two identical

Figure 24. Frequency response of edge-reflection-type SAW resonator for W-CDMA IF. (Courtesy of Murata MFG Ltd.)

Figure 25. Configuration of transversely coupled SAW resonator filter.

one-port SAW resonators are placed in close proximity. Their lateral coupling raises two resonance modes. The field motions in the upper and lower resonators are in phase for the first mode but antiphase for the second one. Here, due to the lateral coupling, the resonance frequencies for these two modes are slightly different from each other.

Tanaka et al. [39] suggested that flat passband shape, high out-of-band rejection, and sharp skirt characteristics could simultaneously be achieved by the double-mode resonator filter, should the location of two resonance peaks be adjusted to partially overlap each other in the frequency domain. However, the bandwidth is intrinsically limited because of weak lateral coupling of the two modes. From its operation, it is called the *transversely coupled dual-mode SAW (DMS) filter*.

Figure 26 shows the frequency response of the transversely coupled DMS filter (TOYOCOM TQS-663AA-7R) for AMPS IF, where ST-cut quartz was employed as a substrate. Low spurious and superior out-of-band rejections are achieved. The insertion loss and -3 dB bandwidth were 4.5 dB and 60 kHz, respectively.

Incidentally the two-port SAW resonator shown in Fig. 19b can also support multiple resonances when the bandwidth of the reflectors is sufficiently wide. This is called the *longitudinally coupled DMS filter* [40]. Similar to the transversally coupled filter, this offers flat passband shape, sharp skirt characteristics, and good out-of-band

Figure 26. Frequency response of transversely coupled DMS filter for AMPS IF. (Courtesy of TOYOCOM, Co. Ltd.)

Figure 27. Frequency response of longitudinally coupled DMS filter for CDMA-Rx. (Courtesy of TOYOCOM, Co. Ltd.)

rejection. In addition, the passband width of this filter can be made relatively larger than that of the transversally coupled filter. This is because the difference in the resonance frequencies is determined simply by the device design.

Figure 27 shows the frequency response of the longitudinally coupled DMS filter composed of three IDTs [40] for CDMA-Rx (TOYOCOM TQS-516EA-7G). An insertion loss of 1.5 dB and a -3 dB bandwidth at 35 MHz are obtained with good out-of-band rejection.

At the upper shoulder of the passband, a relatively strong spurious response is seen. This is called the *transversal response*, which is caused by the direct SAW transmission between two IDTs.

In the DMS filters, the input and output ports are coupled acoustically but isolated electrically. This enables the implementation of various functions of the DMS filters such as balanced-to-unbalanced conversion and impedance conversion. In the current mobile phones, this sort of multifunctional DMS filters are widely used [41].

4.3. Ladder-Type Filter

The ladder-type configuration is historically well known for filter device applications at low frequencies. However, recent technologies have made it possible to apply SAW resonators to ladder-type filters working above GHz ranges. Figure 28 shows an example for the ladder-type SAW filter [42]. This type of filter offers low insertion loss and

Figure 28. Ladder-type filter consisting of five SAW resonators.

Figure 29. Frequency response of ladder-type SAW filters.

high power durability compared with the acoustically coupled SAW resonator filters described above [43].

The basic idea is to design the resonance frequency ω_r^s of Y_s at the series arms to coincide with the antiresonance frequency ω_a^p of Y_p at the parallel arms. Since $Y_s^{-1} \cong 0$ and $Y_p \cong 0$ near these resonance and antiresonance frequencies, the input signal passes through the filter with small attenuation. On the other hand, at the antiresonance frequency ω_a^s of Y_s and resonance frequency of ω_r^p of Y_p , respectively, the series arms become electrically open-circuited and the parallel arms become short-circuited. This results in no transmitted signals at the output. Consequently, the frequency response shown in Fig. 29 is obtained. According to the traditional electric circuit theory, the out-of-band rejection can be improved with an increase in the number of the resonators shown in Fig. 28 at the expense of the increased insertion loss.

Figure 30 shows, for example, the latest ladder-type SAW filters (Fujitsu FAR-F6CP-2G1400-L21M) for a W-CDMA Rx channel, where $42^\circ\text{YX-LiTaO}_3$ [14] was employed as a substrate. It is seen that in addition to good signal rejection of 36 dB (typical) in the Tx band (1920–1980 MHz), a very low insertion loss of 2.4 dB (typical) (the minimum loss of 1.4 dB) is achieved over the Rx band (2110–2170 MHz).

4.4. Antenna Duplexer

Since mobile phones use the same antenna for both the transmission and reception, a circuit element to separate

Figure 30. Frequency response of ladder-type filter for W-CDMA Rx channel. (Courtesy of Fujitsu Media Devices, Ltd.)

Figure 31. Configuration of SAW duplexer.

Figure 32. Frequency response of PCS duplexer. (Courtesy of Fujitsu Media Devices, Ltd.)

incoming and outgoing signals is necessary. In some systems, the separation is carried out in the frequency domain (frequency-domain duplex) and the SAW antenna duplexer is applied for this purpose [43]. Its basic configuration is shown in Fig. 31.

The Tx and Rx SAW filters are connected in parallel via two $\lambda/4$ striplines (see Fig. 31), in order to reduce electrical interference caused by the parallel connection. Usually the striplines are embedded in the ceramic package for the SAW duplexer.

Figure 32 shows the frequency response of the latest SAW duplexer for a personal communication system (PCS) mounted in a $5 \times 5 \text{ mm}^2$ surface mount package [44]. It employs the ladder-type and longitudinally coupled DMS filters for Tx and Rx channels, respectively, and the stripline for the Tx filter was removed to minimize insertion loss.

Adding to very low loss ($< 1 \text{ dB}$), very narrow transition bandwidths are realized in both the Rx and Tx filters. High isolation of 55 dB (at Tx band) and 48 dB (at Rx band) is obtained.

SURFACE MOUNT TECHNOLOGY

WALTER J. TRYBULA
Austin, Texas,
MICHAEL TRYBULA
Cyber Optics Corp.
Minneapolis, Minnesota

Surface mount assembly (SMA) is the description of a technology that incorporates the electrical and mechanical of components to printed wiring boards (PWBs) or a similar type of circuit substrate. The term *surface mount* comes from the methodology of attaching the components. Surface mount places the components on the surface of the supporting media, the PWBs, or other type of substrate. There are two types of connections between the discrete packages and the supporting board material: those with leads, which require plated through-hole (PTH), and others with leads of pads for surface mounting the devices. The surface mount packages with connections that are significantly below those available for through-hole components. This yields a more compact design that reduces the area required and provides a more dense circuit.

Many categories of packages can be employed in surface mount assembly. They can be identified into two categories: leadless devices and leaded chip carriers. The leadless devices include leadless chip carriers, surface mount arrays, capacitors, resistors, and inductors. Leaded devices include packages for active devices, of either plastic or ceramic, and having a particular lead configura-

tion. The resistors, capacitors, inductors, and various types of semiconductor circuits can come in two configurations, leaded and chip. The leaded components are traditionally employed in through-hole mounting and seldom employed in SMA. The chip components are available in protected and unprotected states. The chip is a minimum configuration for the particular device. In the case of capacitors, it may be the actual device that is provided in the leaded package. The bare device has connection points that may be solder plated.

Semiconductors are typically manufactured in a multileaded ceramic or plastic packages, which can be with leads extending from the package or leadless (connections are on the package). (This provides the capability of testing the devices to ensure conformance to specifications.) The specifications for the devices conform to a Joint Electronic Development Engineering Council (JEDEC) standard so that the design of the PWB for attachment can be standardized. Bare chip circuits are also employed in special circumstances. One arrangement, chip-on-board (CoB), requires the application of wire attachment from the chip (semiconductor device) to the PWB. The other configuration is flip-chip. Flip-chip employs the bare semiconductor die (chip) with special solder placement on the surface to provide connection pads (bumps) for the semiconductor device. The chip is mounted circuitry toward the PWB. The processing of the assembly causes the bumps to reflow and attach the chip to the PWB.

Printed wiring boards (PWBs), also known as *printed circuit boards* (PCBs), are the most common interconnect mechanism to complete circuitry. The pattern of electrical circuitry, also known as *paths* or *traces*, is manufactured to provide the appropriate connections between various devices. Surface mount is a card assembly method that relies on a solder connection for both physical and electrical connections as well as package-to-board connections. The plated through holes (PTH) joining method employs a close mechanical fit between the components and the board via hole for location of the component, and the solder provides the final bond as well as the electrical connections. PWBs are manufactured from nonconductive, stable materials. These materials can be employed for the manufacture of single-sided, two-sided, or multilayer PWBs. The single-sided PWB has circuitry on only one side. The components are inserted through the boards and solder to the bottom side, which contains the circuitry. Two-sided boards have circuitry on both sides, and either side or both sides can be employed for soldering components in place. Multilayer boards are constructed of many levels of circuitry that are laminated to form many layers of interconnections. Most PWBs are designed on a grid pattern, which specifies the minimum dimension between different circuit elements. The standard package of the mid-1980s contained a lead pitch, with center-to-center distance between the individual leads of 0.1 in. or 100 mils. Applying the design of complex circuitry with traces of 20 mils provided adequate space to connect the circuit elements. As the circuitry became more complex, the need for more connections witnessed the manufacture of multilayer circuits that could provide more interconnects at the expense of additional processing layers. Also, work is

being done on packages with spacing of less than 20 mils to provide more dense packing. The smaller dimensions provide challenges for both the designer and the manufacturer. As the density of the interconnects increases, the manufacturing tolerances decrease. Decreasing tolerances has a direct impact on yields. The better the design, the greater the manufacturing tolerances. The miniaturization of circuitry causes a greater need for a complete “design for manufacturing” concept. (See the text by Boothroy et al. in the Further Reading list at the end of this article for more details.) The advantage of miniaturization is a decrease in the package size, a decrease in product volume, a decrease in cost, and an increase in the reliability due to better manufacturing control.

1. HISTORY

Surface mount assembly has evolved in response to the manufacturing need for increased miniaturization, for more complex products. Surface mount technology began with the development of thick-film hybrid techniques. The first attempts to manufacture thick-film hybrids were during World War II. Variable resistors were produced by printing a resistive paste on a carrier and firing the circuit. The design of the circuit was such that a movable contact provided the ability to change position on the printed resistor and consequently change the resistance in the circuit. The application of hybrid circuits came into widespread application in the 1960s. The need for military applications, which required more stringent operating environments than the conventional PWBs, required a radical solution. The development of ceramic substrates and conductive pastes provided the ability to develop a stable circuit. Populating the circuit with devices required providing holes in the ceramic substrate, which made the substrate more expensive and weakened it, or developing a means of mounting components directly onto the substrate. The development of the integrated circuit provided another impetus to mount devices to the substrate.

Hybrid circuits have two configurations: thick and thin film. Thick-film circuits are produced by printing conductive and resistive pastes and subsequently firing the pastes to stabilize the material and provide the operational characteristics. Thin-film circuits were similar to thick-film circuits except that the conductors and resistors were vacuum-deposited. This process provides for finer geometries, but cannot handle large amounts of power. Both types of circuits needed additional components to complete their functionality. There was a need to provide a means of mounting and connecting the additional components. Devices can be connected to this circuitry by soldering, eutectic and lower temperature materials, or by epoxy, both conductive and nonconductive. The start of these technologies led to the development of other surface mount techniques.

The early application of high-performance circuitry required a good thermal and electrical contact with the semiconductor. Through a combination of heating and mechanical motion, a eutectic bond can be produced. This was normally a gold-silicon interface that required pro-

cessing temperatures in excess of 400°C. As less stringent circuits were developed, the application of tin-lead solders was employed to attach prepackaged circuits. These were lower-cost devices. As miniaturization of devices accelerated, the drive to produce low-cost devices provided a rationale for experimenting with new approaches to circuit assembly. Prepackaged plastic devices could be attached to the substrate inexpensively, resulting in less expensive products. The driving force behind the initial development of surface mount assembly was high-volume, low-cost consumer products. In the late 1970s, the Japanese were investigating high-volume manufacturing of consumer electronics. The cost of the ceramic substrate was too high for the consumer market. Conventional PWBs were made and components attached to the surface. Since the surface mount component is smaller than the corresponding leaded one, the corresponding package, a SMT assembly, is smaller than a discrete assembly. (This is very understandable since the leaded component can contain the entire surface mount one.) While the initial surface mount assemblies were very elementary circuits, the potential cost savings provided the push needed to look at automating the process. During the early 1980s, assembly equipment manufacturers in the United States emphasized the development of equipment for placing through-hole components, while the Japanese were developing high-speed chip placement equipment. The requirements for high-speed placement equipment necessitated tighter tolerances and fewer selections of dimensions for devices. Those volumes, which were required for the consumer market, caught the attention of the component suppliers. The result was that in the early 1980s, the manufacturers of chip capacitors went from almost 20 different sizes to only 3. This change precipitated lower prices and an increased ease of manufacture. With the availability of inexpensive production, the application of surface mount technology increased. The mid-1980s witnessed the expansion of surface mount technology into higher-quality products. As the reliability of the devices improved, this acceptance increased even more.

The late 1980s witnessed a broad acceptance of surface mount technology in a large number of consumer applications. The development of the multichip module (MCM) during this time provided a highly reliable package that could apply the automated surface mount placement equipment. Successful high-reliability applications, like the fully automated digital electronics module (FADEC) that General Electric developed for the jet engine controls, proved that surface mount assembly in modules provided a packaging technology that could withstand almost any environment. As microprocessors kept shrinking and the functionality kept increasing, the personal computer (PC) market applied surface mount technology to increase reliability and reduce costs.

2. TERMINOLOGY

The terminology employed with surface mount assembly is derived from the two affiliated technologies: PWB assembly and device manufacturing.

2.1. Package Types

The development of packaging standards provided the basis of uniformity and the ability to develop high-speed manufacturing equipment. The Joint Electronic Development Engineering Council (JEDEC) develops the packaging standards. Various packaging types are shown in Fig. 1.

2.2. Three-Letter Acronyms (TLAs)

As with any technology, there develops a code language that simplifies communication within the industry. These acronyms are usually contain two to four letters but are classified as three-letter acronyms. Some of the more typical ones are given below:

- AOI—automated optical inspection: the process of using a machine to look for defects on the circuit board.
- CC—chip carrier: refers to the packaging of an electronic device, usually a semiconductor, into a package that protects the device and provides for electrical contact and mechanical mounting to a more complex circuit. The package can have leads extending from the device or be leadless.
- CoB—chip on board: refers to a packaging technique where bare semiconductor die are epoxied to PWBs and wire-bonded to the conductive paths on the PWB. (Wire bonding is the traditional method for attaching semiconductors to their packages.) The resulting interconnection is then protected by a hard epoxy that provides a thermal expansion match for the PWB and the wirebonds.
- CLCC—ceramic leadless chip carrier: refers to the package type shown in Fig. 1 that contains the device in a ceramic package.
- LCC—leadless chip carrier: a packaging technique that incorporates a device into a carrier that does not have external leads extending from the package. The

leads are actually on the package's periphery and are an integral part of the package.

- MCM—multichip module: a more complex arrangement than the chip carrier in that any number of devices can be interconnected with the package. This is a larger package that provides complex functionality. The advantage of the higher-level package is that more complex functionality can be verified.
- MELF—metallized electrode face: a packaging technique for cylindrical parts without leads. Both ends of the cylinder will have metallized terminations.
- PCB—printed circuit board: the basic building block of electronic circuitry. The printed circuit board is also known as the *printed wiring board* (PWB).
- PLCC—plastic leaded chip carrier: the plastic equivalent of the CLCC. This part will have leads coming off all four sides that wrap underneath the part in a “J” shape.
- PWB—printed wiring board: the material that provides both the platform for supporting the electronic devices and the means of interconnection for these devices. Typically, the material is resin-based and capable of withstanding high-stress environments. The fabrication of the circuitry results in the type of circuit: single-sided, two-sided, or multilayer. *Single-sided* refers to material with the circuitry on only one side. *Double-* or *two-sided* refers to material with the circuitry on both the top and bottom. *Multilayer* refers to material that has more than one level on one of the sides.
- QFJ—quad flatpack J lead: a quad flatpack with “J” leads extending from the package. The leads provide both electrical conductivity and mechanical mounting.
- QFP—quad flatpack: a package that typically is square with contacts on all four sides. The configuration of this package is either leaded or without leads.
- RA—rosin activated: a term referring to agents that are added to solder that increase the ability of the solder to adhere to the circuitry and the device leads. There are potential problems with the use of this activation, which requires especially thorough cleaning of any residues after the solder process.
- RMA—rosin mildly activated: less active than the RA; less aggressive in chemical reactions with the devices or circuitry.
- SMA—surface mount assembly: refers to a process that employs electronic components that are attached to the surface of the circuitry.
- SMT—surface mount technology: refers to the technology that involves any portion of the surface mount assembly process.
- SOIC—small-outline integrated circuit: generic term for parts with multiple leads on two opposing sides and no leads on the other two sides. Typically there will be the same number of leads on both sides of the part, and the lead spacing will be consistent throughout the part, although the center leads may be missing.

Figure 1. Complex surface mount packages that contain smaller surface mount devices. (Courtesy of Die Tech, Inc.)

- SOJ—small-outline J lead: a special case of the SOIC in which all the leads are bent in a “J” shape.
- SOP—small-outline package: frequently a part of the term referring to various types of SOICs (e.g., Q = quarter, S = shrink, T = thin, and V = very).
- SOT—small-outline transistor: rectangular plastic packages that house transistors or diodes. Typically these will have three or four leads.

3. SURFACE MOUNT PROCESSES

The critical element in surface mount assembly is provision of the proper mechanism for attaching the components to the substrates. The process of attaching the components to the circuitry involves either solder attachment or epoxy mount.

3.1. Solder

The process of attaching components by soldering involves raising the temperature of the solder until it becomes molten, and cooling the circuitry until the solder hardens. The solder consists of metals that have a relatively low melting point—usually below 315°C. This liquid metal composition is structured to adhere to both the components and the conductive material on the substrate. The ability of the material to adhere to the surfaces is a function of its wettability. Properly prepared surfaces show good adhesion. Because of the nature of the alloys involved, inorganic materials and metallic oxides can inhibit the formation of the bonds. In cases like these, there are chemicals, fluxes that can be employed to enhance the bondability of the materials.

3.2. Fluxes

The function of the flux is to provide an untarnished surface that is capable of easily spreading the liquid metal to cover the desired surfaces. Since there are varying degrees of contamination and different solubilities of materials, the characteristics of the fluxes have been tailored for specific circumstances. In general three types of fluxes are employed in electronics manufacturing: activated, nonactivated, and mildly activated rosin fluxes. Water white rosin flux is a chemically inactive and electrically insulating flux. When heated above its melting point, it becomes active and will react with some metals. Activated fluxes have additives introduced that exhibit more aggressive behavior that promote solderability in more difficult conditions. The mildly activated fluxes are more aggressive than nonactivated ones but do not have the residue problem of the activated fluxes. The activated fluxes require thorough cleaning to ensure removal of the flux, which can cause damage to the components if left on the circuit.

3.3. Composition

The main constituents of solders have been tin and lead in various compositions. Other materials have been incorporated into the metallurgy more recently in order to reduce the amount of lead employed in the products. *Eutectic*

solder refers to the composition of the material that has either a solid or a liquid state and no plastic state. For tin-lead, this composition is 63/37%. The melting point is 183°C. Other percentages provide melting points that differ slightly according to the percentages of the metals, but they exhibit a transition state where the solder becomes plastic and moldable before melting. Many different compounds are being used in production according to the constraints of the product or the environmental considerations of employing lead in products.

3.4. Adhesives

Two types of adhesives are employed in surface mount assemblies: epoxies and acrylics. The epoxies are further subdivided into thermosetting, thermoplastic, elastomeric, or alloy. Thermosetting involve a chemical or thermally induced reaction. Single-part epoxies normally require thermal elevation to initiate the chemical reaction. Two-part epoxies provide the catalyst by the combination of the two elements. Elastomer is named after material with elongation properties that can be employed in situations where a degree of stress relief is required. The alloy is a combination of material from the proceeding three categories.

3.5. Cleaning

The application of solder has the potential of leaving an undesirable residue after the solder process. Cleaning is a critical element in the process. The application of water white rosin should leave minimal residue and has been employed without cleaning. The slightly more active flux, mildly activated, should always be cleaned from assemblies. Activated flux must be cleaned because the residue is still active and can cause contamination and corrosion. There is a direct correlation between cleanliness and circuit reliability.

4. SURFACE MOUNT ASSEMBLY

In the development of a product, the capabilities of the manufacturing process as well as the functionality of the circuit determine the configuration of the design and the components that are required for the manufacturing process. The production of a high-volume, high-reliability product, such as a digital cellular phone, has constraints different from those for a portable, digital clock. The purpose of this section is not to develop the methodology of design for manufacturing but to overview the processes required for manufacturing. For small-volume or prototype quantities, manual assembly can be employed to produce working product. The potential problem with small-quantity manual assemblies is that the learning required to produce good-quality manual assembly is not immediately available. Consequently, the application and testing of prototype product should not be expected to approach that of a “debugged” assembly process.

For this article, assume that the product being introduced into production has been through a prototyping process that eliminated any design flaws that would

require revision of the assembly. The revision process will not be considered. Finally, we will assume that the design and manufacturing teams have been working together to develop a manufacturable product that does not require modifications or changes to achieve a shippable product. The selection and application of equipment is dependent on the desired volumes. The descriptions below cover manual, semiautomatic, and automatic assembly tools. The selection of the appropriate equipment is left to the reader.

4.1. Selection of Equipment

Once the type of board that will be built is identified, it is necessary to select the equipment that will be used to build the product. This article considers the more common methods of assembly and identifies the equipment that would be typically involved in each stage. The steps discussed will follow the typical order in which a board is built. There are many reasons for deviating from this model. Some of these are discussed in Section 5.

4.1.1. Solder Paste Application. Frequently when building a board, the topside is built first. The topside assembly normally starts by placing solder paste on the board. The paste serves many functions; it holds the part in place during assembly, provides the material to clean the contacts on the part, and provides the material to form the solder joints.

Solder paste is made up of two key components: flux and solder. The flux has the job of holding the compound together and, when the compound is heated, cleaning the pads on the board, the terminations on the components, and the solder particles. The solder has the job of forming the electrical connections when it is melted and cooled.

Because of these functions, the paste must be put on the board in the correct quantities and aligned on the pads. Too much solder, and there might be short circuits; too little solder, and the mechanical bond may not be sufficiently strong to hold the components. There are two basic ways of putting the paste on the board: dispensing and screening.

4.1.1.1. Dispensing Solder Paste. Solder paste dispensing involves having the paste delivered in a syringe (typically 10 or 30 mL). The paste is then forced out onto the PWB at the desired locations. (The methods of forcing the paste out are the same as dispensing glue). There are many machines available to do the dispensing.

The simplest machine is a very simple pump with a handheld syringe that the operator moves from location to location. The operator usually activates a foot switch that will start the dispensing process. At the other extreme, a gantry-style robot moves the dispensing head to the desired location, and the controller dispenses the paste. The advantage of the robots is that they are faster and more repeatable. The advantages and disadvantages of the various dispensing techniques are discussed in Section 4.1.2.

Dispensing solder paste offers some advantages: flexibility, no custom tooling required, and easy cleanup. The machines that dispense paste are normally programmable to allow for quick changes. These machines seldom require

creation of custom tooling per each assembly. Cleanup normally includes cleaning only the nozzle, which is one small piece. For these reasons paste is frequently dispensed for prototype boards.

Dispensing also has its disadvantages; it is slow, requires low-viscosity paste, and lacks repeatability. Because each location on a board must have the paste forced onto it one location at a time, dispensing a board can take a long time, since most assemblies contain multiple locations. To be dispensed, the paste must be thin enough to be forced through the needle. This means that the paste will not want to stay standing on the pads but will slump, leading to potential shorts. Depending on the dispensing method, the volume and the location of the paste may be difficult to repeat. For these reasons, dispensing paste is seldom not used in production.

4.1.1.2. Screen Printing Solder Paste. Screen printing is a simple process where a template is held over the substrate and a viscous fluid is then forced through. In electronics manufacturing the substrate is the PWB, and the viscous fluid is frequently solder paste. The template is either a stencil or a screen.

A stencil is a metal plate, of the same thickness as the desired paste height, with holes cut out in it where the paste is desired. The metal used may be almost any type, although stainless steel is the most common material used currently. The holes may be formed in any number of methods; chemical etching and laser cutting are among the most common. The holes are made in the same size and shape as the desired pattern of paste on the board.

A screen is a mesh, typically made of steel threads closely spaced, that is covered with a coating. (The gauge of the mesh indicates the number of wires per inch; so the higher numbers provide the ability to make thinner coating; e.g., 325-mesh is finer than 200.) The coating is removed from the areas where the paste is desired (the mesh is still there). Each location where paste is desired is actually formed of many smaller openings forcing the screen to thicken to achieve the same volume of paste. Because of the many smaller opening, the choice of paste to use with the screen must be thought out very carefully and may limit the applications that can be used. A screen, while cheaper than a stencil, is rarely used because it does not last as long, gives less desirable results, and is harder to clean.

The viscous fluid, typically paste, is moved along the top of the stencil or screen from one end to the other by a squeegee, which also pushes the paste downward through the openings in the stencil or screen. Typically three variables concerning the squeegee are controlled: hardness, pressure, and speed. The hardness of the squeegee determines how it will react when it is used. Pressure and speed are inversely related to each other. Increasing pressure will have effects similar to those of decreasing speed. The objective with these two variables is to find the right balance that yields good coverage on the board.

Up until now, we have not mentioned a machine. A machine is not required for this process. Many companies use an operator to do the screening. However, this method has several drawbacks, the largest of which is the lack of

consistency. Typically a machine will be used to improve the process. The machines range from semiautomatic to fully automatic. The semiautomatic printers require the operator to place the boards on the machine, verify and align the board and stencil, tell the machine to print, and then remove the board. The automatic machines will perform all the tasks automatically, including passing the board to the next machine.

For all the reasons mentioned above, screen printing has many advantages: repeatable results, speed, choice of pastes, and ease of use. The disadvantages of screen printing are few, related mostly to the cost of the stencil or screen. For these reasons screen printing is usually the preferred choice for placing solder paste on the board for production runs.

4.1.2. Glue Application. Glue is applied to the board to hold the components in place for the rest of manufacturing and for certain user requirements. The bottomside surface mounted devices (SMD) components are typically glued while the top side of the board is usually not. The choice of the glue must be carefully considered, as the glue must be sufficiently strong for manufacturing, easily broken for rework, not harmful to the components or board, and easily worked with and cleaned. There are several ways to put the glue on the board: dispensing, pin transfer, and screen printing.

4.1.2.1. Dispensing. *Dispensing* refers to taking the glue from a container (typically a syringe) and forcing the desired amount through a needle onto the desired location. There are two basic categories for dispensing: time-based and positive displacement. Each has its advantages.

4.1.2.1.1. Time-Based Dispensing. Time-based dispensing involves applying pressure for a certain amount of time to dispense the glue. Air is usually applied to the back of the syringe to supply the pressure to dispense the material. This system is usually referred to as *airover*. *Airover* is inexpensive, easy to maintain, and easy to clean. Unfortunately, the lower in the syringe the glue is, the more time that is required to achieve the same volume of glue. However, this can be compensated for through various machine controls.

4.1.2.1.2. Positive Displacement. In order to overcome the disadvantages of time-based dispensing, various methods of positive displacement have been created. The two most common are piston and screw.

An extremely common method of positive displacement is using a piston to force an exact amount of adhesive out the end of the dispensing tip. This is accomplished by keeping a steady pressure on the syringe and pulling the piston up high enough to allow the adhesive to enter the dispensing chamber. The piston is then brought down to force an amount of glue (equal to the volume of the chamber that the piston then occupies) out onto the substrate.

The screw method utilizes a screw that, when turned forces an amount of adhesive out the chamber that is proportional to the degree to which the screw is turned. This format is very similar to that for many pumps used for

other applications. This method is easy to vary as the more the screw is turned, the more glue that comes out the end.

Positive-displacement systems provide reliable consistent glue dot sizes. With this advantage come a few disadvantages; it is more expensive and more complex.

4.1.2.2. Pin Transfer. The methods of dispensing adhesive mentioned so far are extremely flexible but can require a long time to apply all the adhesive required on the board. There are several industries that do not need the flexibility mentioned above but need very quick cycle times (<8 s to apply all the adhesive). In order to meet this need, pin transfer was created. Pin transfer allows the whole board to be covered at once and allows reloading while the board is being transferred. A die is made for each different type of board and has pins sticking down from it at each locations where adhesive is desired. The die is "loaded" by dipping the pins in a tub of adhesive. A small amount of adhesive will stick to each pin; the quantity varies depending on the size of the pin. The die is then brought over to the substrate, and when contact is made, the adhesive transfers to the substrate. Pin transfer is fast but also expensive because of the tooling and requires long cleanup times.

4.1.2.3. Stencil Printing. Many manufacturers attempting to make use of their current equipment consider another method of adhesive application: stencil printing. Stencil printing adhesive is very similar to stencil printing paste. The advantages are that no new equipment needs to be purchased, but the board must be flat with nothing sticking out on its sides. This limits the number of options that are available in the order of manufacture.

4.2. Placement Equipment

After the material that is to hold the parts on the substrate during assembly is applied, the next step is to start populating the substrate. This requires that the parts be placed on the substrate in the correct location and the correct orientation. There are many standards designed to define what is acceptable and what is not. The standards are a compromise between perfect placements, production speeds required, and requirements of the finished product. Whatever standard is used, the process used must be capable of building to that standard in an efficient and timely manner. There are three basic ways to place parts on a substrate, each with its unique advantages.

4.2.1. Manual. Placing parts manually involves setting up an operator with a picking tool and all the parts to be placed. A machine is optional for this type of placement. The machines can provide instructions and even some assistance in picking and holding the parts. The operator follows a set of directions to determine where each part goes on the board. This is the least expensive and slowest way to build boards, but it is appropriate for prototype work. While this method can be used for production, it relies completely on the operator skills.

Figure 2. Example of placement mechanism of fine-pitch equipment with flexible placement head. (Figure of Philips Eclipse courtesy of North American Philips.)

4.2.2. Semiautomatic. Many machines fall into the semiautomatic range. The machines assist the operator in many ways. The machines may require the operator to place the parts individually in a location that the machine can reach and then tell the machine to go. The other extreme for this class of machines requires the operator only to place the substrate in the machine, let the machine place all the parts, and then remove the board. The machines require less precision from the operator since the operator does not actually place the parts. This class of machine is frequently used in contract manufacturing and other environments where batch processing of the substrates is preferred.

Figure 3. Example of high-speed chip placement equipment with placement rates in excess of 60,000 devices per hour. (Figure of Philips FCM courtesy of North American Philips.)

Figure 4. Example of medium-speed flexible placement machine with placement rates in excess of 14,000 devices per hour. (Figure of Philips Topaz courtesy of North American Philips.)

4.2.3. Automatic. The automatic machines require the least amount of operator intervention. These machines automatically bring the substrates in, populate them, and then pass them to the next machine (Fig. 2). This type of machine is used in environments where the continuous building of product is required. The machines in this class frequently are specialized in order to gain more speed. The machines are typically divided into two categories: chip shooters and fine pitch placers. The chip shooters are designed to put down the small parts (typically resistors, capacitors, and diodes) very quickly. The chip shooters (Fig. 3) typically use tape and reel parts expedite the feed action. These machines are designed so that the operator only has to replenish the parts as the machine uses them up. The fine-pitch placers (Figs. 4 and 5) usually take many types of inputs as the parts frequently come on trays or in sticks. These machines are very flexible and can do just about any type of part but are much slower than the chip shooters. A typical line would consist of a chip shooter and a fine-pitch placer. The automatic machines are usually the most expensive to buy, but are frequently the most cost-effective solution for placing parts.

Figure 5. Example of flexible placement machine. (Figure of Philips Eclipse courtesy of North American Philips.)

4.3. Reflow/Curing Equipment

Once the parts have been placed on either adhesive or solder paste, it will be necessary to process the boards through an oven. In the case of adhesive the oven cures the adhesive so that the parts will stay put through the rest of the process (see Fig. 6a). For solder paste the oven has to activate the flux and allow the flux to eliminate oxidation, and then to melt the solder and allow it to form the solder joints between the board and the parts (see Fig. 6b). In both cases the oven temperature must be carefully controlled so as not to throw the boards and parts into thermal shock. Most surface mount parts can withstand temperature changes up to 4°C/s, but it is not recommended to exceed 2°C/s of heating or cooling.

The ovens fall into in two basic categories: batch and flowline. Batch ovens can work only on one group at a time. The flowline ovens are designed for the continuous introduction and removal of work. Each has its unique advantage.

Batch ovens typically have a sealed chamber to do their work. Because the chamber is sealed, control of the

(a)

(b)

Figure 6. Time-temperature plots for epoxy curing.

environment is easy to maintain. This makes it easier to achieve the ideal profile for the work desired. Batch ovens expose the whole board to the same temperatures at the same time so that the board will not be subjected to two different extremes in temperature at the same time. These ovens are used primarily for small batches of work and are frequently used in prototype environments where workflow may be erratic.

Flowline ovens are designed for the continuous introduction of boards into the process cavity. This means that the entry and exit points are not completely sealed (various techniques are implemented to achieve some degree of isolation). Flowline ovens will have several zones that control the amount of energy is being put into the board to heat it up as it goes through the various phases. By controlling the speed with which the board passes through these phases and the amount of energy applied in these zones, the desired profile can be achieved. Flowline ovens are typically used in production environments.

Regardless of the choice of batch or flowline oven, there are four main types of energy transfer that occurs inside the oven. Infra-Red (IR), convection, vapor phase, and Ultra-Violet (UV) are the main techniques.

Infrared ovens, which are used to cure adhesive and reflow solder paste, rely on IR transmitters to input energy into the oven cavity. As this IR energy is absorbed, it will heat up the object and, through conduction, whatever the object is touching. The choice of IR was made because the green printed wiring boards (typical color) absorb the infrared light. This technique was very common some years ago, but as the process cavity oven became better sealed, the energy transfer method started to become half convection and half IR. Because of the sensitivity of IR ovens to the color of the substrate (prototypes are typically reddish in color), these ovens lost favor with many people.

Convection ovens, which are used to cure adhesive and reflow solder paste, rely on hot gases to provide the transfer of energy to the substrate. The gases in a convection oven are either nitrogen or air. This transfer of energy is not dependent on the color of the substrate. Many different techniques are used to generate the heat and distribute it throughout the various parts of the oven. This technique for energy transfer is very stable and will work well in a wide variety of situations, making it a popular choice for ovens today.

Vapor-phase ovens, both batch and continuous-belt, are used to reflow solder paste. Vapor-phase ovens rely on a combination of fluids (fluorocarbons) brought to boiling temperature. The combination will have two separate boiling temperatures, and each will be used and kept in place by cooling coils. This results in vapors at two separate temperatures. The substrates will then be passed (lowered in batch ovens) through these gases, and the gases will efficiently heat up anything that they come in contact with. The substrates will then be cooled (removed in batch ovens) slowly to allow the solder to gradually solidify. Vapor-phase ovens are used primarily for high-reliability (military) applications and design-critical applications. This technique is no longer popular mainly because of the expense of the chemicals and the potential of these chemicals to damage the environment.

Ultraviolet (UV) ovens, which are used for curing adhesive, rely on UV light to transfer the energy to the adhesive. Several different adhesives may be used in electronics manufacturing that will cure only if exposed to strong UV light for a period of time. Consequently, there is a better control of the curing process, because it will not start without the UV energy. A second reason for using UV adhesives is that few substrates absorb UV light well, so this does not heat the substrate significantly.

4.4. Wave Solder Equipment

If through-hole parts are used, it is necessary to solder the parts in place and form the electrical connections. The parts may be soldered by hand, or more commonly by processing in a wave solder machine. A typical wave solder machine will consist of a fluxer, preheaters, and a solder wave. The fluxer will apply flux to the bottom of the substrate by spraying or foam. The only requirement is that the whole area be covered to ensure that the flux will contact all the surface area to be soldered. After the substrate is fluxed, it moves to the preheaters. The preheaters will activate the flux, enabling it to remove oxidation from the components and the substrate. The preheaters also elevate the substrate temperature to prevent the solder temperatures from providing a thermal shock when the substrate encounters the solder wave. When the soldering takes place, the substrate is moved across a wave of solder so that only a small line of solder is in contact with the substrate at a time. Depending on the system, a second wave may also be used. The waves are generated by pumping molten solder into a pot and allowing it to spill over, or are generated directly from a pump pushing the solder upward.

4.5. Cleaning Equipment

After assembly it may be necessary to clean the substrate. Cleaning is required if the flux residue is corrosive or if the cosmetic appearance of the substrate is critical. The chemicals used will vary depending on the type of flux used. The substrate will be exposed to various washing stages in order to remove all the corrosive material. Some of the newer fluxes available permit the elimination of this step.

4.6. Inspection Equipment

As the devices get smaller and the pin count increases, it is becoming more important to build the boards properly in the first place. This has led to equipment being used to perform the inspection process, and the inspection may take place in many places in the line: inspection of solder paste, postplacement component inspection, and postsolder inspection. Each has its proper place in the overall inspection process. When setting up a line and deciding on the inspection strategy, the costs associated with failure must be analyzed.

4.6.1. Solder Paste Inspection Equipment. The goal of solder paste inspection is to make sure that the correct volume of solder is available for the solder joint to be formed during the reflow process. There are a variety of

methods out there, ranging from fully automated 3D inspections systems to offline sampling processes that involve a lot of human intervention. The goal of all of the systems is simple: to control the process so that good solder joints can be made.

4.6.2. Postplacement Inspection. The goal of inspection after the components are placed on the board and prior to reflow is to troubleshoot production errors while they are still easy and inexpensive to fix. At this point measurements can be taken to verify how well the placement machines are doing their job (accuracy). Additionally, catching mistakes at this point means that not too many boards are in process yet and incorrect parts can be found because of some physical characteristic of the component without waiting until hundreds of them are built. The machines used for this inspection process are collectively referred to as *automated optical inspection* (AOI) equipment.

4.6.3. Postsoldering Inspection. Many companies are performing inspection after the solder joint is formed. In addition to determining whether the correct component is present, inspection done here can also ensure that the solder joints have the correct characteristics. This is difficult to do as many people disagree on what is and what is not a good solder joint. Many different machines are used to perform this inspection process and vary in strategy depending on what the manufacturer perceives to be the most important defects. Many companies use AOI machines to inspect the visible joints and do not worry about the hidden joints [J lead and ball grid array (BGA), for example]. For companies concerned about the internal solder joint integrity or hidden solder joint, X-ray inspection will be incorporated; however, XRD has the disadvantage of inability to isolate the individual sides of the board, and features from the second side may interfere with the solder joint inspection.

4.7. Testing Equipment

After all the assembly steps are completed, it will be necessary to test the assembly. At this point the assembly will be hooked up to various pieces of equipment to find out if it works and what is wrong with it. The testers may test each component separately (using a bed of nails to probe every node of the circuit) or use a functional test (plugging it in and see if it works). All the nonconforming boards are then separated out and are reworked or scrapped.

4.8. Rework Equipment

If the assembly is to be repaired, an operator will remove the problem parts and replace them. The equipment needed to do this may be as simple as a soldering iron, or complex enough to have robotic arms to help solder the parts and hold them in place. The choice is dependent on the parts to be replaced.

5. CONCLUSIONS

Surface mount assembly is a very dynamic field. The cost, size, and reliability advantages of surface mount implies

that this technology will be around for some time. There are many publications that address this field as well as many organizations. Additional information can be obtained from both IEEE/CPMT and IMAPS. Webpage information is provided in the Further Reading Section (below) as a starting point for further investigation. Because there are so many different challenges to implementing surface mount, the authors are not providing details about research on only one part of the process, such as using cobalt composite solder, as too many areas are being worked on. The recommendation is to investigate the publications and Websites to find the latest information.

SYNTHETIC APERTURE RADAR

CANER OZDEMIR
Mersin University
Mersin, Turkey

Synthetic aperture radar (SAR) is a high-resolution airborne and spaceborne remote sensing technique for imaging remote targets on a terrain or, more generally, on a scene. In 1951, Carl Wiley realized that if the echo signal is collected when the radar is moving along a straight path, the Doppler spectrum of the received signal can synthesize a much longer aperture so that very close targets in the along-track dimension can be resolved [1]. In 1953, the first measured SAR image was formed when a C-46 aircraft mapped a section of Key West, Florida [2,3]. The first onboard satellite SAR system was developed by NASA researchers and put on Seasat in 1978. This remarkable satellite provided so much data for oceanographic applications. Since Seasat, several satellites carrying SAR systems have been launched by different countries. Russian Almaz (1987), European ERS-1 (1991), ERS-2 (1995), and Canadian Radarsat (1995) were among some of them. The first space shuttle mission that has a

SAR module was SIR-A (Shuttle Imaging Radar). After SIR-A was launched aboard the space shuttle *Columbia* in 1981, other spaceborne SAR missions were followed. SIR-B (1984) and SIR-C/X-SAR (1994) acquired SAR images in multiple frequencies and polarizations for more advanced applications such as interferometric and polarimetric mapping of terrains.

Although the primary practices of SAR have been for surveillance applications such as detection of opponents' territories, airplanes, and tanks, it has also found many real-world applications from geophysics to archeology. Since the first measured SAR data was collected in 1953 [3], several air and space vehicles have been mapping Earth's surface to help better understand and interpret terrains and associated geological events. The use of SAR by scientists in predicting volcano eruption, coseismic displacement field, and glacier motions are some of the various applications in different sciences. In agriculture, it is mainly used by scientists for crop monitoring. SAR has also been used by environmental scientists for forest classification, deforest monitoring, hazard monitoring, oil spill, detection of squatters in the cities, and so on. With the help of SAR-based subsurface imaging techniques, it is possible to detect mines and unexploded ordnances. Similarly, these techniques have been very helpful in detecting archeological substances.

Synthetic aperture radar has gathered its fame because it can provide fine resolutions both in range and cross-range dimensions. The term *range* (*slant-range*) corresponds to the line-of-sight distance from radar to the target to be imaged. The term *cross-range* (*transverse-range*, *azimuth*, *along-track*) is the dimension that is perpendicular to range or parallel to the radar's along-track axis. High resolution in range is obtained by a wide bandwidth transmitted signal, usually a frequency-modulated "chirp" waveform. Fine resolution in the cross-range dimension is achieved by coherently processing the target's electromagnetic (EM) scattering measured at different aspects while radar moves along a straight path. With this construct, SAR can provide images that have comparable resolutions with optic imaging systems. In fact, SAR can do even better because it can operate day and night or at cloudy and rainy conditions. Furthermore, unlike photographic images that contain only amplitude information of the target's reflectivity of light, SAR provides both the amplitude and the phase information of the scattered electromagnetic field from a scene, which leads to form *interferometric* SAR images, as will be shown in Section 4.2.

1. BASIC THEORY OF SAR

To understand the physics behind the SAR, it is better to first take a look at the operation of conventional radar: Radar transmits an electromagnetic wave; the wave hits the target and its surroundings and scatters in all directions in space. Then, the backscattered signal is collected by the radar that measures the time delay: τ_d between the transmitted and received signals. As EM waves travels with the speed of light, c , it is possible to calculate the range distance of the target as $R = (c \cdot \tau_d)/2$. The number

“2” accounts for the two-way propagation between the radar and the target. As in the case of conventional radar, the SAR sensor also applies this equation in obtaining the range information. The minimum distance to distinguish two close targets in the range or simply the *range resolution* is equal to $\Delta r = (c \cdot \Delta\tau_d)/2$, where $\Delta\tau_d$ is the duration of the transmitted pulse. For instance, if the radar operates at 10 GHz and applies pulses of 1 μ s long, the resolution in range becomes 150 m. Although this number may be sufficient for imaging large portions of the Earth’s surface such as mountains and deserts, it is clearly not enough to image smaller targets. The Fourier theory states that the frequency bandwidth of a time signal whose time duration is $\Delta\tau_d$ is given by $BW_f = 1/\Delta\tau_d$. Therefore, the range resolution of conventional or synthetic aperture radar becomes $\Delta r = c/(2 \cdot BW_f)$. For the conventional radar, sensing two close targets that are in the same range distance is difficult, because the angular beamwidth of any single radar antenna is equal to $\Delta\theta = \lambda/D$, where λ is the wavelength for the operating frequency and D is the maximum physical length of the antenna. As two objects that are at the same range distance R can only be distinguished if they are at different radar beams, then the *cross-range resolution* is equal to one arc length of the radar beam as $\Delta x = \text{arc length} = R \cdot \Delta\theta = R \cdot \lambda/D$, as illustrated in Fig. 1(a). For example, a 2 m long, X-band (at 10 GHz) radar antenna can provide an azimuth resolution of 150 m at a range distance of 10 km. This amount of resolution is again not enough for imaging small targets and for capturing the details of a terrain. However, it is obvious that when the radar is moving, the distance between the radar and the target is changing. As a result, a frequency shift occurs in the returned EM wave because radar pulses experience different travel distances because of motion. This shift in frequency is called *Doppler shift*. In fact, we use

this Doppler effect in a SAR system to enhance the cross-range resolution, as will be explained in Section 1.3.2.

1.1. Range and Cross-Range Resolutions in SAR

We use the term *synthetic aperture* because the idea behind SAR is to synthesize the effect of a large, real aperture radar (RAR) by means of a collection of small-size aperture radars, which is accomplished by moving the small aperture radar along with the imaginary aperture axis to emulate a much larger aperture, as depicted in Fig. 1(b). Typically, the radar is put on an airborne or a spaceborne vehicle and the ground’s EM reflectivity is measured at different time instants while the radar vehicle is moving along-track path (see Fig. 2). Coherent processing of electromagnetic echoes from the illuminated area at different frequencies and apertures makes it possible to form a two- (or three-) dimensional image of the terrain.

The range resolution in SAR, $\Delta r = c/(2 \cdot BW_f)$, is the same as the conventional radar, as explained in Section 1. However, the frequency bandwidth of pulse in SAR is much longer to achieve finer resolutions. According to the Fourier theory, the time duration of the pulse is then required to be very short. On the other hand, it is hard to put enough energy into a very short pulse. As a very small portion of the transmitted power scatters back to radar, it will be almost impossible to sense the received signal above the noise floor for such a short pulse. To circumvent this problem, we use a linear frequency-modulated (LFM) *chirp* signal that has an instantaneous frequency of $f_i(t) = f_c + BW_f \cdot t/T_o$. Here, f_c is a fixed frequency, T_o is the pulse duration, and BW_f is the total bandwidth. Chirp signal has the suited property of providing required bandwidth with longer pulse duration. An X-band, 1 μ s duration chirp pulse with 1 GHz bandwidth can provide a range resolution of 30 cm that is attractive.

A good cross-range resolution in SAR is achieved by forming a synthetic line antenna of length D_{SA} by moving the radar antenna along a straight path [see Fig. 1(b)]. As will be shown in Section 1.3.2, the cross-range resolution in SAR then becomes $\Delta x = R \cdot \lambda/(2D_{SA})$. For example, if SAR platform collects the scattered EM wave at the center frequency of 10 GHz from a target of 10 km away and for a synthetic aperture of 1 km, then the cross-range resolution is 30 cm, which is much better than the RAR case.

Two main modes for SAR operation exist. As illustrated in Fig. 3(a), when the radar collects the EM reflectivity of the alongside region when it travels, observing a strip of a terrain parallel to the flight path, this is called *side-looking SAR*. When the radar focuses its illumination to a fixed, particular area of interest, this mode is called *spot-light SAR*, as shown in Fig. 3(b).

1.2. Range Ambiguity and Pulse Repetition Frequency (PRF)

A SAR system sends out many pulses to the scene. The reason that in SAR, we use discrete pulses instead of a continuous waveform is that very little of transmitted power scatters back to radar. If a continuous wave is used, the leakage from the transmitting unit to the receiving unit would jam and probably dominate the actual

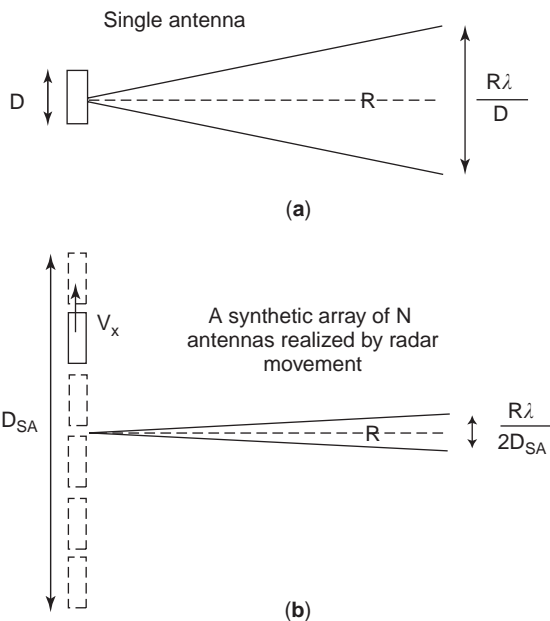

Figure 1. (a) A real aperture single antenna and (b) a synthetic aperture of N antennas.

Figure 2. SAR operation: Radar platform is moving to synthesize the effect of a long real aperture radar.

received power. To avoid this, therefore, SAR first sends out a pulse to the scene, then turns off the transmitter, and listens the echo signal via its receiving unit. However, a limit is placed on the number of pulses that can be involved in a SAR. Suppose that a point target is at R distance away from the radar. For a pulse duration of T_o , the time delay of the returned pulse is $t_d = 2R/c$. Therefore, if a second pulse is sent before the first one arrives back, a phase ambiguity may exist such that the second pulse's echo from the nearest range point may arrive earlier than the first pulse's echo from the farthest range point. Of course, this ambiguity makes it difficult to resolve the points in the range. This situation is named *Range Ambiguity*. To prevent it, a lower limit must be placed on the number of pulses that can be transmitted in 1 second, i.e., *Pulse Repetition Frequency* (PRF), as follows:

$$PRF \leq \frac{1}{T_o + 2(R_F - R_N)/c} \quad (1)$$

where R_F and R_N are the farthest and the nearest range distances inside the swath and under the illumination of the radar beam [4].

1.3. SAR Image Formation

SAR imagery is based on successive signal processing algorithms called range and azimuth compression. The usual raw SAR data are in the form of a two-dimensional (2-D) multifrequency, multiaspect (or multispatial) scattered field data, as shown in Fig. 4. The range compression and azimuth compression are usually applied independently to obtain the ultimate SAR image (see Fig. 4).

1.3.1. Range Compression. As mentioned, we usually use a linear FM chirp waveform in range compression. The word *compression* refers to the frequency content of the chirp signal that is changing rapidly such that the full bandwidth BW_f corresponds to a time duration of $T_p = 1/BW_f$, which is much shorter than the actual pulse duration, T_o . A typical chirp waveform is plotted in Fig. 5(a). The instantaneous frequency of chirp signal is equal to $f_i(t) = f_c + \beta \cdot t/\pi$, where f_c is the initial frequency and β is related to the frequency bandwidth as $\beta = 2\pi BW_f/T_o$. Then, the transmitted signal will have the phase term of

$$p(t) = \exp[j(2\pi f_c t + \beta t^2)] \quad |t| \leq T_o/2 \quad (2)$$

A time-frequency transform of the signal is taken via spectrogram to show how the frequency increases linearly with respect to time in Fig. 5(b). When the range compression is applied, the output signal is depicted in Fig 5(c). The range-compressed one-dimensional (1-D) data, also known as *range profile*, contains distinct peaks corresponding to distinct scatterers along this particular range-bin. The locations of these peaks; t_i 's correspond to range distances: R_i 's of the scattering centers via $R_i = c \cdot t_i/2$. Therefore, the received signal will have the following phase term that contains the time delay of $t_d = 2R/c$:

$$s(t) = \exp[j(2\pi f'_c(t - t_d) + \beta(t - t_d)^2)] \quad (3)$$

Here, f'_c is a shifted version of f_c caused by Doppler shift of amount Δf . After collecting the received signal, it is then

Figure 3. Modes of SAR: (a) side-looking SAR and (b) spotlight SAR.

passed to a *matched filter* whose filter characteristic is the same as the chirp signal:

$$h(t) = \exp[j(2\pi f_c t + \beta t^2)] \quad |t| \leq T_o/2 \quad (4)$$

The matched filter output is just the cross-correlation between the received signal and the filter impulse response

over the pulse duration as

$$\begin{aligned} y(t) &= \frac{1}{T_o} \int_{-T_o/2}^{T_o/2} s(t + \tau)h(\tau)d\tau \\ &= \frac{1}{T_o} \int_{-T_o/2}^{T_o/2} \exp[j(2\pi f'_c(t + \tau - t_d) \\ &\quad + \beta(t + \tau - t_d)^2)] \\ &\quad \cdot \exp[-j(2\pi f_c \tau + \beta \tau^2)]d\tau \\ &\cong \frac{\sin(\beta T_o(t - t_d) + \pi T_o \Delta f)}{\beta T_o(t - t_d) + \pi T_o \Delta f} \\ &\quad \cdot \exp[j(2\pi f'_c(t - t_d) + \beta(t - t_d)^2)] \end{aligned} \quad (5)$$

As the final process of the pulse compression, the high-frequency phase term at f_c is filtered by the following manner:

$$\begin{aligned} r(t) &= y(t) \cdot \exp[-j(2\pi f_c t)] \\ &= \frac{\sin(\beta T_o(t - t_d) + \pi T_o \Delta f)}{\beta T_o(t - t_d) + \pi T_o \Delta f} \\ &\quad \cdot \exp[-j(2\pi f_c t_d - 2\pi \Delta f(t - t_d) \\ &\quad - \beta(t - t_d)^2)] \end{aligned} \quad (6)$$

Here, the Doppler shift Δf depends on the position of the scatterer with respect to radar as well as to the ground velocity of the scatterer if the target is moving. Assuming that the scatterer is stationary, the Doppler shift term both in the amplitude and the phase terms of Eq. (6) produces a minor effect compared with the nominal values of SAR bandwidth. So, it can be ignored. Furthermore, the quadratic phase term in the last part of Eq. (6) also provides very small phase value in comparison with the first phase term, and so it can also be neglected. As a result, the range compressed signal can be approximately reduced to

$$\begin{aligned} r(t) &\cong \text{sinc}[\beta T(t - t_d)] \\ &\quad \cdot \exp[-j(2\pi f_c t_d)] \end{aligned} \quad (7)$$

The amplitude term in Eq. (7) is a *sinc* (sinus cardinalis or $\sin(x)/x$) function centered at $t = t_d$ that is clearly related to the scattered position as $R = t_d \cdot c/2$. The first nulls bandwidth of this sinc function is equal to $\Delta t_d = 1/BW_f$.

Figure 4. SAR image formation via signal processing.

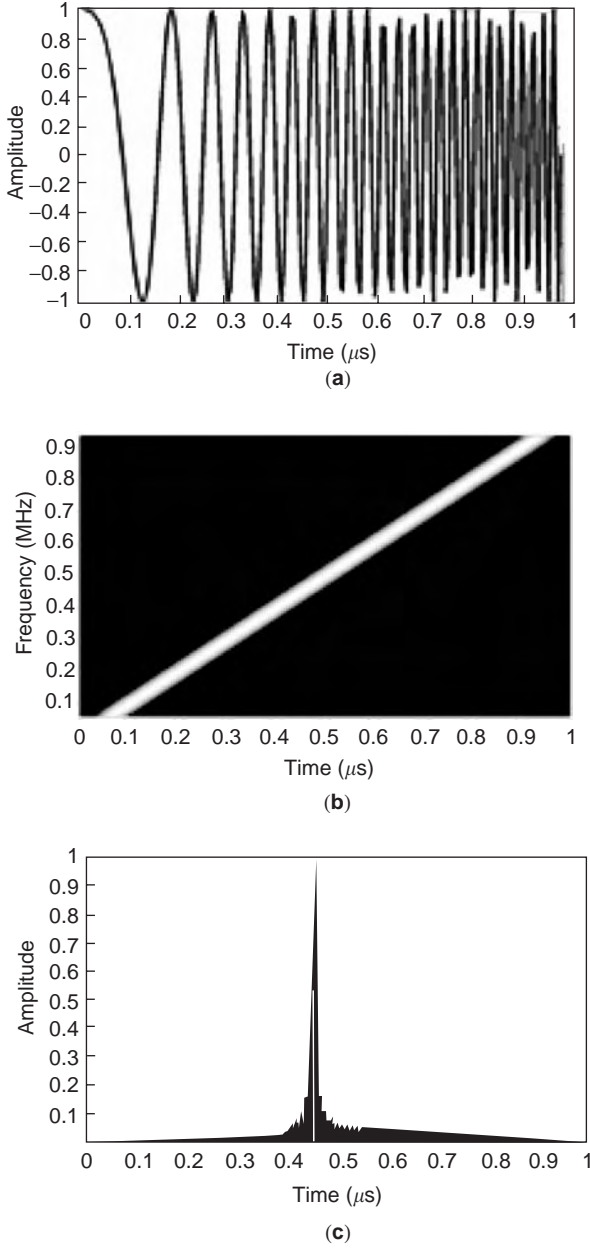

Figure 5. (a) Chirp signal, (b) time-frequency display of the chirp signal, and (c) output of the matched filter: range-compressed data.

Therefore, the range resolution is given by $\Delta r = \Delta t_d \cdot c / 2 = c / (2 \cdot BW_f)$.

1.3.2. Azimuth Compression. The compression in azimuth (or cross-range) is reached by a long synthetic antenna that is achieved by the radar motion. The geometry for SAR azimuth processing is drawn in Fig. 6. Assume that a point scatterer at R_o is away from the center of the synthetic aperture and the radar platform moves with a constant speed of V_x . When the radar travels a distance of $x = V_x \cdot t$ along the aperture, the scatterer's distance from the radar becomes $R = (R_o^2 + x^2)^{1/2}$. Assuming that $x \ll R_o$, the following approximation to the second order can be

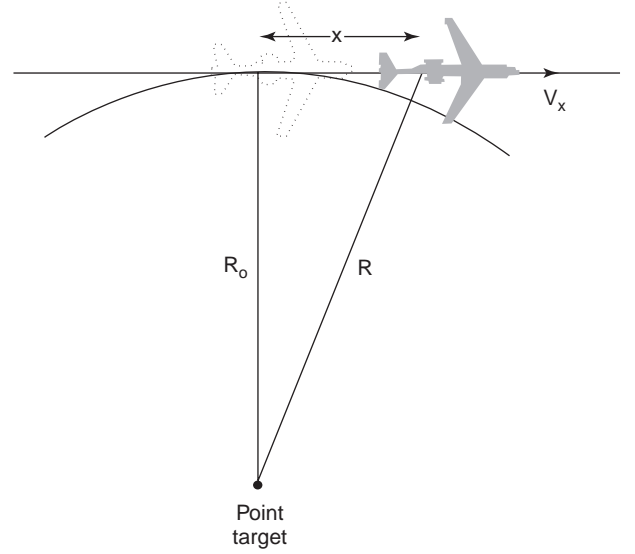

Figure 6. Geometry for SAR.

made:

$$R = R_o \left(1 + \frac{x^2}{R_o^2} \right)^{1/2} \approx R_o + \frac{x^2}{2R_o} \quad (8)$$

Therefore, the EM wave that possesses two-way propagation has a phase term

$$\begin{aligned} \Phi(x) &= \exp(-j2kR) = \exp \left[-j \left(\frac{4\pi}{\lambda} \right) \left(R_o + \frac{x^2}{2R_o} \right) \right] \\ &= \text{const.} \times \exp \left(-j \frac{2\pi x^2}{\lambda R_o} \right) \end{aligned} \quad (9)$$

By neglecting the phase term that has no time dependency, we can write the phase term of the received signal as

$$\Phi(t) = \exp \left(-j \frac{2\pi V_x^2 t^2}{\lambda R_o} \right) = \exp(-j\gamma t^2) \quad (10)$$

where $\gamma = 2\pi V_x^2 / (\lambda R_o)$. Then, the Doppler shift in frequency can be found by taking a time derivative of the phase:

$$f_d(t) = \frac{1}{2\pi} \frac{\partial}{\partial t} \left(-\frac{2\pi V_x^2 t^2}{\lambda R_o} \right) = -\frac{2V_x^2 t}{\lambda R_o} \quad (11)$$

The processing in cross-range dimension can be done by integrating all aperture return over an integration time T_s . This method is called *unfocused-SAR*. Then, the output signal of the azimuth SAR processing is obtained via the following averaging integral:

$$y(t) = \frac{1}{T_s} \int_{-T_s/2}^{T_s/2} \exp(-j\gamma t^2) d\tau \quad (12)$$

In fact, Eq. (12) is in the form of a *Fresnel* integral, which can only be solved numerically [5]. Therefore, the cross-range compressed data can be obtained numerically by solving the Fresnel integral in Eq. (12) in unfocused-SAR imaging. On the other hand, notice that the signal in

Eq. (10) is in the similar form as the chirp signal. Therefore, the processing in azimuth can also be carried out in a similar manner as range. In unfocused-SAR, the path lengths from different aperture points differ, which leads to a resolution mismatch as the radar moves. In photography, a lens focuses the rays from object to image plane. In SAR, this movement is achieved by adjusting the path lengths from all apertures to be the same by applying a matched filter. This process is called *focused-SAR* operation. So, if we can apply matched filter processing to the azimuth SAR data in a similar manner, then the output of the filter can be found via

$$\begin{aligned}
 E_x(t) &= \frac{1}{T_s} \int_{-T_s/2}^{T_s/2} \exp[-j(\gamma(t+\tau)^2)] \\
 &\quad \cdot \exp[j(\gamma\tau^2)] d\tau \\
 &= \sin c(\gamma T_s t) \cdot \exp(-j\gamma t^2) \\
 &= \sin c\left(\frac{2V_x^2 T_s t}{\lambda R_o}\right) \cdot \exp\left(-j\frac{2V_x^2 t}{\lambda R_o}\right)
 \end{aligned} \tag{13}$$

The second term in Eq. (13) is just the phase term. Therefore, only the first term represents the envelope of the azimuth-compressed SAR data. The first nulls bandwidth of the sinc function in Eq. (13) is equal to $\Delta t_x = \frac{\lambda R_o}{2V_x^2 T_s}$. Therefore, the cross-range resolution is equal to $\Delta x = V_x \cdot \Delta t_x$. After some calculation, it reduces to

$$\begin{aligned}
 \Delta x &= V_x \cdot \frac{\lambda R_o}{2V_x^2 T_s} = \frac{\lambda R_o}{2(V_x T_s)} = \frac{\lambda R_o}{2D_{SA}} \\
 &= \frac{\lambda R_o}{2(\lambda R_o/D)} = \frac{D}{2}
 \end{aligned} \tag{14}$$

where D_{SA} is the length of the synthetic aperture and D is the longest dimension of the radar antenna. Therefore, the cross-range resolution is independent of target distance R_o and the wavelength λ and depends only on antenna size for focused-SAR.

Generally, processing in range and cross-range is computationally intensive, because the correlation integral has to be calculated for every pixel of the 2-D SAR data. However, SAR image formation can be accelerated by the convolution theorem that makes it possible for us to use the Fourier transform (FT). In this regard, range or azimuth compressed data can be written in the form of a convolution as follows:

$$E(t) = \int_{-\infty}^{\infty} s(\tau)h(t+\tau)d\tau = s(t) \otimes h(-t) \tag{15}$$

where $s(t)$ is the chirp pulse in range or azimuth SAR signal in Eq. (10) and $h(t)$ is the matched filter impulse response. According to Fourier theory, convolution in time corresponds to multiplication in frequency. Therefore, the convolution in Eq. (15) can easily be sped up via Fourier transforms as shown below:

$$E(t) = IFT\{FT\{s(t)\} \times FT\{h(-t)\}\} \tag{16}$$

where FT and IFT are the forward and inverse Fourier transform operations, respectively. Therefore, clearly the shape of the resulting image response is determined by the Fourier transform of the pulse shape. When it is a rectangular pulse, the image response comes out to be a sinc function. This response is also known as point spread function (PSF) in radar imaging. As the SAR data have to be finite, the limits in the Fourier integral become finite. Therefore, the spreading effect is always unavoidable in SAR imagery. In some cases, a sinc-type PSF can be problematic when a weak scatterer happens to be located very near to a strong scatterer. As the first sidelobe level of the sinc function is only 13 dB lower than the main beam, the weak scatterer may not be detected because of high sidelobes of the strong scatterer. Therefore, we usually use smooth weightings such as Hanning, Hamming, or Kaiser-type windowing whose Fourier transform provide much smaller sidelobe levels. Figure 7 shows the compressed signal for a Hanning weighted chirp signal. It is clear that the sidelobes are well suppressed compared with the sinc response. Therefore, such weightings provide better peak-to-sidelobe ratio (PSLR) at the price of increased mainlobe beamwidth, i.e., worse resolution.

An example of a measured SAR imagery is given in Fig. 8. This image shows the space shuttle SAR image of San Francisco, California. The raw SAR data were collected by the SIR-C/X-SAR when it flew aboard the space shuttle *Endeavor* in 1994. The SAR system on SIR-C/X collected L-, C-, and X-band raw SAR data over 225 km above Earth's surface for multiple frequencies and polarizations to better understand the global environment and how it is changing. The SIR-C/X-SAR system was designed to provide surface resolutions of 30 m both in range and cross-range dimensions. The particular image in Fig. 8 shows the most general features of a typical SAR image. For instance, rough surfaces such as mountain terrains show up in the SAR image as the mixture of bright and dark spots because they experience scattering in all directions. On the other hand, smooth surfaces and regions of calm water such as sea or lake surfaces seen to be black. Because these surfaces behave like mirrors and scatter EM energy according to the Snell's law, almost no energy scatters back in the direction of radar. Hills and other large-scale targets tend to appear bright on the side where illuminated and dark on the other side where there is no EM illumination (shadowing). Man made objects such as

Figure 7. Hanning windowed range-compressed data.

Figure 8. SIR-C/X-SAR image of San Francisco, California. (Courtesy NASA/JPL-Caltech.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

buildings and vehicles behave like corner reflectors, and they appear as brighter spots. When a very strong point scatterer exists (e.g., specular point), it shows up as a very bright cross in the image because of strong sidelobes in range and cross-range dimensions. Most of these features can be observed from the SAR image in Fig. 8.

2. COMMON PROBLEMS IN SAR IMAGERY

2.1. Range Migration

During the SAR operation, the radar platform first approaches and then moves away from any scatterer that is entering its main antenna beam. Therefore, the range distance of any scatterer depicts a parabolic curve called *range curvature* while it is illuminated by the radar beam. This ambiguity in range distance may result in shifting of scatters to the nearby range cells while integrating the raw SAR data over the synthetic aperture time interval. This phenomenon is called *range migration*. For spaceborne SAR, this curvature can be significant because the range extent and the integration time is longer compared with airborne SAR. On the other hand, the antenna's footprint on the ground is much shorter for the airborne SAR. Therefore, the range-delay shift of the scatterer may be less than the range resolution, which may cause no migration in the range. Another cause of range migration

occurs from the phenomena called *range walk*. When the integration time is long, the rotation of earth causes shifting of the position of the scatterer with respect to radar. The same effect happens when the ground target is moving. These reasons result in migration of the scatters in the image cells. To have a focused image, range migration correction is required in the Doppler frequency domain [6–8].

Both range curvature and range walk possess a parabolic track within the real beam of the radar. If the range error resulted by these effects is δR , the total range can be written as

$$R + \delta R = \left(R^2 + \left(\frac{V_p \cdot T_s}{2} \right)^2 \right)^{1/2} \quad (17)$$

Here, V_p is the velocity of the scatterer and T_s is the integration time in SAR azimuth processing. In fact, the integration time can also be written for the target's velocity V_p and the single-look angular extend θ_e as $T_s = R \cdot \theta_e / V_p$. After substituting this formula into Eq. (17) and taking the binomial expansion of the range error, we can get

$$\begin{aligned} \delta R &= \left(R^2 + \left(\frac{R \cdot \theta_e}{2} \right)^2 \right)^{1/2} - R = R \left(1 + \left(\frac{\theta_e}{2} \right)^2 \right)^{1/2} - R \\ &= R \left(1 - \frac{1}{2} \left(\frac{\theta_e}{2} \right)^2 + H.O.T. \right)^{1/2} - R \cong \frac{R \cdot \theta_e^2}{8} \end{aligned} \quad (18)$$

Then, Δr being the range resolution, the migration in the range cell can be found by

$$N \approx \frac{\delta R}{\Delta r} = \frac{R \cdot \theta_e^2}{8 \Delta r} \quad (19)$$

If this number turns out to be more than 1, the range migration correction has to be performed accordingly. If not, no correction is needed.

2.2. Motion Errors

The basic theory of SAR relies on the assumption that the scene or the target is stationary. If a scatterer in the scene is moving, the Doppler shift posed by the scatterer's line-of-sight velocity sets the "incorrect" distance information about the position of the scatterer to the phase of the received EM wave. When the scatterer is moving so fast, it occupies several pixels in the image during the integration interval of SAR. Therefore, the image of the scatterer is blurred like a comet in the sky, which is analogous to optical photography when the object is moving so fast that it occupies larger space until the lens is closed. When the scatterer is in slow motion, the SAR image may not be blurred. However, the location of the scatterer will still not be correct because of Doppler shift. To minimize these

motion errors, *motion compensation* techniques have to be applied (see Section 4.1).

2.3. Speckle Noise

The size of one SAR resolution cell (i.e., a pixel) can vary from a few centimeters to tens of meters depending on the size of the synthetic aperture and the bandwidth in frequency. Generally, Earth’s surface is uneven within one resolution cell. Therefore, one pixel of SAR may not resolve the detailed features of Earth’s surface. As the EM energy diffracted from such uneven patches will have various phase values, the net effect on the image pixel can be constructive or destructive. The resulting noise-like behavior is known as *ground clutter* or *speckle noise*. One way we can reduce speckle noise in SAR imaging is to use multi-look processing [4]. Another method is for us to apply statistical filtering of speckle noise by using proper probability distribution models such as Rayleigh distribution [9,10].

3. INVERSE SYNTHETIC APERTURE RADAR

3.1. SAR versus ISAR

Inverse synthetic aperture radar (ISAR) is a powerful signal processing technique for imaging moving targets in range and cross-range domains. SAR generally refers to the case when radar platform is moving while the target stays stationary. The required spatial (or angular) bandwidth is achieved by the movement of radar around the target or terrain. We use the term *inverse synthetic aperture radar* for scenarios when the radar is standing still and the target is in motion like airplanes, ships, and tanks, as illustrated in Fig. 9. For the ISAR case, stationary radar collects the angular data through the target movement. For the collected echo dataset, ISAR geometry, in fact, can also be thought as the same as spotlight SAR geometry with circular flight path (see Fig. 9).

3.2. Basic Theory of ISAR Imaging

Usually two-dimensional ISAR images in range and cross-range are generated with frequency and aspect diversity of the backscattered signal. Therefore, the echoed data are collected for various frequencies and angles in a two-

Figure 9. ISAR.

Figure 10. Collection of ISAR raw data in Fourier space for the monostatic case.

dimensional data grid as shown in Fig. 10. For *bistatic ISAR*, the transmitter and the receiver are at different locations in space. If the radar operates as both the transmitter and the receiver, this scenario is called *monostatic ISAR*. A simplified ISAR imaging theory for the monostatic case is summarized as follows. As illustrated in Fig. 11, $P(x_o, y_o)$ is a point scatterer situated on the target. Taking the origin as the phase center, the far-field back-scattered field from a point scatterer P at an azimuth angle ϕ can be written as

$$E_s(k, \phi) = A_o \exp(j2\mathbf{k} \cdot \mathbf{r}_o) \tag{20}$$

Here, A_o is the amplitude of the backscattered electric field intensity, \mathbf{k} is the vector wavenumber in propagation direction, and \mathbf{r}_o is the vector from origin to point P . The multiplier “2” in the exponential accounts for the two-way propagation between the radar and the scatterer. \mathbf{k} vector can be written for the wavenumbers in x - and y -directions

Figure 11. Geometry for monostatic ISAR imaging.

as follows:

$$\begin{aligned} \mathbf{k} &= k \cdot \mathbf{a}_k = k_x \cdot \mathbf{a}_x + k_y \cdot \mathbf{a}_y \\ &= k(\mathbf{a}_x \cdot \cos \phi + \mathbf{a}_y \cdot \sin \phi) \end{aligned} \quad (21)$$

where \mathbf{a}_k , \mathbf{a}_x , and \mathbf{a}_y are the unit vectors in k -, x -, and y -directions, respectively. Then, the argument in the phase term of Eq. (1) can be reorganized to give

$$\begin{aligned} \mathbf{k} \cdot \mathbf{r}_o &= k(\cos \phi \cdot \mathbf{a}_x + \sin \phi \cdot \mathbf{a}_y) \\ &\quad \cdot (x_o \cdot \mathbf{a}_x + y_o \cdot \mathbf{a}_y) \\ &= k \cos \phi \cdot x_o + k \sin \phi \cdot y_o \end{aligned} \quad (22)$$

Therefore, we can rewrite Eq. (20) as

$$\begin{aligned} E_s(k, \phi) &= A_o \cdot \exp(j2k \cos \phi \cdot x_o) \\ &\quad \cdot \exp(j2k \sin \phi \cdot y_o) \end{aligned} \quad (23)$$

It is obvious from Eq. (23) that Fourier relationships exist between $2k \cos \phi$ -and- x_o and $2k \sin \phi$ -and- y_o . Therefore, the ISAR image can be generated in range and cross-range domains by the convenience of the 2-D Fourier transform.

3.2.1. Small Bandwidth, Small-Angle ISAR Imaging. This procedure is standard where practical ISAR imaging is concerned. Assume that the frequency bandwidth, BW_f , is small compared with center frequency of operation f_c . Then, the wavenumber in the second phase term of Eq. (23) can be approximated as $k \approx k_c$, where k_c is the wavenumber corresponding to the center frequency. Furthermore, the synthetic aperture angular bandwidth, BW_ϕ , is also selected as small in most of the ISAR applications. Therefore, the following approximations for the angles within the specified angular bandwidth hold true:

$$\begin{aligned} \cos \phi &\approx 1 \\ \sin \phi &\approx \phi \end{aligned} \quad (24)$$

Then, the scattered electric field from point P can be approximated to

$$\begin{aligned} E_s(k, \phi) &\cong A_o \cdot \exp(j2k \cdot x_o) \\ &\quad \cdot \exp(j2k_c \phi \cdot y_o) \end{aligned} \quad (25)$$

With this construct, the two-dimensional polar data in Fig. 10 forms nearly a rectangular grid that makes it possible for us to use discrete Fourier transform (DFT). Then, it is easy for us to take the two-dimensional Fourier transform of Eq. (25) with respect to k and ϕ to get the image of the point scatterer at P in the range and cross-range domains as follows:

$$\begin{aligned} IFT_2\{E_s(k, \phi)\} &= A_o \cdot IFT_1\{\exp(j2k \cdot x_o)\} \\ &\quad \cdot IFT_1\{\exp(j2k_c \phi \cdot y_o)\} \end{aligned} \quad (26)$$

$$E_s(x, y) = A_o \cdot \delta(x - x_o) \cdot \delta(y - y_o)$$

Here $\delta(\cdot)$ represents the impulse (or dirac delta) function. Therefore, the point P manifests itself in the image as a two-dimensional impulse function located at (x_o, y_o) . In summary, a two-dimensional ISAR image of a target is obtained by the following Fourier integral of the scattered field:

$$\begin{aligned} ISAR(x, y) &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} E_s(k, \phi) \cdot e^{j2k \cdot x} \\ &\quad \cdot e^{j2k_c \phi \cdot y} d(k) \cdot d(k_c \phi) \end{aligned} \quad (27)$$

Of course, the limits of the integral in Eq. (27) have to be finite in practice because the field data can be collected within a finite bandwidth for frequencies and angles. Therefore, the image response distorts from the impulse function to the sinc function.

3.2.1.1. Resolution, Bandwidth, and Sampling in ISAR. As is obvious from the first phase term in Eq. (25), the Fourier requirement exposes the following for the range resolution of ISAR:

$$\Delta r = \frac{2\pi}{2BW_k} = \frac{c}{2BW_f} \quad (28)$$

Looking at the second phase term in Eq. (25), the cross-range resolution, Δx , can be obtained with a similar manner as follows:

$$\Delta x = \frac{2\pi}{2k_c BW_\phi} = \frac{c}{2f_c BW_\phi} = \frac{\lambda_c}{2BW_\phi} \quad (29)$$

Therefore, a wide frequency bandwidth provides fine range resolution and a wide angular bandwidth assures good cross-range resolution. For example, if the target's EM reflectivity is collected for an angular bandwidth of 11.5 degrees with a frequency range changing from 9.5 GHz to 10.5 GHz, both the range and the cross range resolutions become 15 cm.

Having found resolutions in range and cross-range domains, the choice of number of sampling points determines the bandwidths in these domains (i.e., the image size). If the frequency range is sampled by N times and the angular range is sampled by M times, corresponding image domain bandwidths are given as

$$\begin{aligned} BW_r &= N \cdot \Delta r = \frac{N \cdot c}{2 \cdot BW_f} \\ BW_x &= M \cdot \Delta x = \frac{M \cdot c}{2 \cdot BW_\phi} \end{aligned} \quad (30)$$

For Eq. (30), if the two-dimensional frequency-aspect data are collected over 128 sampling points in each domain, the image size becomes 19.2 m by 19.2 m.

3.2.2. Wide Bandwidth, Wide-Angle ISAR Imaging. If the small bandwidth and small angle approximations are not valid, the ISAR imaging integration in Eq. (27) becomes in

its general format

$$\begin{aligned}
 E_s(x,y) &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} E_s(k, \phi) \cdot e^{j2k \cdot r} d(k) \cdot d(\phi) \\
 &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} E_s(k, \phi) \cdot e^{j2k \cos \phi \cdot x} \\
 &\quad \cdot e^{j2k \sin \phi \cdot y} d(k) \cdot d(\phi)
 \end{aligned}
 \tag{31}$$

Notice that collected Fourier space data are in polar format. For us to use DFT while forming the ISAR image, the data have to be in a discrete, uniformly spaced rectangular form. Therefore, the data should be reformatted from polar coordinates to Cartesian coordinates as depicted in Fig. 12. This process is known as *polar reformatting*. To minimize the error associated with this reformatting, several interpolation schemes such as four nearest neighbor approximation [11] are employed. After putting these data in their proper formats, the ISAR image can be generated similarly by applying the two-dimensional discrete Fourier transform operation as explained in Section 3.2.1. An example of ISAR imagery is shown in Fig. 13. The raw ISAR data were measured from a ground radar, and the target was an aircraft in flight [12].

4. SOME ADVANCED CONCEPTS IN SAR

4.1. Motion Compensation

As stated, the SAR theory is based on the assumption that the scene is stationary and the SAR platform travels along a straight path with a constant speed. If these assumptions are not valid, some degradation in SAR images is unavoidable. After radar sends an EM wave to the scene and the wave hits the target, the leading edge and then the trailing edge of the wave have different trip distances for a moving target. Therefore, the phase of the backscattered wave is altered such that the resultant image is mislocated in cross-range and defocused in both range and cross-range domains.

As illustrated in Fig. 14, we assume a scatterer point $P(x_c + x_o, y_c + y_o)$ on a target that has both translational and rotational motion. $Q(x_c, y_c)$ in Fig. 14 represents the center point of the target. We would like to estimate the phase error associated with the motion of the target. If the radar is situated at the far field of the target, the point

Figure 12. Rectangular reformatting of polar ISAR data.

Figure 13. ISAR image of an aircraft from the measured data. (Source [12] © 1999 SPIE.)

P has a distance from the target as

$$R = R_c + x_o \cdot \cos(\phi_o - \phi) - y_o \cdot \sin(\phi_o - \phi) \tag{32}$$

Here, R_c is the distance between the radar and the center of the target. If the target has only linear translational velocity V_t and a linear rotational velocity ϕ_r , then the time-varying range distance and the rotation angle can be written as

$$\begin{aligned}
 R_c(t) &= R_o + V_t \cdot t \\
 \phi(t) &= \phi_o + \phi_r \cdot t
 \end{aligned}
 \tag{33}$$

where R_o and ϕ_o are the initial values for the target's distance from radar and the orientation of the target with respect to x -axis, respectively. The phase of the backscattered signal from point P is equal to

$$\Phi(t) = -j2kR(t) = -j2\pi f \frac{2R(t)}{c} \tag{34}$$

Figure 14. Geometry for imaging a target with motion.

Therefore, the Doppler shift caused by motion can be calculated by taking the time derivative of this phase as

$$\begin{aligned} f_D &= \frac{1}{2\pi} \frac{\partial}{\partial t} \Phi(t) = -\frac{2f}{c} \frac{\partial}{\partial t} R(t) \\ &= -\frac{2f}{c} V_t + \frac{2f\varphi_r}{c} [x_o \cdot \sin(\phi_o + \varphi_r t - \phi) \\ &\quad + y_o \cdot \cos(\phi_o + \varphi_r t - \phi)] \end{aligned} \quad (35)$$

Here, the first term represents the translational Doppler frequency shift, $f_D^{Trans} = -\frac{2f}{c} V_t$, and the second term corresponds to the rotational Doppler frequency shift, $f_D^{Rot} = \frac{2f\varphi_r}{c} [x_o \cdot \sin(\phi(t)) + y_o \cdot \cos(\phi(t))]$, where $\phi(t) = \phi_o + \varphi_r t - \phi$.

When the SAR is considered, the backscattered signal can be written as the integration of the returned signals from all scatterers inside the radar beam:

$$g(t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \Gamma(x, y, z) \cdot \exp\left(-j \frac{4\pi f}{c} R(t)\right) \cdot dzdydx \quad (36)$$

Here $\Gamma(x, y, z)$ is the backscattered signal intensity from point (x, y, z) . Substituting the range equation in Eq. (35) into Eq. (36), we can get the following:

$$\begin{aligned} g(t) &= \exp\left(-j \frac{4\pi f}{c} R_c(t)\right) \\ &\times \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \Gamma(x, y, z) \\ &\cdot \exp\left(-j \frac{4\pi f}{c} (x_o \cdot \sin(\phi(t)) + y_o \cdot \cos(\phi(t)))\right) \cdot dzdydx \end{aligned} \quad (37)$$

If the target's initial range R_o and the linear translational velocity V_t is known, the phase term before the above integral can be removed by multiplying Eq. (37) by $\exp\left(j \frac{4\pi f}{c} R_c(t)\right)$ for every pixel in the SAR data. This process is called *range tracking*, and it is the basic procedure for the standard motion compensation. After obtaining the phase-compensated backscattered signal, a Fourier transform operation can be applied to image the backscattered signal intensity function $\Gamma(x, y, z)$ [13]. This process is the coarse motion compensation approach. If the scatterers pass different range cells during the coherent integration, the resultant phase-compensated image will still be defocused. Therefore, a finer compensation called *Doppler tracking* that tries to make the Doppler shifts constant is required [14–16].

An example of motion compensation is depicted in Fig. 15 where an ISAR image of Boeing-727 data with motion compensation is illustrated. In Fig. 15(a), a 2-D ISAR image of the original data is shown. As easily observed from the figure, the image is blurred because of motion errors. In Fig. 15(b), the motion errors are suppressed by applying both translational and rotational motion compensation

Figure 15. ISAR image of simulated B727 data (a) before and (b) after motion compensation. (Source [17] © 1998 IEEE.)

algorithms [17]. Therefore, the image is well focused and the motion errors in range are also mitigated.

4.2. SAR Interferometry

This application of SAR imagery is one of the most unique. When compared with optical imaging that has only the amplitude information of the reflected light, SAR images contain both the amplitude and the phase information of the backscattered electromagnetic energy. Therefore, if the multilook images of the scene from different elevations are obtained, the comparison of the phases can lead to the third dimension (i.e., height) having interferometric images. The first demonstrated interferometric SAR (IFSAR) was presented by Graham when he configured a cross-track interferometer in 1974 [18]. Goldstein and Zebker used an along-track SAR interferometry configuration to measure radial velocity of moving targets in 1987 [19]. In 1988, Gabriel and Goldstein obtained an elevation map of a terrain with the data collected by SIR-B by means of a single antenna with repeat pass [20].

In IFSAR, a second image of the same scene extracts the third dimension, which can be achieved either by an airborne/spaceborne vehicle carrying a two-radar system or by a single-antenna vehicle with repeat passes over the

same scene. For the latter situation, suppose that the vehicle is moving in the x -direction with a speed of V_x and an altitude of h from a reference scatterer point on the scene. Therefore, the phase of the roundtrip EM wave that is reflected from the reference point is

$$\vartheta_1 = \exp[-j2k(x^2 + y^2 + (z - h)^2)^{1/2}] \quad (38)$$

On the next pass, the vehicle keeps the same height and speed, but its track is shifted by a distance of d in the y -direction. Therefore, the phase of the backscattered EM wave from the same reference point becomes

$$\vartheta_2 = \exp[-j2k(x^2 + (y - d)^2 + (z - h)^2)^{1/2}] \quad (39)$$

Multiplying the first phase with the complex conjugate of the second phase and expanding the difference to the first order of d yields

$$\vartheta_2 \times \vartheta_1^* \cong \exp\left(j \frac{4\pi y d}{\lambda R}\right) \quad (40)$$

where $R = (x^2 + y^2 + (z - h)^2)^{1/2}$. In this equation, R , y , and x are already known after applying the range and azimuth compression and the Doppler processing. If the separation d between two passes is known, the only unknown parameter z (i.e., height) can easily be calculated from Eq. (40). This process is the basic approach for IFSAR. An example of interferometric SAR is shown in Fig. 16. This image of Mt. Etna, Italy was obtained by the SIR-C/X-SAR in 1994. The image covers an area of $51.2 \text{ km} \times 22.6 \text{ km}$. Different elevation regions surrounding the volcanic Etna are illustrated with different color values.

4.3. SAR Polarimetry

For a conventional SAR, both the receiver and the transmitter are designed to have only one polarization, i.e., horizontal (H) or vertical (V). However, to extract the full scattering feature of a scene, all polarization signatures, HH, HV, VH, and VV, have to be known. When identical polarizations are used by scientists for transmit and receive, the SAR system is said to be at *copolarization*. When the radar collects the received field at orthogonal polarization to that of the transmitted field, then the SAR system is *cross-polarized*. The images obtained by these two

polarization cases may differ because of the different scattering features of the terrain. For smooth surfaces such as oceans, lakes, and deserts, the copolarized SAR image differs significantly from the cross-polarized one. However, both co- and cross-polarized SAR setups produce almost similar images for rough surfaces like mountains and forests. Manmade objects are always found to appear in the image for any type of polarization because most of them have the feature of a corner reflector. Therefore, identifying the features and material types of terrain structure such as rock type may be possible with the help of SAR polarimetry. Good polarimetric SAR images were presented by Held et al. [21] and Sullivan et al. [22].

4.4. Three-Dimensional SAR/ISAR

Conventional SAR/ISAR provides a 2-D image of a scene/target. For SAR, a 3-D image can be obtained with interferometric/polarimetric techniques as explained in Sections 4.2 and 4.3. For 3-D ISAR, the scattered data are collected in a two-dimensional aperture in angles. Under small bandwidth and small aspect constructs, if BW_f , BW_ϕ , and BW_θ are the bandwidths in frequency, azimuth, and elevation, respectively, then the corresponding image resolutions in range and two cross-range dimensions are given by

$$\Delta x = \frac{c}{2 \cdot BW_f} \quad \Delta y = \frac{\lambda_c}{2 \cdot BW_\phi} \quad \Delta z = \frac{\lambda_c}{2 \cdot BW_\theta} \quad (41)$$

where λ_c is the wavelength corresponding the center frequency. The rest of the imaging process is similar to what is outlined in the ISAR imaging algorithm in Section 3.2. Therefore, a 3-D image can be obtained by taking the following 3-D Fourier integral:

$$\begin{aligned} ISAR_{3D}(x, y, z) = & \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mathbf{E}_s(k, \phi, \theta) \cdot e^{j2k \cdot x} \cdot e^{j2k_c \phi \cdot y} \\ & \cdot e^{j2k_c \theta \cdot z} d(k) \cdot d(k_c \phi) \cdot d(k_c \theta) \end{aligned} \quad (42)$$

Recently, new SAR algorithms called antenna SAR (ASAR) [23] and antenna coupling SAR (ACSAR) [24] to image antenna–platform interaction have been developed. Unlike conventional ISAR imaging that uses backscattered field data from a target, these algorithms use

Figure 16. (SIR-C/X-SAR) Interferometric image of Mount Etna, Italy. (Courtesy NASA/JPL-Caltech.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

radiation field data off the antenna–platform pair. Both ASAR and ACSAR provide good-quality 3-D images of the antenna–platform interaction. An example of 3-D ASAR imagery is shown in Fig. 17. In this example, a monopole antenna operating at X-band is placed above the cockpit of the model aircraft. Three-dimensional multifrequency, multispect radiation data from the antenna–aircraft pair is collected at the far field from the nose-on. Figure 17 demonstrates eight different 2-D ASAR images corresponding to eight different slices of the target [23].

5. CONCLUSION

Synthetic aperture radar is a powerful and useful remote sensing technique primarily used by scientists for imaging Earth's surface. In this article, we mentioned many other applications of SAR from topographic imaging to mine detection. Some limitations and problems may occur while applying the SAR imaging process. For example, both range curvature and range walk may cause migration of the scatterers in the image. Furthermore, any moving target or nonlinear radar motion results in undesired Doppler shifts that lead various degradations (e.g., defocusing, shifting) in the resultant SAR image. Ground clutter or speckle is also a common problem in SAR imagery. Researchers are putting significant effort toward solving these challenging problems. Developments on SAR processing bring out many emerging SAR technologies in different fields. SAR-based *subsurface imaging* techniques

are the alternative approaches for detecting buried objects beneath Earth's surface or situated interior to a visually opaque medium [25–27]. Another interesting application is the *differential interferometry* [28–30]. In this method, SAR platform passes over the scene three times. If a change in the scene (like glacier motion or earthquake movement) occurs, the differential phases between the passes produce a value different than zero. Then, these changes can be detected and imaged. A similar technology is so-called *polarimetric interferometry* [31,32]. The idea in this method is to get the full scattering matrix (i.e., HH, HV, VH, and VV polarizations) at each end of the interferometric baseline. Once the full scattering matrix is acquired, optimum polarization orientation can be solved to maximize the interferometric coherence. In return, it becomes possible to measure interferometric differences at centimeter levels. Compensating induced errors caused by complex aircraft/target motions including 3-D movements has been a challenging topic since the invention of SAR. By applying joint-time frequency (JTF) processing to SAR/ISAR data, it is possible to compensate both the translational and the rotational motion errors that cause shifting and defocusing of scatterers in the resulting image [12].

TARGET TRACKING

OLIVER E. DRUMMOND
Consulting Engineer
Culver City, CA

1. TYPES OF TARGET TRACKING

Target-tracking problems can be broadly categorized into four generic classes, as follows:

1. Sensor tracking of a single (bright) target
2. Tracking of targets that are large
3. Tracking of targets that are medium-sized
4. Tracking of targets that are small

The target sizes indicated in this list are in terms of the number of resolution elements or pixels. The primary differences in each of these problems are the algorithms used in the signal, image, and track processing. The algorithms and processing methods used for each of these problems are substantially different. Of course, the system and its hardware must be designed to be compatible with and take advantage of the appropriate processing methods for an application. These methods depend on the types of algorithms used in the processing.

1.1. Sensor Tracking of a Single Target

Examples of the Class 1 tracking problem above are a gimbal-mounted telescope following a planet and an interceptor pursuing a target. Tracking is achieved typically through signal processing to locate the target in the field of view (FOV) and then guiding gimbals of the telescope (or seeker of an interceptor) to drive the target near the center of the FOV. This type of tracker is sometimes referred to as a closed-loop tracker. The signal from the signal processor is typically temporally filtered before it is sent to the telescope gimbal driver, and this filter may be fairly simple compared with a Kalman filter. For some applications in this class, the target may be small initially and then grow in size, such as with an interceptor sensor. Note that for this class of tracking problem, there is often only a single target in the FOV, and it is bright (high contrast) relative to any false signals or background objects. As a consequence, uncertainty about which are the target pixels and which are not is not a major issue. Thus, using sensor data obtained from a sequence of measurements over timepoints is fairly straightforward. In the future, however, as these systems are required to operate under more challenging conditions, the tracking algorithms developed for the other three tracking categories may be required. More challenging conditions might include initially tracking a dim target or a target with accompanying debris or countermeasures.

1.2. Tracking Large Targets

An example of a Class 2 tracking problem is the use of low-altitude surveillance sensors for locating or tracking ground targets. For that example, the target extent could cover many resolution elements that provide extensive detailed information about each target of interest and the other objects in the scene. With a large target, the components of the target might be identified such as wheels, tank treads, or airplane wings. Tracking and target recognition for this class of target are typically achieved through image-processing or possibly image-understanding methods. With a large target, image-processing methods could be used to determine the details of construction as well as shape of the target from only a single frame of data. With that information, normally a good probability of correctly identifying the target type for each target in the FOV with only a single frame of data is achievable. Furthermore, normally enough information exists to simply sort out and track each target over time. That is, no confusion exists about which target in one frame of data is the same target in another frame of data. Typically, image-understanding processing can be more complex than traditional image processing, but should be more versatile in handling various types of targets, including their shadows and obscurations caused by objects such as trees.

1.3. Tracking Medium-Sized Targets

An example of the Class 3 problem is use of medium altitude surveillance sensors for tracking ground vehicles. Tracking is typically achieved using either a correlation tracker or a centroid tracker. These methods are needed to deal with and possibly take advantage of the extent of the target. A target in this class might be 20 pixels in diameter. Typically, with a target of that size, not enough information useful for image processing is available, yet the extent should be taken into account. For example, for each timepoint, the location of the target needs to be established relative to some point on the target. That point on the target is then used to track the target over time. Thus a consistent point is needed on the target so that the estimated motion is not corrupted by use of different points on the target over time. With a *correlation tracker*, the processor finds the location that maximizes the correlation between the current image of the target and a reference target image. The appearance of the target can depend on the aspect angles, which can change over time, and that complicates the processing. The algorithms for correlation tracking usually are designed to accommodate all possible values of the aspect angles. A *centroid tracker* uses the shape and possibly the signal amplitude profile to establish a point on the target each time it is observed. For this type of target, the size and shape of the target helps in determining which target in one frame of data is the same target in another frame of data. This information can be corrupted by false signals, obscurations by other objects,

similar nearby objects, and random motions of the sensor line of sight.

1.4. Tracking Small Targets

An example of the Class 4 tracking problem is the use of ground-based surveillance sensors for tracking aircraft, cruise missiles, or ballistic missiles. Tracking small targets is achieved using what is commonly referred to as multiple target tracking methods. This class of problem is often referred to as *multiple target tracking*, even though it includes both single, small target tracking with persistent clutter or false signals and the tracking of multiple small targets that may be close or crossing and with possibly persistent clutter or false signals. For this class of tracking problem, uncertainty can exist as to which target is responsible for a measurement, because of closely spaced measurements. This uncertainty greatly complicates the processing. The processing function that decides how to relate the current measurements to the existing target tracks or prior data is called *data association* (sometimes referred to as correlation). The data-association function deals with the ambiguity of which measurement comes from each target that was observed earlier. In most small target tracking, there is not enough information in a sensor measurement to know which target (if any) was the source of the measurement. As a consequence, the wrong measurement might be used to update a target track, and this type of error is often referred to as a *misassociation*.

1.5. Impact of Target Conditions on Processing Methods

Not only does each of these classes of target-tracking problems call for different processing algorithms, but also the processing concepts and the algorithm development methodologies can be very different. For example, for the development of the small target-tracking algorithms, typically a simulation is used to generate data to test the algorithms. Many runs (instances) of a Monte Carlo simulation can then be used to obtain performance with reasonable confidence (given a sufficiently detailed simulation). On the other hand, to test image-processing algorithms for tracking large targets, usually a set of images of real scenes containing targets is used. Because typically it is difficult to obtain and test many hundreds of images, the methodology for algorithm development and performance evaluation of large target-tracking algorithms is very different from that for small targets. Also, the type of algorithms used for image processing are very different from those used for tracking small targets.

The track-processing methods used also depend on the type of sensor or suite of sensors that provide the data for a system application. The phenomena encountered for each type of sensor can have a significant impact on the type of processing required. For example, there are methods that can be used with an active sensor, such as radar, that cannot be used with a passive sensor, such as an electrooptical sensor. As a consequence, some specialized tracking techniques have been developed for some sensors that are not useful for others. Also, multiple-sensor systems require special considerations beyond those tracking

approaches used for single-sensor tracking. The type of target and its environment also have a major impact on the selection of the appropriate algorithms and the sequence of functions. The sequence of processing functions is often referred to as the *processing chain* or *algorithm architecture*. The algorithm architecture and specific algorithms appropriate to tracking ground targets can be very different from those used for surveillance of ballistic missiles.

2. INTRODUCTION TO SMALL TARGET TRACKING

Because each class of tracking problem poses different algorithm development issues, this article will concentrate on only one class of tracking, namely, tracking of small targets using multiple target-tracking methods. Multiple target tracking is a relatively new field. The first book dedicated exclusively to multiple target tracking was published in 1986 [1] and a number of books have been published since then [2–7]. In addition to the numerous papers and reports in the open literature (too numerous to be listed here), there is an on-going series of annual SPIE conferences concerned exclusively with signal and data processing of small targets that started in 1989 [8]. This article freely extracts and paraphrases material from some of the author's prior documents [9–15] and view graphs [16,17].

For this discussion, a *small target* is characterized as one that does not provide enough data for traditional automatic target recognition (ATR) using a single frame of data [9]. In contrast, a target large enough for ATR typically extends beyond a diameter of about 10 resolution elements, for example, larger than 10 by 10 pixels. Note that it is not uncommon to refer to all objects as targets whether they are of interest or not. Small targets include:

- Point source targets
- Small extended targets, including unresolved closely spaced objects
- Clusters (groups) of point source and small extended targets

The width of a typical point source target in the field of view is from 1 pixel to about 12 pixels (resolution elements), depending on the sensor design, for instance, the sensor spread function. Although the processing of point targets has been studied extensively, there are still many interesting challenges in this field. In contrast, the state of the art for processing small extended objects and clusters is far less mature, but interest is growing. Small targets that are not point-source objects include both small extended objects and unresolved closely spaced objects, sometimes called clumps. An *unresolved closely spaced object* (UCSO) refers to a measurement caused by a number of targets for which the location of each individual target could not be established by the signal processor because they were all too close relative to the resolution of the sensor. In many current systems, the data forwarded by the signal processor to the tracker do not give any indication of which measurement is probably a UCSO.

Although UCSOs and small extended targets provide little detailed information useful for ATR, they do exhibit some shape and size information that might be useful in tracking. Also, an extended object may partially obscure rather than add to the background or be partially obscured. The apparent size and shape of the target can differ from sensor to sensor and over time; this may have to be taken into account. Similarly, cluster processing offers significant advantages and challenges.

Developing a tracker to follow a single small target without false signals or persistent clutter is not particularly difficult. In contrast, developing a tracker is difficult for challenging conditions with resolved or unresolved closely spaced measurements caused by false signal, persistent clutter, or close targets plus possibly countermeasures or abrupt target maneuvers. Distributed multiple sensors that exhibit platform location uncertainty and residual sensor measurement biases pose additional challenges as do multiple sensors that exhibit different sensor phenomena, such as fusing data from radars and IR sensors.

There have been many advancements in small target processing algorithms in recent years. These advancements are, in part, because of opportunities to implement more advanced and complex algorithms because of the greatly increased capabilities of processors. Ongoing development of algorithms for new systems and upgrading existing systems is driven by improved sensors, increasingly demanding system requirements, processor and communications hardware limitations, severe operating environments, efficacious countermeasures, and challenging threat scenarios. There is growing interest in the ability to track dim targets or in a moderate to dense population of threshold exceedances caused by clutter, false signals, or targets that are close or crossing.

A common approach for processing target data from a single sensor is to partition the processing into the two major functions of signal processing and data processing, as shown in Fig. 1. The *signal processing* usually converts the sensor data into digital form, processes and thresholds the data to detect potential targets, and establishes the parameters of the measurement vector for each threshold exceedance. The type of signal processing algorithm used is highly specialized, based on the type of sensor. For systems that require detection of dim targets, multispectral sensor processing and the more complex multiple frame processing should be considered, such as the so-called

track-before-detect and the velocity filter approaches. The signal processor forwards the measurements to the data processor. Measurements are sometimes referred to as reports, returns, observations, hits, plots, or threshold exceedances, depending on the type of sensor. Typically, the signal processor forwards the measurements to the data processor in the form of a sequence of frames of data. A *frame of data* is simply a collection of measurements. For radar, a frame might consist of all the measurements from a single dwell, and for an IR imaging sensor, a frame of data might be all the measurements from a single look of the imager. Note in Fig. 1 the possible use of track data at the signal processing level. There is a growing recognition of the importance of using all available information in every stage of the processing and in the feedback of information [9].

The primary functions of the *data processing* of sensor data are tracking and target classification or discrimination; however, estimation of sensor registration biases, sensor resource management, situation assessment, combat identification, target weapon assignment, and other functions may also be included. Typically, a target evolves through the three processing stages of (1) track initiation, (2) track maintenance, and (3) track termination, see Fig. 2. The basic tracking functions for each stage are data association, filtering, and the track promotion and demotion logic. As mentioned earlier, the data-association function deals with the ambiguity of which measurement is from the same target as that of a track or a sequence of prior measurements.

The *filter* uses the measurement vector to update the target state estimate, its error covariance matrix, and possibly additional information. The elements of the target state typically consist of the target position and velocity in each direction plus possibly higher derivatives and other information, such as signal signature information or target features. For this discussion, the filter is assumed to be a Kalman filter or its mathematical equivalent [1,2,5]. Usually, process noise can be used in the filter model to accommodate gradual target maneuvers. If a target can make abrupt maneuvers, then a bank of Kalman filters might be used as with the interacting multiple model filters [5,18], which accommodates switching from one model to another. A bank of Kalman filters can also be used for multiple model problems that do not exhibit switching, sometimes called static multiple models [19,20]. An example

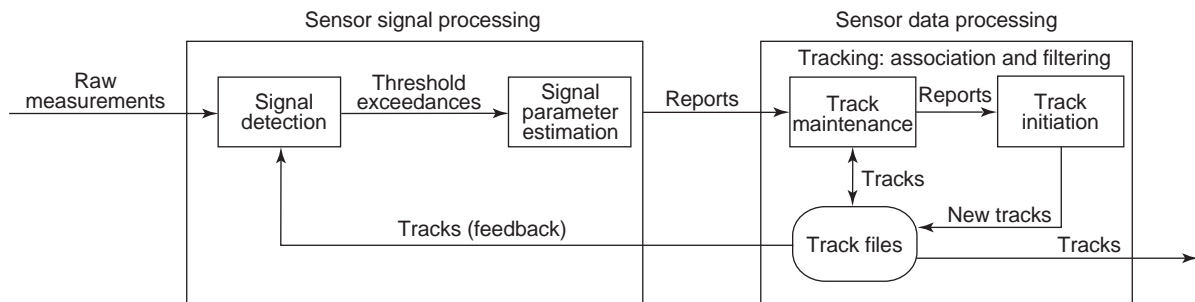

Figure 1. Block diagram of the major sensor processing functions of signal processing and data processing [9].

of the use of static multiple models is for tracking a single-stage booster that might be one of a number of different types of boosters.

Note that the Kalman filter equations are not very difficult to implement; it is the selection of the structure of the model and its parameter values used to design the filter that require pertinent background and experience. In addition, most target-sensor mathematical models are neither linear nor Gaussian, and thus some variant of an extended Kalman filter is typically used [2,5]. Nonlinearities can introduce biases in the estimation errors [6] and, in addition, unexpected results caused by the approximations used to deal with the nonlinearities are not uncommon.

For target tracking, the accuracy of both the target state estimate and its error covariance matrix (or mean square error matrix) are important. For many filtering problems other than for tracking, the accuracy of the state estimate is more important than the consistency of the error covariance matrix. Consistency in this context refers to how well the filter computed error covariance matrix reflects the actual covariance matrix of the state estimation errors. In addition, the state estimate is somewhat adaptive to model errors, but the error covariance matrix is not, which is because the computation of the state estimate is a function of the measurements that depend on the target location and motion. As a consequence, even with model errors, the computed state estimate is influenced by the true target trajectory. In contrast, the covariance matrix depends on the mathematical model used for the filter design, and in a linear system, for example, the computed filter error covariance matrix is not a function of the measurements.

In most tracking systems, the data-association function performance depends on the consistency of the computed filter covariance matrix. Hence the consistency of the error covariance consistency is substantially more important in tracking than in many other types of filtering applications and should be evaluated during the algorithm development process. Note that because the track error covariance matrix indicates how accurate a track is, this information might be useful for the functions downstream of the tracker. The consistency of the error covariance matrix is degraded by not only the filter design model errors but also by misassociations and more so with some data-association algorithms than others.

A fundamental characteristic of small target tracking is that optimal tracking is not practical. The algorithms that would provide optimal tracking performance are too complex primarily because of the data-association function but also because most systems are neither linear nor Gaussian. For *optimal tracking* performance, each possible combination of all target tracks with all the measurements obtained up to the current time must be enumerated, and that is not practical. As a consequence, a wide variety of suboptimal methods have been devised. In algorithm development, the major trade is between tracking performance and the processor loading plus, if applicable, communications loading. This is the major tradeoff, because improved performance can be obtained by more complex algorithms that are more hardware resource intensive.

Another fundamental characteristic of small target tracking is that it involves both discrete and continuous random variables or parameters. The measurement-track ambiguities introduce discrete random variables or hypotheses. Each *hypothesis* represents one combination that accounts for all the apparent targets and all the measurements. The continuous random variables are the elements of the target state vectors. Most estimation theory deals with random variables from a continuous sample space and decision theory deals primarily with random variables from discrete sample space. The combination of continuous and discrete random variables can lead to unusual results compared with the more classic estimation problems. The hypotheses can cause the *a posteriori* state probability density function to be multimodal, which can lead to unexpected tracking performance and estimation errors that clearly do not exhibit a Gaussian distribution.

As a consequence of the resulting complex nature of the estimation errors, multiple target-tracking performance evaluation and prediction are not very amenable to analysis. Therefore, usually performance is evaluated through Monte Carlo simulations followed by field testing. Monte Carlo runs are needed because tracker performance is data dependent because of misassociations and system nonlinearities. In addition, low-probability events might cause surprisingly poor performance that might not be uncovered with only one or a few Monte Carlo runs. The need for a simulation poses a dilemma because the performance evaluation results of simplistic simulation can be misleading and not reveal realistically all the phenomena or anomalies that will occur in the ultimate system. On the other hand, a more credible simulation of the targets, sensors, and signal processing characteristic can be very costly, and the simulation can be complex and difficult to manage. Typically, the simulation used to design and develop a system evolves, starting from simple simulations for preliminary evaluation of well selected critical functions to a complex high-fidelity simulation of the entire tracking system. The simulation environment needs to be flexible enough to easily accept major revisions to the tracker algorithms and the algorithms architecture, as well as new or modified sensor designs and targets.

Because optimal tracking methods are too complex to be practical, ad hoc algorithms are typically devised that take advantage of the particular targets, sensors, and related conditions of the system for which the tracker is designed. As a consequence, there is no universal tracker, although there might be a tracker that is developed for a particular type of scenario. Trackers are continually being developed to accommodate new requirements or target threat characteristics and to take advantage of increases in processor and communications capability as well as new or improved sensors.

Algorithm development of a tracker for a system is typically an experimental and iterative process, which is because of the undesirable performance that results from misassociations and unexpected operating conditions that are revealed through high-fidelity simulations and hardware in the loop testing. Each stage of the algorithm development spiral typically includes a reevaluation of the requirements and performance obtained during the

prior stage, algorithm redesign or replacement, performance evaluation testing, and study of the results. During algorithm development, it is not uncommon to have to replace some algorithms (or make major modifications to them) because of unexpected operating conditions or performance results. Thus care is needed in undertaking software development of the deliverable code before the algorithm development process is complete.

In describing the various target-tracking methods, tracking with data from a single sensor is discussed before discussing tracking with multiple sensors, which is more complex. Also, single target tracking is discussed before multiple target tracking because the tracking of multiple targets is substantially more complex than tracking a single target. The major emphasis in this article is on the data-association function, because that is the process that is unique to small target tracking relative to most other estimation tasks. The targets are assumed to be noncooperative in that, typically, they do not purposely communicate to the trackers their identity or location as is done for air-traffic control.

3. SINGLE TARGET TRACKING WITH FALSE SIGNALS

The methods used to track a single target can be useful also for tracking multiple targets, provided they are far apart. Targets that are far apart are sometimes referred to as isolated targets [16,17]. *Isolated targets* are far enough apart so that all of the measurements in the immediate neighborhood of a target track have a very low probability of being caused by another target. In both single and multiple target tracking, a processing function is used to compute a track gate that defines the immediate neighborhood of measurement for a track. The processing functions for tracking isolated targets are shown in Fig. 2.

3.1. Track Gate

A *track gate* is also called a validation region or correlation window [1,2,6]. For most tracking methods the gate function simply serves to reduce the processing load and has

little impact on performance if the track gate is big enough. To compute a simple yet practical gate, the filter function computes the expected location of the measurement for a target, which establishes the center of the gate. Then it establishes the extent of the track gate by computing the region around the predicted measurement in which the measurement caused by the target is expected to be located with a prescribed probability (given that the target is detected). A practical value is 0.99 for the prescribed probability that the correct measurement is in the track gate [17].

The size of the target gate region is computed using the innovations covariance matrix. The *innovations vector* is the difference between the measurement vector and the predicted measurement computed from the predicted target state vector. Thus the innovations covariance matrix takes into account the error in the prior target state estimate, the prediction error, and the measurement errors. The innovations are sometimes called the residuals, which is not to be confused with the measurement residuals. The *measurement residual* vector is the difference between the measurement vector and the estimated measurement computed from the estimated target state vector after being updated using that measurement.

The use of two gates each with a different shape can help reduce the processing load. For two-dimensional measurements such as with a passive sensor, for example, the first gate is a rectangle that is sized to include the second gate, which is an ellipse. The rectangular gate is less computationally intensive but is not as effective. The rectangular gate eliminates most of the measurements that will not be in the elliptical gate. The elliptical gate requires more computations, but is more effective in that it produces fewer measurements in a gate for a given probability that the correct measurement is in the gate [1,17]. An elliptical gate involves the computation of a chi-square static. In contrast, determining if a measurement is in a rectangular gate requires the computation of only a few comparisons, each preceded by the computation of the absolute value of a difference. There are other methods of computing a track gate, but for brevity they are not discussed here.

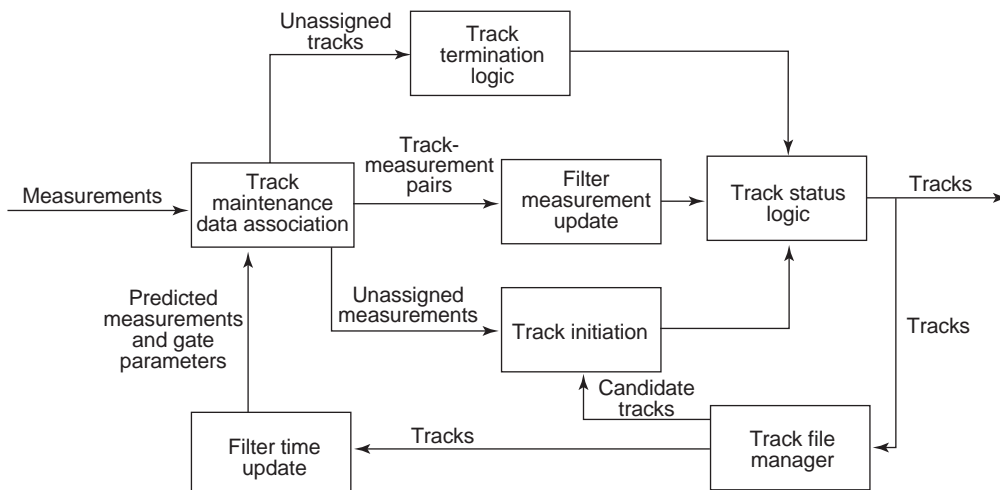

Figure 2. Block diagram of the processing functions for tracking isolated targets [17].

3.2. Data-Association Methods

For simplicity, consider single target-track maintenance, that is, assume that the target track has already been established. The tracking methods for multiple isolated targets is very similar, and track initiation, which is more complex, will be addressed later. The gate computation is the first function of the data-association process. Then, given the track gate, identify the measurements in the track gate by testing each measurement to determine first if it is in the rectangular gate and, if so, determine if it is in the elliptical gate. For a measurement vector that contains more than two elements, the rectangular and elliptical gates are replaced by their higher dimensioned counterparts. How the measurements that are in the track gate are subsequently processed depends on the chosen data-association method.

Data-association approaches can be classified as single-frame and multiple-frame methods [10,16,17]. For single target tracking, a measurement in a track gate is either a false signal or the detected target. (Note that a measurement could be because of persistent clutter. An estimate of the location of persistent clutter should be maintained because the target might pass through its neighborhood. Accordingly, persistent clutter is equivalent to a target that is not of interest and hence is in the multiple target tracking category rather than single target tracking.) Two single-frame approaches are described for single target tracking, whereas discussion of the multiple-frame data association methods are deferred to the multiple target-tracking section.

A *single-frame association* approach typically enumerates most or all the possible hypothesis tracks for a frame of data. The hypotheses are generated based on a single prior track that remains after completing the processing for the prior frame of data. For single target tracking with M measurements in the track gate, there are $M+1$ hypotheses, one for each measurement in the gate and one for the null hypothesis that the target was not detected in the gate for that frame of data. After the hypotheses are enumerated, the number of tracks is reduced to, at most, one track per apparent target for use with the next frame of data. Typically, the number of tracks of the current hypotheses is reduced to a single track by eliminating some, combining some, or both. The resulting single-state estimate will be referred to as the *composite state estimate*, and the composite state estimate and its covariance matrix (plus possibly additional information) will be referred to as the *composite track* [11].

A single-frame data-association algorithm does not reprocess sensor data from prior frames, does not update the prior probabilities of the hypotheses, and carries forward in time at most one track per apparent target. As a consequence, multiple-frame data-association approaches, described later, typically perform better than single-frame approaches. To their advantage, single-frame data-association algorithms are not as complex or processing intensive as multiple-frame methods and do not require as extensive an algorithm development effort.

The two best known single-target, single-frame data-association approaches are the nearest neighbor and the

probabilistic data-association filter. These approaches illustrate two very different types of decisions. The nearest neighbor approach makes *hard decisions*, that is, the association weight used for each measurement in a track gate is either zero or one. By contrast, the probabilistic data-association filter makes *soft decisions*, that is, the association weight used for each measurement in a track gate is usually between zero and one. With soft decisions, typically the sum of the weights for a track is one. The weights for a track include a weight for the possibility that none of the measurements in a gate are caused by the target.

3.2.1. Nearest Neighbor Tracking. The nearest neighbor (NN) algorithm is designed for tracking a single target, and only one track is carried forward for processing the next frame of data. This algorithm is sometimes referred to as the independent nearest neighbor (INN) algorithm to emphasize that each track is processed without regard to any other track. It *trims* (prunes) the hypotheses down to a single hypothesis by eliminating all but one hypothesis [1,2,6,16,17]. For each frame of data, the NN algorithm assigns the (statistically) nearest measurement to the track. The statistical distance measure used is typically the same chi-square value that is computed for the elliptical (or hyperellipsoidal) track gate. If the gate extent is sized appropriately, then an empty gate corresponds to the hypothesis that every measurement outside the gate is more probably a false signal than a detection of the target. Essentially, this is equivalent to finding the most probable hypothesis for each frame of data constrained by the decisions of the prior frames.

The NN algorithm is easily understood and implemented. It does not perform well, however, except with a low measurement density, such as up to an average of about 0.1 false signals in a 0.99 gate [1,2,16,17]. (A 0.99 gate means that there is a 0.99 probability that the measurement caused by the target will be in the gate given that it is detected.) Note that the average number of false signals in a 0.99 track gate is a relative measure of density, not absolute, because it depends on the gate size that depends, in turn, on the accuracy of the track and measurements. With the NN algorithm, how dense the measurements can be and still provide adequate performance depends on the specific application and its characteristics, such as probability of detection and number of elements in the measurement vector. The error covariance matrix for the resulting composite track is the covariance matrix of the most probable hypothesis track. The error covariance matrix of the composite track does not take into account the possibility that the most probable hypothesis track is the wrong track. In effect, this is equivalent to neglecting the possibility that the selected hypothesis is not the correct one. Thus the error covariance matrix for the NN track is optimistic, that is, the variance elements of the filter computed error covariance matrix are frequently smaller than the corresponding actual variances exhibited by the estimation errors.

3.2.2. Probabilistic Data-Association Filter. With the probabilistic data-association filter (PDAF) approach, all

current hypotheses are computed and then *combined* to obtain a single track for the apparent target [1,2,6,16,17]. Conceptually, the target state estimate and its error covariance matrix are computed for each hypothesis. Then the target state estimates of the hypotheses are combined into a single-composite target state estimate by computing their average using a weighted average. The weights are the probabilities of each of the hypotheses. The probabilities are a function of the same chi-square values that are used in track gating.

The error covariance matrix of the resulting composite state estimate is the sum over the hypotheses of the probability of each hypothesis times the error covariance matrix for the hypothesis plus the outer product of the difference between the hypothesis estimate and the composite state estimate. The equations for these computations are a special case of the ones discussed later in the multiple target-tracking section. However, if the measurement error covariance matrix is the same for all measurements and only one track is brought forward from the prior frame of data, the computations can be simplified [1,2,6]. The composite track is then provided to the user, and it consists of the composite estimated state and its error covariance matrix for the apparent target. (The term *apparent target* is used because a track might not be following a target, but instead can be based on mostly, or exclusively, false signals.) This track is also used for processing the next frame of data, that is, the composite track is used instead of the hypotheses tracks as a basis to enumerate the hypotheses for the next frame of data. Accordingly, the number of hypotheses that must be enumerated for the next frame of data is greatly reduced.

Typically, the PDAF exhibits better tracking accuracy and fewer lost tracks than does an NN tracker if more than an occasional false signal in the track gate occurs [2,6]. A *lost track* is one that was following a target but later was not following any single target. The mean-squared estimation errors are typically smaller for the PDAF than for the NN tracker because the weighted averaging using the association weights tends to “hedge the bets.” A disadvantage of the PDAF tracker is that it is more processor intensive than the NN tracker and soft decisions might degrade features or attributes used for target classification or by the battle manager.

The PDAF-computed composite error covariance matrix is usually more realistic than that of the NN tracker. The error covariance matrix of the PDAF composite estimate adapts to the sensor data because it depends on the number of measurements in the gate and how they are distributed. The variance elements of the error covariance matrix of the composite track usually will be small when there has been a sequence of frames with few false signals and large when there have been many false signals. Also, the value of the variance elements in the covariance matrix will increase when the track gate is empty. Thus both the PDAF composite state estimate and its covariance matrix are data dependent. The actual (true) error covariance matrix of a composite estimation problem is usually data dependent and the covariance matrix computed by the PDAF is also because it is an approximation to the actual error covariance matrix. Note that this is

very different from a traditional linear, Gaussian estimation problem, for which a single Kalman filter can be used, and both the actual and computed state estimation error covariance matrix do not depend on the values of the measurements.

In some tracking systems, single target-tracking approaches are used to track multiple targets. For example, the NN algorithm or the PDAF might be used to track multiple targets. As a result, each apparent target is tracked independent of the other apparent targets, that is, without the aid of information from tracks of the other apparent targets. Independent target tracking is justified with isolated targets. If some targets are closely spaced, improved performance will be obtained by using a multiple target-tracking approach that coordinates the processing of the tracks by using the prior multiple track data more effectively rather than using an isolated target-tracking approach.

4. MULTIPLE TARGET TRACKING

A variety of single-frame and multiple-frame data-association methods have been devised for tracking multiple targets with data from a single sensor. In discussing some of these methods, it is assumed that false signals and closely spaced targets can occur. Furthermore, it is assumed that persistent clutter points are treated as targets; however, to simplify the discussion, the assumption is that no UCSOs occur. When discussing hypotheses for multiple target tracking, the term *hypothesis* refers to a multiple-target hypothesis; that is, each hypothesis accounts for all target tracks and all measurements in the applicable sensor data.

In multiple target tracking, a frame of data will normally contain measurements from many targets. Most tracking algorithms assume that the signal processor provides measurements in a sequence of proper frames of data. A *proper frame of data* is a collection of measurements wherein no two measurements are from the same target. Performance is expected to degrade if the frames of data are smaller than is practical or are not proper frames.

Before discussing some of these suboptimal tracking methods, it is instructive to first discuss optimal tracking. It is useful to discuss optimal tracking for at least two reasons. First, the equations of optimal tracking are also used in suboptimal tracking but in a different way. Second, optimal tracking displays important properties that are helpful in understanding the characteristics of practical, suboptimal multiple target-tracking methods and in designing those methods.

4.1. Optimal Tracking of Multiple Targets

There is no single method for optimal tracking because different optimization criteria lead to different optimal tracking algorithms even for a linear, Gaussian problem [15]. This characteristic of target tracking is very different from the more traditional linear, Gaussian estimation problem, for which the Kalman filter is optimal for most optimization criteria. Other complexities unique to the multiple target estimation task also exist that muddy the

issue of what is meant by the optimal estimate, but that issue need not be explored here [15]. To limit this discussion, a simple scenario is addressed and with but two optimization criteria.

Suppose that at time zero the tracking system receives a handoff of tracks from another system that has (somehow) established a set of tracks for all the targets that includes credible error covariance matrices for all the target tracks. Furthermore, the handoff estimation errors for each target exhibit a Gaussian probability distribution and are not cross-correlated from target to target. The system has a linear sensor with measurement errors that exhibit a Gaussian probability distribution. Furthermore, the target motion is described by linear vector state equation and, if process (state) noise is applicable, it exhibits a Gaussian probability distribution. Note that this is not only a “nice” linear, Gaussian problem, but the number of targets is known, which greatly simplifies the problem.

In optimal tracking, all hypotheses and all their tracks must be retained for use in processing the subsequent frames of data. A bank of Kalman filters can be used to compute the state estimates for each target track for each hypothesis. Fortunately, a target track based on a specific sequence of measurements is used in more than one hypothesis so that some economy of processing is obtained by taking advantage of that fact. Equations for computing the probability for each hypothesis are given in Table 1. These equations apply to optimal multiple target tracking

for most optimization criteria. The notation used here is consistent with typical Kalman filter notation, except that the estimates are also conditioned on the hypothesis, as can be seen from Eq. (1d). The optimization criterion determines how the estimates of the hypotheses are processed to establish the single best track for each target. For the minimum mean-square error (MMSE) criterion, the equations for the optimal composite estimate are given in Table 2. Table 3 amplifies on the equations used to compute the probability of the innovations used to compute the probability of each hypothesis. All the current hypotheses are retained and used as a basis for computing the hypotheses’ tracks when the next frame of data becomes available. In contrast, the composite tracks are re-computed after every frame of data becomes available, based on the tracks of all the current hypotheses and their probabilities.

Note that the equations in Table 1 permit the targets’ state vectors to be handled in two different ways. If any of the random variables related to one target are cross-correlated with those of another target, then state vectors of all the targets are concatenated into a single “system state vector,” which consists of all the state vectors for all the targets. The equations of Table 2 are treated this way. Note from Eq. (2d) of Table 2 that the individual target tracks of the composite estimate are cross-correlated because of the last term, that is, the outer product in that equation. The second method for handling the target

Table 1. Block 2 Optimal Multiple Target Estimation Equations [16,17]

$p[z(n) Z(n-1)] = \sum_{k_n} \omega_{k_n}^*(n)$	(2a)
$\omega_{k_n}(n) = \omega_{k_n}^*(n) / \sum_{k_n} \omega_{k_n}^*(n)$	(2b)
$\hat{\mathbf{x}}(n) = \sum_{k_n} \omega_{k_n}(n) \hat{\mathbf{x}}_{k_n}(n)$	(2c)
$P(n) = \sum_{k_n} \omega_{k_n}(n) [P_{k_n}(n) + [\hat{\mathbf{x}}_{k_n}(n) - \hat{\mathbf{x}}(n)] [\hat{\mathbf{x}}_{k_n}(n) - \hat{\mathbf{x}}(n)]^T]$	(2d)
where	
$\omega_{k_n}(n) = p[k_n Z(n)] = \text{hypothesis probability}$	(3a)
$\hat{\mathbf{x}}(n) = E[\mathbf{x}(n) Z(n)] = \text{composite estimate}$	(3b)
$P(n) = \text{composite estimate covariance}$	(3c)

states applies if no target-to-target cross-correlation exists [see Eq. (1w)].

To illustrate that two different optimization criteria lead to different optimal multiple target-tracking algorithms, Table 4 provides the optimal composite estimate for the joint maximum a posteriori probability (JMAP) criterion [11,15–17]. Note that Eq. (2d) in Table 4 shows that any estimate that is not the same as optimal MMSE estimate will have a larger actual error covariance matrix [11,16,17]. Also note from that equation that any suboptimal hypothesis estimate will exhibit cross-correlations between the individual target hypothesis tracks because of the outer product term.

The optimal single track (in the minimum mean square sense) for an apparent target at any one time is a composite track that is the appropriately weighted sum of tracks for that apparent target contained in all the multiple-target hypotheses. To illustrate the magnitude of the complexity for optimal tracking without missed signals or false signals, N_T targets and N_F frames of data would require the enumeration of $(N_T!)^{N_F-1}$ hypotheses (assuming no tracks based on prior data are available).

It is the retention of all the hypotheses and all their tracks that makes optimal tracking impractical. Clearly, optimal tracking is a multiple-frame data-association approach with the number of frames in the data association equal to number of frames of data available. The so-called “gated optimal” tracking is optimal tracking except that gates are used to eliminate unlikely track-measure-

Table 3. Hypothesis Innovations Probability Equations for Optimal Multiple-Target Estimation [15–17]

For linear, Gaussian conditions:	
$p[v(n)] = \frac{e^{-\chi^2/2}}{(2\pi)^{M/2} \sqrt{ S }}$ for $\chi_{k_n}^2$ or χ_{ij}^2	(1)
$\chi^2 = \hat{\mathbf{v}}^T(n) R^{-1} \hat{\mathbf{v}}(n) + [\hat{\mathbf{x}}(n n-1) - \hat{\mathbf{x}}(n)]^T P^{-1} (n n-1) [\hat{\mathbf{x}}(n n-1) - \hat{\mathbf{x}}(n)]$	(2a)
$\chi^2 = \mathbf{v}^T(n) S^{-1} \mathbf{v}(n)$, $\mathbf{v}(n) = \mathbf{z}(n) - H(n) \hat{\mathbf{x}}(n n-1)$	(2b)
$S^{-1} = R^{-1}(n) - R^{-1}(n) H(n) P(n) H^T(n) R^{-1}(n)$	(3)
$S = H(n) P(n n-1) H^T(n) + R(n)$	(4)
where	
$S \triangleq E[\mathbf{v}(n) \mathbf{v}^T(n)]$, $M = \text{length} [v(n)]$	(5)
$\hat{\mathbf{v}}(n) = \mathbf{z}(n) - H(n) \hat{\mathbf{x}}(n)$	(6)

$P_{\text{MS}}(n) = \text{MMSE mean square error matrix}$	(3e)

ment pairs [16,17]. The gating process reduces processing complexity, but, because it is a trimming process, the results are suboptimal.

4.2. Single-Frame Data-Association for Track Maintenance

Single-frame data-association approaches for multiple target-track maintenance include the global nearest neighbor algorithm and joint probabilistic data association.

4.2.1. Global Nearest Neighbor Tracking. The global nearest neighbor (GNN) tracker uses a single-frame data-association algorithm that makes hard decisions. It is an extension of the INN tracker for use with multiple targets. There is a number of different implementation approaches to GNN tracking. One version of the GNN finds the most probable (multiple-target) hypothesis for each frame of data constrained by the decisions of the prior frames. This version will be referred to as (multiple-target) single-frame most probable hypothesis (SF-MPH) tracking. Only one track per apparent target is carried forward for processing the next frame of data. Rather than enumerate all the hypotheses, typically an *optimal, unique, 2-D assignment algorithm* is used to find the most probable hypothesis, and that greatly reduces the amount of computations [1]. The assignment algorithm assigns measurements to tracks. The term *unique* in this context means that no track is assigned to more than one measurement and no measurement is assigned to more than one track. The 2-D qualifier refers to two dimensions because there are two data sets that are involved, namely, measurements and tracks, and therefore the assignment cost array is a matrix. Note that although finding the optimal (minimum cost) solution to a two-dimensional assignment problem is tractable, it turns out that a higher dimensional assignment problem is not. Also note that an optimal unique assignment algorithm does not provide optimal tracking.

In the past, suboptimal assignment algorithms were used to further reduce the amount of computations. However, there is little advantage to using a suboptimal assignment algorithm because now very fast optimal 2-D assignment algorithms are available. These

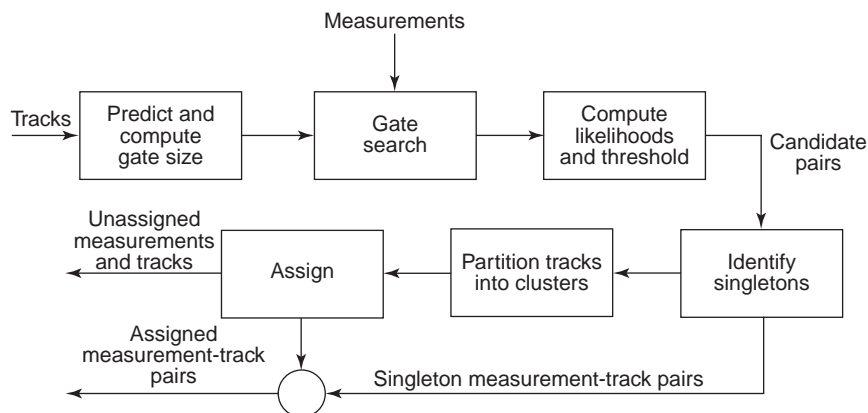

Figure 3. Typical block diagram of functions for single-frame data association [16,17].

algorithms are fast because they take advantage of the sparseness of the cost matrix. The sparseness occurs because not every measurement is in every track gate. A unique assignment algorithm is able to find the most probable hypothesis because of the basic structure of the equation for the probability of a hypothesis, provided the target-track-to-target-track cross-correlations are neglected.

Figure 3 displays a block diagram of the data-association functions for use of a 2-D assignment algorithm. The gate search function determines which measurements are in the rectangular track gates (or its higher dimensioned version). A simplistic algorithm should not be used for this function if many targets occur in any one region. For example, if two loops were used (one for measurements and one for tracks) for the gate search function, then 100 targets and 100 measurements would require 10,000 evaluations to determine which measurements are in each track gate. More ingenious methods will greatly reduce this number. The likelihood function serves to perform the elliptical (or hyperellipsoidal) gate process and also to compute the cost value for use in the assignment matrix. The chi-square calculation of Eq. (2) in Table 3 is often used for the cost in the assignment matrix [1,16,17]. *Singletons* are simply obvious measurement-track pairs for which there is no contention and thus need not be included in the assignment algorithm [16,17]. If many targets occur, then there may be an advantage to partitioning the tracks into what are called track clusters may exist. Tracks are partitioned so that no measurement in the gate of a track in one cluster is also in the gate of a track that is in another cluster. Track clusters should not be confused with target clusters, which are groups of targets whose state vectors are approximately the same. The purpose of partitioning tracks is to reduce the processing load but will not necessarily reduce processing if a state-of-the-art assignment algorithm is used.

The last function in Fig. 3 is the assignment algorithm, which uniquely assigns measurements to tracks. This block diagram is applicable with modification to other data-association approaches. The unassigned measurements are normally forwarded to the track-initiation function, and the unassigned tracks are tested for possible termination (see Fig. 2). The advantage of the GNN approach is that it does take into account multiple tar-

gets by using the multiple tracks and all the measurements in a frame of data (or partition). Also, it is relatively easy to implement, compared with other data-association methods and is not very processing intensive. In addition, this approach tends to adjust for shifts in the data from frame to frame because of interframe jitter. The disadvantage is that false signals and new targets tend to degrade performance. This might be an appropriate tracking approach for implementation early in the algorithm development stage for a new system and then followed later by a more advanced and complex tracking approach, if needed, when the system characteristics are better understood and established.

4.2.2. Joint Probabilistic Data Association. The joint probabilistic data-association (JPDA) tracker uses a single-frame data-association approach that makes soft decisions. It is an extension of the PDAF tracker for use with multiple targets [1,2,6]. In the JPDA approach, all current hypotheses are computed and then combined to obtain a single composite track for each apparent target. These composite tracks are used to provide to the user the estimated state and its covariance matrix for each apparent target. Also, for processing the next frame of data, the composite tracks are used instead of the hypotheses' tracks. Accordingly, the number of hypotheses that must be enumerated for the next frame of data is greatly reduced compared with optimal tracking. The equations of Table 1 are applicable to JPDA, but normally the target-track-to-target-track cross-correlations are neglected. A JPDA tracker is expected to perform better than the GNN tracker as the number of false signals or new targets increases. The JPDA is more processing intensive and requires more complex computer programming and algorithm development effort than the GNN approach. In addition, the soft decisions of the JPDA tracker might degrade features or attributes used for target classification or by the battle manager. Fortunately, the computed composite error covariance matrix of a JPDA tracker is usually more realistic than that of the GNN tracker.

A unique feature of the JPDA approach is that it permits the computation of the probability that a specific measurement is caused by because of the same target that a specific track is following. Similarly, the probability that a

measurement is a false signal or caused by a new target can also be computed. These probabilities can be used for a variety of purposes beyond simply computing the composite state estimate and the error covariance matrix for each track. These probabilities are sometimes referred to as marginal association probabilities, and the details for computing them depend in part on a number of assumptions, such as the mathematical model used for the false signals [1,2,6].

4.3. Multiple-Frame Data Association for Track Maintenance

Multiple-frame data-association approaches include the algorithm by Singer, Sea, and Housewright, multiple-hypothesis tracking, Poore's tracker, and other algorithms [10,11]. Typically multiple-frame data-association approaches enumerate (and also carry forward to the next frame) more candidate tracks than do single-frame approaches. Consequently, multiple-frame data-association approaches typically provide better estimation accuracy and fewer false and missed tracks than single-frame approaches. However, multiple-frame data-association algorithms are more complex and processing intensive, and they require substantially more effort in design, development, and test.

4.3.1. Singer, Sea, and Housewright Tracker. The Singer, Sea, and Housewright (SSH) tracker was designed for tracking a single target with false signals [21], but has been extended to multiple target tracking. It is sometimes referred to as the " n -scan back" approach [2] and is similar to the JPDA approach, except that it maintains more than one track per target for processing the next frame of data. The algorithm uses local combining to reduce the number of tracks. Tracks are selected to be combined if they use the same measurements in the latest N frames of data and the same target track $N + 1$ scans back. The number of frames, N , used in the combining process is a design parameter. Although the SSH algorithm can be classified as a multiple-frame, probabilistic data-association approach, it uses local rather than global combining and uses measurements as the criteria for forming local composite tracks. Because it usually retains more than one candidate track per target from frame to frame, it should perform better than JPDA but increases the processor load and requires more extensive algorithm and software development.

4.3.2. Multiple-Hypothesis Tracking. Multiple-hypothesis tracking (MHT) typically carries more than one hypothesis track per apparent target forward for processing the next frame of data. Many different versions of MHT have been developed since its original conception [22]. In MHT, for practical reasons the number of hypotheses is limited by both eliminating and combining some hypotheses and tracks [1,7,22]. In the original MHT, the typical combining (merging) process is local rather than global. Given four hypotheses' tracks for a single apparent target, for example, two similar hypotheses tracks might be combined (merged) to form one hypothesis track, a "local" composite. As a result, the four hypotheses tracks would be reduced to three. Then

one of these three, the one with the smallest hypothesis probability, might be eliminated so that only two tracks would be forwarded for processing with the next frame of data for that apparent target. In order to compute the needed probabilities, all the current hypotheses are enumerated and the (multiple target) hypotheses' probabilities computed. The computations for these probabilities are similar to those in Table 1.

MHT should perform better than the other tracking approaches just discussed. Improved performance is obtained at the expense of an increase in processing load, computer programming, and algorithm-development effort. Many organizations either have developed or are developing MHT or similar trackers and some are on their second- or third-generation (incarnation) multiple-frame tracker. Some of the more recent MHT approaches use a sliding window of multiple frames of data, which is similar to the method discussed in Section 4.3.3. In MHT, however, there is additional pruning of unlikely candidate tracks and combining of similar candidate tracks for a target to reduce the number of multiple target hypotheses that must be enumerated.

4.3.3. Multiple-Frame Most Probable Hypothesis Tracker.

Poore's tracker is similar to MHT but does not use any local combining or trimming; it uses deferred global trimming. His tracker employs a sliding window of $M - 1$ frames of data [23]. The window also includes tracks based on data up to and including M frames back, that is, the tracks are based on all data except the latest $M - 1$ frames of data. The tracker then uses an M -D assignment algorithm to seek the most probable hypothesis for the $M - 1$ frames of data given the tracks M frames back. This is a multiple-frame most probable hypothesis (MF-MPH) tracker. The M frames back tracks are then updated just one frame of data using the measurements in frame $M - 1$ back that are paired with those tracks in the most probable hypothesis.

It is not practical for most systems, however, to find the optimal solution to the M -D assignment algorithm with M greater than 2. To circumvent this problem, search for the optimal solution in Poore's M -D assignment algorithm is stopped when the current solution is close enough to the optimal assignment solution relative to the uncertainty caused by the random variables. His assignment algorithm is able to determine bounds on how close the current solution is to the optimal solution. This tracker makes a firm decision on the measurements in $M - 1$ frames back and tentative decisions on all subsequent measurements so that the current target state estimates can be computed for all apparent targets. A *firm decision* is an irreversible decision and a *tentative decision* is one that may be revisited and changed at a later time. After this processing is completed, the window is moved forward one frame of data and the process repeated.

4.3.4. Related Comments. There are also other multiple-frame data-association algorithms that have been devised, and some employ *retrodicted probabilities* [10,11], which are "smooth" decisions that are analogous to smoothing of continuous random variables in Kalman

filtering. (Note that in Kalman filtering, it seems that it might be more appropriate to refer to a “smoothed” estimate as a *retrodicted estimate*, i.e., an estimate of the state for a specific time given subsequent measurements.) More complex track processing can be expected in the future as the processing capabilities of computers continue to improve and thus permit tracking to approach optimal performance more closely.

Note that the hypotheses’ probabilities of all the sub-optimal tracking approaches discussed above, that is, except for optimal tracking, are not truly probabilities but “pseudoprobabilities.” A pseudoprobability is an approximation to the probability that the measurements assigned to the tracks for a hypothesis are the correct ones. The pseudoprobabilities are approximations because all previous hypotheses have not been maintained and used in the computations. The pseudoprobabilities are usually computed as if the deleted hypotheses were not possible and that no loss of information results from combining hypotheses.

Some target-tracking approaches partition the processing into the three major stages of (1) track initiation (formation), (2) track maintenance (extension or continuation), and (3) track termination, as in Fig. 2. Each track is started in the track-initiation processing and then continued in track-maintenance processing until terminated by the track-termination logic. The optimal, MHT, and MF-MPH approaches typically integrate all three phases in the process of enumerating hypotheses and generating tracks. In contrast, the NN, PDAF, JPDA, GNN, and SSH approaches are typically track-maintenance approaches that must be augmented by separate track-initiation and track-termination processing functions [1–4,17]. The algorithm for the track-termination function might be as simple as to terminate tracks that are not updated L frames in a row, or possibly not updated L frames out of J frames, where L and J are selected using Markov chain analysis. Markov chain analysis can be used to trade off the number of tracks incorrectly terminated versus the number of false tracks that are not terminated soon enough. This type of analysis can be used also to establish parameters for track initiation [1].

4.4. Track Initiation

Typically a sequence of more than two measurements is needed to initiate a track. Fortunately, tracks do not have to be initiated very often. The measurements not used by track maintenance are usually forwarded for use by the track-initiation function. In some approaches, all measurements are also used by the track-initiation function [3,4]. With a very sparse population of measurements, it may be sufficient to initiate tracks by using the same NN algorithm as used in track maintenance. The first measurement used to start a new track is called an *initiator*. An initiator starts a candidate initial track that is updated using the NN algorithm as appropriate measurements are provided to the track-initiation function. A score based on chi-square statistics can be updated as a candidate track is updated. When the score exceeds a prescribed threshold, the candidate initial track is promoted to a

mature track and processed by the track-maintenance function thereafter.

Note that in track initiation, not enough information exists to compute the first gate using only one measurement. After an initiator is identified, the first gate (and possibly more) is computed using *a priori* information on the velocity (and possibly higher derivatives) because the data of the initiator does not include complete velocity information, if any.

If more than just a few measurements exist in a region that are forwarded to the track-initiation function, there can be contention for measurements by a number of different candidate initial tracks. One approach that addresses this issue is to use binary linear programming or an optimal, unique M - D assignment algorithm to resolve the contentions and find all the appropriate sequences of measurements for promotion to mature tracks [24]. If this is too processing intensive, then it might be sufficient to use a unique suboptimal M - D assignment algorithm, such as the so-called greedy algorithm. A variety of other methods have been developed for track initiation. Track initiation is complex because usually more than just a few frames of data are needed to initiate tracks with reasonable confidence.

5. MULTIPLE-SENSOR ALGORITHM ARCHITECTURES

There are many different ways that data from multiple sensors can be combined. The differences between the various multiple sensor approaches may not be important with respect to performance for tracking with a sparse population of measurements. With challenging conditions of a moderate to dense population of measurements, the difference between the various tracking approaches can have a significant impact on both performance and hardware loading. In designing an algorithm architecture for multiple-sensor tracking, ultimately, the major considerations are typically cost, communication load, processor load, survivability, and performance. Performance considerations typically include estimation accuracy, number of false tracks, number of missed tracks, covariance matrix credibility, and robustness. There is virtually an infinite number of possible algorithm architectures for multiple target tracking with multiple sensors. One view of the different types of algorithm architectures is summarized in this section and then compared.

5.1. Alternative Fusion Algorithm Architectures

Four pure generic types of algorithm architectures for track maintenance and for track initiation have been identified. This classification of algorithm architectures is based primarily on how the association processing is performed over time and over the ensemble of sensors [10,12,17]. The four types of track maintenance algorithm architectures are as follows:

- *Type I:* Independent sensor algorithm architecture
- *Type II:* Track fusion algorithm architecture

- *Type III*: Composite measurement fusion algorithm architecture
- *Type IV*: Central measurement fusion algorithm architecture

In the *independent sensor algorithm architecture* (Type I), the tracks are processed for each sensor without use of the data from the other sensors. Frame-to-frame data association and filtering are performed without any sensor-to-sensor processing. Each user obtains tracks based on a single sensor. Note that each measurement is subjected to only one association process, but single-sensor tracks need to be retained in track files for each sensor. Also, there is no improvement in the track quality because of the existence of multiple-sensor data.

In the *track fusion algorithm architecture* (Type II), tracks are first processed for each sensor without use of data from the other sensors. Single-sensor frame-to-frame association and filtering are followed by sensor-to-sensor processing. Single-sensor tracks are fused using track-to-track association followed by filtering to form multiple-sensor (global) tracks. Note that each measurement is subjected to two association processes. Multiple-sensor tracks as well as single-sensor tracks for each sensor are retained in track files. This process is sometimes called hierarchical or distributed algorithm architecture and is complicated by the property that typically sensor-level tracks are cross-correlated with the global-level tracks. Feedback of the multiple-sensor global tracks to the single-sensor track processing can be employed. The vanilla architecture without feedback to the lower levels is designated Type IIa. Feedback to the lower levels usually improves the track accuracy at both that level and the higher levels, and that architecture is designated Type IIb. In systems where there are multiple sensors on each platform and each platform is at a different location, it is common to have three processing levels: (1) sensor-level tracking, (2) platform-level tracking, and (3) global-level tracking.

There are a number of methods for dealing with the track-to-track error cross-correlation in track fusion. In some methods, the track data are distributed in the form of a tracklet. A *tracklet* is a track computed so that its errors are not cross-correlated with any other data distributed in the system for the same target [12]. Tracklets can be computed by decorrelating the sensor tracks [25] or formed from a sequence of measurements [12]. One of the major benefits of track fusion compared with the other types of fusion is that the communications load can be greatly reduced by not distributing the track data after every measurement is obtained for a target. The *tracklet interval*, the time between when tracklets are distributed by a sensor for a target, can often be from 5 to 30 measurement sampling periods, depending on the application. Thus data compression is obtained with little loss of information. The original tracklet methods were designed for nonmaneuvering targets, and those methods might not provide adequate performance if the targets are maneuvering, because with maneuvers they do not provide lossless information [26]. If the possibility of misassociations exist at the local or fusion level, then a number of

considerations need to be addressed in deciding whether to distribute target tracks or tracklets [27].

In the *composite measurement fusion algorithm architecture* (Type III), multiple-sensor processing of the measurements from all sensors is first employed. The processing of measurements consists of associating measurements from one frame of data from all sensors and computing an improved estimate of a projection of the state vector for each target, such as estimated position. Note that normally for accurate fusion with this approach, either the sensors must obtain measurements at the same time or the targets and sensors must be moving slowly relative to the frame period. These composite measurements are then used in frame-to-frame association and filtering. Sensor-to-sensor processing precedes frame-to-frame processing. Note that each measurement is subjected to two association processes, but only one set of multiple-sensor tracks need be retained in track files.

In the *central measurement fusion algorithm architecture* (Type IV), measurement-to-track association is followed by filtering using the prior multiple-sensor tracks. This architecture is sometimes referred to as measurement fusion or central-level fusion [1,7]. In its simpler form, the data-association processing uses the multiple-sensor tracks and one frame of data from a sensor; the tracks are updated and then a frame of data from another sensor along with the updated multiple-sensor tracks is processed. Note that each measurement is subjected to only one association process and only one set of multiple-sensor tracks need be retained in track files.

In addition to the pure generic methods for track maintenance is one more type of fusion approach that is not a pure approach, namely, a hybrid approach. One devised hybrid approach is flexible and adaptive because it permits the distribution of tracklets, composite measurements, or measurements for each apparent target, depending on the needs of the system for data on that target at the current time [12].

Report responsibility is a multiple-sensor, multiple target-tracking algorithm architecture that is popular in the radar community. This approach might be viewed as a special case of the Type II, track fusion algorithm architecture. However, in report responsibility, data from more than one sensor are not combined to form a multiple-sensor track, and so it could be considered in a class by itself. It is discussed here for completeness in preparation for a qualitative comparison of algorithm architectures.

In report responsibility, each sensor tracker is responsible for providing the tracks for a subset of all the targets. The intent is for one and only one sensor tracker to broadcast a track for a target. The sensor tracker that provides the best track for a target is responsible for broadcasting the track for that target on the network to the users and all the other sensor trackers; no other sensor tracker is supposed to broadcast a track for that target. Consequently, the issue of track cross-correlation does not apply to this approach. A number of approaches on how to coordinate the decisions to achieve the intent of report responsibility exist. Depending on how report responsibility is coordinated, transients can exist with more than one sensor tracker broadcasting a track for a

target. Some advantages of report responsibility include very low communications rate and use of the best sensor track. In report responsibility, however, the sensor tracks for a target from multiple sensors are *not* combined, so that the full advantage is not taken of the capabilities of fusion and so-called “geographic diversity.”

5.2. Comparison of Fusion Algorithm Architectures

It would be very desirable to be able to compare algorithm architectures rigorously. The state of the art of target tracking and target typing is such that apparently no one can afford the cost of a comprehensive comparison of algorithm architectures or of the algorithms for each of the tracking functions. Performance is data dependent and requires simulations for evaluation. Comparing the fault tolerance of the various possible system designs is certainly not easy, and a comparison of the hardware required for alternative system designs can be extremely complex.

In lieu of an extensive quantitative comparison, a subjective qualitative comparison of some algorithm architectures has been made [12]. This comparison, shown in Table 5, is only an initial effort, assumes no process noise, and compares only five algorithm architectures. It must be stressed that this is a qualitative comparison in that a rating of 4 might be substantially better than a rating of 3 or only slightly better than a rating of 3 if measured quantitatively. Also, this comparison does not explicitly include all the dimensions or trade issues listed in the beginning of this section. The comparison of Table 5 is only intended to indicate some of the critical issues in selecting an algorithm architecture. This table is more applicable to track maintenance than to track initiation because the properties of some sensor combinations require special consideration for track initiation. For example, two sensors may not have much information in common with only a few frames of data, such as an active sensor with relatively inaccurate angle data and an accurate passive sensor with no range data.

A big influence in Table 5 is the relative location of the sensors. With all sensors at one location (on one platform), the communications load is not an issue and central fusion might be preferred. Communication between distant

participating units is a major consideration and, so with distributed platforms, track fusion might be preferred in order to reduce the communications load. Also, registration and sensor measurement biases are extremely important in the fusion of multiple-sensor data and typically must be estimated. The residual biases appear to cause more misassociations with central fusion than with track fusion.

The asterisks in Table 5 indicate that for best tracking accuracy, the selection of the best algorithm architecture depends heavily on how different the participating sensor characteristics are, the size of the residual biases, and the types of targets. For example, for best tracking accuracy, very similar sensors may make central fusion preferred whereas track fusion may be preferred for disparate sensors. Two benefits of central fusion is its data timeliness, which is critical for highly maneuverable targets and the aspect that each measurement goes through one association process. However, the number of misassociations exhibited by track fusion and central fusion can be very different. With diverse sensors and a very different number of targets observed by each sensor, central fusion might introduce many more misassociations than would track fusion.

Another consideration in the selection of a fusion approach is the impact on the existing hardware. Some sensor processors provide only sensor tracks and do not provide measurements. If a central fusion approach were chosen, then the processors would have to be changed, which could be expensive. Also, some existing trackers do not provide the track error covariance matrices. The error covariance matrices are not needed for some approaches to report responsibility, but are required to compute the tracklet if the tracks are to be decorrelated for track fusion, and the expense of this hardware change should be considered. Hybrid fusion that distributes tracklets or measurement data exhibits the best characteristics of both central fusion and track fusion because the choice of what is distributed can be based on the needs at any one time.

A clear distinction should be made between the functional (logical) algorithm architecture (discussed in Section 5.2) and the physical distribution of the processing. With multiple platforms and onboard processing, each function

Table 5. Qualitative Comparison of Fusion Algorithm Architectures [12]

	Report Responsibility	Track Fusion without Feedback	Track Fusion with Feedback	Measurement Fusion	Hybrid Fusion
Track accuracy, false/missed tracks	1	2	3.5*	3.5*	5
• Increase effective sampling rate	1	2.5	2.5	5	4
• Utilize diversity-geometrical/accuracy	1	3.5	3.5	3.5	3.5

of an algorithm architecture can be physically distributed in many ways over the sensor platforms and a central processing station, if applicable. Also, each of the generic algorithm architectures can be implemented in many ways.

An important example of a specific combination of both the algorithm architecture and the physical distribution of the processing is what could be called measurement fusion with distributed data association. Consider distributed sensor platforms with a fusion processor on each platform. For track maintenance, each platform is responsible for the assignment of its measurements to the fusion (network) tracks, and then each measurement is tagged with its assigned fusion track number. Each measurement with its fusion track tag is distributed to all the other platforms. When a platform receives a tagged measurement from another platform, the data-association function can be bypassed and the measurement is sent to the filter function for use to update the track with the track number as indicated by the measurement's tag. The track initiation function assigns new track numbers to new tracks, and processing is needed to attempt to identify and eliminate redundant tracks from being proliferated.

There are also four track-initiation architectures that are conceptually the same as the track-maintenance architectures summarized above. The type of track-initiation architecture need not be the same as the selected type of track maintenance. Note that for a number of fusion approaches, no simple obvious approach exists for upgrading from single-frame data association to multiple-frame data association as exists for tracking with data from a single sensor. One exception to this challenge is measurement fusion at a single ground station because it is very similar to processing with data from a single sensor.

6. PERFORMANCE EVALUATION

Ultimately, the performance of tracking algorithms is judged by the success of the system that they support. Evaluation of tracking performance serves as an intermediate measure of system effectiveness, to diagnose the algorithms, and to predict performance for use in system studies. However, ambiguities can occur in evaluating performance because of misassociations [13]. Misassociations can cause missed targets and false tracks such as redundant, spurious, and lost tracks. As a result, it may not be clear which target a track is following, if any. Measures of performance cannot be evaluated with the aid of a

simulation (or through field tests) without first designating which target a track is following. There are a number of evaluation methodologies that have been proposed to address this problem [28]. Care is needed not to use a methodology that gives unfair advantage to one tracking approach over another.

One methodology for resolving these ambiguities is to use an assignment algorithm to uniquely assign the tracks to targets [13,15]. The use of the statistical distances between targets and tracks for the cost elements in the assignment matrix tends to treat the alternative tracking algorithms fairly. Then the tracking errors and other measures of performance can be computed given these unique track-target assignments. This two-stage methodology is shown in Fig. 4. Some of the common measures of performance include the error biases, the mean sum square of the position errors and the velocity errors, covariance consistency, the number of misassociations, track purity, track duration, average time to initiate tracks, and the number of missed and false tracks [29]. If the system involves multiple platforms, then performance metrics may also be needed to determine if all platforms exhibit the same information about the threat and friendly forces. This property is sometimes called *single integrated air picture* (SIAP). For most tracking applications, no single critical performance metric exists that can be used to evaluate one or more trackers. For one reason, a collection of metrics are needed because usually the tracker parameters could be adjusted to favor one metric at the expense of others.

Both tracking performance and hardware loading should be evaluated. As mentioned earlier, choices of the algorithm architecture, algorithms for each function, and the algorithm parameters will impact both performance and required processor capacity (and communications load, if applicable). An example of this tradeoff between performance and required hardware resources is shown in Fig. 5. This figure summarizes results of the simulation of tracking a single target with passive sensor data that included false signals. The results are shown after seven frames of data have been processed. Two algorithms were evaluated. One algorithm was optimal for the MMSE criterion. The other was similar to a single-target version of Poore's tracker. The number of frames in the sliding window was varied from 1 to 6 so that the curve in the figure was obtained. The values for the horizontal and vertical axes have been normalized by dividing by the corresponding value that is exhibited by tracking without false signals. Note that the results for the NN algorithm is at the left end of each of the two curves. This figure illustrates

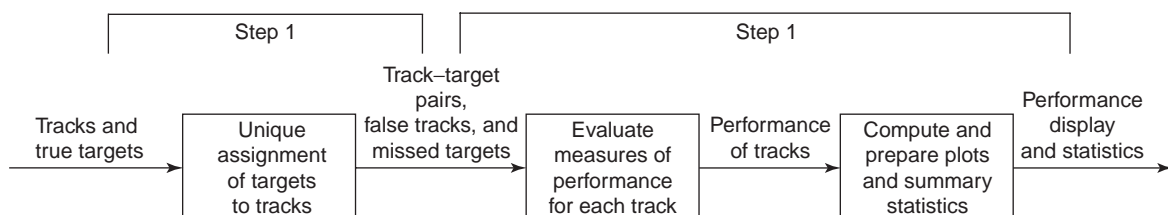

Figure 4. Diagram of a two-stage performance-evaluation methodology [17].

Figure 5. Illustration of major trade-off parameters for single-target tracking [14].

the major tradeoff between performance and required processor capacity (processing time or required memory).

TELEMEDICINE

CHANG WEN CHEN
University of Missouri-Columbia

Applications of information and communications technologies have become increasingly widespread because of the rapid development of microelectronics and computers. One of the most important applications is the use of advanced telecommunications and computer technologies to improve healthcare services and systems. Telemedicine—which combines many innovative information technologies that integrate research areas in human–computer interaction, data storage, processing, and compression with communications networking to improve health-care—has been recognized as a way to provide an effective and versatile solution to many of the intransigent problems in healthcare delivery.

A formal definition for telemedicine has recently been adopted by the Institute of Medicine (IOM), Washington, D.C. In the report developed by a 15-member committee of the Institute of Medicine, the term *telemedicine* is defined as “the use of electronic information and communication technologies to provide and support health care when distance separates the participants” [1]. The committee adopted this definition of telemedicine after consulting several suggested definitions. A list of these definitions is

shown in Table 1 [2–13]. The committee identified three common elements in these definitions: (1) information or telecommunications technologies, (2) distance between participants, and (3) health or medical uses.

The adopted definition of telemedicine includes all three common elements and covers a broad context in terms of both technologies employed and application areas considered. Traditionally, video conferencing is perceived as the defining technology for telemedicine, and the clinical application is considered as the defining mode for telemedicine. However, the adopted definition encompasses a wide variety of forms of communication, including telephone conversation, still-image transmission, and medical file electronic access. The definition of technologies also includes computer-based capturing, manipulating, analyzing, retrieving, and displaying of the related data and information. Both clinical and nonclinical uses of telemedicine are considered in the definition. In general, clinical applications of telemedicine involve patient care such as diagnosis, treatment, and other medical decisions and services. Nonclinical applications of telemedicine involve non-decision-making processes such as continuing medical education and management meetings. The boundary for clinical and nonclinical applications often cannot be clearly defined, because remote learning and consultation by participants will result in the application of acquired knowledge to future diagnostic and treatment decision-making processes. The third element, the geographic separation or distance between the participants, is the defining characteristic for telemedicine. In many cases, it is the separation of participants, not the distance between the participants, that requires telemedicine to overcome problems associated with patient care.

The concept of healthcare services performed over a distance first appeared in 1924 in an imaginative cover for

Table 1. Definitions of Telemedicine Consulted by the Institute of Medicine Committee

Proposer and Reference	Definition
Van Goord and Christensen [2], cited in Gott [3], p. 10 Weis [4], p. 151	The investigation, monitoring, and management of patients, and the education of patients and staff using systems that allow ready access to expert advice, no matter where the patient is located The use of telecommunications techniques at remote sites for the purpose of enhancing diagnosis, expediting research, and improving treatment of illnesses
Kansas Telemedicine Policy Group [5], p. 1.6 Grigsby et al. [6], p. 1.3	The practice of healthcare delivery, diagnosis, consultation, treatment, transfer of medical data, and education using . . . audio, visual, and data communications The use of telecommunication technology as a medium for providing healthcare services for persons that are at some distance from the provider
Council on Competitiveness [7], p. 6 Perednia and Allen [8], p. 483 Bashshur [9], p. 19	The use of two-way, interactive telecommunications video systems to examine patients from remote locations, to facilitate medical consultations, and to train healthcare professionals The use of telecommunications technologies to provide medical information and services An integrated system of healthcare delivery and education that employs telecommunications and computer technology as a substitute for face-to-face contact between provider and client
Office of Technology Assessment (OTA) [10], p. 224 Physician Payment Review Commission (PPRC) [11], p.135	The use of information technology to deliver medical services and information from one location to another An infrastructure for furnishing an array of individual services that are performed using telecommunication technologies
Lipson and Henderson [12], p. I-1–4 Puskin et al. [13]	Telemedicine encompasses all of the healthcare, education, information, and administrative services that can be transmitted over distances by telecommunications technologies The use of modern telecommunications and information technologies for the provision of clinical care to individuals at a distance and the transmission of information to provide that care

the magazine *Radio News*. The cover showed a "radio doctor" who could talk with the patient by a live picture through radio links [1]. However, the technology to support such a visionary concept, namely, television transmission, was not developed until three years later, in 1927. According to a recent review, the first reference to telemedicine in medical literature appeared in 1950 [14] and described the transmission of radiological images by telephone over a distance of 24 miles. The interactive practice of telemedicine began during the 1960s when two-way, closed-circuit microwave televisions were used for psychiatric consultation by clinicians at the Nebraska Psychiatric Institute [15]. Following the Nebraska program, several other telemedicine programs were developed in the 1960s. Some of these early programs aimed at improving health services in remote populations that traditionally had limited access to quality healthcare. One such early attempt was sponsored by the U.S. Department of Health, Education and Welfare, the National Aeronautics and Space Administration (NASA), and the Lockheed Company and was called the Space Technology Applied to Rural Papago Advanced Health Care (STARPAHC) program [16]. The program offered medical care through a mobile health unit (MHU), a medically equipped van that traveled over a prescribed route through the Papago Indian Reservation in the Sonora Desert, west of Tucson and south of Phoenix, Arizona. The MHU clinic and a fixed clinic at Santa Rosa, Arizona were linked via telemedicine facilities to a hospital in Phoenix. Other programs aimed to improve health services in urban emergency and urgent situations [17,18]. Although these pioneering telemedicine efforts demonstrated both technical and medical feasibility and received enthusiastic appraisal from the healthcare recipients [16], the issue of cost-effectiveness was debated at a premature stage by telemedicine authorities, especially the major funding agencies. The prevailing fear was that as the technologies for telemedicine became sophisticated, the cost of telemedicine would increase [15]. Such fear has been proven to be unfounded. Many applications of telemedicine are considered to have the potential to reduce healthcare costs or to reduce the rate of cost escalation [1]. The rapid advances of modern communications and information technologies during the 1990s have been a major driving force for the strong revival of telemedicine today.

The development of telemedicine has depended on the associated enabling technologies. One of the reasons that first-generation telemedicine projects did not succeed is that the technologies available at the time were, by today's standard, relatively primitive. The rapid advances in digital compression, fiber optics, and computer miniaturization and portability and their application to telemedicine systems were not even predicted during the early stage of telemedicine system development. In the case of communications, dedicated telephone lines were used in many telemedicine projects. However, such lines could only transmit slow-scan analog images, and digital compression techniques were not incorporated into the first generation of telemedicine systems. The recent rapid advances in digital communications, computer technology, and information science have provided a much broader

range of enabling technologies for today's telemedicine systems. For example, the original telephone-based communications mode has now reached very high capacity because of the revolutionary development in computer modem design. The transmission bandwidth of the telephone line is now more than 10 times greater than it was during the 1960s [19]. Other modes of modern communications, such as the integrated services digital network (ISDN) and asynchronous transfer mode (ATM), have been playing increasing roles in telemedicine systems. These new communications technologies enable the telemedicine system to operate with more flexibility and at a higher efficiency. In addition to these more advanced communication technologies, developments in digital compression (especially digital audio and video compression), and computer networking (in particular the Internet), have injected much needed versatility into the design of today's telemedicine systems. These greatly improved technologies and, more important, the decreasing cost of these technologies have allowed a wide-scale implementation of telemedicine.

The clinical applications of telemedicine have been adapted by a wide range of medical specialties and healthcare disciplines. Many of the current telemedicine applications involve the transmission of medical images for diagnosis and treatment. Two such primary image-related applications are teleradiology and telepathology. *Teleradiology* can be defined as the practice of radiology from a distance, and the initial interest in teleradiology as a practical cost-effective method of providing professional radiology services to underserved areas began some 30 years ago. Early teleradiology was considered as an alternative to recruiting radiologists for remote and isolated communities; it facilitated local patient care and avoided the unnecessary transport of patients to distant hospitals. However, until recently, technical deficiencies in the hardware, software, and telecommunications links have hindered the acceptance of teleradiology by radiologists and other physicians [20,21]. *Telepathology*, on the other hand, was developed more recently, during the late 1980s, and is still in its infancy compared with teleradiology. Two significantly different and competing techniques are currently used in telepathology: dynamic imaging and static imaging. *Dynamic imaging systems* provide real-time video imaging capability via a remotely controlled light microscope and a broadband communications link. With dynamic imaging systems, telepathologists are able to operate the microscope remotely via a keypad, mouse, or other input device so that the systems approximate the usual techniques of pathological examination. *Static imaging systems* are usually based on less expensive conventional telephone lines to transmit a limited number of still images. In this case, the consulting telepathologists are virtually excluded from the process of selecting the microscope fields for imaging. Other clinical applications of telemedicine include teledermatology, teleoncology, telepsychiatry, and more generally, the delivery of quality primary medical care to remote and isolated populations.

The nonclinical applications of telemedicine have received increased attention because of rapid developments in the telecommunications industry and the deployment of the National Information Infrastructure

(NII). In such cases, telemedicine systems are often employed to enhance educational and management activities through video conferencing and multimedia presentations. It has been recognized that nonclinical uses of telemedicine for educational and administrative activities will also contribute to the effectiveness of many clinical applications, especially when the clinicians gain greater familiarity with the telemedicine technologies through nonclinical uses. Examples of nonclinical uses of telemedicine include continuing medical education, online health-care information resources, coordinating research at multiple sites, and video conferencing for administrative meetings [1]. With Internet and World Wide Web resources, health-care information can be readily obtained for the formal and informal provision of medical advice, and continuing medical education can be implemented at multiple sites with effective multimedia presentations. Health-related research may also be conducted over telemedicine systems based on the patients' data collected and distributed at multiple sites to maximize the use of all available data. For health-care administrations, video conferencing for managers of integrated health-care systems allows such meetings to combine evaluation with quality monitoring.

More recently, public health has been identified as another nonclinical application of telemedicine with great potential. Public health for the most part is massive information transfer, teaching people how to find clean water, wash, and change lifestyles as well as disease monitoring. Telemedicine systems in the future will be able to provide the connectivity needed for mass education on disease prevention and the global network needed for disease monitoring. Such nonclinical applications of telemedicine can contribute to the improvement of human health on a global scale.

1. TECHNOLOGIES FOR TELEMEDICINE

As defined previously, telemedicine is the application of information and communications technologies to health-care. As a result, the development of telemedicine has largely been constrained by the balance of the supply and demand of technologies applicable to various telemedicine applications. The degree to which a particular telemedicine application is able to develop depends greatly on the development of appropriate technologies associated with the application. In general, the development of telemedicine applications are constrained by three fundamental aspects of information and communications technologies: information-carrying capacity, communications media, and information processing and digital technologies. These technologies determine the availability, quality, and affordability of many telemedicine applications.

The information-carrying capacity of a communications system is called *bandwidth*. Bandwidth measures the amount of information that can be carried at one time through the communications system. The advances in digital communications have offered various possibilities to transmit health-care-related information over communications systems with very high information-carrying

capacities. Usually, however, a communications system with higher bandwidth tends to be more expensive to install and maintain. Therefore, the demand for information-carrying capability, or bandwidth, depends on the needs and resources of the telemedicine users. Many recent advances in information and communications technologies have sought to increase the capacity of various communications systems by improving transmission media and by configuring the information in such a way as to reduce bandwidth requirements. The core modern information and communication technologies applicable to telemedicine are digital communications, digital video and video compression, digital imaging, and multimedia integration.

1.1. Digital Communication

The telecommunications industry is moving rapidly toward digital systems for various applications. This is because digital systems can easily facilitate more efficient transmission, more accurate signal reproduction, and more flexible information multiplexing. These characteristics of digital communications will benefit the further development of telemedicine systems. The more efficient transmission of a digital communications system can reduce the cost of transmission and therefore may spawn new applications in telemedicine. More accurate reproduction of the digital transmission will improve the quality of the received information and hence the quality of the telemedicine services. More flexible information multiplexing offers the integration of audio, video, and data signals into multimedia information so that more greatly enhanced telemedicine services can be made possible.

Historically, telemedicine was developed to overcome health-care problems arising from geographic separation between people who needed health-care and those who could provide it. Naturally, telemedicine applications have relied on existing telecommunications networks and technologies to resolve the geographic-separation issues. Depending on the nature of the telemedicine information to be transmitted, a particular type of communications media and network may be selected so that a tradeoff between the costs of and the need for timely connection can be achieved. Many telemedicine applications have depended on the public switched telephone network (PSTN) to transmit both time-critical and non-time-critical health-care information from one place to another. The carrier systems for such information transmission may include traditional telephone service, T-1 carrier systems, and ISDN.

The telephone network has several major advantages over the other two, more advanced technologies for some telemedicine applications. These advantages include ubiquity, relatively low cost for installation, and low cost per use. In addition, modern telephone systems offer a range of flexible services that have emerged during the past decade. Among them, telephone conferencing offers the opportunity for relatively large numbers of people who are geographically dispersed to meet together by phone. Voice mail enables the transmission of voice messages when instant response is not required. Fax service

facilitates the transmission of material on paper via the telephone system. With currently available computer modems, the exchange of electronic mail, data, documents, and even images can now be easily accomplished through the telephone system. In the near future, the videophone will provide more versatile and low-cost communications services for telemedicine participants.

The T-1 carrier system was the first successful system designed to use digitized voice transmission over the telephone network [19]. It was first developed to resolve the problems with the old analog telephone systems so that the system would be able to increase call-carrying capability and improve transmission quality. The first step of development was the deployment of mixed analog and digital transmission capabilities so that end users could use analog transmission through the twisted pair cable on the local loop, while the interoffice trunks were operating through digital carriers with digital switching systems. As the T-1 system evolved from the old analog telephone system, some of the features of the old telephone system remained compatible, such as the four-wire circuits in the local loop and full-duplex capability. However, many digital characteristics have been introduced in the T-1 carrier system. These characteristics include pulse-coded modulation (PCM), time-division multiplexing, framed format, bipolar format, byte-synchronous transmission, and channelized or nonchannelized services. With these digital technologies, the T-1 carrier system is able to provide a basic rate of digital transmission at 1.5444 Mbps, the rate of the digital signal level 1 (DS1) as defined by the time-division multiplexing hierarchy. This rate of the digital link is the result of multiplexing 24 standard 64-kbps PCM signals, also known as DS0 digital signals. With these higher capacity transmission links, many telemedicine applications are now able to transmit time-critical high-bandwidth requirement information, such as live video signals, over the telephone network via T-1 carrier systems.

The original motivation for the development of the T-carrier system was to provide lower cost and better quality dial-up telephone services. However, the technologies that evolved from such developments form the basis for a full end-to-end digital network, (ISDN), to support the simultaneous transmission of voice, data, video, image, text, and graphics information. ISDN provides a wide range of services using a limited set of connection types and multipurpose user-network interface arrangements [19,22]. ISDN is intended to be a single worldwide public telecommunications network to replace existing public telecommunications networks that are currently not totally compatible among various countries [23]. There are two major types of ISDN with different capacities: narrowband ISDN and broadband ISDN (BISDN). Narrowband ISDN is based on the use of a 64 kbps channel as the basic unit of switching with primarily a circuit-switching mode of transmission supported by frame-relay protocols. BISDN offers very high data rates at the order of hundreds of megabits per second with primarily a packet-switching mode of transmission supported by asynchronous transfer mode (ATM) protocols. Narrowband ISDN provides the transmission bandwidth ranging from

64 kbps to 1.544 Mbps, while BISDN provides broader transmission bandwidth, ranging from 44.736 Mbps, or DS3 in the digital signal hierarchy, to 2.48832 Gbps, or OC-48 in the optical carrier hierarchy in the synchronous optical network (SONET). Narrowband ISDN offers these services: (1) speech, (2) 3.1 kHz audio, (3) 3 kHz audio, (4) highspeed end-to-end digital channels at a rate between the basic rate of 64 kbps and the super-rate of 384 kbps, and (5) packet-mode transmission [24]. BISDN offers a variety of interactive and distribution services, including (1) broadband video telephony and video conferencing, (2) video surveillance, (3) highspeed file transfer, (4) video and document retrieval service, (5) television distribution, and (6) potentially many more future services [24]. Depending on a particular application and cost-effective consideration, a telemedicine system may employ either narrowband ISDN or BISDN to accomplish desired healthcare tasks. The development of ISDN enables a telemedicine system to encompass a much wider variety of applications, ranging from interactive videoconferencing-based diagnosis and treatment to the transfer of patient records and other healthcare-related documents for consultation and management.

1.2. Digital Video and Video Compression

As noted, video conferencing is considered the defining technology for telemedicine. Recent rapid development of video technologies, especially digital video and video compression, have enabled telemedicine to continue its strong revival.

Video refers to visual or pictorial information, which includes both still images and image sequences. Most common examples of video include television and motion pictures. The recording, storage, and transmission of video signals has traditionally been handled in analog form. Rapid advances in computer and communications technology, however, have exposed the limitations of traditional analog video. In particular, the analog video lacks interactivity and is difficult to be integrated with computer systems that accept and process digitized information and modern communications systems that transmit digital signals. As a result, efficient digital representation of the video signal has been extensively studied to take full advantage of the remarkable developments in digital communications and computer systems. Digital video is a coded sequence of data that represent the intensity and color of successive discrete points along the scan lines. Details in the digital representations of video signal are beyond the scope of this article and can be found in Refs. 25 and 26.

Digital video offers many advantages over its analog counterpart. Digital video allows the existence of video at multiple resolutions in the spatial and temporal domains, interactivity suitable for search and retrieval of video databases, variable-rate transmission based on user demand, and more important, integration of digital video with other digital media, such as digital audio, text, and graphics, for true multimedia computing and communications. These benefits of digital video create new opportunities for a telemedicine system to integrate a high level of

interactivity and flexibility into routine healthcare activities, such as efficient patient-information gathering, computerized therapy management, and automatic patient follow-up. These new opportunities are not possible with telemedicine systems that are based on analog communications. Because digital video typically requires huge storage and transmission bandwidth capacities, however, a fundamental issue is the development of video compression algorithms and the implementation of compression in hardware. For example, digital video requires a much higher data rate and transmission bandwidth than digital audio. For compact disk (CD)-quality digital audio, the data rate is about 700 kbps, whereas for a high-definition television (HDTV) signal, the data rate will be about 550 Mbps. Without appropriate compression, the sheer size of digital video will overwhelm many current storage and transmission systems. Therefore, video compression is a key technology that determines the cost and the quality of the interactive video transmission, which, in many cases, can determine the quality of the healthcare service in a specific telemedicine system. The temporal, spatial, intensity, and color resolutions required by specific telemedicine applications along with available communications channel bandwidth often dictate the desired compression performance. For example, the ISDN line with a data rate of 384 kbps may be adequate for face-to-face discussion among healthcare providers. However, remote real-time high-fidelity display of cardiological ultrasound image sequences would need a 45 Mbps communications channel. The video-compression requirements for these two applications would be quite different.

Compatibility among applications and manufacturers is often essential for the exchange and successful transmission of video data among different systems. As a result, several video-compression standards have recently been developed. Two major categories of such standards are reviewed here: (1) Standards H.261 and H.263 for video conferencing applications and (2) the MPEG series, including MPEG-1 for CD read-only memory (ROM) access, MPEG-2 for HDTV, and MPEG-4 for the true multimedia communications standard that encompasses audio coding, video coding, multiplexing of coded data, coding of text and graphics, and audiovisual scene composition.

An understanding of these video-compression standards starts with JPEG, a standard for coding single-frame color images developed by the International Standardization Organization (ISO) Joint Photographic Experts Group (JPEG). Compression of image data without significant degradation of the visual quality is usually possible because images often exhibit a high degree of spatial, spectral, and psychovisual redundancies. Spatial redundancy is due to the correlation among neighboring pixels. Spectral redundancy is due to the correlation among color components. Psychovisual redundancy is due to perceptual properties of the human visual system. For video signals, the compression algorithms also take advantage of the temporal redundancy due to usually very high correlation between neighboring frames. For the compression of still-frame images, the process is generally composed of three steps: (1) transformation, (2) quantization, and (3) symbol coding. The transforma-

tion in the JPEG standard is the discrete cosine transform (DCT), which is employed to pack the energy of the image signal to a small number of coefficients. As a result, the image can be well approximated by a small number of DCT coefficients. The quantization is needed to generate a finite number of symbols from originally continuously valued coefficients, whereas the symbol coding assigns a code word, or a binary bit stream, to each symbol generated by the quantization step. Intuitively, the coarser the quantization, the fewer the number of symbols. Higher compression can be used for coarser quantization; however, there is more degradation in the visual quality of the compressed image. In the case of symbol coding, variable length codes are usually employed to minimize the average length of the binary bitstream by assigning short codewords to more probable symbols. Huffman and arithmetic coding techniques are used as variable length coding in the JPEG standard [27].

In the compression of video signals, motion compensation is a basic technique to reduce the temporal redundancy of the image sequences. This is also the major difference between image compression and video compression. The temporal redundancy is due to the fact that there usually exists certain portion of an image that changes little from one image frame to the next. In the H.261 standard, which is the video-compression standard developed for video conferencing by the International Telecommunication Union-Telecommunication Standardization Sector (ITU-T), block-based motion compensation is performed to compute interframe differences. In this case, image data in the previous frame are used to predict the image blocks in the current frame. Only differences, typically of small magnitude, between the displaced previous block and the current block need to be coded. As in the case of JPEG, DCT and variable-length coding techniques are employed. However, interframe differences, instead of the frame itself in the case of JPEG, are transformed with DCT and coded with variable-length coding. The development of the H.261 standard began in 1984 and was completed in late 1989. This video-compression standard was developed for the application of video conferencing over low-bit-rate ISDN lines with target bit rate of p times 64 kbps, where p is between 1 and 30. Only two image formats are assumed: common intermediate format (CIF) and quarter-CIF (QCIF). CIF images consist of three components: luminance Y and color differences C_B and C_R . The size of a CIF image is 352 pixels per line by 244 lines per frame. As the H.261 standard is designed for real-time communication, it uses only the closest previous frames as a prediction to reduce the coding delay. In summary, the H.261 standard is a compromise among coding performance, real-time requirements, implementation complexity, and system robustness. This standard has been implemented in various video conferencing products. Many telemedicine systems with interactive video services are based on real-time video conferencing system over ISDN lines with the H.261 standard.

Standard H.263 was defined by the same group that developed the H.261 standard. The activities of the H.263 standard started in 1993 and were adopted in 1996. The main goal of Standard H.263 was to design a video coding

standard for applications with bit rates of less than 64 kbps. Examples of such applications include video data transmission over the public service telephone network and the mobile network in which the video bit rates range from 10 kbps to 24 kbps. As Standard H.263 was built on top of Standard H.261, the main structure is essentially the same. However, Standard H.263 offers several enhanced techniques over Standard H.261. These enhancements include the support of more image formats, the use of half-pel motion compensation, three-dimensional variable length coding, and a variable quantization step at each microblock. With the H.263 standard, telemedicine systems will have extended options in the choice of video transmission channels, the selection of image formats, and a much-improved picture quality at low-bit-rate transmission. It also opens up a new opportunity for telemedicine to use mobile communications, which may be very much desired in emergency and battlefield situations.

In parallel to the efforts by the ITU-T standards, the ISO Moving Picture Experts Group (MPEG) has developed both audio and video compression standards that can compress many types of video sources for storage and transmission on various digital media, including compact disk, remote video database, video-on-demand, digital television, and network video. The MPEG committee started its activities in 1988, and the MPEG-1 standard was approved by the end of 1992 [27]. The MPEG-1 standard has been developed for the storage of digital video and its associated audio at about 1.5 Mbps on various digital storage media. The target application for the MPEG-1 standard is the interactive multimedia system, in which video data can be decoded in real time to allow random access and fastforward/reverse with reasonable coding/decoding delays. In some telemedicine applications, in which interactive access to the desired video database is required, the MPEG-1 standard will be able to play a very important role. To reach the target bit rate of 1.5 Mbps, the input video is usually downsampled to MPEG standard input format (SIF) before compression. The SIF consists of noninterlaced frames of 352 pixels by 240 lines at a frame rate of 30 frames per second, with a 2:1 color subsampling both horizontally and vertically. The compression approach of the MPEG-1 standard uses a combination of JPEG and H.261 standards. In particular, the MPEG-1 standard also employs a block-based two-dimensional DCT to exploit spatial redundancy as in the JPEG and H.261 standards. However, the MPEG-1 standard uses bidirectional temporal prediction to achieve higher compression than the H.261 standard, which employs only forward prediction.

The second phase of the ISO MPEG standard, MPEG-2, began in 1990 and was approved as an international standard in 1994. Standard MPEG-2 provides a video coding solution for applications not originally covered or envisaged by the MPEG-1 standard. Specifically, the MPEG-2 standard was given the charter to code interlaced video at a bit rate of 4 Mbps to 9 Mbps and provide video quality not lower than National Television Systems Committee (NTSC)/Phase Alternation Line (PAL) and up to that of International Radio Consultative Committee (CCIR) 601

[26]. Emerging applications, such as digital cable TV distribution, networked database services via ATM, digital video tape recorder (VTR) applications, and satellite and terrestrial digital broadcasting distribution, were seen to benefit from the increased quality expected from the MPEG-2 standardization phase. Work was carried out in collaboration with the ITU-T SG 15 Experts Group for ATM video coding, and in 1994, the MPEG-2 Draft International Standard (which is identical to the ITU-T H.262 recommendation) was released. The specification of the standard is intended to be generic—hence, the standard aims to facilitate the bitstream interchange among different applications, transmissions, and storage media.

Basically the MPEG-2 standard can be seen as a superset of the MPEG-1 coding standard and was designed to be compatible with MPEG-1: Every MPEG-2-compatible decoder can decode a valid MPEG-1 bitstream. Many video coding algorithms were integrated into a single syntax to meet the diverse application requirements: Prediction modes were developed to support efficient coding of interlaced video, and scalable video coding extensions were introduced to provide such additional functions as embedded coding of digital TV and HDTV and graceful quality degradation in the presence of transmission errors.

The MPEG-2 standard offers enhanced capability of many telemedicine applications. At the higher bit rate of MPEG-2, a telemedicine system can take advantage of emerging video communications services to provide more flexible services and expand some remote medical consultation services over ATM, satellite, and terrestrial digital broadcasting distributions. As the MPEG-2 standard targets mainly HDTV and digital TV applications, telemedicine applications will benefit greatly the superior video quality in terms of both spatial and temporal resolution. Such high-quality video will enable telemedicine to tap many new applications that otherwise cannot be explored, among them real-time transmission of some high-resolution teleradiology images and telepathology images.

Anticipating the rapid convergence of telecommunications industries, computer, TV, and film industries, the MPEG group officially initiated a new MPEG-4 standardization phase in 1994—with the mandate to standardize algorithms and tools for coding and flexible representation of audiovisual data that are able to meet the challenges of future multimedia applications [28]. Four major future needs are identified and addressed in the development of the MPEG-4 standard: (1) universal accessibility and robustness in error-prone environments, (2) high interactive capability, (3) coding of natural and synthetic data, and (4) high compression efficiency. Bit rates targeted for the MPEG-4 video standard are between 5 kbps and 64 kbps for mobile or PSTN video applications and up to 2 Mbps for TV and film applications. The release of the MPEG-4 International Standard was targeted for late 1998.

Although the MPEG-4 standard encompasses a much wider scope of applications than telemedicine systems intended to accommodate, it will have a great impact on the quality of many telemedicine applications. These applications may include (1) video-based telemedicine services over the Internet and Intranets; (2) telemedicine video

transmission over wireless channels, such as an in-hospital mobile network and combat-field wireless links; (3) a video database search in heterogeneous network environments, including various medical image storage facilities and hospital medical record management environments; and (4) virtual-reality applications in healthcare such as remote visualization and image-guided surgery. As the demand for more sophisticated multimedia applications in healthcare grows and computer and communications systems integration continues, various video coding standards that have been developed or are currently under development are expected to facilitate enhanced telemedicine systems as well as improved healthcare services.

1.3. Digital Imaging

Imaging devices have been an integral part of healthcare service, especially diagnosis, since its very beginning. Many imaging devices have actually been invented primarily for medical applications. Traditional media used to record static diagnosis images include sheet and roll film for radiography and photography, whereas traditional media used to record dynamic images include movie film and videotapes. Modern medical imaging devices often create digital images directly. These digital imaging modalities include computer tomography (CT), magnetic resonance imaging (MRI), single-photon emission computer tomography (SPECT), and positron emission tomography (PET). For the images and videos acquired with traditional media to be exchanged over the telemedicine network, they must be converted into digital format by an appropriate digitization process to preserve the required image quality for diagnosis. A typical 11 in. \times 17 in. chest film requires at least 2000×2000 pixels and an optical dynamic range of at least 4000 to 1 (12 bits) to represent the image adequately [15]. The compression of medical images is often needed for telemedicine applications to reduce the storage and transmission costs and to reduce access time. Various image and video compression techniques and standards have been discussed previously. However, many of these generic compression techniques cannot be directly applied to diagnostic images as they employ lossy compression schemes.

The American College of Radiologists and the National Electrical Manufacturers Association (ACR-NEMA) sponsored and developed the Digital Imaging and Communications in Medicine (DICOM) Standard to meet the needs of manufacturers and users of medical imaging equipment, particularly computer radiography (CR), CT, MRI, and picture archiving and communication systems (PACS) for interconnection of devices on standard networks. The DICOM standard also provides a means by which users of imaging equipment may assess whether two devices claiming conformance are able to exchange meaningful information. As the DICOM is a standard for the transmission of radiological images from one location to another for the purpose of interpretation or consultation [29], it will have a great impact on development of telemedicine systems. In addition to personnel qualifications, licensing, and quality control, the standard includes equipment guidelines for digitization of both small and large matrix

images, display capabilities, and patient database requirements.

The DICOM standard allows digital communications between diagnostic and therapeutic equipment and systems from various manufacturers. Such connectivity is important to cost effectiveness in healthcare and therefore is crucial to the development of cost-effective telemedicine systems. Telemedicine systems with the DICOM standard can provide radiology services within facilities as well as across geographic regions. Therefore, they gain maximum benefit from existing resources and keep costs down through compatibility of new equipment and systems. For example, workstations, CT scanners, MR imagers, film digitizers, shared archives, laser printers, and computers from multiple vendors and located at one site or many sites can talk to one another by means of the DICOM standard across an open-system network. As a result, medical images can be captured and communicated more quickly and the healthcare providers in a telemedicine system can make diagnoses and treatment decisions more quickly. In summary, digital imaging and the related DICOM standard are able to facilitate an improved quality of healthcare through a networked telemedicine system.

1.4. Multimedia Integration

Today's telemedicine systems have evolved from simple video conferencing between the service provider and participant to integrating multiple types of media into a coherent medical information system for the service provider to optimize decision making in the diagnosis and treatment process. In general, multimedia resources enable telemedicine system developers to integrate a high level of interactivity into routine healthcare activities, such as patient-information gathering, problem solving, therapy management, and treatment follow-up. The integration of multimedia in a telemedicine system is characterized by computer-controlled production, manipulation, presentation, storage, and communications of several types of different media. Such integration enhances the value of the telemedicine system in that the traditional audiovisual world has been augmented by the processing of a variety of healthcare-related information to reinforce the diagnostic and treatment decision. It creates new opportunities for home-based multimedia integrated telemedicine systems, in which patients are able to monitor, treat, and learn more about their own health problems through the manipulation of a wide variety of health-related information. A telemedicine system with multimedia integration capability offers additional opportunities for healthcare providers to explore medical options that cannot be accomplished through traditional face-to-face healthcare services.

One specific area in which multimedia integration can play an important role is the coherent interpretation of patient data obtained from either direct or indirect patient observations. Direct observation of a patient may produce the data obtained from senses such as sight, sound, touch, and smell and through interaction with the patient. Indirect observations of a patient may be accomplished

through diagnostic instruments, including many medical imaging devices. These observations may be compared with the patient's health history to derive the progression of changes for a specific health problem. In the conventional healthcare setting, the clinician usually makes verbal notes and marks some sketches to characterize the observations. With multimedia integration tools, quantification of the patient data, such as computational analysis of the diagnostic images, becomes possible. Such quantification allows objective comparisons of the patient data at the follow-up examination and enables consistent treatment protocols even when the patient is assigned to a different healthcare provider at the follow-up examination.

Another application for multimedia integration is the management of the electronic medical record. With multimedia integration, electronic patient medical records, including those acquired at a remote site, can be shared online in a telemedicine system among physicians, patients, and specialists, as well as offline to facilitate consultation and second opinions. The management of the electronic medical records through multimedia integration has been made possible because, in a telemedicine system, the primary patient data can be electronically captured as images, videos, sounds, graphics, and text. In addition, the networked telemedicine systems allow sharing of patient data that may be located away from the service site or distributed at several sites.

Finally, multimedia integration is the key to access to Internet resources, including continuing medical education and case consultation. As the Internet offers hyperlinked multimedia information for either public or restricted access, it may be an integral part of a telemedicine system to provide access for the general public to medical education or for a restricted pool of participants to provide sharing of specific medical information. It is anticipated that the potential for multimedia integration will be further expanded in many information systems, including various telemedicine applications.

In summary, the convergence of communications and computer technologies has shaped a wide range of new telemedicine applications. As the technologies advance to new levels, new applications will transform the daily routine of a healthcare provider and offer enhanced service quality.

2. HUMAN AND POLICY CONTEXTS OF TELEMEDICINE

The success of the telemedicine system does not depend exclusively on technological infrastructures. Technological infrastructures are necessary conditions for the implementation of telemedicine systems. However, they are not sufficient conditions for implementation. An important factor that influences the success of a telemedicine system is the human infrastructure, which can be complex [30]. In fact, it has been reported that most failures of telemedicine programs are associated with the human aspects of implementation [31]. Several factors have been identified that could impede the acceptance and adoption of telemedicine, including the documentation of benefits

for clinicians and patients, incorporation of telemedicine with existing practices, operation of the equipment by participants, assessment of needs and preferences [32], and government policies [1]. As telemedicine practice involves both patients and healthcare providers, the success of an advanced system will eventually be determined by human participants, not the technologies that support the system.

The documentation of benefits for clinicians and patients is in fact a cultural and social factor. The benefits for the clinician may include professional image and healthcare quality improvement. In terms of professional image, the adoption of relatively new technology such as telemedicine by the clinicians may be regarded poorly by their peers, even though in many cases, the quality of the care has indeed been improved. Documentation on how telemedicine can help improve professional image and quality of healthcare service is greatly needed. The benefits for patients have been better documented, especially in the case of enhancing rural healthcare through telemedicine. However, more efforts are needed to educate patients and customers about the benefits of a well-staffed and well-equipped central hospital in a telemedicine system. Such benefits are evident when multimedia integration of patients' data can be made possible by a telemedicine system so that an optimal medical decision can be derived.

The next three issues are human factors. First, it is often difficult to incorporate telemedicine with existing practices. Interactive applications require primary-care and consulting practitioners at different locations to be present simultaneously to take advantage of a real-time system. This is quite different from the existing practice, in which consulting by peers is usually performed asynchronously. Many telemedicine systems are centrally located, requiring healthcare providers to travel from their traditional location of practice to use the systems. With practical and affordable multimedia desktop workstations soon to be widely available, it will be easier to incorporate telemedicine into the existing mode of healthcare practice.

Second, the operation of telemedicine equipment is usually not user friendly. The difficulties associated with this issue include the initial installation of the telemedicine system and continual maintenance and upgrading. In general, healthcare providers lack sufficient time to learn how to use complicated hardware and software, which usually require quite extensive training. This problem is further complicated by many information technology products that are designed from the perspective of the technology developer rather than that of the end user. As a result, users can find it very difficult to operate telemedicine equipment, and such problems can affect the quality of healthcare in a telemedicine system.

Third, the assessment of needs and preferences is inadequate. The needs of patients and medical practitioners are often not well communicated to the developer of a specific telemedicine system. The needs of patients include health status and problems, whereas the needs of practitioners include individual and organization characteristics, capacities, and objectives. The preferences are

related mostly to healthcare providers. Often, a practitioner would prefer a certain form of presentation of patient data to make a comfortable decision. Those preferences, however, may not be possible as a result of technical limitations and financial considerations. As such needs and preferences are usually individual, it will be a challenge to develop effective methods and tools for assessing them and to provide technology that can incorporate them. A continual exchange between the users and designers of telemedicine systems is critical to their success.

In addition to these human factors, the success of telemedicine also depends on public policies at both federal and state levels. One recent federal policy that will shape the future of telemedicine is the Telecommunication Bill of 1996. The part of the policy most relevant to telemedicine is the assurance of universal communication services at affordable rates for rural, high-cost, or low-income areas. Even though the National Information Infrastructure initiative includes more elements than just telemedicine, such a policy presents an incentive for the development of telemedicine systems, especially when many telemedicine systems are designed to enhance healthcare services for rural and underserved areas. State policies provide mixed incentives for the development of telemedicine. For example, policies regarding professional licensure have been greatly challenged by telemedicine. In particular, the medical practice through telemedicine complicates the decision as to whether the practitioner should be licensed if the practitioner and the patient are located across state lines. Existing state laws usually require that any out-of-state physician who evaluates and treats a patient in the state to be licensed in that state. Most states also provide an exception that allows physicians licensed in that state to consult with physicians from other states or even other countries, and this exception could be applied to some telemedicine applications. State policies of consultation exception are not uniform, however, and many of them limit the exception to one-time or occasional consultations. Furthermore, some states even have amended or are considering amending physician licensure to prohibit out-of-state physicians from practicing without a license in that state [33,34]. The inflexible or over-restrictive licensing policies of many states have a negative impact on the development of telemedicine systems. A national legislation that would create a national telemedicine license seems unlikely, unless telemedicine can prove itself despite regulatory obstacles. Several other policy issues also have impact on the development of telemedicine. These include policies on privacy, confidentiality, and security; payment policies for telemedicine practice; and policies on the regulation of medical devices. Privacy and confidentiality issues also exist in conventional healthcare practice, but the electronic recording, storage, transmission, and retrieval of patient data in a telemedicine system increase opportunities for infringing on patients' privacy and confidentiality rights. Payment policies for telemedicine practice must also be addressed. In fact, insurer and healthcare restrictions on fee-for-service payments to physicians for telemedicine consultations could hinder the growth of telemedicine development. Issues include lack of information on the value of telemedicine compared with

conventional service and uncertainty about whether telemedicine would cause excess service use or increase inappropriate use. The policies on the regulation of medical devices have been handled by the U.S. Food and Drug Administration (FDA) mainly through the Center for Devices and Radiological Health (CDRH). Many of the devices used in telemedicine have been regulated by CDRH to ensure that these devices are safe, effective, and properly manufactured. Most devices are hardware equipment such as medical imaging devices and can be appropriately regulated. However, the regulation of software used to transmit, store, process, display, and copy medical images is more complicated. The FDA is currently still exploring new policies that can better regulate software.

3. CONCLUSION

Telemedicine applications can expand the availability and accessibility of healthcare and improve the quality of medical services. Telemedicine is not a single technology or a small group of related technologies. Instead, it is an integration of many communications and information technologies. Key technologies in telemedicine include digital communications, digital video and video compression, digital imaging, and multimedia integration. In addition to technical infrastructure, human factors will also have a profound influence on the success of telemedicine.

Telemedicine will continue to evolve; the development of communications, computer, and information technologies is still moving forward at an unprecedented pace. There are great opportunities for telemedicine to improve diagnostics, therapeutics, and education in healthcare. However, great challenges remain. In particular, social, cultural, and legal obstacles must be overcome to achieve the maximum potential of telemedicine.

TELEMETRY

VICTOR BOYADZHIAN
Jet Propulsion Laboratory

The purpose of a telemetry system is to convey measurement information reliably and transparently from a remotely located data generating source to users located in space or on earth. Typically, data generators are scientific sensors, science housekeeping sensors, engineering sensors, and other subsystems on board a spacecraft.

The advent of capable microprocessor-based hardware will result in data systems with demands for greater throughput and a requirement for corresponding increases in spacecraft autonomy and mission complexity. These facts, along with the current technical and fiscal environments, create a need for greater telemetering capability and efficiency with reduced costs.

The telemetry link is the voice of the spacecraft, providing two basic types of information: performance and experimental information. By performance measurement, we mean spacecraft operating conditions consisting of temperature, pressure, voltage, current, subsystem monitoring, and so forth. The experimental measurements are related to scientific objectives of the mission, like investigations of solar plasma, magnetic fields, and micrometeorites. Because of the large number of measurements to be performed, it is necessary to time-multiplex them according to some priority.

Telemetry data can be categorized into three basic forms: *engineering parameter data*, *attitude*, and *payload*.

Engineering parameter data, also known as housekeeping data, keep check on the operating status and health of the spacecraft's onboard equipment. The following are a few forms and examples:

1. *Temperature*. Thermistors are usually used to convert temperature data into their voltage analog. In case of high temperatures, thermocouples are used to detect the temperature whose output does not exceed more than a few millivolts. This voltage signal corresponding to temperature is dc amplified to a level more suitable for the telemetry encoder.
2. *Pressure*. Various forms of pressure transducers are used to monitor pressure in fuel tanks and plenum chambers.
3. *Operating Status*. The operating status of a particular piece of equipment is represented by a single bit that indicates a function mode is enabled (Logic

Hi) or disabled (Logic Low). For proportional status information, such as amplifier gain setting, the bits are grouped into words of appropriate length.

4. *Redundancy Status*. The redundant status indicates which redundant side of equipment is in use. This is monitored by a status bit (either Logic Hi or Logic Low).
5. *Deployment of Mechanisms*. A microswitch is used to provide a status bit of separation from the launcher.
6. *Voltages and Currents of Equipment and Power Supplies*. Usually, these voltages are scaled to a common full-scale range. Current monitoring may involve a few signal processing circuits.

These are just a few examples of engineering parameter data to be monitored on a modern satellite payload. The result of every command is checked via the telemetry. Typical sampling and updating of these data are performed from every few seconds to every few minutes and hence require small bandwidths, which makes the engineering parameter data bit rate a few hundred per second for sufficient transmittal of total information.

Attitude data develop from a variety of sensors, such as gyroscopes, star mappers, accelerometers, and sun and earth sensors. The data can be analog, digital, or both.

During the transfer and intermediate orbit phase, the attitude and velocity will change rapidly, and frequent sampling is needed (i.e., one to four times per second). High sampling rates needed during some mission phases may lead to a bandwidth that exceeds that which can be provided conveniently by a standard PCM data system.

Payload data are variable and require individual consideration. For example, applications and scientific payloads are likely to need only few channels of data, but their rates may be high. Data compression may be required to reduce the downlink rate.

After launch, the command link is required in conjunction with telemetry link to supply information needed by the various spacecraft subsystems. Many commands are necessary for the routine operation and control of spacecraft functions; some are provided for changing the mission emphasis if unusual or unexpected conditions are encountered, whereas others are required to correct erratic operations or to salvage the mission if a spacecraft failure occurs. Command operation varies in complexity from simple on-off operations to trajectory-correction factors (based on tracking) for maneuvers. Usually, all of the commands will fall into two classes: (1) the discrete command for switching functions, which requires only an address for identification and execution, and (2) the quantitative command, which requires a magnitude in addition to the address.

1. TELEMETRY DATA ENCODING

All data considered develop from three basic forms: analog, digital bilevel, and digital serial. In conditioning *analog data*, the first step is scaling it to a common full-scale range; 0 V to 5 V is the usual range. The frequency

components greater than half the sampling frequency are then removed by a low-pass filter to prevent aliasing errors. Filtering channels are then sampled and converted to a digital word. An overall accuracy of about 1% is sufficient, and an 8 bit A/D converter is used to achieve this.

In *digital bilevel* data, the OFF state is represented by zero voltage and the ON state by +5 V for complementary metal-oxide semiconductor (CMOS) and 2.4 V for transistor-transistor logic (TTL). Individual groups are then arranged into 8 bit words and sampled by logic gates whose outputs are serialized and mixed with the main PCM data stream.

Digital data are usually acquired in serial form for reasons of simplifying the spacecraft's cable harness. Such data are initially stored as an 8 bit or 16 bit word in the shift register located in the equipment generating the data.

The usual spacecraft telemetry system is broken down into two major conceptual categories: a packet telemetry concept [1] and a telemetry channel coding concept [2].

Packet telemetry is a concept that facilitates the transmission of space-acquired data from source to user in a standardized and highly automated manner. Packet telemetry provides a mechanism for implementing common data structures and protocols that can enhance the development and operation of space mission systems. Packet telemetry addresses the following two processes:

1. The end-to-end transport of space mission data sets from source application processes located in space to distributed user application processes located in space or on earth.
2. The intermediate transfer of these data sets through space data networks; more specifically, those elements that contain spacecraft, radiolinks, tracking station, and mission control centers as some of their components.

Packet telemetry along with telemetry channel coding services provide the user reliable and transparent delivery of telemetry information.

2. TELEMETRY SYSTEM CONCEPT

The system design technique known as layering was found to be a very useful tool for transforming the telemetry system concept into sets of operational and formatting procedures. The layering approach is patterned after the International Organization for Standardization's Open Systems Interconnection layered network model, which is a seven-layer architecture that groups functions logically and provides conventions for connecting functions at each layer. Layering allows a complex procedure such as the telemetering of spacecraft data to the users to be decomposed into sets of peer functions residing in common architectural strata.

Within each layer, the functions exchange data according to established standard rules, or protocols. Each layer

draws on a well-defined set of services provided by the layer below and provides a similarly well-defined set of services to the layer above. As long as these service interfaces are preserved, the internal operations within a layer are unconstrained and transparent to other layers. Therefore, an entire layer within a system may be removed and replaced as dictated by user or technological requirements without destroying the integrity of the rest of the system. Furthermore, as long as the appropriate interface protocol is satisfied, users can interact with the system/service at any of the component layers. Layering is therefore a powerful tool for designing structured systems that change because of the evolution of requirements or technology.

A companion standardization technique that is conceptually simple, yet very robust, is the encapsulation of data within an envelope or header. The header contains the identifying information needed by the layer to provide its service while maintaining the integrity of the envelope contents.

2.1. Packetization Layer

Within packet telemetry, spacecraft-generated application data are formatted into end-to-end transportable data units called TM (transfer frame) source packets. These data are encapsulated within a primary header that contains identification, sequence control, and packet length information and an optional trailing error control field. A TM source packet is the basic data unit teleme-tered to the user by the spacecraft and generally contains a meaningful quantity of related measurements from a particular source.

2.2. Segmentation Layer

To provide assistance with data flow control, the Packet Telemetry Recommendation provides the capability to segment large packetized transportable data units into smaller communication-oriented TM source packets (Version 1 format) or TM segments (Version 2 format) for transfer through the space data channel. Consequently, the TM source packets and/or TM segments are of proper size for placement into the data field of the data unit of the next lower layer.

2.3. Transfer Frame Layer

In spacecraft communication, the TM (transfer frame) is used to transport source packets and segments through the telemetry channel to the receiving telecommunica-tions network. TM transfer frame protocols offer a range of delivery service options. An example of such a service option is the multiplexing of TM transfer frames into virtual channels (VCs).

The TM transfer frame begins with an attached frame synchronization marker and is followed by a primary header. The primary header contains frame identification, channel frame count information, and frame data field status information. The transfer frame data field may be followed by an optional trailer contain-ing an operational control field and/or a frame error

control field. The first of these fields provides a standard mechanism for incorporating a small number of real-time functions (e.g., telecommand verification or spacecraft clock calibration). The error control field provides the capability for detecting that which may have been introduced into the frame during the data handling process. The delivery of transfer frames requires the services provided by the lower layers (e.g., carrier, modulation/detection, and coding/decoding) to accomplish its role.

2.4. Channel Coding Layer

As a basic system requirement is the error-free delivery of the transfer frames, telemetry channel coding is used to protect the transfer frames against telemetry channel noise-induced errors. Reference 2 describes the Consultative Committee for Space Data Systems (CCSDS) Recommendation for Telemetry Channel Coding, includ-ing specification of a convolutionally encoded inner chan-nel concatenated with a Reed–Solomon block-oriented outer code [4]. The basic data units of the CCSDS Telemetry Channel Coding that interface with the layer below are the channel symbols output by the convolutional encoder. These are the information bits representing one or more transfer frames as parity-protected channel symbols.

The RF channel physically modulates the channel symbols into signal patterns interpretable as bit repre-sentations. Within the error detecting and correcting capability of the channel code chosen, errors that occur as a result of the physical transmission process may be detected and corrected by the receiving entity.

Telemetry source packets may be segmented and placed into the data field of telemetry segments, which are preceded by a header. The source packets and/or the segments are placed into the data field of the transfer frame, which is preceded by a transfer frame header. If the specified Reed–Solomon code is used in the channel coding scheme, the transfer frame is placed into the Reed–Solomon data space of the Reed–Solomon codeblock, and the codeblock is preceded by an attached synchronization marker.

2.5. Relationship Between Telemetry and Telecommand Systems

A different level of understanding is revealed by consider-ing interactions between the telemetry system and other systems in the operational environment. There is a balanced relationship between the telemetry system and the uplink telecommand system. The two systems work hand-in-hand to ensure the transfer of user directives from the sending end (traditionally on the ground) to the receiving end (controlled process, device, or instrument). Of course, the telemetry system does a great deal more than simply returning command receipt status informa-tion to the sender: Its usual function is to provide reliable, efficient transfer of all spacecraft data (housekeeping, sensor readings, etc.) back to users.

3. TELEMETRY DATA FORMATTING

The baseband data $d_i(t)$ can have different formats, as illustrated in Fig. 1. With a nonreturn to zero-level (NRZ-L) data format, a logical one is represented by one level and a logical zero by the other. With NRZ-M (mark), a logical one is represented by a change in level and a logical zero by no change. Two other formats, biphase and Miller, are also defined in Fig. 1.

Referring to Fig. 1 and assuming that binary waveform levels are $\pm A$, the NRZ signaling format falls into the class of signals [5] whose spectrum is given by

$$S_m(f) = \frac{1}{T} p(1-p) |S_1(f) - S_2(f)|^2 + \frac{1}{T^2} \sum_{n=-\infty}^{\infty} \left| pS_1\left(\frac{n}{T}\right) + (1-p)S_2\left(\frac{n}{T}\right) \right|^2 \delta\left(f - \frac{n}{T}\right) \quad (1)$$

As the elementary signal is a rectangular pulse of width T , its Fourier transform is

$$S_1(f) = -S_2(f)AT \exp(-j\pi fT) \frac{\sin(\pi fT)}{\pi fT} \quad (2)$$

Substituting Eq. (2) into Eq. (1), and letting $E = A^2T$, we get

$$\frac{S_m(f)}{E} = \frac{1}{T} (1-2p)^2 \delta(f) + 4p(1-p) \left[\frac{\sin^2(\pi fT)}{(\pi fT)^2} \right] \quad (3)$$

When $p = 1/2$, the dc spike at the origin disappears and the NRZ signaling format falls into the noise equivalent power (NEP) class with

$$\frac{S_m(f)}{E} = \left[\frac{\sin^2(\pi fT)}{(\pi fT)^2} \right] \quad (4)$$

3.1. RZ Baseband Signaling

In the RZ case, we have $S_1(f) = 0$, and $S_2(f)$ corresponds to the Fourier transform of a half-symbol-wide pulse; that is,

$$S_2(f) = \frac{AT}{2} \exp\left(\frac{-j\pi fT}{2}\right) \left[\frac{\sin\left(\frac{\pi fT}{2}\right)}{\left(\frac{\pi fT}{2}\right)} \right] \quad (5)$$

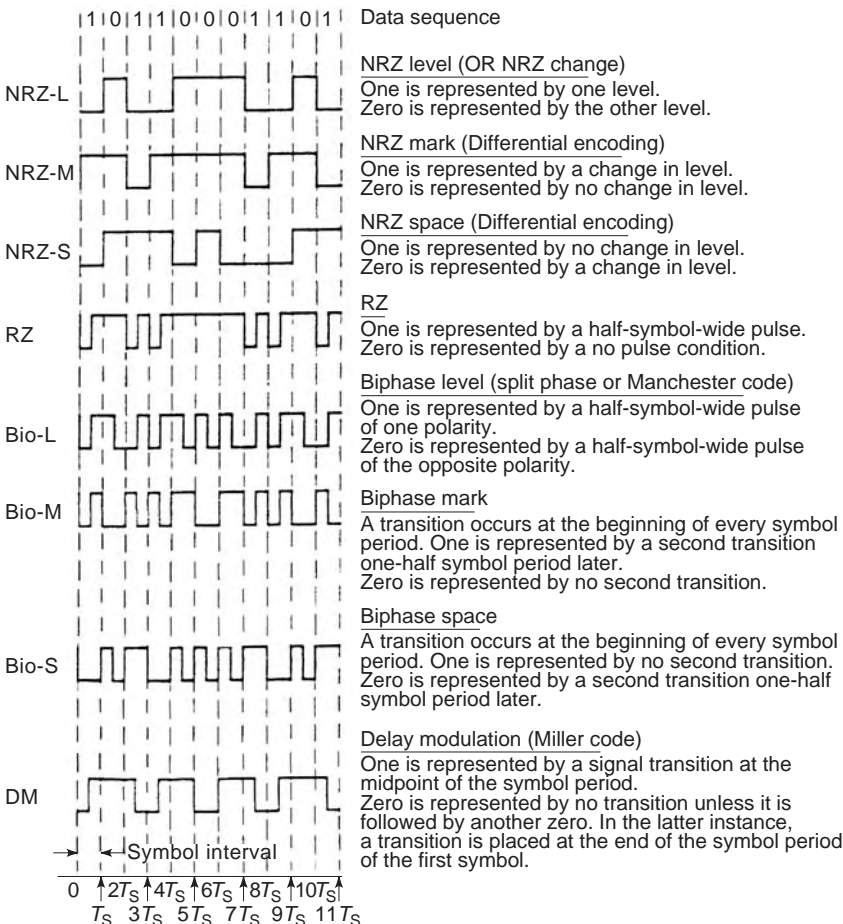

Figure 1. Various binary PCM waveforms.

As the source is again purely random, substituting Eq. (5) into Eq. (1) gives

$$\begin{aligned} \frac{S_m(f)}{E} &= \frac{1}{4T}(1-p)^2\delta(f) + \frac{1}{4T}(1-p)^2 \\ &\times \sum_{\substack{n=-\infty \\ n \neq 0}}^{\infty} \left(\frac{2}{n\pi}\right)^2 \delta\left(f - \frac{n}{T}\right) \\ &+ \frac{1}{4}p(1-p) \left[\frac{\sin^2\left(\frac{\pi f T}{2}\right)}{\left(\frac{\pi f T}{2}\right)^2} \right] \end{aligned} \quad (6)$$

3.2. Biphase (Manchester) Baseband Signaling

Two rudimentary signals in Manchester baseband signaling are defined by

$$\begin{aligned} s_1(t) &= A; \quad 0 < t < T/2 \quad \text{and} \quad -A; \quad T/2 < t < T \\ s_2(t) &= -s_1(t) \end{aligned} \quad (7)$$

Replacing the Fourier transform of Eq. (7) into Eq. (1) will yield

$$\begin{aligned} \frac{S_m(f)}{E} &= \frac{1}{T}(1-2p)^2 \sum_{\substack{n=-\infty \\ n \neq 0}}^{\infty} \left(\frac{2}{n\pi}\right)^2 \delta\left(f - \frac{n}{T}\right) \\ &+ 4p(1-p) \left[\frac{\sin^4\left(\frac{\pi f T}{2}\right)}{\left(\frac{\pi f T}{2}\right)^2} \right] \end{aligned} \quad (8)$$

for $p = 1/2$, the line spectrum disappears, and

$$\frac{S_m(f)}{E} = \left[\frac{\sin^4\left(\frac{\pi f T}{2}\right)}{\left(\frac{\pi f T}{2}\right)^2} \right] \quad (9)$$

The Miller coding scheme can be modeled as a Markov source with four states whose stationary probabilities all equal 1/4 and whose transition matrix is given by

$$P = \begin{bmatrix} 0 & 1/2 & 0 & 1/2 \\ 0 & 0 & 1/2 & 1/2 \\ 1/2 & 1/2 & 0 & 0 \\ 1/2 & 0 & 1/2 & 0 \end{bmatrix} \quad (10)$$

Another property of the Miller code is that it satisfies the recursion relation

$$P^{4+i}\Gamma = -\frac{1}{4}P^i\Gamma, \quad i \geq 0 \quad (11)$$

where Γ is the signal correlation matrix whose ik th is defined by

$$\gamma_{ik} \equiv \frac{1}{\sqrt{E_i E_j}} \int_0^T s_i(t)s_k(t)dt \quad i, k = 1, 2, 3, 4 \quad (12)$$

For the Miller code, the four rudimentary signals are defined as

$$\begin{aligned} s_1(t) &= -s_4(t) = A; & 0 \leq t \leq T \\ s_2(t) &= -s_3(t) = A; & 0 \leq t \leq T/2 \\ s_2(t) &= -s_3(t) = -A; & T/2 \leq t \leq T \\ \text{and } E_i &= A^2T; & i = 1, 2, 3, 4 \end{aligned} \quad (13)$$

Substituting Eq. (13) into Eq. (12), and putting the results in the form of a matrix,

$$\Gamma = \begin{bmatrix} 1 & 0 & 0 & -1 \\ 0 & 1 & -1 & 0 \\ 0 & -1 & 1 & 0 \\ -1 & 0 & 0 & 1 \end{bmatrix} \quad (14)$$

Finally, using Eqs. (10), (11), and (14) in the general PSD result, which is

$$\begin{aligned} S_m(f) &= \frac{1}{T} \sum_{i=1}^M p_i |s'_i(f)|^2 + \frac{1}{T^2} \sum_{n=-\infty}^{\infty} \left| \sum_{i=1}^M p_i s_i\left(\frac{n}{T}\right) \right|^2 \delta\left(f - \frac{n}{T}\right) \\ &+ \frac{2}{T} \text{Re} \left[\sum_{i=1}^M \sum_{k=1}^M p_i s_i^*(f) P_{ik} (e^{-j2\pi f T}) \right] \end{aligned} \quad (15)$$

where $S_i(f)$ is the Fourier transform of the i th elementary signal $s_i(t)$ and

$$P_{ik}(z) \equiv \sum_{n=1}^{\infty} P_{ik}^{(n)} z^n \quad (16)$$

$$s'_i(t) = s_i(t) - \sum_{k=1}^N p_k s_k(t) \quad (17)$$

yields the result of Miller code [5]

$$\begin{aligned} \frac{S_m(f)}{E} &= \frac{1}{2\theta^2(17 + 8 \cos \theta)} (23 - 2 \cos \theta - 22 \cos 2\theta \\ &- 12 \cos 3\theta + 5 \cos 4\theta + 12 \cos 5\theta \\ &+ 2 \cos 6\theta - 8 \cos 7\theta + 2 \cos 8\theta) \end{aligned} \quad (18)$$

where

$$\theta \equiv \pi f T \quad (19)$$

Spectral properties of the Miller code that make it valuable are as follows:

1. The majority of the signaling energy lies in frequencies less than one-half of the data rate, $R = 1/T$.
2. The spectrum is small, in the vicinity of $f = 0$. This spectral minimum facilitates carrier tracking, which can also be more efficiently achieved than Manchester coding.

3. The Miller coding is insensitive to the 180° phase ambiguity common to NRZ-L and Manchester coding.
4. Bandwidth requirements are approximately one-half those needed by Manchester coding.

When the data pulse stream experiences data asymmetry, distortion of the continuous component of the PSD as well as the presence of a line spectrum in PSD occurs. This problem obviously degrades the error probability of the receiving system. Let us look at the PSD of NRZ and Manchester streams when data asymmetry is present.

3.2.1. NRZ Data. Let us assume that +1 NRZ symbols are elongated by $\Delta T/2$ (relative to their nominal value of T -s) when a negative-going data transition occurs and -1 symbols are shortened by the same amount when a positive-going data transition occurs. During the absence of data transition, the symbols maintain their nominal T -s value.

Using generalized M -ary source model, where $M = 4$ with

$$\begin{aligned}
 s_1(t) &= A; & -T/2 \leq t \leq T(1 + \Delta)/2 \\
 s_1(t) &= 0; & \text{otherwise} \\
 s_2(t) &= -A; & -T/2 \leq t \leq T(1 - \Delta)/2 \\
 s_2(t) &= 0; & \text{otherwise} \\
 s_3(t) &= A; & -T/2 \leq t \leq T/2 \\
 s_3(t) &= 0; & \text{otherwise} \\
 s_4(t) &= -A; & -T/2 \leq t \leq T/2 \\
 s_4(t) &= 0; & \text{otherwise}
 \end{aligned} \tag{20}$$

The stationary probabilities associated with those four waveforms are

$$\begin{aligned}
 p_1 &= pp_t; & p_2 &= (1 - p)p_t; \\
 p_3 &= p(1 - p_t); & p_4 &= (1 - p)(1 - p_t)
 \end{aligned} \tag{21}$$

where p refers to the transition probability, which is related to the priori probability of the +1 NRZ symbol, p , by

$$p_t = 2p(1 - p) \tag{22}$$

Taking the Fourier transform of Eq. (20) and substituting the results in Eq. (1), with a great detail of simplification we get

$$\begin{aligned}
 S_m(f) &= A^2 T \frac{\sin^2(\pi f T)}{(\pi f T)^2} [A_1(p_t) + A_2(p, p_t, \eta)] \\
 &+ A^2 T \frac{\sin^2(\pi f T \eta)}{(\pi f T)^2} A^3 T \frac{\sin^2(\pi f T \eta)}{(\pi f T)^2} A^3(p_t, \eta) \\
 &+ A^2 T \frac{\sin(2\pi f T)}{(\pi f T)^2} [A_4(p, p_t, \eta) - A_5(p, p_t)] \\
 &+ A^2 [2p - (1 - \eta p_t)]^2 \delta(f) \\
 &+ \frac{2A^2}{\pi^2} p_t^2 \sum_{n=1}^{\infty} \frac{1}{n^2} C(n, p, \eta) \delta\left(f \frac{n}{T}\right)
 \end{aligned} \tag{23}$$

where

$$\begin{aligned}
 A_1(p_t) &= p_t(1 - p_t)[1 + 2(1 - p_t)] - p_t^3 \\
 A_2(p, p_t, \eta) &= (3p_t^3 + p_t(1 - p_t)[1 + 2(1 - 2p)]) \cos^2(\pi f T \eta) \\
 A_3(p_t, \eta) &= p_t^t(1 + p_t^2 - p_t) \cos^2(\pi f t) + p_t^3 \cos(2\pi f T \eta) \\
 A_4(p, p_t, \eta) &= (p_t(1 - p_t)(1 - 2p) \left[\frac{1}{2} \cos(2\pi f T \eta) \right. \\
 &\quad \left. - p \sin(2\pi f T \eta) \right]) \\
 A_5(p, p_t) &= \frac{1}{2} p_t(1 - p_t)(1 - 2p) \\
 C(n, p, \eta) &= \sin^2(n\pi\eta) [\cos^2(n\pi\eta) + (1 - 2p)^2 \sin^2(n\pi\eta)] \\
 \eta &= \frac{\Delta}{2}
 \end{aligned} \tag{24}$$

3.2.2. Manchester Data. Let us assume that for +1 data bit, the first half of the Manchester symbol is elongated by $\Delta T/4$ (relative to its nominal value of $T/2$). The same will extend to the -1 symbol—the first half of the Manchester symbol shortened by the same amount. When no data transition occurs, the second half of the Manchester symbol retains its T -s value. In view of the preceding asymmetry model, we can use the generalized M -ary source model, where $M = 4$, with

$$\begin{aligned}
 s_1(t) &= A; & -T/2 \leq t \leq \Delta T/4 \\
 s_1(t) &= -A; & \Delta T/4 \leq t \leq (T/2)(1 + \Delta/2) \\
 s_1(t) &= 0; & \text{otherwise} \\
 s_2(t) &= -A; & -T/2 \leq t \leq -\Delta T/4 \\
 s_1(t) &= A; & \Delta T/4 \leq t \leq (T/2)(1 - \Delta/2) \\
 s_2(t) &= 0; & \text{otherwise} \\
 s_3(t) &= A; & -T/2 \leq t \leq \Delta T/4 \\
 s_3(t) &= -A; & \Delta T/4 \leq t \leq (T/2) \\
 s_3(t) &= 0; & \text{otherwise} \\
 s_4(t) &= -A; & -T/2 \leq t \leq -\Delta T/4 \\
 s_4(t) &= A; & \Delta T/4 \leq t \leq (T/2) \\
 s_4(t) &= 0; & \text{otherwise}
 \end{aligned} \tag{25}$$

As before, the stationary probabilities are associated with Eq. (21). Taking Fourier transforms of Eq. (25), and substituting the results in Eq. (1), we get

$$S_m(f) = (S_m(f))_c + (s_m(f))_d \tag{26}$$

where for $p = p_t = 1/2$ the discrete component $(S_m(f))_d$ is given by

$$(s_m(f))_d = \frac{9}{4}A^2\eta^2\delta(f) + \frac{2A^2}{\pi^2} \sum_{m=1}^{\infty} \frac{1}{m^2} [H_1(m, \eta) + H_2(m, \eta) + H_3(m, \eta)]\delta\left(f - \frac{m}{T}\right) \tag{27}$$

with

$$\begin{aligned} \eta &= \frac{\Lambda}{4} \\ H_1(m, \eta) &= \frac{\sin^2(m\pi\eta)[1 + 2h_1(m, \eta)]^2}{4} \\ H_2(m, \eta) &= \sin^2(2m\pi\eta) \\ H_3(m, \eta) &= 2 \sin^2(m\pi\eta)(\cos m\pi\eta)[1 + 2h_1(m, \eta)] \end{aligned} \tag{28}$$

where

$$h_1(m, \eta) = \cos^2\left(\frac{m\pi\eta}{2}\right); \text{ for } m \text{ odd} \tag{29}$$

and

$$h_1(m, \eta) = \sin^2\left(\frac{m\pi\eta}{2}\right); \text{ for } m \text{ even}$$

Likewise, for $p = p_t = 1/2$, the continuous component of Eq. (26) is given by

$$\begin{aligned} (S_m(f))_c &= \frac{A^2T^4 \sin^4\left(\frac{\pi f T}{4}\right)}{\left(\frac{\pi f T}{4}\right)^2} \\ &- A^2T[c_1(\eta) + c_2(\eta) + c_3] \frac{\sin^2(\pi f T \eta)}{\left(\frac{\pi f T}{2}\right)^2} \\ &- A^2TC_4(\eta) \frac{\sin^2\left(\frac{\pi f T \eta}{2}\right)}{\left(\frac{\pi f T}{2}\right)^2} \\ &+ A^2TC_5(\eta) \frac{\sin^2\left(\frac{\pi f T(1 + \eta)}{2}\right)}{\left(\frac{\pi f T}{2}\right)^2} \\ &+ A^2TC_6(\eta) \frac{\sin^2\left(\frac{\pi f T(1 - \eta)}{2}\right)}{\left(\frac{\pi f T}{2}\right)^2} \end{aligned} \tag{30}$$

where

$$\begin{aligned} C_1(\eta) &= \frac{1}{4} \sin^2\left[\frac{\pi f T(1 + \eta)}{2}\right] \left\{ \sin^2\left[\frac{\pi f T(1 - \eta)}{2}\right] + \cos \pi f T \eta \right\} \\ C_2(\eta) &= \frac{1}{8} \cos \pi f T \eta \left\{ 2 \sin^2\left[\frac{\pi f T(1 - \eta)}{2}\right] - \sin^2\left[\frac{\pi f T \eta}{2}\right] \right\} \\ C_3(\eta) &= \frac{1}{8} \left[1 - 4 \cos\left(\frac{\pi f \eta}{4}\right) \right] \\ C_4(\eta) &= \frac{\sin \pi f T \eta}{8} \left\{ \sin\left(\frac{\pi f T \eta}{2}\right) \right. \\ &\quad \left. + \sin\left(\frac{5\pi f T \eta}{2}\right) [1 - \cos \pi f T \cos \pi f T \eta] - \right. \\ &\quad \left. - \frac{3}{8} \sin\left(\frac{\pi f T}{4}\right) \sin\left(\frac{\pi f T \eta}{4}\right) \right. \\ &\quad \left. + \frac{1}{8} [2 \cos 3\pi f T \eta + \cos 2\pi f T \eta] \right\} \\ C_5(\eta) &= \frac{1}{8} \left\{ \sin^2\left(\frac{\pi f T(1 - \eta)}{2}\right) - \frac{3}{2} \sin^2\left[\frac{\pi f T(1 + \eta)}{2}\right] \right\} \\ C_6(\eta) &= \frac{3}{16} \sin^2\left(\frac{\pi f T(1 - \eta)}{2}\right) + \frac{1}{4} \sin^2\left(\frac{\pi f T}{2}\right) \cos \pi f T \eta \end{aligned} \tag{31}$$

4. TELEMETRY SYSTEM DESCRIPTION AND RATIONALE

4.1. Packet Telemetry

The traditional way of transmitting scientific applications and engineering data has been the time-division multiplexing (TDM) method. Packet telemetry represents an evolutionary step from the traditional TDM method. The packet telemetry process conceptually involves:

1. Encapsulating, at the source, observational data (to which may be added ancillary data to then interpret the observational data), thus forming an autonomous packet of information in real time on the spacecraft
2. Providing a standardized mechanism whereby autonomous packets from multiple data sources on the spacecraft can be inserted into a common frame structure for transfer to another space vehicle or to earth through noisy data channels and delivered to facilities where the packet may be extracted for delivery to the user

The packet telemetry process has the following conceptual attributes:

1. Facilitating the acquisition and transmission of instrument data at a rate appropriate for the phenomenon being observed

2. Defining a logical interface and protocol between an instrument and its associated ground support equipment that remains constant throughout the life cycle of the instrument (bench test, integration, flight, and possible reuse)
3. Simplifying overall system design by allowing microprocessor-based symmetric design of the instrument control and data paths (telecommand packets in, telemetry packets out) compatible with commercially available components and interconnection protocol standards
4. Eliminating the need for mission-dependent hardware and/or software at intermediate points within the distribution networks through which space data flow; in particular, enabling the multimission components of these networks to be designed and operated in highly automated fashion, with consequent cost and performance advantages
5. Facilitating interoperability of spacecraft whose telemetry interfaces conform to CCSDS guidelines (i.e., allowing very simple cross strapping of spacecraft and network capabilities between space agencies)
6. Enabling the delivery of high-quality data products to the user community in a mode that is faster and

less expensive than would be possible with conventional telemetry

Figure 2 shows a functional diagram of the telemetry data flow from the creation of a dataset by an application process operating within a spacecraft “source” (instrument or subsystem), through to the delivery of the same data to a user “sink” (application process) on the ground. As many of the elements of this flow are currently mission unique, a primary objective of packet telemetry is to define stable, mission-independent interface standards for the communications path within the flow.

4.2. Telemetry Source Packet

A telemetry source packet is a data unit that encapsulates a block of observational data that may include ancillary data and that may be directly interpreted by the receiving end application process. Detailed discussion of the format specification for the telemetry source packet is specified in Ref. 1. The source packet format (Version 1), with the addition of a secondary header and packet error control field, is reproduced in Fig. 3 for the convenience of the reader.

From the viewpoint of data processing efficiency, the CCSDS strongly recommends that all major fields of all

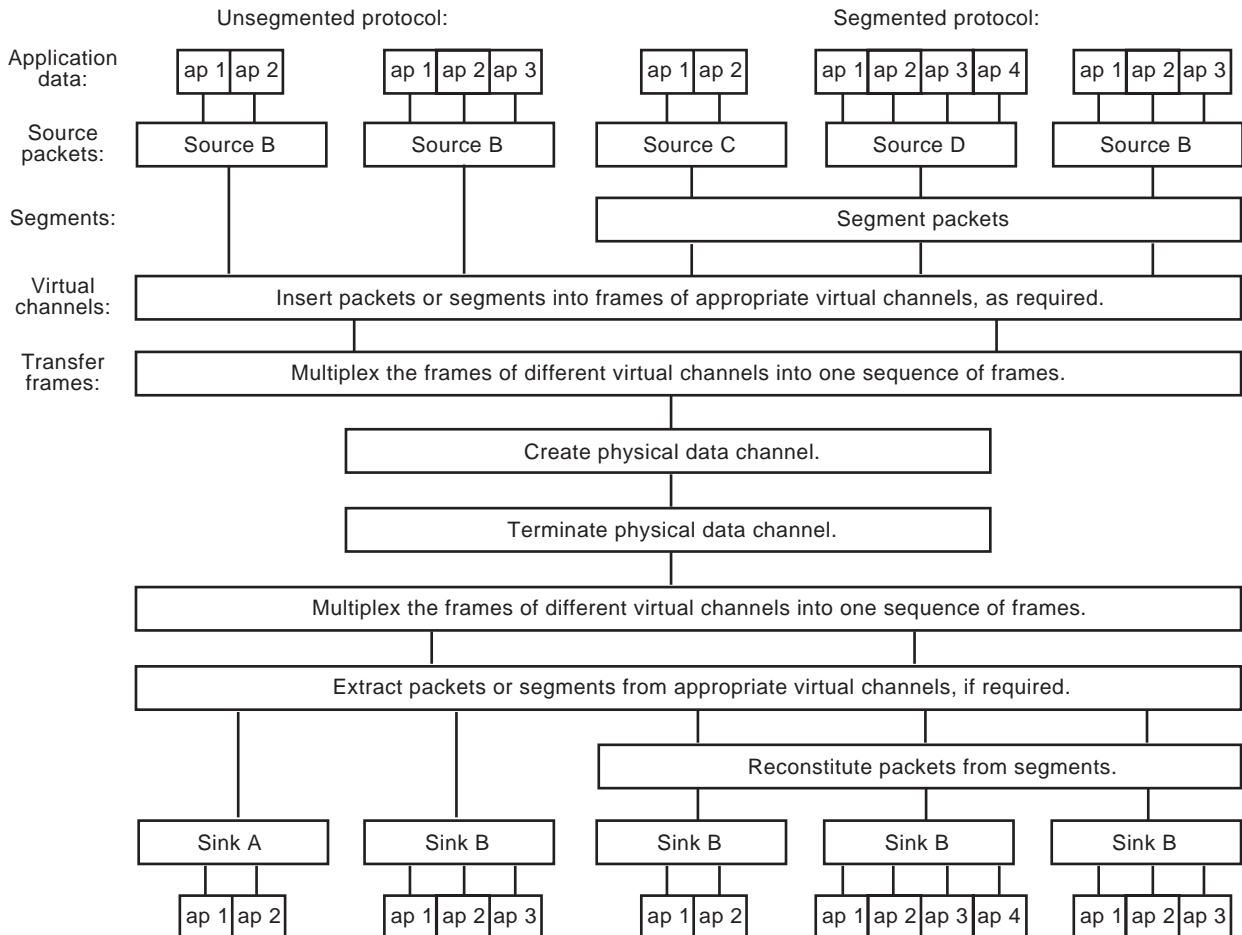

Figure 2. Telemetry data flow.

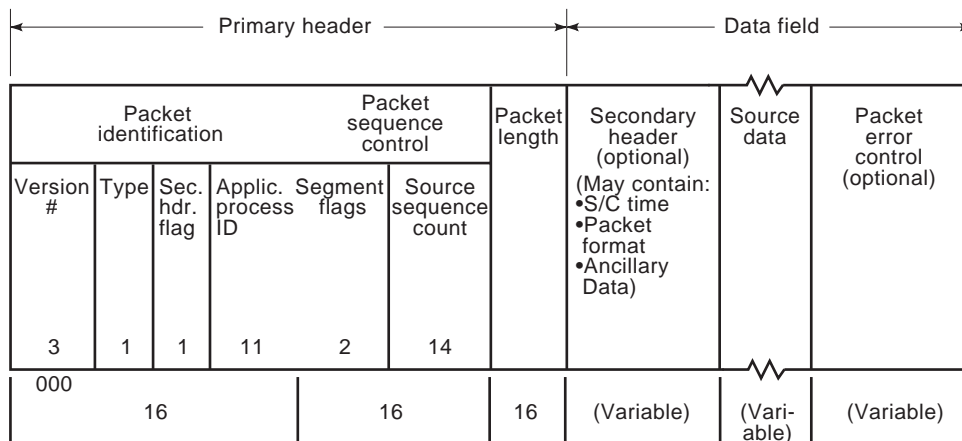

Figure 3. Source packet.

telemetry formats should be an even number of octets. This facilitates efficient internal processing within 16 bit or 32 bit computers, which are anticipated to be widely used in application processes.

User application data are encapsulated within a packet by prefacing them with a standard label or primary header, which is used by the data transport system to route the data through the system and to allow the user to reconstruct the original data set. The primary header consists of three main fields: packet identification, packet sequence control, and packet length.

4.3. Packet Identification

4.3.1. Version Number. The version number is the first of four subfields of packet identification. This subfield explicitly indicates the version of the formatted packet, and its length of 3 bits allows eight different versions to be identified. Although only two versions are currently defined, this arrangement allows a reasonable growth capability to support future needs. However, in the interest of constraining the proliferation of standards, additional versions will be discouraged unless it can be demonstrated that the current versions are truly inadequate.

4.3.2. Type. The second subfield is a 1 bit identifier to signal that this packet is a telemetry packet and not a telecommand packet. It is always set to zero for telemetry packets. (In the first issue of Ref. 1 [May 1984], this field was described as a “reserved spare” and was, by convention, set to zero for telemetry. In Issue 2 [January 1987], the value of the field had not changed, but its function had been established.)

4.3.3. Secondary Header Flag. The third subfield is a 1 bit secondary header flag. The CCSDS recognizes that users may need a means of encapsulating ancillary data (such as time, internal data field format, spacecraft position/attitude), which may be necessary for the interpretation of the information contained within the packet. Therefore, this flag, when set to one, indicates that a secondary header follows the primary header.

4.3.4. Application Process ID. The last subfield in the packet identification field is used to identify the originating source packet application process. In conventional free flyer spacecraft, source data (packets) are traditionally routed to the corresponding user application process on earth; this field could then also be used as a destination ID. (As such, the need for separate destination ID does not seem apparent. However, if users require one or more different destination IDs, these could be placed in the secondary header.) Eleven bits are allocated to the application process ID, permitting identification of up to 2048 separate application processes per spacecraft, sufficient for any envisioned free flyer spacecraft. For positive identification, one can consider this subfield an extension of the spacecraft ID, which is in the transfer frame primary header (see Fig. 5).

4.4. Packet Sequence Control

4.4.1. Segmentation Flags. The first subfield of the packet sequence control field is called segmentation flags and provides for a logical representation of four types of segmentation status. These flags identify whether the source data field contains the first, continuing, or last segment of a source packet, or if it contains no segment (meaning it contains a complete set of source application data).

4.4.2. Source Sequence Count. This second subfield provides for each packet to be numbered in a sequential manner, thus providing a method of checking the order of source application data at the receiving end of the system. It is normally used for ground accounting purposes to measure the quantity, continuity, and completeness of the data received from the source. The field provides a straight sequential count to modulo 16,384. Longer-term unambiguous ordering (beyond 16,384 packets) may be accomplished by associating the measurement time code contained within the packet with the source sequence count.

4.4.3. Packet Length. The last major field of the primary header delimits the boundaries of the packet. It is a count of the number of octets in the packet, beginning with the first octet after the 48 bit primary header and ending with the last octet of the packet. The 16 bit field allows packet lengths up to 65,536 octets (not counting the 48 bit primary header). This packet limit was a compromise between the majority of users (who produce medium-size packets) and the few users who may produce exceptionally long packets. Placing a reasonable limit on packet size helps avoid the flow control problems associated with very long packets and eliminates the overhead penalty of a larger-length field for the great majority of packet producers.

4.4.4. Data Field. The remainder of the packet may consist of any data desired, although some suggestions are provided by the Recommendation. The total length of all subsequent data should be an even number of octets (a multiple of 16 bits) for efficiency in computer processing. In addition, Fig. 3 indicates three possible subfields: secondary header, source application data, and a packet error control field.

4.4.5. Secondary Header. A secondary header may be desirable for providing any ancillary data generated by another application process (time, spacecraft position/attitude) or for providing an internal data field format. The CCSDS has not developed a recommendation for the format, but in order to allow for the future standardization of the secondary header, the most significant bit (bit 0) of the first octet of each secondary header shall be set to 0 to signify a non-CCSDS-defined secondary header.

4.4.6. Source Data. Following the secondary header, the source data subfield contains source application data generated by the application process identified in the primary header. For efficiency in computer processing, this subfield should be a multiple of 16 bits.

4.4.7. Packet Error Control. At the discretion of the user, an optional error detection code may be included at the end of the packet to verify that the overall integrity of the message has been preserved during the transport process. The particular implementation of such an error detection code, including the selection of the encoding polynomial and the length of the field, is left to the user or to the local agency.

4.5. Flow Control Mechanisms

Space telecommunications systems are usually constrained by the capacity or the bandwidth of the telecommunications channel that connects the spacecraft to the data capture element located in space or on earth. Flow control becomes crucial when multiple users must share the same telecommunications channel. The telemetry system must ensure that all sources have proper access to this common resource frequently enough to ensure timely delivery as well as to control the need to buffer data while other sources are being serviced. Long source

packets may present flow control problems if they monopolize the data channel for unacceptable periods of time while forcing other sources to implement unreasonably large local buffering of their data. Several alternative solutions to the problem of flow control are presented in the Recommendation.

4.5.1. Virtual Channelization. One solution to the flow control problem is to assign each source (which generates long packets) its own virtual channel. This is accomplished by inserting these packets into specially identified transfer frames. These dedicated frames form a virtual channel and may be interleaved with other frames containing data from other users.

4.5.2. Source-Internal Segmentation: Source Packet (Version 1). Another solution to the flow control problem is accomplished entirely within the source, whereby it manipulates its own segmentation flags when producing packets. That is, if the source is producing a very long message or data unit, it breaks the unit into segments that can fit into working-size Version 1 packets. This way, the spacecraft data system and ground see and handle normal packets whose data fields actually contain segments of a long message whose reassembly by the application can be assured by use of the packet sequence control.

4.5.3. Packet Identification. Except for the secondary header flag, the packet identification fields of each of the source packets created from the original very long message are identical. For example, the secondary header flag may indicate a secondary header present in the first packet of the sequence and not in subsequent packets of the sequence.

4.5.4. Packet Sequence Control. The packet containing the first segment of the original very long message is identified by setting the segmentation flags in the primary header to 0,1. The source sequence count value is incremented by one for each packet of the sequence. The actual value for the first segment depends on the running count at the time the first segment is to appear. Packets containing continuation segments are identified by setting the segmentation flags to 0,0. The sequence of packets is identified by incrementing the source sequence count for each packet. The packet containing the last segment of the original very long message is identified by setting its segmentation flags to 1, 0.

4.5.5. Packet Length. As the packet length field is used to point to the beginning of the next packet for purposes of extraction from the transfer frame, the packet length must always refer to the length of the source packet being handled. The total length of the original very long message can be provided by the user through private, internal message labeling.

4.5.6. Spacecraft Segmentation: Source Packet (Version 1). Instead of source-internal segmentation, another alternative is a more centralized approach to dataflow control wherein the spacecraft data system performs the segmentation.

Spacecraft segmentation is accomplished by breaking up a completely formed original long source packet and inserting the pieces into newly generated, shorter Version 1 source packets; but in this case, the shorter source packets are created by the spacecraft data system instead of the source itself and carry the “S/C data system” application process ID.

4.5.7. Packet Identification. The application process ID in the packet identification field indicates that the spacecraft data system is generating the source packets containing the segments.

4.5.8. Packet Sequence Control. The segmentation flags are set as described in section 4.5.7. The source sequence count subfield contains the count value generated by the spacecraft data system and is incremented for each segment produced. (The original long packet sequence count value remains hidden in the data field of the first packet generated by the spacecraft data system.)

4.5.9. Packet Length. As in section 4.5.8, the packet length field indicates the length of the newly generated packet.

4.5.10. Spacecraft Segmentation: Telemetry Segment (Version 2). The segmentation options discussed previously utilize the source packet (Version 1) format, in which the length is always based on the length, in octets, of the data field (packet or segment) that is transmitted, and the sequence count increments once per packet generated by a given application process. When a long packet (Version 1) requires segmentation, the monotonically increasing nature of the source sequence count, during the source packet generation process, may be disrupted.

For those missions that require the source sequence count for a given application process to increase without any gaps in the sequence, another formatting option exists. Version 2 of the packet format, called a telemetry segment, is a format within which the length field in the data unit defines the length of an original packet that remains to be transmitted, and the sequence count field remains static because it refers to the numbering of the

original source packet generated by its application process. The length and sequence count of the data unit being transmitted are, therefore, semantically different between the two versions.

It is assumed that telemetry segments (Version 2) are always generated by an application process other than the original application process. In most cases, such telemetry segments will be generated by the spacecraft data system.

The telemetry segment (Version 2) structure is shown in Fig. 4.

4.5.11. Segment Identification. When a long source packet (Version 1) is segmented using the telemetry segment protocol, the packet ID field is modified only by changing the version number subfield to indicate Version 2. This implies that a separate application process is doing the segmentation, and therefore, the application process ID subfield contains the value of the original application process.

4.5.12. Segment Sequence Control. The protocol for the segmentation flags subfield is the same as for the Version 1 format except that the sequence count subfield indicates the count of the original long packet being segmented and is not incremented for each segment generated. As such, it would seem as though each segment cannot be uniquely identified, but in fact, the following fields do provide a mechanism for assigning a serial number to each segment. The serial number may then be used to recombine segments should their natural order be disturbed during transmission or the data handling process.

4.5.13. Segment Length. Instead of indicating the length of the segment, the Version 2 format segment length field is based on the length of data (in octets) from the original long packet (including that contained within the segment) that remains to be transmitted. The length of the segment is a fixed value (256, 512, or 1024 octets) for each virtual channel and is specified in the transfer frame header.

As the fixed segment lengths are defined to be binary values of octets, by utilizing the decrementing length approach, the value of the segment length field will

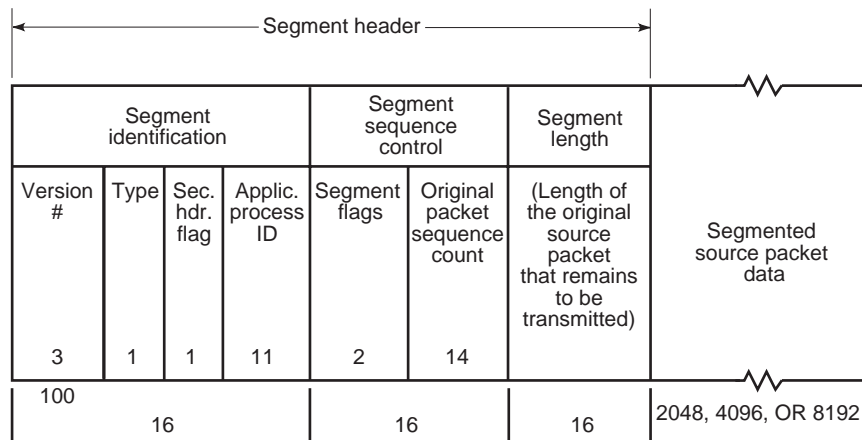

Figure 4. Telemetry segment.

decrease in binary countdown fashion as successive segments are transmitted. This information provides a “serial number” for the segment that may be used to recombine segments should their natural order be disturbed during transmission.

4.6. Telemetry Transfer Frame

The source packet data structures described in the previous sections are unsuitable for transmission directly through the communication links that interconnect the spacecraft and data capture element in space or on earth. They must be embedded within a data transfer structure that provides reliable, error-controlled transfer through the media. The CCSDS has developed such a data structure, the telemetry transfer frame, which has a fixed length for a given mission or spacecraft. The attributes of the transfer frame and its supporting rationale will follow during the discussion of the transfer frame format. Figure 5 illustrates the telemetry transfer frame format.

4.6.1. Synchronization Marker. Attached to the beginning of the transfer frame primary header is a 32 bit frame synchronization marker that is used by the receiving network to acquire synchronization with the frame boundaries after transmission through the data channel. A 32 bit synchronization pattern is selected because it provides good synchronization qualities in a noisy channel environment. The 32 bit pattern is also double-octet compatible

with 32 bit computers. The particular bit pattern and its performance characteristics are found in Refs. 1 and 6.

In conjunction with the selection of the 32 bit marker, the recommendations currently require that all transfer frames in a single physical data channel in a given mission be of constant length. When the frame is of fixed length, conventional “flywheeling” techniques may be used to maintain frame synchronization in a noisy environment.

The maximum distance from one attached sync marker to the next when using the maximum-length transfer frame (8920 bits), Reed–Solomon check symbols (1280 bits), and sync marker (32 bits) is 10,232 bits.

4.6.2. Frame Identification. The first major field of the transfer frame primary header is the frame identification field.

4.6.3. Version Number. Only one version of the transfer frame has been defined by the CCSDS, although this 2 bit field allows growth to four. The version refers to the frame structuring principles, which are described in this section. Given the small number of tracking networks, as opposed to the number of end users (packet creators), and the flexibility built into this version to meet future needs, the size of the field is considered adequate.

4.6.4. Spacecraft ID. The spacecraft identification field provides for positive identification of the spacecraft that generated the transfer frame. The 10 bits assigned to

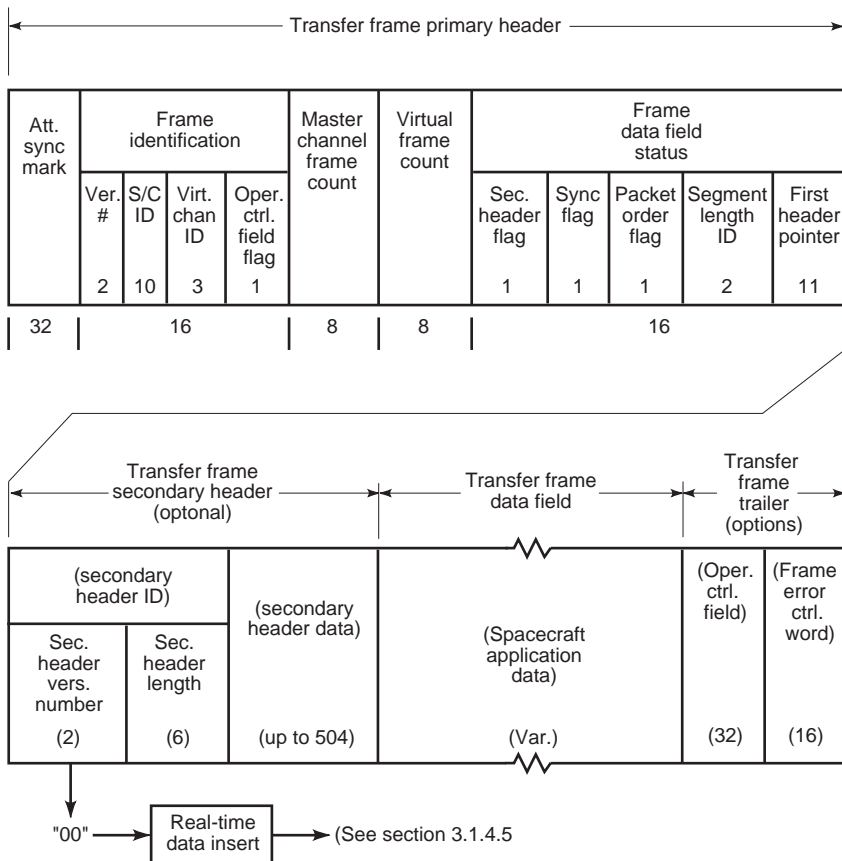

Figure 5. Telemetry transfer frame format.

spacecraft identification allow up to 1024 separate positive IDs. Spacecraft IDs are assigned per the procedures in Ref. 7 by the CCSDS, and analysis [8] has shown that under those procedures, 1024 is an adequate number for future needs.

4.6.5. Virtual Channel ID. This 3 bit subfield allows up to eight virtual channels to be run concurrently on a particular physical data channel. Frames from different virtual channels are multiplexed together on the telecommunications channel, and, with this identifier in each frame, can be easily split apart after receipt at the ground. Virtual channels can be used for a variety of purposes, such as flow control to prevent long packets from “hogging” the channel and selecting different types of data for stream splitting at the ground. Eight virtual channels are considered sufficient to provide adequate flexibility for envisioned future free flyer spacecraft.

4.6.6. Operational Control Field Flag. The last bit of the frame identification field, when set to one, signals the presence of the 32 bit operational control field, which is contained within the frame trailer. The information in this field is defined to provide a standardized spacecraft reporting mechanism for spacecraft telecommanding.

4.6.7. Master Channel and Virtual Channel Frame Count. The next two fields provide a running count of the number of frames transmitted. These counters provide a degree of data accountability (for short-duration data outages); the ambiguity level is defined by the field lengths.

4.6.8. Master Channel Frame Count. This 8 bit field provides a sequential count (modulo 256) of the number of frames transmitted by a single physical spacecraft data channel. The counter is long enough to provide a reasonable probability of detecting a discontinuity, in a sequence of frames, when the physical channel is briefly interrupted. If such a discontinuity does occur, the virtual channel accounting process can provide a greater probability of detecting the number of missing frames.

4.6.9. Virtual Channel Frame Count. This 8 bit field provides accountability for each of the eight independent virtual channels. This field is used with the virtual channel ID subfield to provide accountability via a sequential count (modulo 256). The rationale for the counter ambiguity level is the same as for the master channel frame counter. If only one virtual channel is incorporated for a given mission, both the virtual channel frame counter and the master channel frame counter must increment once per generated transfer frame (i.e., the two fields should not be concatenated into a master frame counter). This is because the ground facilities would normally be designed to handle the general case of spacecraft with multiple virtual channels.

4.6.10. Frame Data Field Status. The frame data field status field provides control information that allows the

receiving end to extract and reconstitute packets and/or segments.

4.6.11. Secondary Header Flag. The first subfield indicates the presence or absence of the optional secondary header. If its presence is so indicated, the secondary header must appear in every frame transmitted through a physical data channel, and its length must also be fixed. Rationale for this requirement is provided later in the discussion about the secondary header.

4.6.12. Synchronization Flag. This flag indicates whether the packet or segment data units are inserted into the transfer frame data field on octet boundaries. If they are, then they are said to be synchronously inserted (packet octet boundaries align with frame octet boundaries), and the extraction technique (pointing to specific octet) is valid. If the flag indicates asynchronous data insertion (i.e., unstructured [nonpacketized] data contents or packets are inserted without regard to octet boundaries), then the transfer frame layer at the receiving end will not be able to reconstitute the original data sets without additional knowledge.

4.6.13. Packet Order Flag. This flag indicates whether the sequence count order of the contained packet or segment is increasing (forward) or decreasing (reverse). This has important implications when tape recorded data are played back opposite to their recorded direction. When this is the case, the spacecraft electronics rejustify the bit direction of each packet/segment so each packet or segment individually flows in the forward direction and its header can be read to allow proper packet extraction from the transfer frame. Even though the playback packets appear individually to flow the same as the rest of the data, the sequence of packets will be running backward in time, as indicated by the decreasing sequence counter.

4.6.14. Segment Length ID. The segment length identifier subfield identifies which of three fixed segment lengths are contained within the data field of the standard Version 2 telemetry segment. The lengths are fixed in order to provide a method of serializing each telemetry segment, as explained in Section 4.3.1 in Ref. 1. The 2 bit flag allows for indication of three different lengths (2048, 4096, or 8192 bits) or an indication that the Version 2 telemetry segment is not being used on this virtual channel. Three lengths provide efficient flow control for the types of data and missions envisioned. Shorter lengths are not considered because the overhead becomes unacceptably large, whereas higher values are not considered because virtual channelization becomes a more effective flow control method.

4.6.15. First Header Pointer. The first header pointer subfield points directly to the location of the starting octet of the first packet or segment header structure within the frame data field. It counts from the end of the primary header (secondary header if present) and effectively delimits the beginning of the first packet/segment. The

packet/segment length field, in turn, delimits the beginning of the next packet/segment, and so on.

As the pointer counts octets, this feature works only when the headers are aligned with octet boundaries (i.e., when the packet/segment data are synchronously inserted [data field synchronization flag set to zero]). The 11 bits allocated to the pointer allow for a count to 2048 octets, which exceeds the count required to point to an octet at the end of the data field. Special pointer values are used to denote the following:

1. No packet/segment header is contained in this frame, but there is valid data.
2. No valid data are contained in this frame (“idle channel”).

4.6.16. Frame Secondary Header (Optional). An optional secondary header is provided for users who desire a means for deterministically inserting real-time data (e.g., time-division multiplexed data) that may be required for spacecraft monitoring and control applications.

When the secondary header presence is indicated by the secondary header flag, its length must be of a fixed value and must appear in every frame transmitted through a physical channel. Given the requirement for fixed transfer frame length, a fixed secondary header length simplifies data processing and packet extraction at the receiving end.

4.6.17. Secondary Header ID. The first part of the secondary header has two subfields. The first is the secondary header version number, a 2 bit field allowing four versions (or structuring rules). Only one version is currently defined by the CCSDS. This provides for a reasonable future growth capability.

The second subfield, secondary header length, indicates what length has been selected for the secondary header. This 6 bit subfield provides a binary count of the total number of octets contained within the entire transfer frame secondary header (including the ID field itself, which is one octet in length). This limits the total secondary header length to 64 octets (512 bits), which is considered adequate for currently understood applications.

4.6.18. Secondary Header Data. This subfield contains up to 504 bits of user-specified data.

4.6.19. Transfer Frame Data Field. The transfer frame data field contains an integral number of octets of data (e.g., source packets and/or telemetry segments) to be transmitted from the spacecraft to the receiving element. The maximum length of this field depends on which optional fields are implemented. As discussed in Ref. 2, if frame lengths shorter than the 8920 bit maximum are implemented and the frame is encoded using the recommended Reed–Solomon algorithm, then the length of the frame data field must be selected, bearing in mind the constraint that virtual fill (see the glossary at the end of this article) must occur in fixed increments. This is

necessary to simplify data processing at the receiving end. This field may also accommodate an unstructured bit stream (not necessarily packetized) as its data contents. In such a case, standard data extraction services would not be provided.

4.6.20. Transfer Frame Trailer (Optional). An optional transfer frame trailer is provided and is divided into two main fields, each of which is optional.

4.6.21. Operational Control Field. The presence or absence of the operational control field is indicated by a flag located in the frame identification field of the primary header. When present, this field facilitates closed-loop reporting of standardized real-time functions. The first bit (bit 0) of this field indicates the type of report and is currently set to zero, which signifies that this field contains a command link control word, which is used for acceptance reporting of spacecraft command activity and certain other front-end telecommunication status. This reporting mechanism is fundamental to the automated telecommand system, which is summarized in Ref. 9. The standardized internal format of the command link control word is fully defined in Ref. 10.

4.6.22. Frame Error Control Word. When present, this field occupies the two trailing octets of the transfer frame. Its presence or absence is implicitly defined from the spacecraft identifier and, thus, must or must not appear in all frames of a given spacecraft ID. It provides the capability for detecting errors that may have been introduced into the frame during the data handling processes. Its presence is mandatory if the transfer frame is *not* Reed–Solomon encoded but is optional if the frame is synchronously contained within the data space of a Reed–Solomon codeblock.

A cyclic redundancy code (CRC) has been selected for this purpose because of its effectiveness and simplicity and is defined and specified in Ref. 1, Section 5.5.2. Parity is generated over the entire transfer frame (less the final 16 bits), and the 16 bits of parity checks are then appended to complete the frame. To maintain compatibility with already built systems, it was necessary to allow for two options over which the CRC is applied; that is, it may include the sync marker or it may exclude it. As the marker pattern is always known, the preferred choice is to omit the marker when encoding. This is explained in Ref. 1, Section 5.5.2.

5. TELEMETRY CHANNEL CODING

Channel coding is a method by which data can be sent from a source to a destination by processing data so that distinct messages are easily distinguishable from one another. This allows reconstruction of the data with low error probability. In spacecraft, the data source is usually digital, with the data represented as a string of zeroes and ones. A channel encoder is a device that takes this string of binary data and produces a modulating waveform as output. If the channel code is chosen correctly for the

particular channel in question, then a properly designed decoder will be able to reconstruct the original binary data even if the waveforms have been corrupted by channel noise. If the characteristics of the channel are well understood and an appropriate coding scheme is chosen, then channel coding provides higher overall data throughput at the same overall quality (bit error rate) as uncoded transmission—but with less energy expended per information bit. Equivalently, channel coding allows a lower overall bit error rate than the uncoded system using the same energy per information bit.

There are other benefits that may be expected from coding. First, the resulting “clean” channel can benefit the transmission of compressed data. The purpose of data compression schemes is to map a large amount of data into a smaller number of bits. Adaptive compressors will continually send information to direct a ground decompressor in how to treat the data that follow. An error in these bits could result in improper handling of subsequent data. Consequently, compressed data are generally far more sensitive to communication errors than uncompressed data. The combination of efficient low error rate channel coding and sophisticated adaptive data compression can result in significant improvement in overall performance [11–14].

Second, a low bit error rate is also required when adaptive telemetry is used. Adaptive telemetry is much like adaptive data compression in that information on how various ground processors should treat the transmitted data is included as part of the data. An error in these

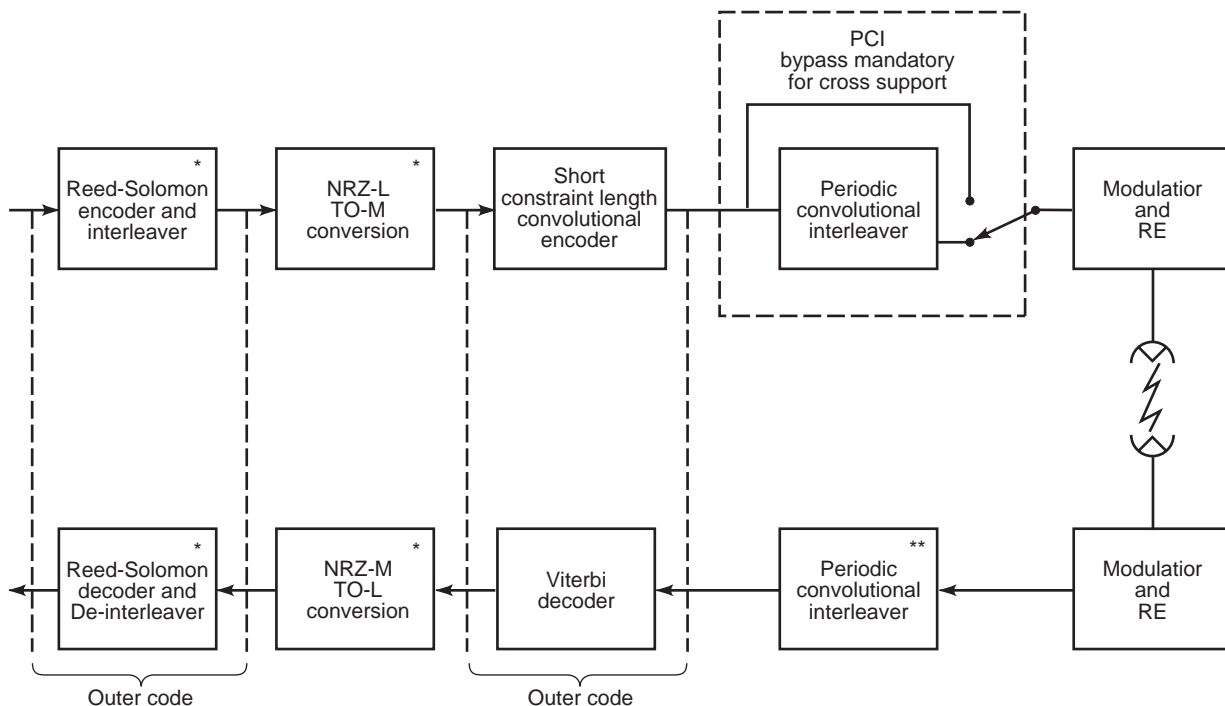

instructions could cause improper handling of subsequent data and the possible loss of much information.

Third, low error probability telemetry may allow a certain amount of unattended mission operations. This is principally because the operations systems will know that any anomalies detected in the downlink data are extremely likely to be real and not caused by channel errors. Thus, operators may not be required to try to distinguish erroneous data from genuine spacecraft anomalies.

In a typical space channel, the principal signal degradations are because of the loss of signal energy with distance and the thermal noise in the receiving system. The codes described in Ref. 2 can usually provide good communication over this channel. An additional degradation, caused by interference from earth-based pulse radars, may occur for users of the Tracking and Data Relay Satellite System (TDRSS). Such users may consider adding periodic convolutional interleaving (PCI) to their coding system; in this case, they should carefully analyze the effects of the PCI on their systems.

If interagency cross support requires one agency to decode the telemetry of another, then the codes recommended in Ref. 2 should be used. A block diagram of the recommended coding system appears in Fig. 6.

The relative performance of the various codes in a Gaussian channel is shown in Fig. 7. Here, the input is constrained to be chosen from between two levels, because biphase modulation is assumed throughout this Recommendation. These performance data were obtained by software simulation and assume that there are no

*Optional (may be bypassed)

**At White Sands Ground Station only

Figure 6. Block diagram of recommended coding system.

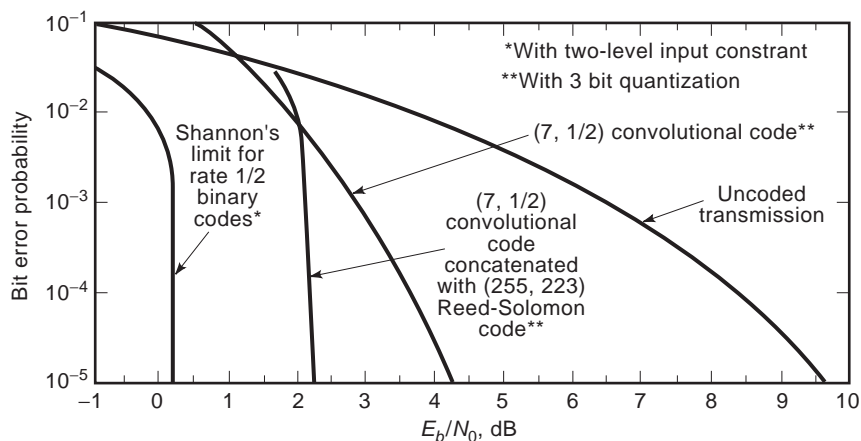

Figure 7. Performance of various codes in a Gaussian channel.

synchronization losses. The channel symbol errors were assumed to be independent. This is a good assumption for the deep-space channel. Also, infinite interleaving was assumed in the Reed–Solomon code. The use of the outer Reed–Solomon code results in an additional 2.0 dB of coding gain. Note that Fig. 7 does not necessarily represent the performance of the TDRSS channel.

These codes are included in the CCSDS Recommendation because they represent state-of-the-art coding technology and provide substantial coding gain over an uncoded system. They have already been incorporated, or are planned to be incorporated, into missions of member agencies of the CCSDS.

Sections 5.1–5.3 explain the choice of the codes and the parameters of each code in more detail.

5.1. Convolutional Code

A rate 1/2, constraint length 7 convolutional code with Viterbi (maximum likelihood) decoding is already a standard for both NASA and the European Space Administration (ESA). It has been used in several missions and has demonstrated the expected coding gain.

The encoder for this code is extremely simple. It consists of a shift register of length six and some exclusive OR gates that implement the two parity checks. The two checks are then multiplexed into one line. This means that the encoder can be made small and that it dissipates very little power. These are good attributes for spacecraft hardware. It has been customary to invert one or the other parity check in the encoder. This is to ensure that there are sufficient transitions in the channel stream for the symbol synchronizer to work in the case of a steady-state (all zeroes or all ones) input to the encoder.

Historically, ESA, NASA-Goddard Space Flight Center (GSFC), and NASA-Jet Propulsion Laboratory (JPL) have each used a different ordering of the two parity checks or inverted a different parity check. Performance is not affected by these minor differences. Although interim cross support of these different conventions may require minor differences in ground station equipment, all agencies are encouraged to adopt for all facilities the single convention described in Ref. 2, which is the NASA-GSFC convention.

5.2. Periodic Convolutional Interleaving

Low earth-orbiting spacecraft sending telemetry to the ground using the services of the TDRSS S-band single-access (SSA) channel when symbol rates exceed 300 kilosymbols/second (ks/s) may experience pulsed radio interference, which is expected to degrade the link performance severely during certain portions of the user orbit. To be able to maintain specified performance on this link at all times, the user satellite must employ an interleaving technique in conjunction with the convolutional coding and must increase the effective isotropic radiated power (EIRP). These techniques will ensure that no more than one of the dependent symbol errors because of a single radiofrequency interference (RFI) pulse is within the path memory length of the decoder at any given time, and that the signal energy has been increased sufficiently to offset the increased symbol error probability [15]. The interleaving parameters have been selected to achieve this goal for a particular worst-case pulse interference signature and the maximum symbol rate (6 Ms/s) of the SSA channel. Deinterleaving must take place before convolutional decoding and therefore is accomplished at the White Sands Ground Terminal.

5.3. Reed–Solomon Code

As a result of the nature of Viterbi decoding, the decoded bit errors of the (7, 1/2) convolutional code tend to clump together in bursts. For this reason, in a concatenated coding system that uses a convolutional inner code, the outer code should be tailored to a burst error environment. The code that is recommended as the outer code is a (255, 223) Reed–Solomon code. This is a nonbinary code. Each member of its coding alphabet is one of 256 elements of a finite field rather than zero or one. A string of 8 bits is used to represent elements in the field so that the output of the encoder still looks like binary data.

Reed–Solomon codes are block codes. This means that a fixed block of input data is processed into a fixed block of output data. In the case of the (255, 223) code, 223 Reed–Solomon input symbols (each 8 bits long) are encoded into 255 output symbols. The Reed–Solomon code in the Recommendation is systematic. This means that some portion of

the codeword contains the input data in unalterable form. In this case, the first 223 symbols are the input data. The Reed–Solomon decoder almost always knows when there are too many errors to correct a word. In the event that this happens, the decoder can inform the user of this fact.

A Reed–Solomon symbol size of 8 bits was chosen because the decoders for larger symbol sizes would be difficult to implement with current technology. This choice forces the longest codeword length to be 255 symbols. A 16 Reed–Solomon symbol error correction capability was chosen, as this was shown to have the best performance when concatenated with the (7, 1/2) convolutional inner code [11,14,16]. As two check symbols are required for each error to be corrected, this results in a total of 32 check symbols and 223 information symbols per codeword.

The (255, 223) Reed–Solomon code is capable of correcting up to 16 Reed–Solomon symbol errors in each codeword. As each symbol is actually 8 bits, this means that the code can correct up to 16 short bursts of error because of the inner convolutional decoder.

In addition, the Reed–Solomon codewords can be interleaved on a symbol basis before being convolutionally encoded. As this separates the symbols in a codeword, it becomes less likely that a burst from the Viterbi decoder disturbs more than one Reed–Solomon symbol in any one codeword. This improves the performance of the Reed–Solomon code. An interleaving depth of five was chosen for two reasons [14]: A depth of five results in performance that is virtually indistinguishable from a depth of infinity. Also, a depth of five results in a frame length (a set of five codewords that, together with the check symbol field, constitutes a codeblock) that is a good compromise considering ease of handling, data outages (quality, quantity, and continuity), and frame synchronization rate.

The same encoding and decoding hardware can implement a shortened (n , $n - 32$) Reed–Solomon code, where $n = 33, 34, \dots, 254$. This is accomplished by assuming that the remaining symbols are fixed: In the case of the Recommendation, they are assumed to be all zero. This virtual zero fill allows the frame length to be tailored, if necessary, to suit a particular mission or situation.

The method currently recommended for synchronizing the codeblock is by synchronization of the transfer frame, which contains a frame synchronization marker of 32 bits. However, advanced approaches being studied (e.g., self-synchronizing Reed–Solomon codes) may enable these two functions to be separately synchronized in the future.

The Reed–Solomon code, like the convolutional code, is a transparent code. This means that if the channel symbols have been inverted somewhere along the line, the decoders will still operate. The result will be the complement of the original data. However, the Reed–Solomon code loses its transparency if virtual zero fill is used. For this reason it is mandatory that the sense of the data (i.e., true or complemented) be resolved before Reed–Solomon decoding.

The two polynomials that define the Reed–Solomon code [Sections 4.2(4) and 4.2(5) in Ref. 2, and Ref. 17] were chosen to minimize the encoder hardware. The code generator polynomial is a palindrome (self-reciprocal poly-

nomial) so that only half as many multipliers are required in the encoder circuit. The particular primitive element “a” (and hence the field generator polynomial) was chosen to make these multipliers as simple as possible. An encoder using the “dual basis” representation requires for implementation only a small number of integrated circuits or a single VLSI chip.

GLOSSARY

- Block encoding = A one-to-one transformation of sequences of length k of elements of a source alphabet to sequences of length n of elements of a code alphabet $n > k$.
- Channel symbol = The unit of output of the innermost encoder that is a serial representation of bits, or binary digits, that have been encoded to protect against transmission-induced errors.
- Clean data (bits) = Data (bits) that are error free within the error detection and optional error correction capabilities of the TM system.
- Codeblock = A codeblock of an (n , k) block code is a sequence of n channel symbols that were produced as a unit by encoding a sequence of k information symbols and will be decoded as a unit.
- Code rate = The average ratio of the number of binary digits at the input of an encoder to the number binary digits at its output.
- Codeword = In a block code, one of the sequences in the range of the one-to-one transformation (see *block encoding*).
- Command link control word = The telecommand system transfer layer protocol data unit for telecommand reporting via the TM transfer frame operational control field.
- Concatenation = The use of two or more codes to process data sequentially with the output of one encoder used as the input of the next.
- Constraint length = In convolutional coding, the number of consecutive input bits that are needed to determine the value of the output symbols at any time.
- Convolutional code = As used in this article, a code in which a number of output symbols are produced for each input information bit. Each output symbol is a linear combination of the current input bit as well as some or all of the previous $k-1$ bits, where k is the constraint length of the code.
- Fill bit(s) = Additional bit(s) appended to enable a data entity to fit exactly an integer number of octets or symbols.

Inner code	= In a concatenated coding system, the last encoding algorithm that is applied to the datastream. The datastream here consists of the codewords generated by the outer decoder.	Transparent	= The invisible and seemingly direct (virtual) transfer of measurement information from the spacecraft source application process to the user (receiving application process).
Modulating waveform	= A way of representing databits (1 and 0) by a particular waveform.	Transparent code	= A code that has the property that complementing the input of the encoder or decoder results in complementing the output.
NRZ-L	= A modulating waveform in which a data one is represented by one of two levels, and a data zero is represented by the other level.	User	= A human or machine-intelligent process that directs and analyzes the progress of a space mission.
NRZ-M	= A modulating waveform in which a data one is represented by a change in level and a data zero is represented by no change in level.	Virtual channel	= A given sequence of transfer frames that are assigned a common identification code (in the transfer frame header), enabling all transfer frames who are members of that sequence to be uniquely identified. This allows a technique for multiple source application processes to share the finite capacity of the physical link (i.e., through multiplexing).
Octet	= An 8 bit word consisting of eight contiguous bits.	Virtual fill	= In a systematic block code, a codeword can be divided into an information part and a parity (check) part. Suppose that the information part is N symbols long (<i>symbol</i> is defined here to be an element of the code's alphabet) and that the parity part is M symbols long. A "shortened" code is created by taking only S ($S < N$) information symbols as input, appending a fixed string of length $N - S$ and then encoding in the normal way. This fixed string is called fill. As the fill is a predetermined sequence of symbols, it need not be transmitted over the channel. Instead, the decoder appends the same fill sequence before decoding. In this case, the fill is called virtual fill.
Outer code	= In a concatenated coding system, the first encoding algorithm that is applied to the datastream.		
Packet	= An efficient application-oriented protocol data unit that facilitates the transfer of source data to users located in space or on earth.		
Protocol	= A set of procedures and their enabling format conventions that define the orderly exchange of information between entities within a given layer of the TM system.		
Reed–Solomon (R-S) symbol	= A set of J bits that represents an element in the Galois field $GF(2^J)$, the code alphabet of a J -bit Reed–Solomon code.		
Reliable	= Meets the quality, quantity, continuity, and completeness criteria that are specified by the TM system.		
Segment	= A protocol data unit that facilitates telemetry flow control through the breaking of long source packets into communication-oriented data structures.		
Systematic code	= A code in which the input information sequence appears in unaltered form as part of the output codeword.		
Telemetry system	= The end-to-end system of layered data handling services that exist to enable a spacecraft to send measurement information, in an error-controlled environment, to receiving elements (application processes) in space or on earth.		
Transfer frame	= A communication-oriented protocol data unit that facilitates the transfer of application-oriented protocol data units through the space-to-ground link.

TELEVISION AND FM BROADCASTING ANTENNAS

O. BENDOV
Dielectric Communications

1. BASICS FOR TV AND FM ANTENNAS

Antennas for television and FM broadcasting are usually installed on tall towers to maximize the service area. The maximum allowable tower height everywhere in the United States is 2000 ft aboveground. The distance to the horizon from a height of 2000 ft over flat terrain is 63 miles. The average tower height in the United States is 1200 ft, and the corresponding distance to the horizon is 49 miles.

A high-power transmitter feeds the broadcast antenna to provide “passable” picture and sound at distances approaching 70 m. In the UHF range (TV channels 14 to 69), the transmitter's peak power could be as high as 280 kW. In the VHF range (TV channels 2 to 13 and FM), a transmitter's peak power of 70 kW is not unusual. In this article, references made to channels and bands (VHF, FM, and UHF) are based on the U.S. designation.

In addition to high power-handling capability, broadcast antennas must continue to perform under severe weather conditions, such as ice storms and hurricane winds. As a protection against adverse weather conditions, broadcast antennas are supplied with a protective radome or with electrical deicing heaters. Because downtime due to antenna failure would result in severe financial loss, TV and FM broadcast antennas must be designed with extremely high reliability.

The radiation pattern of broadcast antennas is shaped in the elevation and azimuthal planes to provide service for as many households as possible. When the tower is geographically located near the population center, an omnidirectional azimuthal pattern is common. When the tower is geographically separated from the area served, a directional azimuthal pattern is more desirable.

Antennas, especially for television broadcasting, must be designed to accept and radiate all of the power delivered by the transmitter. Even a small percentage of the delivered power reflected back toward the transmitter is a cause for concern. In analog television, if 0.1% of the delivered power is reflected back by the antenna and then radiated by a second reflection at the transmitter, an annoying picture “ghost” appears on an average size TV screen.

After years of experimentation, transition from analog to digital television broadcasting in the United States was scheduled to begin in late 1998. Antennas for digital television must be designed to meet more stringent specifications than those for antennas for analog television. In analog TV, poor specifications translate into degradation of picture quality. In digital television, picture quality remains unaffected by poorly designed antennas. Instead, poor antenna design for digital television broadcasting results in loss of coverage area.

1.1. Elevation and Azimuthal Radiation Patterns

Broadcast antennas are designed to focus power toward the radio horizon. The radiation is described by two patterns, one in the elevation plane and one in the azimuthal plane. The elevation pattern depicts the relative field strength radiated at various depression angles above and below the horizon. Figure 1 shows a typical elevation pattern before and after shaping. The purpose of radiation pattern shaping is to direct maximum power toward the radio horizon and to provide essentially equal field strength to all users from the base of the tower to the radio horizon.

1.2. Null Fill and Beam Tilt

Pointing maximum power toward the horizon is accomplished by tilting the elevation pattern, usually less than

Figure 1. Elevation pattern.

2° below the horizontal plane. In Fig. 1, the tilt angle of the shaped pattern is 1°. Typically, the tilt angle corresponds to the depression angle Θ toward the horizon, which can be calculated from the formula

$$\Theta = 0.0153\sqrt{H} \text{ degrees}$$

where H is the height of the antenna above the average terrain in feet as defined by the Federal Communications Commission (FCC).

The shaping of the elevation pattern to provide essentially equal field strength to all viewers requires that all nulls in the elevation pattern are filled at depression angles below the horizon. The ideal shape of the elevation pattern before and after shaping, when applied to angles below the horizon, can be expressed as

$$\frac{\sin x}{x}$$

before shaping and

$$\frac{1}{\sin x}$$

after shaping

The azimuthal pattern depicts the relative field strength radiated at various angles around the horizontal plane. Figure 2 shows a typical omnidirectional pattern and an example of a directional pattern.

A broadcast antenna is an array of individual radiators, such as dipoles, slots, or helices. The number of individual radiators varies between 2 and 24 in a VHF array and, between 8 and 180 in a UHF array. Pattern shaping, such as shown in Figs. 1 and 2, is accomplished by nonuniform distribution of the phase and current feeding individual radiators in the array.

1.3. Gain and ERP

The gain of an antenna is a figure of merit that describes the antenna's ability to focus the input power within

Figure 2. Azimuthal pattern.

a certain angular sector. For example, referring to Fig. 1, most of the power in the elevation plane is contained within $\pm 2^\circ$ around the peak of the elevation pattern.

The gain of broadcast antennas is specified relative to a half-wave dipole rather than relative to an isotropic radiator. Because the gain of a half-wave dipole relative to an isotropic radiator is 1.64, the peak gain of a broadcast antenna is given by

$$G_P = g_A g_E = 4\pi\eta \frac{|E(\theta, \phi)|^2}{1.64 \iint |E(\theta, \phi)|^2 \sin \theta d\theta d\phi}$$

where $E(\theta, \phi)$ is the electric field strength in the direction (θ, ϕ) at which the gain is desired and η is the power transfer efficiency of the array's distribution system. The peak gain is calculated in the direction of the peak of the elevation and azimuthal patterns.

It is customary to assume that the elevation pattern is not a function of azimuth. With that assumption, the double integral is separable into a product of two integrals, and the peak gain becomes the product of the azimuthal pattern gain g_A and the elevation pattern g_E .

The effective radiated power (ERP) is the product of the antenna's gain and the power delivered to the antenna. The maximum allowable ERP is set by each country's regulatory agency so as to maximize the service to consumers and to minimize the interference to and from all broadcast stations and other services. In the United States, the maximum allowable ERP for analog TV service is 100 kW for VHF channels 2 to 6, 316 kW for VHF channels 7 to 13, and 5,000 kW for UHF channels 14 to 69.

1.4. Coverage and Service

Passable picture and good sound quality require that a minimum level of field strength be available at the receiver. In the United States, the defining field strengths for analog TV broadcasting are shown in Table 1.

The coverage contour is described by the maximum radii beyond which, for a given transmitter power and

Table 1. Field Strengths for Analog TV Broadcasting

TV Channel	2-6	7-13	14-69
dBu ^a	47.00	56.00	64.0
mV/meter	0.22	0.63	1.6

^aAssuming an outdoor antenna 30 ft aboveground. dBμ = dB above 1 μV/m. dBu = dBμV/m is an 0 term.

antenna height aboveground, the field strength falls at or below the minimum level. Coverage contours are thermal-noise-limited. Where unacceptable interference from another station penetrates the thermal-noise-limited coverage contour, the coverage contour is modified into a service contour.

As an example, consider the UHF antenna described by the elevation patterns of Fig. 1 and the azimuthal patterns of Fig. 2. The antenna gain and input power were set to radiate ERP equal to 1000 kW. The field strength versus distance from the transmitter is shown in Fig. 3 in the direction of N135°E, as marked on Fig. 2. One of the two curves in Fig. 3 is for the omnidirectional antenna without elevation pattern shaping, and the other is for the directional antenna with a shaped elevation pattern. As shown in Fig. 3, both antennas can provide a passable picture (64 dBu) for at least 53 m, but the antenna without beam shaping will not deliver a usable signal at 5.5, 2.7, and 1.8 m from the transmitting tower.

The curves of Fig. 3 were obtained with US-FCC's F(50,50) propagation curves that translate the known ERP and antenna height into dBu versus distance. The 50,50 designation refers to the field strength that will be exceeded "at least 50% of the time at the best 50% of the locations."

Figure 3. F(50,50) Field strength.

1.5. Polarization

For most TV stations, the electric field of the radiated power is polarized so that its vector lies in the horizontal plane, essentially parallel to the ground. Horizontal polarization was originally selected for broadcasting because its propagation is least affected by vertical obstructions, such as trees and utility poles and because measurements, conducted during the early stages of television development, showed that the polarization of man-made noise is more pronounced in the vertical than in the horizontal plane.

Circular polarization for broadcasting was introduced in the United States during the 1960s, first to FM and later to TV. Circular polarization allows for substantially improved reception of FM and TV with small receiving antennas of arbitrary physical orientation, such as those in automobiles or on top of portable TV sets.

By definition, circular polarization requires that equal power be radiated in the horizontal and vertical planes and that the two electric fields be phase-shifted 90° relative to each other. In practical antennas, the conditions for circular polarization cannot be met in all directions. The improved reception of circular and elliptical polarization broadcasting is best explained with the aid of Fig. 4.

Figure 4(a) shows the relative voltage delivered by a small, rotating dipole in any direction from the transmitting antenna when facing an essentially circularly polarized incoming signal. In the azimuthal direction of 40°, rotation of the receiving antenna varies the voltage available to the set by 1.4 dB at most. In contrast, if the incoming signal was horizontally polarized and the receiving dipole was positioned perpendicularly to the ground, the available voltage would drop to zero.

Figure 4(b) shows the relative voltage delivered by the same dipole when facing an essentially elliptically polarized incoming signal. In the azimuthal direction of 40°, rotating the receiving antenna causes the voltage delivered to the set to vary by as much as 7.6 dB, not as stable as the voltage available from a circularly polarized signal.

The gain of broadcast antennas for circular or elliptical polarization is normally specified in either the horizontal polarization plane or the vertical polarization plane. Because the two planes are orthogonal, it can be shown that

$$\text{Gain of horizontal polarization} = \frac{G_h}{1 + (G_h/G_v)|P|^2}$$

and

$$\text{Gain of vertical polarization} = \frac{G_v}{1 + (G_v/G_h)|P|^2}$$

where G_h is the gain in the absence of vertical polarization, G_v is the gain in the absence of horizontal polarization, and $P = E_v/E_h$ is the ratio of the vertical component of the electric field to the horizontal component of the electric field in the direction in which the gain is calculated.

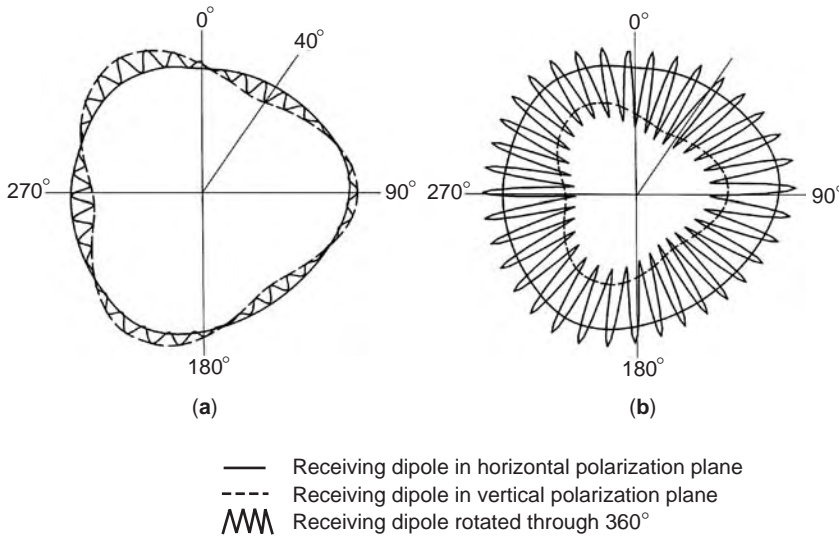

Figure 4. Voltage induced at the output terminals of a linear dipole receiving antenna: (a) Circularly polarized transmission; (b) Elliptically polarized transmission.

1.6. Coaxial and Waveguide Transmission Lines

The output power of the transmitter is delivered to the antenna via a coaxial or waveguide transmission line. A coaxial line is made of a circular pipe with a circular inner conductor. A waveguide is made of a hollow pipe of circular, elliptical, or rectangular cross section. For VHF channels 2 to 13, coaxial lines with outside diameters from 3 in. to 8 in. are used. For UHF channels 14 to 69, either coaxial lines or waveguides of various sizes are used, depending primarily on channel and power requirements. The widest cross section of waveguides for UHF broadcasting varies from 11.5 in. to 18 in. depending on the TV channel.

The main attribute of a waveguide transmission line is the high power-carrying capacity. Because of its large size with a typical vertical run of a 1000 ft up the tower, a waveguide is a major contributor to wind-load stresses on the tower. For a given cross section, a waveguide is limited to carrying only those UHF channels that propagate in its dominant mode. In contrast, for diameters not exceeding 7 in., a coaxial line accommodates any broadcast channel from 2 to 69.

In transferring the power from the transmitter to the antenna, some loss of power due to surface heating of the transmission line is inevitable. The power-transfer efficiency of a transmission line is defined by

$$\eta(\%) = 100 \frac{\text{Input Power}}{\text{Output Power}} = \frac{100}{\text{Antilog}(\alpha l / 100)}$$

where α is the attenuation in decibels/100 ft and l is the transmission line's length in feet.

2. ANTENNAS FOR TELEVISION BROADCASTING

2.1. Single-Station VHF Antennas

Most VHF antennas designed to accommodate a single TV station fall into the three distinct categories shown in Fig. 5.

The most popular category worldwide is an antenna made of a central support pole with a multiplicity of dipoles wrapped around the pole. One version of such an antenna, designed for circular polarization transmission, is shown in Fig. 5(a). This antenna accommodates any TV or FM channel. A typical gain of such an antenna is

Figure 5. Single-station VHF antennas: (a) channels 2-6; (b) channels 7-13; (c) panel antenna.

3.0 in either the horizontal polarization plane or the vertical polarization plane. The height and weight of the antenna vary from 68 ft and 5.7 tons for channel 6 (United States) to 97 ft and 9.9 tons for channel 2 (United States).

A second category, popular mostly in the United States, is the slotted-pipe traveling-wave antenna, the horizontal-polarization version of which is shown in Fig. 5(b). The radiofrequency power enters this antenna at its bottom and continues to travel toward the beacon at the top. While traveling upward, power leaks outward through the slots, decaying exponentially. The remainder of the power is forced out of the top slot.

The panel antenna shown in Fig. 5(c) is composed of an array of dipoles, each placed approximately one quarter-wavelength in front of a reflecting screen. Then the array is wrapped around a support spine, which is often the tower itself. The panel antenna is popular mostly outside the United States because it is easily installed. In the United States, VHF panel antennas are used primarily where a directional pattern is required, if the top of the tower is unavailable, or as a support structure for one or more antennas stacked over the panel antenna.

2.2. Single-Station UHF Antennas

Most UHF antennas for TV broadcasting in the United States are the slotted pipe variety shown in Fig. 6(a) (horizontal polarization) and Fig. 6(b) (circular polarization). In the circular polarization version of the slotted-pipe antenna, a parasitic Z-shaped dipole is placed approximately one eighth of a wavelength in front of each slot. The Z-shaped dipole intercepts some of the horizontal polarization power emitted by the slot and radiates the intercepted power as vertical polarization, phase-shifted -90° relative to the horizontal polarization. The Z-shaped dipole

Figure 6. Single-station UHF antennas: (a) horizontal polarization; (b) circular polarization; (c) panel antenna.

can be adjusted for any power ratio of horizontal to vertical polarization. When the power ratio is one, the polarization is circular. For an unequal ratio, the result is elliptical polarization. Both elliptical and circular polarization provide superior analog TV reception on sets equipped with small indoor antennas, such as loops or monopoles.

In contrast, most UHF antennas for TV broadcasting outside the United States are made of an array of panels as shown in Fig. 6(c) (horizontal polarization). The panel antenna is relatively inexpensive, and its azimuthal pattern is easily shaped for directional antenna application. The panel antenna exhibits some drawbacks. The most noticeable drawbacks are large aerodynamic area and multiplicity of pressurized components, which adversely affect the long-term reliability and maintainability of the panel antenna.

2.3. Broadband VHF and UHF Panel Antennas

One of the most vexing problems for TV and FM broadcasters is the scarcity of tower space, especially at locations that permit maximum service. This problem is especially acute due to safety, legal, and environmental regulations in major metropolitan areas. Because of the scarcity of tower space and to save construction costs, broadcasters have been using antennas designed to accommodate multiple channels on single antennas. These so-called “broadband” panel antennas are used for VHF and UHF channels. A stack of two such antennas is shown in Fig. 7. The top antenna accommodates a multiplicity of UHF channels in the range from 450 MHz to 800 MHz, subject to average and peak power limitations.

Figure 7. Broadband panel antennas.

The bottom antenna accommodates a multiplicity of VHF channels in any one of three bands. These bands (United States) are 54 MHz to 66 MHz (Low-V), 66 MHz to 88 MHz (Mid-V), and 174 MHz to 216 MHz (Hi-V).

2.4. Multistation Master Tower

Another solution to the problem of tower scarcity is deploying a master TV/FM tower that supports all the antennas necessary to serve the market, and placing it near the center of population. Master towers are either in the form of candelabras, where several antennas are installed side-by-side on a platform at the top of the tower, or a stack of several antennas installed one on top of another beginning at the top of the tower.

Two examples of a master tower, a candelabra and a stack are shown in Fig. 8. The stack shows all of the analog TV antennas on top of the north tower of the World Trade Center in New York City. This stack has been in operation since the 1970s. The height of the stack is 350 ft above the roof. The second master tower is a proposed design of a candelabra to be constructed early in the twenty-first century to support future digital TV service on channels 2 to 51 in New York City. The triangular top platform of the candelabra has a corner-to-corner width of 45 ft. A stack of three, slotted-pipe UHF antennas occupies each corner of the platform. One of the nine antennas designed to serve two multiplexed channels has a total tower capacity of ten digital TV stations.

2.5. Radiation Pattern Distortion

When an antenna is positioned close to other antennas or side-mounted on the support tower, undesired scattering of the intercepted primary radiation by nearby obstructions results. This undesired scattering combines vectori-

ally with the primary radiation to produce a new pattern that could significantly differ from the desired primary radiation pattern.

For example, when a perfectly omnidirectional antenna is mounted on top of the support tower without any nearby obstructions, its primary azimuthal pattern remains undistorted, as shown in Fig. 9. When side-mounted 8 ft from the center of a triangular tower with a 10-ft side, the same antenna shows a marked distortion in its pattern. Further, the distorted pattern shows significant variation in some directions when swept over the 6 MHz of the TV channel. Such a distorted pattern causes a significant reduction in the picture quality of analog TV in many directions. In the case of digital TV, total loss of picture and sound can be expected in the directions where the signal power is low or where power variation over the channel width of 6 MHz is significant. Depending on the country, the channel width could be 6, 7, or 8 MHz. In North America, it is 6 MHz.

In contrast, a directional antenna properly mounted close to a support tower, exhibits relatively small distortion of its primary pattern, as shown in Fig. 10. By judiciously mounting the antenna so that the minimum of its primary pattern points in the direction of the largest obstruction, the level of significant pattern distortion due to scattering is limited to an angular sector of 90° to 120° behind the support tower.

3. ANTENNAS FOR FM BROADCASTING

3.1. Single-Station Antennas

FM antennas for single-channel broadcasting are designed to be inexpensive relative to TV antennas. They are also designed to add a minimum of aerodynamic stress

Figure 8. Multistation master antennas in New York: (a) present stack on World Trade Center 1; (b) future candelabra on World Trade Center 2.

Figure 9. Tower distortion over 6 MHz for omnidirectional antenna.

Figure 10. Tower distortion of directional antenna pattern.

on the support tower. These two objectives are relatively easy to meet because of the narrow bandwidth of the FM channel. The FM channel width in North America is 200 kHz, in Europe 100 kHz, and in Africa 86 kHz.

FM broadcasting was originally planned for reception by an outdoor antenna, and the polarization of the electric vector was linear, polarized either in the horizontal or vertical plane. Since the introduction of low-cost, portable, solid-state radios for automobiles and homes, polarization of the FM signal has gradually shifted worldwide to circular polarization.

The most popular implementation of the single-channel, low-cost, circular polarization FM antenna is shown in Fig 11. The antenna is an array of 1 to 12 radiators or “bays.” Each radiator consists of two to four interwoven, bent, half-wave dipoles. The dipoles are typically bent around a circular form approximately 20 in. in diameter. In another implementation of this design, the interwoven dipoles are bent in a V-shape. The radiators are mounted along a pipe, the diameter of which depends on the number of radiators and on whether the antenna is to be top-mounted or side-mounted on the tower.

Several disadvantages are associated with the single-channel antenna shown in Fig. 11. The antenna is designed to be omnidirectional and to radiate circular polarization in the absence of the pipe supporting the “bays.” When mounted on the pipe as shown, the antenna radiates elliptical polarization, and the vertical component of the electric field is substantially attenuated in the shadow of the support pipe. If the antenna with the support pipe is then side-mounted on the transmission tower, as is often the case, the radiation patterns in the elevation and azimuthal planes are further severely distorted. Another difficulty due to the physically small radiator of this antenna is a somewhat excessive downward radiation that may raise the level of the RF power density near the ground above the allowable protective limit. The

Figure 11. Single-station FM antenna.

downward radiation level can be reduced by spacing the array elements at half-wavelength intervals.

3.2. Multistation Master Antennas

The master FM antenna, capable of supporting multiple FM stations on a single antenna, is gradually replacing single-station antennas in major cities worldwide. Such a master antenna, made of multiple broad-band panels, is shown in Fig. 12. The master FM antenna does not exhibit any of the disadvantages of the single-station antenna and is ideal where tower space is scarce. Master FM antenna construction is similar to that of VHF-TV panel antennas with a high price to match. The installation cost is sometimes shared by the individual FM channels, which are multiplexed on the master antenna, making the antenna affordable.

4. ADVANCED TOPICS: ANALOG VERSUS DIGITAL TV

4.1. Spectral Distribution

Fundamental differences exist in the performance specifications of antennas for analog and digital TV broadcasting.

Reception of analog TV is subject to fading, manmade noise, and picture degradation in poor reception areas. In contrast, the reception of digital TV yields a perfect picture and sound all of the time or not at all. The same sources that cause poor reception of analog TV combine to reduce

Figure 12. Multistation master FM antenna.

the coverage area of digital TV. Some of the coverage area of analog TV is traded off for the higher picture and sound quality of digital TV much as the long range and poor sound quality of AM radio are traded off for the shorter range and higher quality sound of FM radio.

An understanding of the specifications required for digital TV can be gained by comparing the spectra of analog TV and digital TV at the transmitter and at the receiver. Figure 13(a) shows the flat (except for the pilot) power distribution of the digital signal over 6 MHz, superimposed over the analog signal at the transmitter output. As shown in Figure 13(b), poor antenna response and undesired reflections at the receiver have significantly distorted the digital spectrum. Having most of the power centered near the picture and sound carrier hardly affects the analog spectrum.

From these spectra, it is clear that the antenna specifications in analog TV are critical only around the three carriers. In contrast, antenna specifications for digital TV are equally critical throughout the TV channel.

4.2. Voltage Standing-Wave Ratio

The magnitude of the voltage standing-wave ratio (VSWR) inside the transmission line, which connects the antenna to the transmitter, is an example of an antenna specification that depends on the spectral distribution. In analog TV, the VSWR must be minimized around the picture carrier to a value of 1.025, as shown in Fig. 14, to avoid an echo that appears as a “ghost” image. In other portions of the channel, the VSWR can be higher, up to 1.10 at band edges. In contrast, the VSWR must be minimized and equalized across the digital channel to a value not exceeding 1.05.

Figure 13. Analog and digital spectra: (a) at the transmitter; (b) at the receiver.

4.3. Effective Radiated Power

The ERP is a product of the antenna gain and the total input power to the antenna at the picture carrier frequency. For analog transmission, the total input power may include undesirable power components, such as intermodulation products and internal reflections. The undesirable components affect the picture quality of analog TV but not

Figure 14. Antenna VSWR for a 6 MHz channel.

its range. The same undesirable power components affect the range of digital TV but not its picture quality. Therefore, the calculation of the ERP of digital TV must be based on the net useful power, rather than on the total available power.

4.4. Gain

In analog TV, antenna gain is specified at the picture carrier frequency around which most of the power is concentrated. In digital TV, where the power out of the antenna may be unevenly spread across the channel due to distortion, the electric field in the gain equation must be replaced by its value averaged over the operating channel bandwidth.

4.5. Pattern and Polarization Bandwidth

The same reasoning that was applied to the VSWR, ERP, and gain specifications requires that the antenna's transfer characteristics be specified across the digital TV channel rather than at a single frequency, as with analog TV. In particular, knowledge of the radiation pattern's behavior, including the polarization behavior across the TV channel, is fundamental to proper specification of broadcast antennas for digital TV.

4.6. Peak and Average Power

In analog TV, the peak-of-sync power is the significant parameter. It is used for ERP, coverage, and interference calculations. The peak-of-sync is defined by the root-mean-square amplitude of the carrier during the horizontal and vertical sync periods.

The average power of analog TV is not constant, unlike the peak-of-sync power during synchronization pulses. It depends on the picture being transmitted. Measurements over long periods indicate that the average picture power is 4.32 dB below peak-of-sync. With total blanking, the average picture (black) power is constant and is 2.2 dB below peak-of-sync. For analog TV, the peak-of-sync, the peak instantaneous, and the average power are given by the following:

$$P_{\text{SYNC}} = \frac{V_{\text{RMS}}^2}{Z_0} = \frac{V_{\text{PEAK}}^2}{2Z_0}$$

$$P_{\text{PEAK}} = \frac{V_{\text{PEAK}}^2}{Z_0} = 2(\sqrt{P_{\text{AURAL}}} + \sqrt{P_{\text{SYNC}}})^2$$

and

$$P_{\text{AVG}} = P_{\text{SYNC}}\text{APL} + P_{\text{AURAL}}$$

where Z_0 is the characteristic impedance of the transmission line and APL is the average picture level that is 0.6 during blanking and 0.37 during program transmission.

During program transmission (APL = 0.37) and with $P_{\text{AURAL}}/P_{\text{SYNC}} = 0.1$ (typical for UHF channels),

$$\frac{P_{\text{PEAK}}}{P_{\text{AVG}}} = 8.68 \text{ dB}$$

In digital TV, the average power is the significant parameter. It is independent of the content of the image being transmitted, and unlike analog TV, it has a constant value. The average power of digital TV is used for ERP, coverage, and interference calculations.

The average and peak instantaneous powers of digital TV are related by

$$P_{\text{PEAK}} = \frac{V_{\text{PEAK}}^2}{Z_0} = R_{\text{PA}}P_{\text{AVG}}$$

where R_{PA} is the ratio of peak instantaneous power to average power at the transmitter output.

Depending on the modulation scheme and channel filters, the peak instantaneous power of the digital TV signal can reach 7 dB to 13 dB above the average power, and 7 dB peaks occur as often as 0.01% of the time.

TELEVISION ANTENNAS

HARUO KAWAKAMI
Antenna Giken Corporation

At the present time, the superturnstile antenna (of which the batwing antenna is a radiating element) [1], the supergain antenna (dipole antennas with a reflector plate), invented in the United States, and the Vierergruppe antenna, invented in Germany and sometimes called the *two-dipole antenna* in Japan, are widely used for very high-frequency television (VHF-TV) broadcasting around the world. The superturnstile antenna [2] is used in Japan, as well as in the United States.

Figure 1 shows the appearance of the original batwing antenna, when it was first made public by Masters [1]. The secret lies in its complex shape. It is called a *batwing antenna* in the United States and *Schmetterlings Antenne* (butterfly antenna) in Germany, in view of this shape.

The characteristics of the batwing antenna were calculated using the moment method proposed by Harrington [3], and experiments were conducted on this antenna. The model antenna was approximately two-fifths the size of a full-scale batwing antenna, with its design center frequency at 500 MHz.

It has been reported that for thick cylindrical antennas, a substantial effect on the current distribution appears because of nonzero current on the flat end faces. The assumption of zero current at the flat end face is appropriate for a thin cylindrical antenna; however, in the case of a thick cylindrical antenna, this assumption is, not valid.

Specifically, this article applies the moment method to a full-wave dipole antenna, with a reflector plate supported

Figure 1. Historical shape of the batwing radiator.

1. THE BATWING ANTENNA ELEMENT

The antenna is installed around a support mast, as shown in Fig. 2, and fed from points f and f' , through a jumper from a branch cable with a characteristic impedance of 72Ω . The conducting support mast is idealized by an infinite, thin mast. The batwing antenna element is divided into 397 segments for the original type, with triangular functions as the weighting and expansion functions, and the analysis of the batwing antenna elements carried out using the Galerkin's method. The batwing antenna is fed with unit voltage. The currents flowing in each antenna conductor are calculated over a frequency range of 300–700 MHz.

Figure 3 illustrates these current distributions $I_i(i = 1 \sim 12)$ on the conductors at frequencies of 300,

by a metal bar, such as those widely used for TV and frequency modulated (FM) broadcasting [4]. In the present study, the analysis is made by including the flat end-face currents. As a result, it is found that the calculated and measured values agree well, and satisfactory wideband characteristics are obtained.

Next, the twin-loop antennas, most widely used for ultra high-frequency (UHF)-TV broadcasting, are considered. Previous researchers analyzed them by assuming a sinusoidal current distribution. Others adopted the higher order expansions (Fourier series) of the current distribution; however, their analyses did not sufficiently explain the wideband characteristics of this antenna.

This article applies the moment method to a twin-loop antenna with a reflector plate or a wire screen-type reflector plate. As for the input impedance, 2-L-type twin-loop antennas have reactance near zero [in the case where $l_1 = 0.15 \lambda_0$, that is, where the voltage standing-wave ratio (VSWR) is nearly equal to unity]. Also, satisfactory wideband characteristics are obtained. The agreement between the measurement and the theory is quite good. Thus, it may become possible in the future to improve practical antenna characteristics, based on the results obtained. Several popular television (transmitting) antennas [5,6] were mentioned, such as slot array, normal mode helix, and V-dipole antennas.

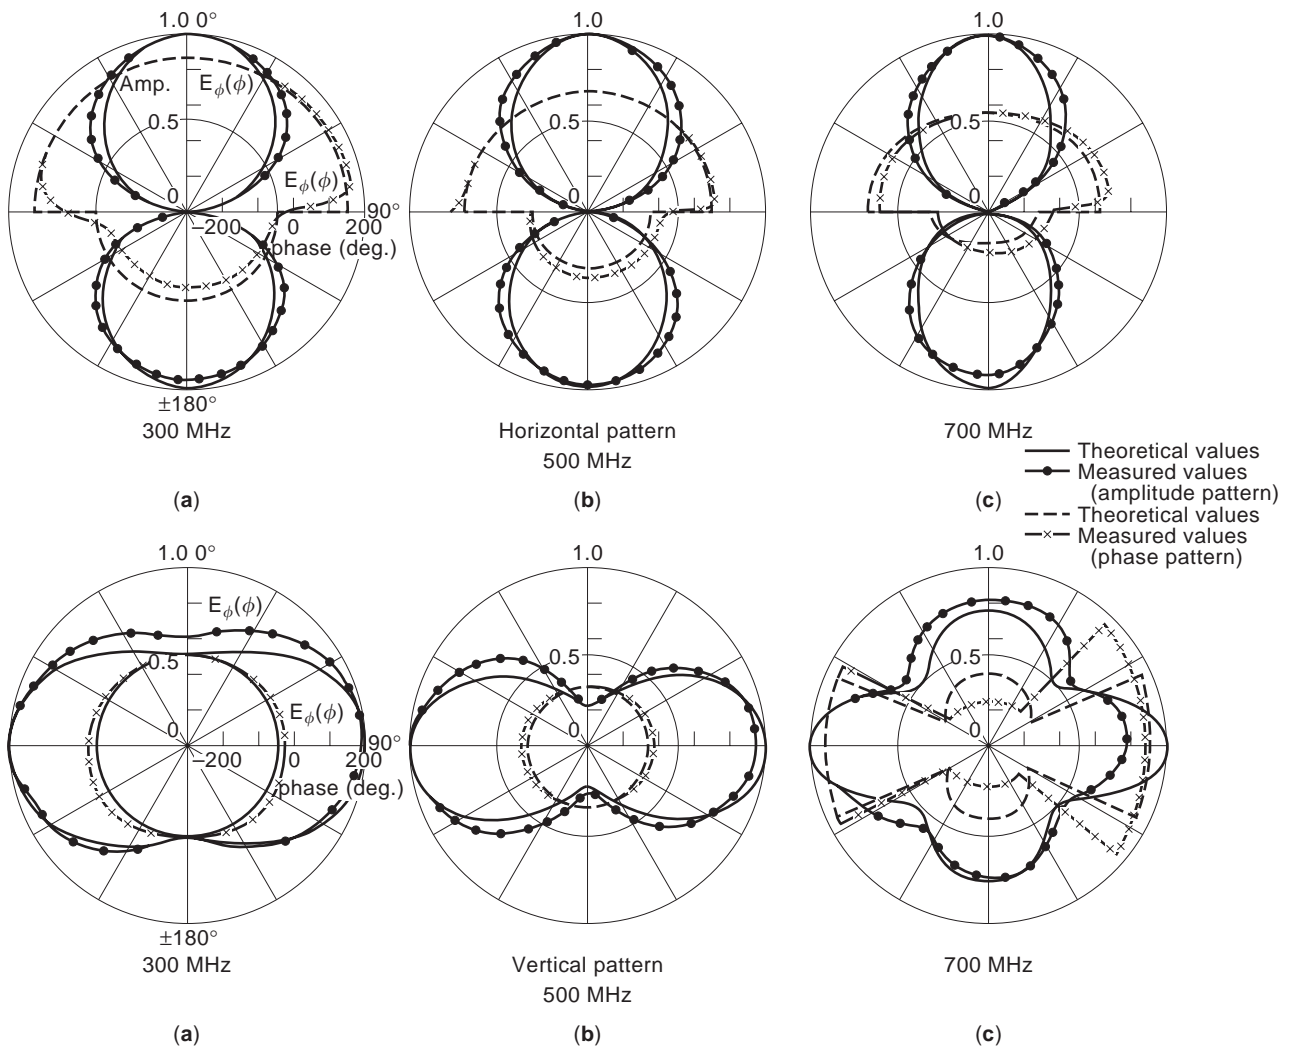

Figure 4. Amplitude and phase characteristics of radiation patterns at 300, 500, 700 MHz (with support mast).

Figure 5. Theoretical and measured values of the input impedance as function of frequency (mast is infinite thin $\alpha = 0^\circ$).

500, and 700 MHz. As the distribution of currents along each conductor is calculated, this allows calculation of the radiation characteristics. Figure 4 illustrates the amplitude and phase characteristics of radiation patterns in the horizontal and vertical planes. It is seen from this figure that the theoretical values agree well with the measurements.

Figure 5 illustrates the theoretical and measured input impedance of a batwing antenna mounted on an aluminum plate, $3\text{ m} \times 3\text{ m}$. Both curves coincide closely with each other, with the input impedance having a value close to $72\ \Omega$, which is the proper match to the characteristic impedance of the branch cable. Vernier impedance matching is carried out in practice by connecting a metal jumper between the end of the branch cable and the feed point of the antenna element or the support mast. The feed strap's length, width, or form is varied to derive VSWR values below 1.10.

The power gain of the antenna at 500 MHz is calculated to be 3.3 dB. Figure 6 shows the gain of the antenna in the $\phi = 0^\circ$ direction as a function of the frequency, referenced to a half-wavelength dipole. Figure 7 illustrates three-dimensional amplitude characteristics of radiation patterns in the horizontal and vertical planes at each frequency.

2. THEORETICAL ANALYSIS OF METAL-BAR-SUPPORTED WIDEBAND FULL-WAVE DIPOLE ANTENNAS WITH A REFLECTOR PLATE

Wideband full-wave dipole antennas with a reflector plate supported by metal bars were invented in Germany. The construction is shown in Fig. 8. A full-wave dipole antenna is located in front of a reflector, and supported directly by a metal bar attached to a reflector. This antenna was also analyzed by the moment method described previously.

As the supporting bar (see Fig. 8) is metallic, leakage currents may cause degradation of the radiation characteristics. To calculate these effects, the radial component of field, E_ρ , must be taken into consideration. In other words, E_ρ is needed for the calculation of $Z_{m,n}$, as defined by inner products of the expansion functions on the supporting bar and weighting functions on the antenna element or on the parallel conductors. We assume the supporting bar to be separated from the feed point by a distance l_1 . Also, the radius of the supporting bar is fixed at one-fourth of the radius of the antenna element (i.e., at $\lambda_0/100$), and then is

Figure 11. Input impedance characteristics of metal-bar supported full-wave dipole antennas (two-bay) with a wire screen-type reflector plate.

varied to be $0.2 \lambda_0$, $0.25 \lambda_0$, and $0.3 \lambda_0$. Figures 9–12 indicate various calculated performance characteristics. Note that the leakage current of the supporting bar is minimized for $f/f_0 = 0.7$, and that this current is substantial at other frequencies. The current distribution is shown only for the case of $l_1 = 0.25 \lambda_0$.

3. CHARACTERISTICS OF 2L TWIN-LOOP ANTENNAS WITH INFINITE REFLECTOR

As shown in Fig. 13, a twin-loop antenna has the loops connected by a parallel line: The 2L-type, 4L-type, and 6L-type are used, according to the number of loops. For actual use, a reactive load is provided by the trap at the top end, which also serves as the antenna support. The dimensions used for this article are as follows: center frequency $f_0 = 750$ MHz (wavelength $\lambda_0 = 40$ cm), length of the parallel line part $2l_1 = \lambda_0/2$ ($l_1 = 10$ cm), $12 = \lambda_0/2$ ($l_2 = 20$ cm),

Figure 12. Gain of metal-bar supported full-wave dipole antennas (two-bay) with a wire screen-type reflector plate.

Figure 13. Structure of 2L-type twin-loop antenna and its coordinate system for analysis.

interval of the parallel line part, $d = \lambda_0/20$ ($d = 2$ cm), loop radius $b = \lambda_0/2\pi$ ($b = 6.366$ cm), distance from the reflector to the antenna $l_3 = \lambda_0/4$ ($l_3 = 10$ cm), conductor diameter $\phi = 10$ mm, and top-end trap $l_t = 0$ to $\lambda_0/4$, changed in intervals of $\lambda_0/16$. 2L twin-loop antennas were arranged in front of an infinite reflector, and calculations were executed in regard to the frequency characteristics of the trap length.

The radiation pattern of the type 2L antenna is shown in Fig. 14. Up to $l_t = \lambda_0/8$, the main beam gradually becomes sharper with increasing frequency, and it can be seen that the sidelobes increase. When l_t increases in this way to $\lambda_0/8$ and $\lambda_0/4$, the directivity becomes disturbed.

Figure 14 shows $l_1 = 0.15 \lambda_0$ and $l_1 = 0.25 \lambda_0$ characteristics of the radiation pattern in a polar display. The antenna gain for both lengths ($l_1 = 0.15 \lambda_0$ and $l_1 = 0.25 \lambda_0$) shows a small change of approximately 9.5–8.5 dB.

The input impedance has a value very close to 50Ω , essentially the same as the characteristic impedance of the feed cable. As for the input impedance, the 2L twin-loop antenna has reactance nearest zero (for the case where $l_1 = 0.15 \lambda_0$), that is, the VSWR is nearly equal to unity.

In the above calculation, the reflector was considered to be an infinite reflector, and the effect of the reflector on the antenna elements was treated by the image method. In the case of practical antennas, however, it is the usual practice to make the reflector finite, or consisting of several parallel conductors. Therefore, a calculation was executed for a reflector in which 21 linear conductors replaced the infinite reflector, as shown in Fig. 15.

The results are shown along with those for the infinite-reflector case. Based on these results, it was concluded that no significant difference was observed in input impedance and gain between the infinite reflector case and the case where the reflector consisted of parallel conductors.

The wire screen-type of reflector plate had a height of $3 \lambda_0$ (120 cm), a width of λ_0 (40 cm), and a wire interval of

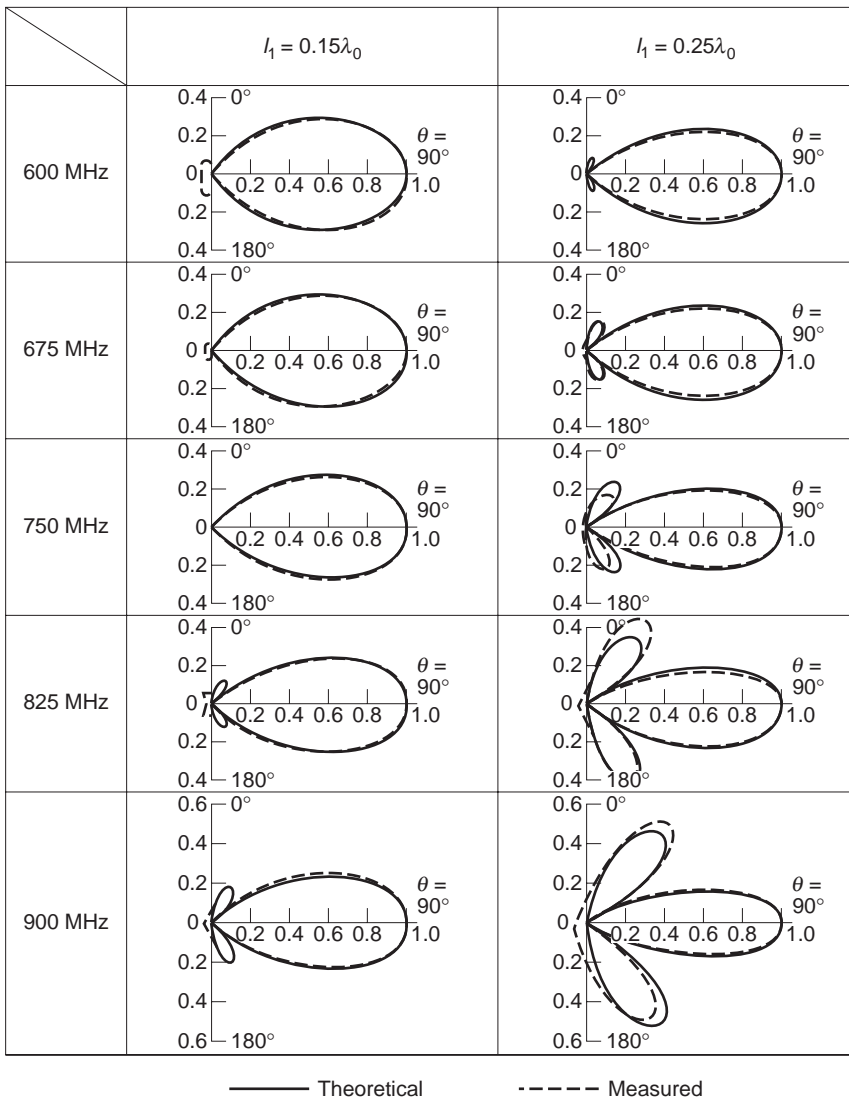

Figure 14. Vertical radiation pattern of 2L-type twin-loop antenna.

0.15λ₀ (6 cm). The radiation pattern is shown in Fig. 16. With regard to the pattern in the horizontal plane, no difference was found in comparison with an infinite reflector, but a backlobe of approximately -16 dB exists to the rear of the reflector. The same figure also shows the phase characteristics. With regard to the pattern in the vertical plane, the phase shows a large change where the pattern shows a cut.

4. SEVERAL POPULAR TRANSMITTING ANTENNAS

4.1. Slot Antennas

Both resonant and nonresonant end-fed arrays of slots are used for TV broadcasting. The resonant arrays are restricted to UHF applications because of their limited bandwidth. The traveling-wave slot antenna illustrated in Fig. 17 is a large end-fed coaxial transmission line with a slotted outer conductor. The slots are arranged in pairs at each layer, with the pairs separated by a quarter wave-

length along the length of the antenna. Adjacent pairs occupy planes at right angles to each other. The slot pairs, which are approximately one-half wavelength long, are fed out of phase by the coaxial line by capacitive probes projecting radially inward from one side of each slot so as to produce a figure-eight pattern. The probes are placed on opposite sides of adjacent inline slots that are spaced one-half wavelength to provide in-phase excitation. The quarter-wavelength separation of layers in conjunction with the space-quadrature arrangement of successive layers of slots effects a turnstile-type feed that produces a horizontally polarized azimuth pattern with a circularity of ±1 dB for VHF applications. An equal percentage of the power in the coaxial line is fed to each layer of slots, which results in an exponential aperture distribution that provides null fill.

Reflections from adjacent layers tend to cancel, which allows the traveling-wave operation. The top slots are strongly coupled to the line to reduce reflections. For high-gain applications, one-half of the slots may be

Figure 15. Structure of 2L-type twin-loop antenna with a wire screen-type reflector plate.

eliminated, resulting in a one-wavelength spacing of in-line slots. The standing-wave antenna consists of layers or bays of one or more axial slots spaced by one wavelength and fed by a coaxial line with the slotted pipe forming the outer conductor. Azimuth patterns are controlled by the number of slots per bay. One slot per bay produces a skull-shaped pattern, two slots a peanut-shaped pattern, and three slots a trilobe pattern. Four or more slots per bay are usually required for an omnidirectional pattern with a circularity of ± 1 dB. A typical omnidirectional pattern is shown in Fig. 18.

4.2. Helix Antennas

Figure 19 shows a single bay of a single-arm right-hand and left-hand helix fed in phase at the center so that the vertically polarized components of the two helices cancel in the broadside direction. The pitch angle is about 12° so that the vertically polarized radiation from each helix is about 10 dB down from the horizontally polarized radiation, which produces about 0.5 dB loss in gain because of cross-polarization radiation. As the beam of each helix scans about 2.7° per 1% change in frequency, the bay length is limited to about six wavelengths. Sidefire helical antenna pattern is shown in Fig. 20.

4.3. V-Shaped Antennas

The multi-V antenna has been designed especially to mount on the side of existing towers that are used for standard broadcast radiators or TV supporting towers. The multi-V antenna array (Fig. 21) consists of a number

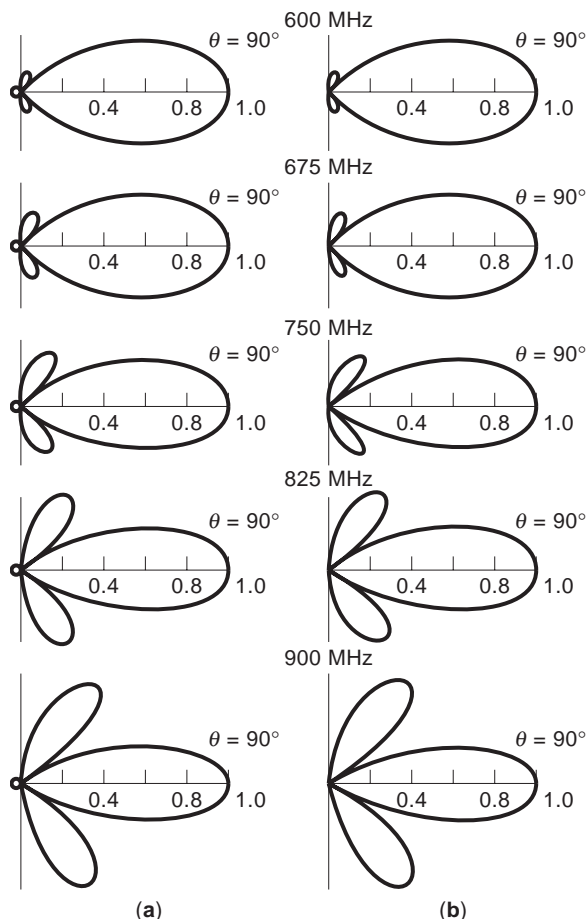

Figure 16. Comparison between characteristics of 2L-type twin-loop antenna with a wire screen-type reflector and with an infinite reflector.

Figure 17. The traveling-wave slot antenna.

Figure 18. A typical omnidirectional pattern.

of V elements stacked vertically to provide power gain in the horizontal plane and vertical directivity. The resulting horizontal radiation pattern is essentially omnidirectional. The pattern remains approximately circular when side-mounted on a tower having a uniform cross section with 2 ft on a side.

The bays, or V's, are so designed that the input impedance of each pair is 50Ω , enabling them to be fed by standard coaxial transmission lines. The feed system enables an even number of bays from two to eight to be employed to obtain power gains ranging from 1.6 to 7.3. The design is such that it is necessary to tune the antenna at the factory for the desired frequency. It is very simple, with one feed point per bay and a maximum of four power-dividing elements for an eight-bay array. The radiating elements are grounded for maximum lightning protection.

Figure 22 shows the four-bay V antenna pattern for various values of space.

5. CONCLUSION

Previous researchers [1,2] have analyzed batwing antennas by approximating the current distribution as a sinusoidal

Figure 20. The horizontal and vertical pattern of sidefire helical antenna.

Figure 21. The construction of V-shaped antenna.

distribution. Wideband characteristics are not obtained with a sinusoidal current distribution. In this article, various types of modified batwing antennas, as the central form of the superturnstile antenna system, were analyzed theoretically with the aid of the moment method. The results were compared with measurements in order to examine the performance of the antenna elements in detail.

It is also evident from this research that the shape of the jumper has a remarkable effect on the reactance of the input impedance, and that the distance between the support mast and the antenna element also markedly influences the resistance of this impedance. Thus, a satisfactory explanation is given with regard to the matching conditions. As a result, it was found that the calculated and measured values agree well, and satisfactory wideband characteristics are obtained.

Next, an analytic method and calculated results for the performance characteristics of a thick cylindrical antenna were presented. The analysis used the moment method and takes the end face currents into account. The calculated results were compared with measured values, demonstrating the accuracy of the analytic method.

Using this method, a full-wave dipole antenna with a reflector supported by a metal bar was analyzed. The input impedance was measured for particular cases, thus obtaining the antenna dimensions for which the antenna input impedance permits broadband operation. In conclusion, wideband characteristics are not obtained with a one-bay antenna. The wideband characteristic is obtained by means of the mutual impedance of the two-bay arrangement. In the frequency region of $f/f_0 = 0.7$, the resistance of the input impedance is considered to be constant. In this case, the leakage current to the support bar is small. With regard to the radiation pattern, it was seen that a degradation of characteristics was caused by the metal support bar.

It is noted that the present method should be similarly useful for analyzing antennas of other forms where the end face effect is not negligible.

Next, the twin-loop antennas were considered for use as wideband antennas. The analysis results for $2L$ type

Figure 22. Vertical and horizontal pattern of V-shaped antenna.

showed that the change in the characteristics with a change in frequency becomes more severe with increasing trap length l_t , and the bandwidth becomes small, whereas a short trap length l_t shows a small change and a tendency for the bandwidth to become wide. For $l_t = 0$, a wide bandwidth for pattern and gain was obtained for the $2L$ type. The input impedance has a value very close to 50Ω , essentially the same as the characteristic impedance of the feed cable over a very wide frequency range. Thus, a

satisfactory explanation was given with regard to the matching conditions. Popular television antennas cover the properties of many basic types of antennas that are the mainstream of antenna technology. It has been reported here that a rigorous theoretical analysis has been achieved almost 30 years after the invention of these VHF-UHF antennas.

TELEVISION BROADCAST TRANSMISSION STANDARDS

ALAN S. GODBER
 JAMES R. REDFORD
 IEEE BTS Audio-Video
 Techniques Standards
 Committee

Since the invention of television, images and sound have been captured, processed, transmitted, received, and displayed using analog technology, where the picture and sound elements are represented by signals that are proportional to the image amplitude and sound volume.

In more recent years, as solid-state technology has developed, spurred primarily by the development of computers, digital technology has gradually been introduced into the handling of the television signal, both for image and sound. The digital electric signal representing the various elements of the image and sound is composed of binary numbers that represent the image intensity, color, and so on, and the sound characteristics.

Many portions of television systems are now hybrid combinations of analog and digital, and it is expected that eventually all television equipment will be fully digital, except for the transducers, cameras, and microphones (whose inputs are analog) and the television displays and loudspeakers (whose outputs are analog).

The currently used broadcast television transmission standards [National Television Systems Committee (NTSC), phase alternate line (PAL), and sequential and memory (SECAM)] for 525- and 625-line systems were

designed around analog technology; although significant portions of those broadcast systems are now hybrid analog/digital or digital, the "over the air" transmission system is still analog. Furthermore, other than for "component" processed portions of the system, the video signals take the same "encoded" form from studio camera to receiver and conform to the same standard.

The recently developed ATSC Digital Television Standard, however, uses digital technology for "over the air" transmission, and the digital signals used from the studio camera to the receiver, although they represent the same image and sound, differ in form in portions of the transmission system. This variation is such that in the studio, maximum image and sound information is coded digitally; but during recording, special effects processing, distribution around a broadcast facility, and transmission, the digital signal is "compressed" to an increasing extent as it approaches its final destination at the home. This permits practical and economical handling of the signal.

1. ANALOG TELEVISION SYSTEMS

1.1. Black-and-White Television

It is the purpose of all conventional broadcast television systems to provide instantaneous vision beyond human sight, a window into which the viewer may peer to see activity at another place. Not surprisingly, all of the modern systems evolved to have similar characteristics. Basically, a sampling structure is used to convert a three-dimensional image (horizontal, vertical, and temporal variations) into a continuous time-varying broad-band electrical signal. This modulates a high-frequency carrier with the accompanying sound, and it is broadcast over the airwaves. Reasonably inexpensive consumer television sets are capable of recovering the picture and sound in the viewer's home.

1.1.1. Image Representation. The sampling structure first divides the motion into a series of still pictures to be sequenced rapidly enough to restore an illusion of movement. Next, each individual picture is divided vertically into sufficient segments so that enough definition can be retrieved in this dimension at the receiver. This process is called *scanning*. The individual pictures generated are known as *frames*, each of which contains *scanning lines* from top to bottom.

The number of scanning lines necessary was derived from typical room dimensions and practical display size. Based on the acuity of human vision, a viewing distance of four to six picture heights is intended. The scanning lines must be capable of enough transitions to resolve comparable definition horizontally. The image *aspect ratio* (width/height) of all conventional systems is 4:3, from the motion picture industry "academy aperture." All systems sample the picture from the top left to bottom right.

In professional cinema, the projection rate of 48 Hz is sufficient to make flicker practically invisible. Long-distance electric power distribution networks throughout the world use slightly higher rates of 50 Hz to 60 Hz alternating current. To minimize the movement of vertical "hum"

satisfactory explanation was given with regard to the matching conditions. TELEVISION BROADCAST TRANSMISSION STANDARDS

ALAN S. GODBER
 JAMES R. REDFORD
 IEEE BTS Audio-Video
 Techniques Standards
 Committee

Since the invention of television, images and sound have been captured, processed, transmitted, received, and displayed using analog technology, where the picture and sound elements are represented by signals that are proportional to the image amplitude and sound volume.

In more recent years, as solid-state technology has developed, spurred primarily by the development of computers, digital technology has gradually been introduced into the handling of the television signal, both for image and sound. The digital electric signal representing the various elements of the image and sound is composed of binary numbers that represent the image intensity, color, and so on, and the sound characteristics.

Many portions of television systems are now hybrid combinations of analog and digital, and it is expected that eventually all television equipment will be fully digital, except for the transducers, cameras, and microphones (whose inputs are analog) and the television displays and loudspeakers (whose outputs are analog).

The currently used broadcast television transmission standards [National Television Systems Committee (NTSC), phase alternate line (PAL), and sequential and memory (SECAM)] for 525- and 625-line systems were

designed around analog technology; although significant portions of those broadcast systems are now hybrid analog/digital or digital, the "over the air" transmission system is still analog. Furthermore, other than for "component" processed portions of the system, the video signals take the same "encoded" form from studio camera to receiver and conform to the same standard.

The recently developed ATSC Digital Television Standard, however, uses digital technology for "over the air" transmission, and the digital signals used from the studio camera to the receiver, although they represent the same image and sound, differ in form in portions of the transmission system. This variation is such that in the studio, maximum image and sound information is coded digitally; but during recording, special effects processing, distribution around a broadcast facility, and transmission, the digital signal is "compressed" to an increasing extent as it approaches its final destination at the home. This permits practical and economical handling of the signal.

1. ANALOG TELEVISION SYSTEMS

1.1. Black-and-White Television

It is the purpose of all conventional broadcast television systems to provide instantaneous vision beyond human sight, a window into which the viewer may peer to see activity at another place. Not surprisingly, all of the modern systems evolved to have similar characteristics. Basically, a sampling structure is used to convert a three-dimensional image (horizontal, vertical, and temporal variations) into a continuous time-varying broad-band electrical signal. This modulates a high-frequency carrier with the accompanying sound, and it is broadcast over the airwaves. Reasonably inexpensive consumer television sets are capable of recovering the picture and sound in the viewer's home.

1.1.1. Image Representation. The sampling structure first divides the motion into a series of still pictures to be sequenced rapidly enough to restore an illusion of movement. Next, each individual picture is divided vertically into sufficient segments so that enough definition can be retrieved in this dimension at the receiver. This process is called *scanning*. The individual pictures generated are known as *frames*, each of which contains *scanning lines* from top to bottom.

The number of scanning lines necessary was derived from typical room dimensions and practical display size. Based on the acuity of human vision, a viewing distance of four to six picture heights is intended. The scanning lines must be capable of enough transitions to resolve comparable definition horizontally. The image *aspect ratio* (width/height) of all conventional systems is 4:3, from the motion picture industry "academy aperture." All systems sample the picture from the top left to bottom right.

In professional cinema, the projection rate of 48 Hz is sufficient to make flicker practically invisible. Long-distance electric power distribution networks throughout the world use slightly higher rates of 50 Hz to 60 Hz alternating current. To minimize the movement of vertical "hum"

in the picture caused by marginal filtering in direct current power supplies, the picture repetition rate was made to equal the power line frequency.

A variation of this process used by all conventional systems is *interlaced scanning*, whereby every other line is scanned to produce a picture with half the vertical resolution, known as a *field*. The following field “fills in” the missing lines to form the complete frame. Each field illuminates a sufficient portion of the display so that flicker is practically invisible; yet only half the information is being generated. This conserves bandwidth in transmission. For both fields to start and stop at the same point vertically, one field must have a half scanning line at the top, and the other field must have a half scanning line at the bottom of the picture. This results in an odd number of scanning lines for the entire frame.

Mechanical systems using rotating disks with spiral holes to scan the image were investigated in the 1920s and 1930s, but these efforts gave way to “all electronic” television. Prior to World War II, developers in the United States experimented with 343-line and 441-line systems. Developers in Great Britain began a 405-line service, and after the war, the French developed an 819-line system, but these are no longer in use.

1.1.2. Synchronization. In most of North and South America and the Far East, where the power line frequency is 60 Hz, a 525-line system became the norm. This results in an interlaced scanning line rate of 15.750 kHz. The development of color television in Europe led to standardization of 625 lines in much of the rest of the world. The resulting line frequency with a 50 Hz field rate is 15.625 kHz. The similar line and field rates enable the use of similar picture tube deflection circuitry and components.

Horizontal and vertical frequencies must be synchronous and phase-locked, so they are derived from a common oscillator.

Synchronization pulses are inserted between each scanning line (Fig. 1) and between each field to enable the television receiver to present the picture details with the same spatial orientation as that of the camera. The *sync* pulses are of opposite polarity from the picture information, permitting easy differentiation in the receiver. The line sync pulses, occurring at a faster rate, are narrower than the field sync pulses, which typically are the duration of several lines. Sync separation circuitry in the receiver discriminates between the two time constants. Sync pulses cause the scanning to rapidly *retrace* from right to left and from bottom to top.

1.1.3. Blanking. To provide time for the scanning circuits to reposition and stabilize at the start of a line or field, the picture signal is *blanked*, or turned off. This occurs just before (front porch) and for a short time after (back porch) the horizontal sync pulse, as well as for several lines before and after vertical sync. During vertical sync, *serrations* are inserted to maintain horizontal synchronization. Shorter *equalizing pulses* are added in the several blanked lines before and after vertical sync (Fig. 2). All these pulses occur at twice the rate of normal sync pulses so that the vertical interval of both fields (which are offset by one-half line) can be identical, simplifying circuit design.

Additional scanning lines are blanked before the active picture begins; typically there is a total of 25 blanked lines per field in 625-line systems and 21 blanked lines per field for the 525-line system M. Modern television receivers complete the vertical retrace very soon after the vertical

Figure 1. 525-line system M: Line-time signal specifications.

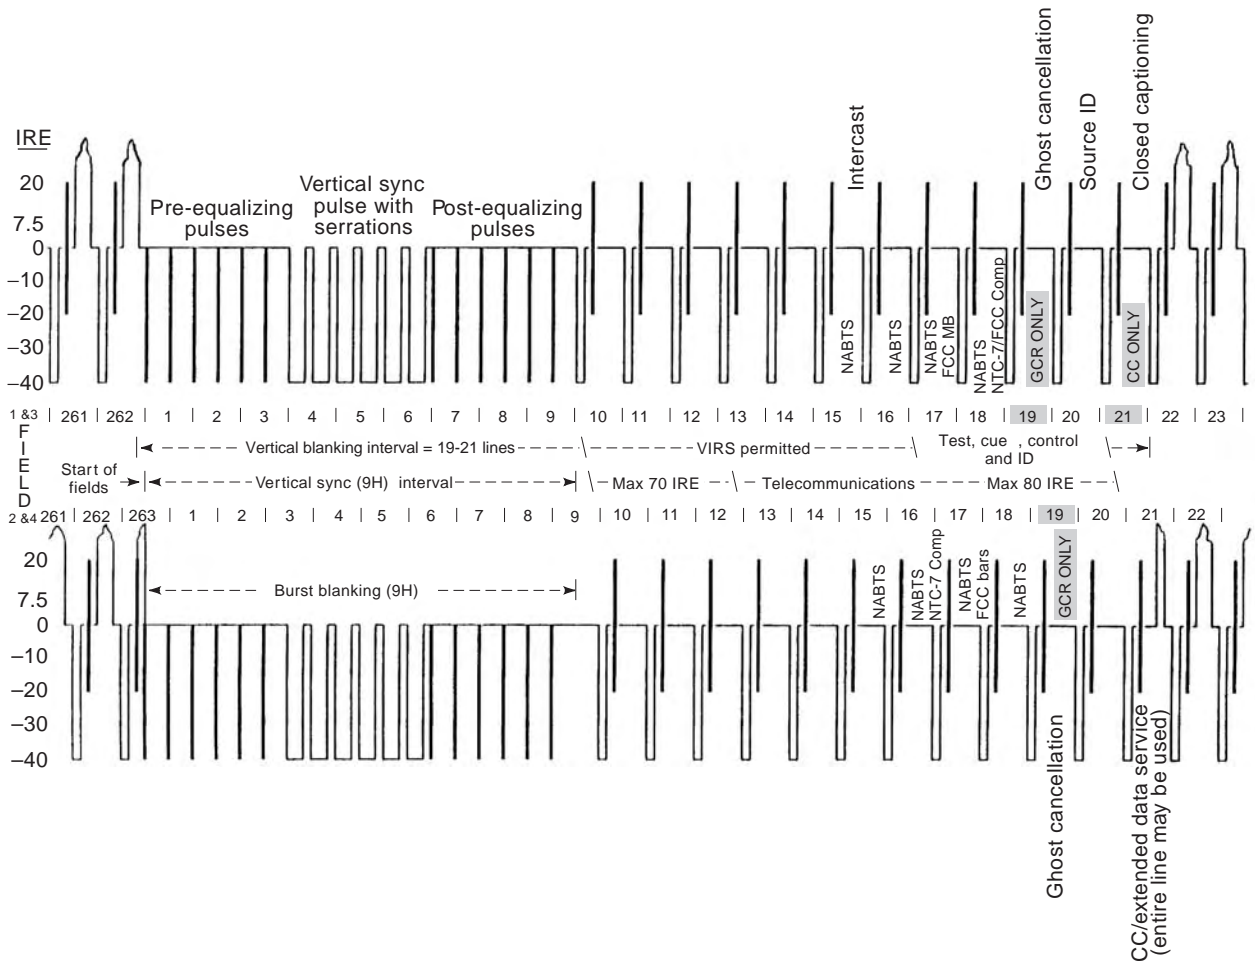

Figure 2. 525-line system M: field-time and vertical interval signal specifications.

sync pulse is received. The extra blanked lines now contain various ancillary signals, such as for short-time and line-time distortion and noise measurement, ghost cancellation, source identification, closed captioning, and teletext.

Fields and lines of each frame are numbered for technical convenience. In the 625-line systems, field 1 is that which begins the active picture with a half line of video. In the 525-line system M, the active picture of field 1 begins with a full line of video. Lines are numbered sequentially throughout the frame, beginning at the vertical sync pulse in the 625-line systems. For the 525-line system M, the line numbering begins at the first complete line of blanking for each field. Field 1 continues halfway through line 263, and then field 2 continues through line 262.

1.1.4. Signal Levels. During blanking, the video signal is at 0 V, the reference used to measure picture (positive-going) and sync (negative-going) levels. Signal amplitudes are measured directly in millivolts, except, because of changes made during the conversion to color, the 525-line system uses *IRE units*. A specialized oscilloscope is used to monitor characteristics of the signal amplitude and period. The *waveform monitor* has its voltage scale calibrated in millivolts (or IRE units for 525-line applica-

tions), and its time base is calibrated to scanning line and picture field rates, as well as in microseconds (Fig. 3).

Originally, the 525-line system used an amplitude of 1 V peak-to-peak (p-p) for the picture information, and it

Figure 3. Typical NTSC-M waveform monitor graticule. Several additional markings are for measurement of various signal distortions.

used 0.4 V for sync. So that color information (modulated onto a *subcarrier* which can extend above peak white level) could be accommodated within the same dynamic range of existing equipment, the 1.4 V p-p scaling was compressed in amplitude to 1 V p-p. This created fractional voltage levels for peak white (714.3 mV) and sync (−286.7 mV), so a 1 V scale of 140 IRE units was adopted to simplify measurement. The 625-line standards did not have this historical complication. The peak white level is 700 mV, and the sync level is −300 mV.

Another anachronism of the 525-line system is the use of a direct-current (dc) offset of the picture black from blanking level. This was done to ensure that during retrace, the electron beam in the display tube was completely cut off, so *retrace lines* did not appear in the picture. This *setup level* originally varied between 5 and 10 IRE units above blanking, but it was standardized at 7.5 IRE for color TV, although it has been discarded altogether in Japan. Setup, or “lift,” was used to some extent in earlier systems but abandoned by the advent of 625-line services.

The electrical-to-optical transfer characteristic (*gamma*) of the cathode-ray picture tube is nonlinear. Doubling the video signal level applied to the control grid of the picture tube does not cause the light output to double; rather, it follows a power law of approximately 2.5. To correct for this, the video signal itself is made nonlinear, with an opposite transfer characteristic of about 0.4. This correction is applied at the camera in all systems.

1.1.5. Resolution. Resolution in the vertical direction is determined by taking the total number of scanning lines and subtracting those used for vertical blanking. This is multiplied by 0.7, the *Kell factor*, a correction for slight overlap between adjacent lines and the effect of imperfect interlace. By convention, television resolution is expressed in *television (TV) lines per picture height*, in contrast to photographic “line pairs per millimeter.” As the resolution is fixed by the scanning system, picture size is immaterial. Note that a vertical “line pair” in television requires two scanning lines.

To compute the bandwidth necessary for equal horizontal resolution, the vertical resolution is multiplied by the aspect ratio of 4/3 and is divided by the ratio of total scanning line time to active picture (unblanked) line time. This number is halved because an electric cycle defines a line pair, whereas a “TV line of resolution” is really only one transition. Multiplying the number of cycles per scanning line by the total number of scanning lines in a field, and then multiplying the number of fields per second, gives the bandwidth of the baseband video signal.

1.1.6. Broadcasting Standards. The various systems have been assigned letter designations by the International Telecommunications Union (ITU). The letters were assigned as the systems were registered, so alphabetical order bears no relation to system differences (Table 1), but a rearrangement highlights similarities (Table 2). Only scanning parameters and radiofrequency (RF) characteristics are defined; color encoding is not specified. Systems A, C, E, and F are no longer used.

Portions of the very-high-frequency (VHF) and ultra-high-frequency (UHF) RF spectrum are divided into *channels* for television broadcast. Modern channel assignments are 6 MHz wide in the Americas and the Far East. Elsewhere, they are generally 7 MHz in VHF and 8 MHz in UHF, with the carrier a fixed distance from one edge. As, in most systems, the picture carrier is near the lower edge and the audio signals are at the upper end, when the opposite is true, the channels are called *inverted*.

As a bandwidth-saving technique, the amplitude-modulated RF signal is filtered so that only one sideband is fully emitted; the other sideband is *vestigial*, or partially suppressed, which aids in fine-tuning to the correct carrier frequency at the receiver. The full sideband, which represents the video bandwidth, extends in the direction of the audio carrier(s), but sufficient guard band is included to prevent interference.

Bandwidth of the vestigial sideband varies among systems as does the placement of the audio carrier in relation to the picture carrier (Fig. 4). These factors complicate receiver design in areas where signals of two or more systems may exist. The main audio signal is sent via an amplitude-modulated or, more commonly, frequency-modulated carrier. Peak deviation in frequency modulation (FM) is ± 50 kHz, with 50 μ s preemphasis, except ± 25 kHz and 75 μ s for systems M and N. Preemphasis for improving the signal-to-noise ratio is common in FM systems; its use in some amplitude-modulation (AM) systems was to simplify receivers that could accommodate both modulation schemes.

Amplitude modulation is used in all systems for the video waveform, which, unlike audio, is not sinusoidal. Most systems employ a *negative sense of modulation*, such that negative excursions of the baseband signal produce an increase in the amplitude of the modulated carrier. This allows the constant amplitude sync pulses to serve as an indication of the received RF signal level for automatic gain control. Also, interfering electric energy tends to produce less noticeable black flashes in the received picture, and the duty cycle of the signal is reduced, which consumes less power at the transmitter.

1.2. Multichannel Sound

Early attempts to provide stereo sound for special TV events involved *simulcasting*, whereby an FM radio station in the same coverage area broadcast the stereo audio for the program. Due to the high profitability of FM radio today, this scheme is becoming impractical. For the 525-line system M, with channels of only 6 MHz bandwidth, a multiplexing scheme is used on the existing single audio carrier. Due to the wider channel bandwidths in 625-line systems, multiple sound carriers emerged as the solution.

1.2.1. Multiplex Sound Systems. In the United States, Zenith Electronics developed multichannel television sound (MTS), a pilot-tone system in which the sum of the two stereo channels (L+R) modulates the main TV audio FM carrier, providing a monophonic signal to conventional receivers. A difference signal (L−R) is dbx-TV suppressed-carrier amplitude-modulated onto an audio

subcarrier at twice the line scanning frequency ($2f_H$), whereas a pilot is sent at the line frequency as a reference for demodulation. A second audio program (SAP) may be frequency modulated at $5f_H$, and nonpublic voice or data may be included at $6.5f_H$.

Japan's NHK developed a similar *FM/FM* stereo system using FM of the L – R subchannel at $2f_H$. A control subcarrier at $3.5f_H$ is tone-modulated to indicate whether stereo or second audio programming is being broadcast.

1.2.2. Multiple Carrier Systems. In Germany, IRT introduced *Zweiton*, a dual-carrier system for transmission standards B and G. In both standards, the main carrier is frequency-modulated at 5.5 MHz above the vision carrier. For stereo, this carrier conveys the sum of the two channels (L + R). The second frequency-modulated sound carrier is placed 15.5 times the line scanning frequency above the main carrier, or 5.742 MHz above the vision carrier. For transmission system D, a similar relationship exists to the 6.0 MHz main channel. For stereo, this carrier conveys the right audio channel only.

A reference carrier at $3f_H$ is tone-modulated, and the particular tone frequency switches receivers for stereo or second audio channel sound. A variant is used in Korea where the second carrier is placed at 4.72 MHz above the vision carrier and conveys L – R information.

The British Broadcasting Corporation (BBC) in Britain developed near-instantaneous companded audio multiplex (NICAM), a digital sound carrier system. Both audio channels are sampled at 32 kHz with 14-bit resolution. Each sample is compressed to 10 bits and then arranged into frame packages of 728-bit length. These are rearranged, and then the data are scrambled to disperse the effect of noise at the receiver. Finally, two bits at a time are fed to a QPSK modulator for transmission.

Either stereo or two independent sound signals may be transmitted. Other possible combinations are (1) one

sound and one data channel or (2) two data channels. The original analog-modulated single-channel sound carrier is retained for older receivers. The digital carrier is 6.552 MHz above the vision carrier for transmission system I, or 5.85 MHz for systems B, G, and L.

1.3. NTSC Color Television

It has long been recognized that color vision in humans results from three types of photoreceptors in the eye, each sensitive to a different portion of the visible spectrum. The ratio of excitation creates the perception of hue and saturation, whereas the aggregate evokes the sensation of brightness. Stimulating the three types of photoreceptors using three wavelengths of light can produce the impression of a wide gamut of colors. For television, the image is optically divided into three primary color images, and this information is delivered to the receiver, which spatially integrates the three pictures, something like tripack color film and printing.

1.3.1. Sequential Color Systems. The first attempts at commercial color TV involved transmitting the three color images in a *sequential* fashion. Compatibility with existing transmitters was essential from an economic standpoint. Because line-sequential transmission caused crawl patterning, field-sequential was preferred. However, there was no separate *luminance* signal for existing black-and-white receivers to use.

To reduce flicker caused by the apparent brightness difference between the three primary colors, the field rate had to be increased, and maintaining an equivalent channel bandwidth required the number of scanning lines to be reduced. These changes aggravated the compatibility problem with existing sets. A field-sequential system developed by the Columbia Broadcasting System (CBS)

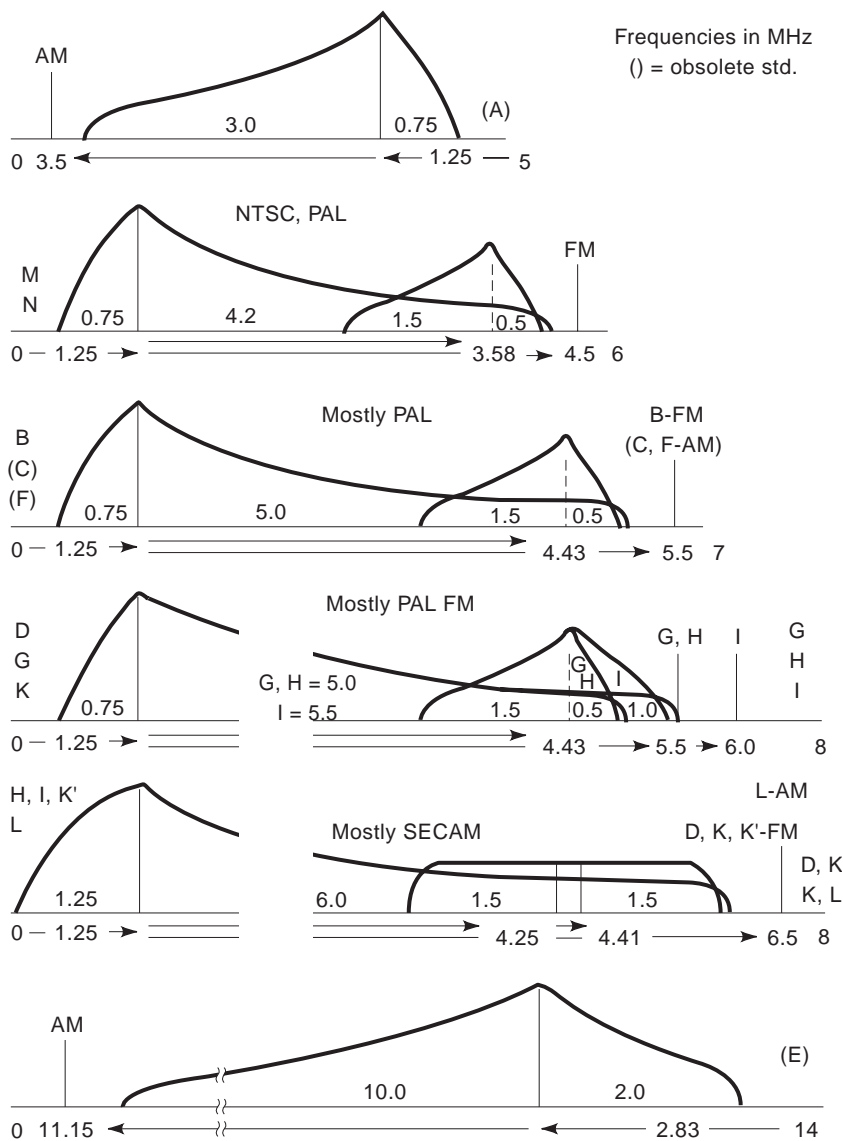

Figure 4. Television RF channel spectra for the various world television systems. For simplicity, only a single illustration of the lower and upper portions of the channel spectra is shown for the 8 MHz wide channels. Therefore, for systems D, H, I, and K, the lower and upper illustrations are not adjacent to each other.

network was briefly commissioned in the United States during 1951.

To be *compatible*, a color television system must have the same channel bandwidth as existing monochrome transmitters and receivers, use equivalent scanning parameters, and supply the same luminance signal, as if the picture were black and white. An all-industry body, the NTSC, was set up in the United States to devise such a color TV system.

1.3.2. Separate Luminance and Mixed Highs. The human visual system senses shapes and edges from brightness variations. Color only fills in the larger areas, much like a child's coloring book. At the suggestion of Hazeltine Electronics, the existing wide-bandwidth luminance signal of black-and-white television was retained. The color information is limited to a much narrower bandwidth, on the

order of 1 MHz, restricting its resolution in the horizontal direction.

This first led to a dot-sequential system that sampled the three colors many times along each scanning line to form a high-frequency chrominance signal. The frequency of sampling may be likened to a *subcarrier* signal whose amplitude and phase are changing according to color variations along the line. At the receiver, the "dot" patterns of each primary resulting from sampling are averaged in lowpass frequency filters. The result is a continuous but low-resolution full-color signal. Equal amounts of their higher frequency components are summed to form a *mixed-highs* signal for fine luminance detail ($Y = \frac{1}{3} R + \frac{1}{3} sG + \frac{1}{3} B$), an idea from Philco.

1.3.3. Quadrature Modulation. The dot-sequential concept formed the basis for a more sophisticated simultaneous system. The luminance signal contains both

high- and low-frequency components. Only two lower resolution color signals are needed (the third can be derived by subtracting their sum from the low-frequency portion of luminance). The spectral composition of green is nearest to that of luminance, so transmitting the red and blue signals improves the signal-to-noise performance. These low-frequency color signals are sampled using a time-multiplexing technique proposed by Philco, known as *quadrature modulation*.

The chrominance signal is formed by the addition of two subcarriers, which are locked at the same frequency but differ in phase by 90°. The two subcarriers are modulated by separate baseband signals such that each is sampled when the other carrier is at a null. This results in the subcarrier being modulated in both amplitude and phase. The amplitude relates to the saturation of the color, whereas the phase component corresponds to the hue (Fig. 5).

1.3.4. Frequency Multiplexing. The sampling rate is more than twice the highest frequency of the color signals after lowpass filtering, so the chrominance information shares the upper part of the video spectrum with luminance. This frequency-multiplexing scheme was put forward by General Electric. The scanning process involves sampling the image at line and field rates; therefore, energy in the video signal is concentrated at intervals of the line and field frequencies. These *sidebands* leave pockets between them where very little energy exists.

The exact subcarrier frequency was made an odd multiple of one half the line scanning frequency. This causes sidebands containing the color information to likewise fall

Figure 5. Quadrature modulation. Addition of two amplitude-modulated signals whose carrier frequencies are in phase quadrature (same frequency but offset in phase by 90°) produces an output signal whose carrier is modulated in both amplitude (AM) and phase (PM) simultaneously. This method of combining two baseband signals onto a single carrier is called quadrature modulation. In the case of NTSC or PAL encoding for color television, the two baseband components represent the two chrominance signals (I and Q for NTSC, U and V for PAL). The resulting amplitude of the subcarrier relates to the saturation, whereas the phase conveys the hue information. The frequency of the subcarrier is unchanged.

in between those of the existing luminance signal (Fig. 6). Therefore, the phase of the subcarrier signal is opposite line-to-line. This prevents the positive and negative excursions of the subcarrier from lining up vertically in the picture, and it results in a less-objectionable “dot” interference pattern between the subcarrier and luminance signal. Comb filtering to separate luminance and

Figure 6. Frequency spectrum of composite NTSC-M color television signal showing relationships between the baseband and channel spectra and between sidebands of the picture carrier and color subcarrier.

chrominance may be employed by examining the phase of information around the subcarrier frequency on adjacent lines. The dot pattern is further concealed because the subcarrier phase is also opposite frame-to-frame.

A *four-field sequence* is established whereby the two interlaced picture fields, together with the alternating phase of subcarrier on sequential frames, requires the proper sequence to be maintained. Sources to be intercut or mixed must be properly timed, and editing points must be chosen to preserve the sequence of the four color fields.

A slight modification was necessary to the line and field scanning frequencies because one of the sidebands of the new color subcarrier fell right at the rest frequency of the FM sound carrier for system M, 4.5 MHz. Existing black-and-white receivers did not have adequate filtering to prevent an annoying buzz when the program sound was low and color saturation was high. By reducing the scanning frequencies by a mere 0.1%, the sidebands of luminance and chrominance remained interleaved, but shifted to eliminate the problem. Hence, the field frequency became 59.94 Hz, and the line frequency became 15.734 kHz.

1.3.5. Color-Difference Signals. Another suggestion came from Philco: Interference with the luminance signal is minimized by forming the two color signals as the difference between their respective primary and luminance (i.e., $R - Y$, $B - Y$). This makes the color-difference signals smaller in amplitude because most scenes have predominantly pale colors.

The subcarrier is suppressed, so that only the sidebands are formed. When there is no color in the picture, the subcarrier vanishes. This necessitates a local oscillator at the receiver. A *color-burst* reference is inserted on the back porch of the horizontal sync pulse, which synchronizes the reference oscillator and provides an amplitude reference for color saturation automatic gain control.

1.3.6. Constant Luminance. With the constant-amplitude formulation ($Y = \frac{1}{3}R + \frac{1}{3}G + \frac{1}{3}B$), the luminance signal does not represent the exact scene brightness. Part of the brightness information is carried by the chrominance channels, so unwanted irregularities in them, such as noise and interference, produce brightness variations. Also, the gray-scale rendition of a color broadcast on a black-and-white receiver is not correct.

Hazeltine Electronics suggested weighting the contributions of the primaries to the luminance signal according to their actual addition to the displayed brightness. The color-difference signals will then represent only variations in hue and saturation, because they are “minus” the true brightness ($R - Y$, $B - Y$). A design based on this principle is called a *constant-luminance* system. For the display phosphors and white point originally specified, the luminance composition is $Y = 30\% R + 59\% G + 11\% B$.

1.3.7. Scaling Factors. The two low-bandwidth color-difference signals modulate a relatively high-frequency subcarrier superimposed onto the signal level representing luminance. However, the peak subcarrier excursions for some hues could reach far beyond the original black-and-white limits, where the complete picture signal is

restricted between levels representing blanking and peak white picture information. Over-modulation at the transmitter may produce periodic suppression of the RF carrier and/or interference with the synchronizing signals. If the overall amplitude of the composite (luminance level plus superimposed subcarrier amplitude) signal was simply lowered, the effective power of the transmitted signal would be significantly reduced.

A better solution was to reduce the overall amplitude of only the modulated subcarrier signal. However, such an arbitrary reduction would severely impair the signal-to-noise ratio of the chrominance information. The best solution proved to be selective reduction of each of the baseband $R - Y$ and $B - Y$ signal amplitudes to restrict the resulting modulated subcarrier excursions to $\pm\frac{4}{3}$ of the luminance signal levels. The $R - Y$ signal is divided by 1.14, and $B - Y$ is divided by 2.03. The resulting 33.3% overmodulation beyond both peak white and blanking levels was found to be an acceptable compromise, because the incidence of highly saturated colors is slight (Fig. 7).

1.3.8. Proportioned Bandwidths. RCA proposed that the axes of modulation be shifted from $R - Y$, $B - Y$ to conform to the greater and lesser acuity of human vision for certain colors. The new coordinates, called I and Q, are along the orange/cyan and purple/yellow-green axes. This was done so that the bandwidths of the two color signals could be proportioned to minimize crosstalk (Fig. 8).

Early receivers made use of the wider bandwidth of the I signal; however, it became evident that a very acceptable color picture could be reproduced with the I bandwidth restricted to the same as that of the Q channel. Virtually all NTSC receivers now employ “narrowband” I channel decoding. A block diagram of NTSC color encoding is shown in Fig. 9. These recommendations were adopted by the American Federal Communications Commission in late 1953, and commercial color broadcasting was begun in early 1954.

1.4. Sequential and Memory (SECAM)

Economic devastation of World War II delayed the introduction of color television to Europe and other regions. As differences between 525- and 625-line scanning standards made videotapes incompatible anyway, and satellite transmission was unheard of, there seemed little reason not to explore possible improvements to the NTSC process.

1.4.1. Sequential Frequency Modulation. The most tenuous characteristic of NTSC proved to be its sensitivity to distortion of the phase component of the modulated subcarrier. As the phase component imparts color hue information, errors are noticeable, especially in skin tones. Also of concern was variations in the subcarrier amplitude, which affects the color saturation. Most long-distance transmission circuits in Europe did not have the phase and gain linearity to cope with the added color subcarrier requirements.

A solution to these drawbacks was devised by the Campagnie Française de Télévision in Paris. By employing a one-line delay in the receiver, quadrature

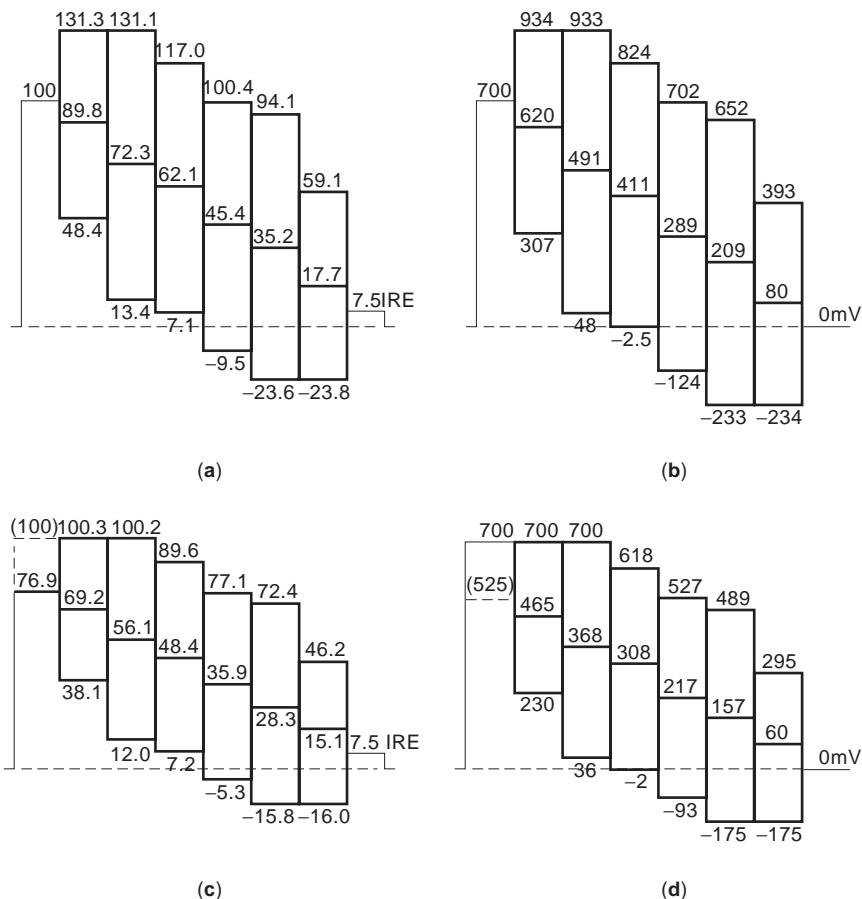

Figure 7. (a) 100% NTSC color bars (100/7.5/100/7.5). (b) 100% PAL color bars (100/0/100/0). (c) Standard 75% “EIA” color bars (75/7.5/75/7.5). (d) Standard 75% “EBU” color bars (100/0/75/0).

modulation of the subcarrier could be discarded, and the color-difference signals (called D_R and D_B in SECAM) sent sequentially, on alternate lines. This reduces vertical resolution in color by half; however, it is sufficient to provide only coarse detail vertically, as is already the case horizontally.

In early development, AM was contemplated; however, the use of FM also eliminated the effects of subcarrier amplitude distortion. In addition, FM allowed the composite signal to be recorded on conventional black-and-white tape machines because precise time base correction, required by phase modulation, was not necessary.

1.4.2. Compatibility. With FM, the subcarrier is always present, superimposed on the luminance signal at constant amplitude (unlike NTSC, in which the subcarrier produces noticeable interference with the luminance only on highly saturated colors). To reduce its visibility, several techniques are employed.

First, preemphasis is applied to the baseband color-difference signals to lessen their amplitudes at lower saturation, but preserve adequate signal-to-noise ratio (low-level preemphasis; see Fig. 10). Second, different subcarrier frequencies are employed, which are integral multiples of the scanning line frequency; f_{oB} is 4.25 MHz (272 H), and f_{oR} is 4.40625 MHz (282 H). The f_{oR} signal is

inverted before modulation so that the maximum deviation is toward a lower frequency, reducing the bandwidth required for the dual subcarriers.

Third, another level of preemphasis is applied to the modulated subcarrier around a point between the two rest frequencies, known as the “cloche” frequency of 4.286 MHz (high-level preemphasis, the so-called “anti-bell” shaping shown in Fig. 11). Finally, the phase of the modulated subcarrier is reversed on consecutive fields and, additionally, on every third scanning line, or, alternately, every three lines.

1.4.3. Line Identification. Synchronizing the receiver to the alternating lines of color-difference signals is provided in one of two ways. Earlier specifications called for nine lines of vertical blanking to contain a field identification sequence formed by truncated sawteeth of the color-difference signals from the white point to the limiting frequency (so-called “bottles”; see Fig. 12). This method is referred to as “SECAM-V.”

As use of the vertical interval increased for ancillary signals, receiver demodulators were fashioned to sample the unblanked subcarrier immediately following the horizontal sync pulse, providing an indication of line sequence from the rest frequency. Where this method is employed, it is called “SECAM-H.” An advantage of this

Figure 8. Vector relationship among chrominance components and corresponding dominant wavelengths. 75% Color bars with 7.5% setup. Linear NTSC system, NTSC luminophors, illuminant C. Hexagon defines maximum chrominance subcarrier amplitudes as defined by 100% color bars with 7.5% setup. *Caution:* The outer calibration circle on vectorscopes does not represent exactly 100 IRE P-P.

method is near-instantaneous recovery from momentary color field sequence errors, whereas SECAM-V receivers must wait until the next vertical interval.

1.4.4. Issues in Program Production. High-level preemphasis causes the chrominance subcarrier envelope to increase in amplitude at horizontal transitions, as can be seen on a waveform monitor (Fig. 13). Unlike NTSC, the subcarrier amplitude bears no relation to saturation, so, except for testing purposes, a luminance lowpass filter is employed on the waveform monitor. A vectorscope presen-

tation of the saturation and hue is implemented by decoding the FM subcarrier into baseband color-difference signals and applying them to an X-Y display.

Unfortunately, the choice of FM for the color subcarrier means that conventional studio production switchers cannot be employed for effects such as mixing or fading from one scene to another because reducing the amplitude of the sub-carrier does not reduce the saturation. This necessitates using a component switcher and then using encoding afterwards. In cases where the signal has already been encoded to SECAM (such as from a prerecorded video

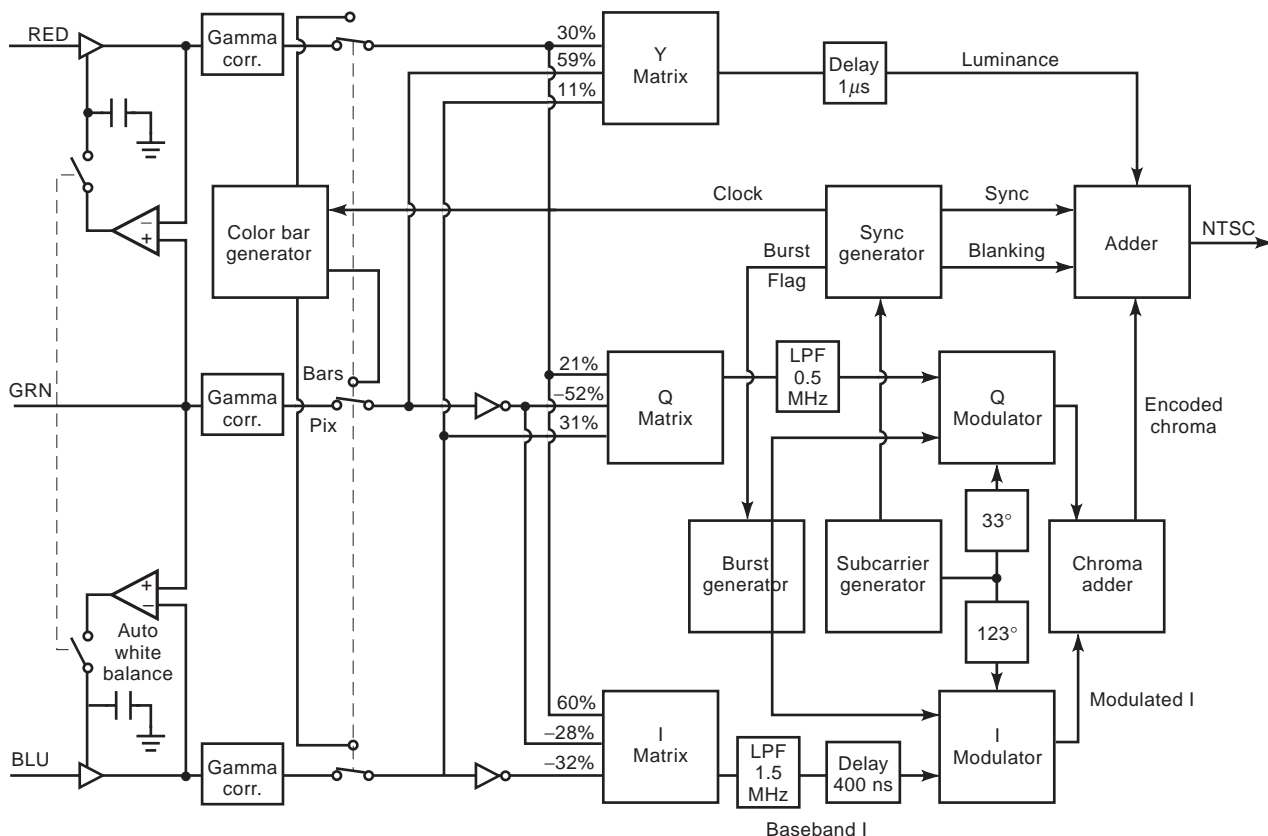

Figure 9. Block diagram of RGB to NTSC encoding (and related circuitry).

tape), it must be decoded prior to the component switcher and then reencoded.

Like NTSC, program editing must be done in two-frame increments. Although the subcarrier phase is reversed on a field-and-line basis, establishing a “12-field sequence,” it is the instantaneous frequency—not phase—which defines the hue. However, the line-by-line sequence of the

color-difference signals must be maintained. The odd number of scanning lines means that each successive frame begins with the opposite color-difference signal. As described above, mixes or fades are never done with composite signals.

Since the instantaneous frequency of the subcarrier is not related to the line scanning frequency, it is impossible

Figure 10. SECAM baseband (low-level) preemphasis.

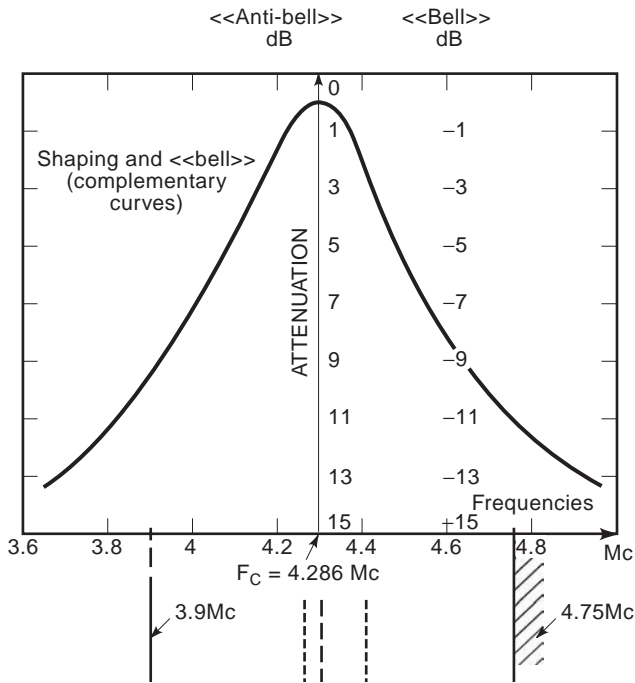

Figure 11. SECAM RF (high-level) preemphasis.

Figure 13. SECAM color bar waveforms.

to employ modern comb-filtering techniques to separate the chrominance and luminance in decoding. Increasingly, special effects devices rely on decoding the composite TV signal to components for manipulation, then reencoding. Every operation of this sort impairs luminance resolution because a notch filter must be used around the subcarrier frequency. These concerns have led many countries which formerly adopted SECAM to switch to PAL for program production, transcoding to SECAM only for RF broadcasting.

1.5. Phase Alternate Line (PAL)

To retain the ease in program production of NTSC, yet correct for phase errors, the German Telefunken Company developed a system more comparable with NTSC that retains quadrature modulation. Because of the wider channel bandwidth associated with 625-line systems, the color subcarrier could be positioned so that the sidebands from

both color-difference signals have the same bandwidth. This means that R-Y and B-Y signals could be used directly, rather than I and Q as in NTSC. Identical scaling factors are used, and the signals are known as V and U, respectively.

1.5.1. Color Phase Alternation. In the PAL system, the phase of the modulated V component of the chrominance signal is reversed on alternate lines to cancel chrominance phase distortion acquired in equipment or transmission. Any phase shift encountered will have the opposite effect on the displayed hue on adjacent lines in the picture. If the phase error is limited to just a few degrees, the eye integrates the error, because, in the vertical direction, more chrominance detail is provided than can be perceived at normal viewing distances. Receivers based on this principle are said to have "simple PAL" decoders.

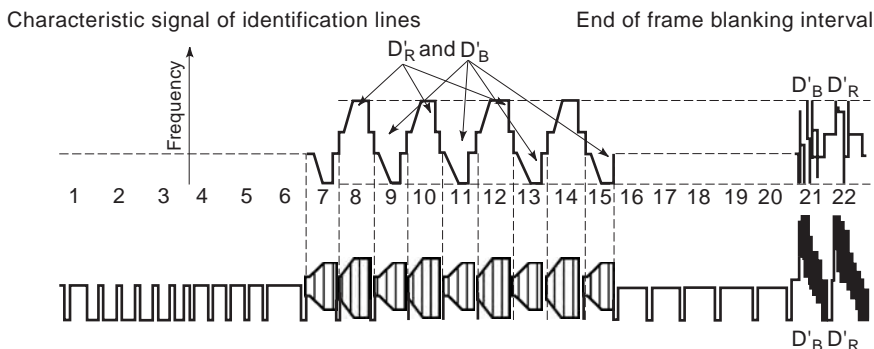

Figure 12. SECAM field identification "bottles."

If the phase error is more than a few degrees, the difference in hue produces a venetian-blind effect, called *Hanover bars*. Adding a one-line delay permits integrating chrominance information from adjacent scanning lines electrically, with a slight reduction in the saturation for large errors. Color resolution is reduced by half in the vertical direction but more closely matches horizontal resolution due to band-limiting in the encoder. This technique of decoding is called “deluxe PAL.” A reference is provided to indicate which lines have +V or -V phase by also shifting the phase of the color burst signal by $\pm 45^\circ$ on alternate lines.

1.5.2. Compatibility. The line-by-line phase reversal results in identical phase on alternate lines for hues on or near the V axis. To sustain a low-visibility interference pattern in PAL, the subcarrier frequency is made an odd multiple of one quarter of the line frequency (creating eight distinct color fields). This effectively offsets the excursions of the V component by 90° line-to-line and offsets those of the U component by 270° . As this 180° difference would cause the excursions of one component to line up vertically with those of the other in the next frame, an additional 25 Hz offset ($f_v/2$) is added to the PAL subcarrier frequency to further reduce its visibility.

In early subcarrier oscillator designs, the reference was derived from the mean phase of the alternating burst signal. Interlaced scanning causes a half-line offset between fields with respect to the vertical position so that the number of bursts actually blanked during the $7\frac{1}{2}$ H vertical interval would be different for the odd versus even fields. As the phase of burst alternates line-to-line, the mean phase would then appear to vary in this region, causing disturbances at the top of the picture.

This is remedied by a technique known as “Bruch blanking.” The burst blanking is increased to a total of

nine lines and repositioned in a four-field progression to include the $7\frac{1}{2}$ H interval, such that the first and last burst of every field has a phase corresponding to $(-U + V)$, or $+135^\circ$. The burst signal is said to “meander” so that color fields 3 and 7 have the earliest bursts.

1.5.3. Issues In Program Production. In PAL, because the subcarrier frequency is an odd multiple of one quarter the line frequency, each line ends on a quarter-cycle. This, coupled with the whole number plus one-half lines per field, causes the phase of the subcarrier to be offset each field by 45° . Thus, in PAL, the subcarrier phase repeats only every eight fields, creating an “eight-field sequence.” This complicates program editing, because edit points occur only every four frames, which is slightly less than 1/10 s in time.

Comb filtering to separate chrominance and luminance in decoding is somewhat more complicated in PAL; however, it has become essential for special picture effects. On a waveform monitor, the composite PAL signal looks very much like NTSC, except that the 25 Hz offset causes a slight phase shift from line to line, so that when viewing the entire field, the sine wave pattern is blurred. Because of the reversal in phase of the V component on alternate lines, the vectorscope presentation has a mirror image about the V axis (Fig. 14).

1.5.4. Variations of PAL. The differences between most 625-line transmission standards involve only RF parameters (such as sound-to-picture carrier spacing). For 625-line PAL program production, a common set of technical specifications may be used. These standards are routinely referred to in the production environment as “PAL-B,” although the baseband signals may be used with any 625-line transmission standard.

Several countries in South America have adopted the PAL system. The 6 MHz channel allocations in that region

Figure 14. Typical PAL vectorscope graticule.

meant that the color subcarrier frequency had to be suitably located, about 1 MHz lower in frequency than for 7 MHz or 8 MHz channels. The exact frequencies are close to, but not the same as, those for NTSC. The 625-line system is known as PAL-N. Studio production for this standard is done in conventional “PAL-B,” then converted to PAL-N at the transmitter.

The 525-line PAL is known as PAL-M, and it requires studio equipment unique to this standard, although the trend is toward using conventional NTSC-M equipment and transcoding to PAL-M at the transmitter. PAL-M does not employ a 25 Hz offset of the subcarrier frequency, as is done in all other PAL systems.

1.6. Similarities of Color Encoding Systems

The similarities of the three basic color television encoding systems are notable (see Table 3). They all rely on the concept of a separate luminance signal that provides compatibility with black-and-white television receivers. The “mixed-highs” principle combines high-frequency information from the three color primaries into luminance, where the eye is sensitive to fine detail; only the relatively low-frequency information is used for the chrominance channels. All three systems use the concept of a subcarrier, located in the upper frequency spectrum of luminance, to convey the chrominance information (Fig. 15).

All systems use color-difference signals, rather than the color primaries directly, to minimize crosstalk with the luminance signal, and all derive the third color signal by subtracting the other two from luminance. The constant luminance principle is applied in all systems, based on the original NTSC picture tube phosphors, so the matrix formulations for luminance and color-difference signals are identical (some recent NTSC encoders use equal-bandwidth R–Y and B–Y signals, instead of proportioned-bandwidth I and Q signals).

All of the systems use scaling factors to limit excessive subcarrier amplitude (NTSC/PAL) or deviation (SECAM) excursions. Finally, all three systems use an unmodulated subcarrier sample on the back porch of the horizontal sync pulse for reference information in the decoding process.

Because of these similarities, conversion of signals between standards for international program distribution is possible. Early *standards converters* were optical in nature, essentially using a camera of the target standard focused on a picture tube operating at the source standard. Later, especially for color, electronic conversion became practical.

The most serious issue in standards conversion involves motion artifacts, owing to the different field rates between 525- and 625-line systems. Simply dropping or repeating fields and lines creates disturbing discontinuities, so interpolation must be done. In modern units, the composite signals are decoded into components, using up to three-dimensional adaptive comb filtering, converted using motion prediction, and then reencoded to the new standard. Table 4 lists the transmission and color standards used in various territories throughout the world.

1.7. Component Analog Video (CAV)

The advent of small-format videotape machines that recorded luminance and chrominance on separate tracks led to interest in component interconnection. Increasingly, new equipment decoded and reencoded the composite signal to perform manipulations that would be impossible or cause significant distortions if done in the composite environment. It was reasoned that if component signals (Y, R–Y, B–Y) could be taken from the camera and if encoding to NTSC, PAL, or SECAM could be done just before transmission, then technical quality would be greatly improved.

However, component signal distribution required some equipment, such as switchers and distribution amplifiers, to have three times the circuitry, and interconnection required three times the cable and connections as composite systems. This brought about consideration of *multiplexed analog component* (MAC) standards, whereby the luminance and chrominance signals are time-multiplexed into a single, higher bandwidth signal. No single standard for component signal levels emerged (Table 5), and the idea was not widely popular. Interest soon shifted to the possibility of digital signal distribution.

1.8. Digital Video

Devices such as time-base correctors, frame synchronizers, and standards converters process the TV signal in the digital realm but with analog interfaces. The advent of digital videotape recording set standards for signal sampling and quantization to the extent that digital interconnection became practical.

1.8.1. Component Digital. The European Broadcasting Union (EBU) and Society of Motion Picture and Television Engineers (SMPTE) coordinated research and conducted demonstrations in search of a component digital video standard that would lend itself to the exchange of programs on a worldwide basis. A *common data rate* of 13.5 Mbps based on line-locked sampling of both 525- and 625-line standards was chosen. This allows analog video frequencies of better than 5.5 MHz to be recovered and is an exact harmonic of the scanning line rate for both standards, enabling great commonality in equipment.

A *common image format* of static orthogonal shape is also employed, whereby the sampling instants on every line coincide with those on previous lines and fields and overlay the samples from previous frames. There are 858 total luminance samples per line for the 525-line system, 864 samples for the 625-line system, but 720 samples during the picture portion for both systems. This image structure facilitates filter design, special effects, compression, and conversion between standards.

For studio applications, the color-difference signals are sampled at half the rate of luminance, or 6.75 MHz, co-sited with every odd luminance sample, yielding a total data rate of 27 Mbps. This provides additional resolution for the chrominance signals, enabling good special effects keying from color detail. The sampling ratio for luminance and the two chrominance channels is designated “4 : 2 : 2.” Other related ratios are possible (Table 6).

Table 3. Principal Characteristics of Color Television Encoding Systems

System	NTSC	PAL	SECAM
Display primaries	FCC	EBU	EBU
White reference	CIE III C	CIE III D ₆₅	CIE III C
Display gamma	2.2	2.8	2.8

Chroma BW/Deviation (kHz)	$Q = 620, I = 1300$	$U + V = 1300$	$\Delta f_{oB} = \pm 230 + 276 / - 120,$ $\Delta f_{oR} = \pm 280 + 70 / - 226$
Vestigial sideband (kHz)	+ 620	+ 570(PAL-B, G, H), + 1070(PAL-I), + 620(PAL-M, N)	—
Composite color video signal (CCVS)	$E_M = E'_Y + E'_Q (\sin \omega t + 33^\circ)$ $+ E'_I (\cos \omega t + 33^\circ)$	$E_M = E'_Y + E'_U \sin \omega t$ $\pm E'_V \cos \omega t$	$E_M = E'_Y + G_{sc} \times \cos 2\pi(f_{oB} + D * _B \Delta f_{oB}) t$ $+ G_{sc} \times \cos 2\pi(f_{oR} + D * _B \Delta f_{oR}) t$
Modulated subcarrier amplitude/pre-emphasis	$G_{sc} = \sqrt{E'_{Q^2} + E'_{I^2}}$	$G_{sc} = \sqrt{E'_{U^2} + E'_{V^2}}$	$G_{sc} = D * _B / D * _R \times 0.115E'_Y (P - P) \times \left \frac{1 + j(16)F}{1 + j(1.26)F} \right $
SC/H frequency relationship	$f_{sc} = (455/2)f_H$	$f_{sc} = (1135/4)f_H + f_{v/2}$ (PAL-B, G, H, I) $= (909/4)f_H$ (PAL-M) $= (917/4)f_H + f_{v/2}$ (PAL-N)	$F = \frac{f_B/f_R}{f_0} - \frac{f_0}{f_B/f_R}$ ($f_0 = 4.286 \pm 0.02\text{MHz}$) $f_{oB} = 272f_H f_{oR} = 282f_H$ $f_{oB} = 4.250000 \pm 2 \text{ kHz},$ $f_{oR} = 4.406250 \pm 2 \text{ kHz}$
Subcarrier frequency (MHz)	$3.579545 \pm 10 \text{ Hz}$	$4.43361875 \pm 5 \text{ Hz}$ (PAL-B, G, H, I); $\pm 1\text{Hz}$ (PAL-I) $3.57561149 \pm 10 \text{ Hz}$ (PAL-M)	
Phase/Deviation of SC reference	180°	$3.58205625 \pm 5 \text{ Hz}$ (PAL-N) $+ V = + 135^\circ, -V = - 135^\circ$	$D_B = - 350 \text{ kHz}, D_R = + 350 \text{ kHz}$
Start of SC reference (μs)	5.3 ± 0.1	5.6 ± 0.1 (PAL-B, G, H, I, N); 5.2 ± 0.5 (PAL-M)	5.7 ± 0.3
SC reference width (cycles)	9 ± 1	10 ± 1 (PAL-B, G, H, I,); 9 ± 1 (PAL-M, N)	—
SC reference amplitude (mV)	$286(40 \text{ IRE} \pm 4)$	300 ± 30	$D_B = 167, D_R = 215$

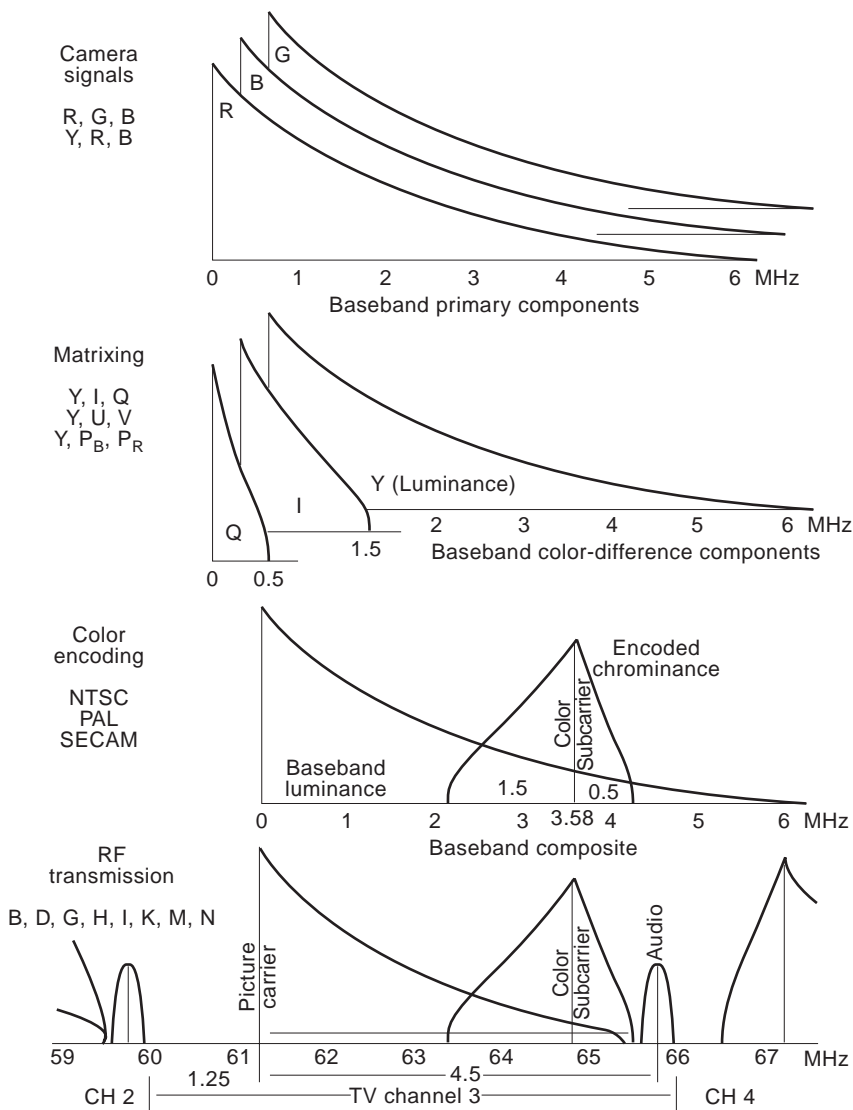

Figure 15. Four-stage color television frequency spectrum showing the compression of three wideband color-separation signals from the camera through bandwidth limiting and frequency multiplexing into the same channel bandwidth used for black-and-white television.

Quantization is uniform (not logarithmic) for both luminance and color-difference channels. Eight-bit quantization, providing 256 discrete levels, was found to provide adequate signal-to-noise ratio for videotape applications. However, the 25-pin parallel interface selected can accommodate two extra bits, because 10-bit quantization was foreseen as desirable in the future. Only the active picture information is sampled and quantized, allowing better resolution of the signal amplitude. Sync and blanking are coded by special signals (Figs. 16 and 17).

These specifications were standardized in ITU-R BT.601— hence the abbreviated reference, “601 Video.” The first component digital tape machine standard was designated “D1” by SMPTE. This term has come to be used in place of more correct designations. For widescreen applications, a 360 Mbps standard scales up the number of sampling points for 16:9 aspect ratio.

Interconnecting digital video equipment is vastly simplified by using a serial interface. Originally, an 8/9 block code was devised to facilitate clock recovery by preventing long strings of ones or zeros in the code. This would have

resulted in a serial data rate of 243 Mbps. To permit 10-bit data to be serialized, scrambling is employed, with complementary descrambling at the receiver. NRZI coding is used, so the fundamental frequency is half the bit-rate of 270 MHz.

1.8.2. Composite Digital. Time-base correctors for composite 1 in. videotape recorders had been developed with several lines of storage capability. Some early devices sampled at three times the color subcarrier frequency ($3f_{sc}$); however, better filter response could be obtained with $4f_{sc}$ sampling. The sampling instants correspond with peak excursions of the I and Q subcarrier components in NTSC. The total number of samples per scanning line is 910 for NTSC and is 1135 for PAL. To accommodate the 25 Hz offset in PAL, lines 313 and 625 each have 1137 samples. The active picture portion of a line consists of 768 samples in NTSC and 948 samples in PAL. These specifications are standardized as SMPTE 244 M (NTSC) and EBU Tech. 3280 (PAL).

^aOther levels possible with this generic designation.

Unlike component digital, nearly the entire horizontal and vertical blanking intervals are sampled and quantized, which degrades the amplitude resolution (Fig. 18). However, in PAL, no headroom is provided for sync level, and the sampling instants are specified at 45° from the peak excursions of the V and U components of subcarrier (Fig. 19). This allows a “negative headroom” in the positive direction. Thus, an improvement of about 0.5 dB in signal-to-noise ratio is obtained.

Rate conversion between component and composite digital television signals involves different sampling points

and quantizing levels. Each conversion degrades the picture, because exact levels cannot be reproduced in each pass. An important advantage of digital coding is thereby lost. In addition, decoding composite signals requires filtering to prevent cross-luminance and cross-color effects. This forever removes a part of the information; therefore, this process must be severely limited in its use.

Ancillary data may be added to digital component and composite video signals. AES/EBU-encoded digital audio can be multiplexed into the serial bit stream. Four channels are possible with the composite format, and 16 channels are possible with component digital video.

1.9. Component Video Standards

The video signals from a camera before encoding to NTSC, PAL, SECAM, or the ATSC Digital Standard are normally green (G), blue (B), and red (R). These are described as

component signals because they are parts or components of the whole video signal. It has been found more efficient of band-width use for distribution and sometimes for processing to convert these signals into a luminance signal (Y), and two color-difference signals, blue minus lumi-

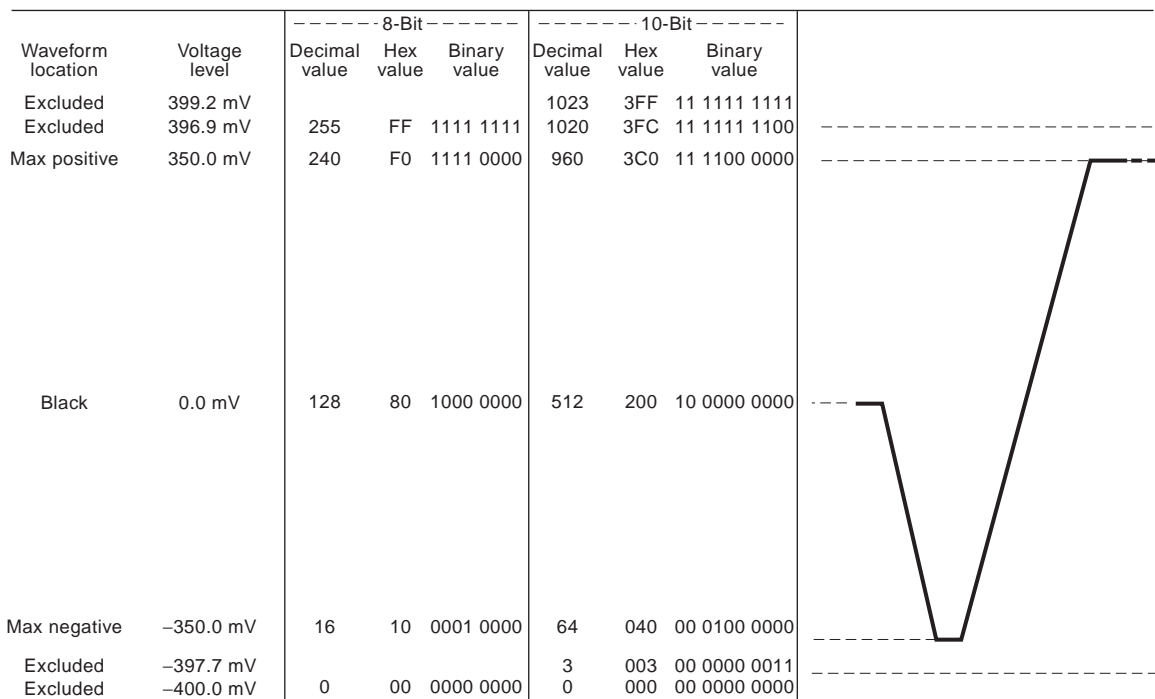

Figure 17. Quantizing levels for component digital color difference.

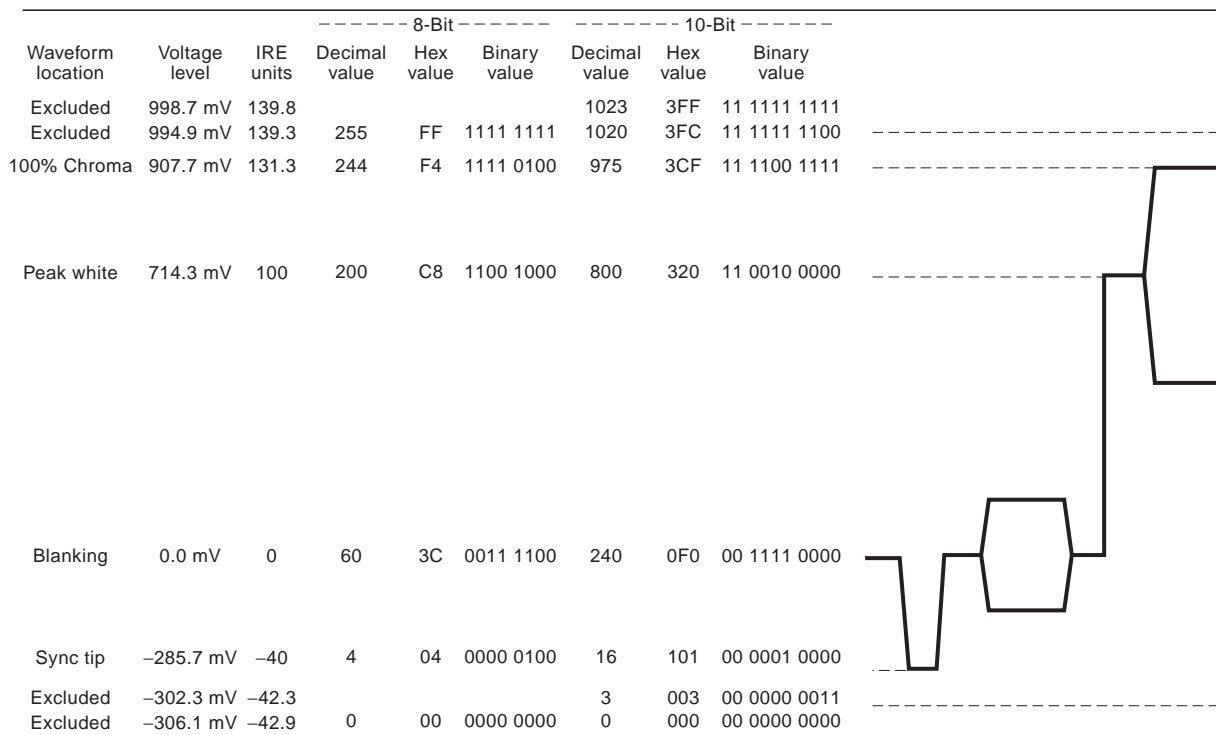

Figure 18. Quantizing levels for composite digital NTSC.

nance (B–Y) and red minus luminance (R–Y), where the color difference signals use one half or one quarter of the bandwidth of the luminance signal. The SMPTE/EBU Standard N10 has been adopted that has a uniform sig-

nal specification for all 525/60 and 625/50 television systems. The color difference signals in this standard, when they are digitally formatted, are termed C_b and C_r , respectively. At the same time, due to the lower sensitivity of

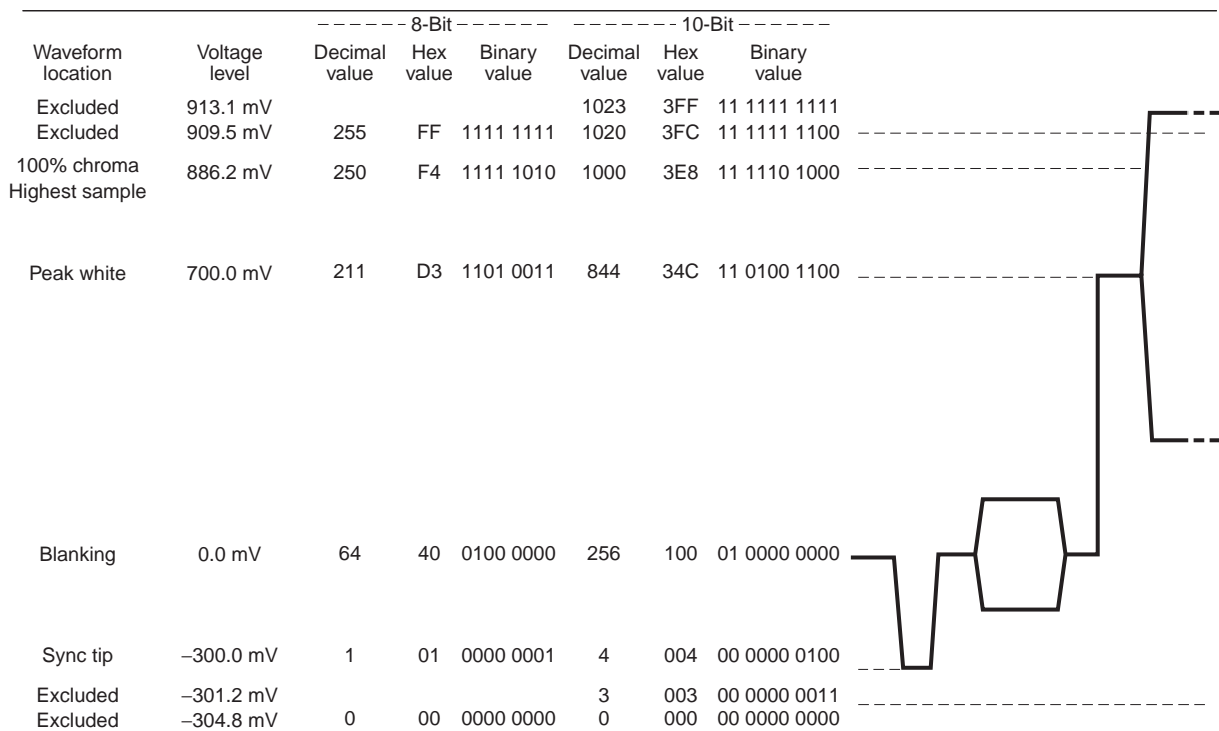

Figure 19. Quantizing levels for composite digital PAL.

the human eye to fine detail in color, it is possible to reduce the bandwidth of the color difference signals compared with that of the luminance signal.

When these signals are digitized according to International Telecommunication Union, Radiocommunication Sector, (ITU-R) Recommendation 601, for both 525/60 and 625/50 systems, there are several modes of transmission that may be used, all based on multiples of a 3.75 MHz sampling rate. For the ATSC standard, 4:2:0 is used (see below and the ATSC digital television standard). Either 8, or more frequently, 10 bits per sample are used.

1.9.1. 4:4:4 Mode. The G, B, R or Y, C_b , C_r signal with an equal sampling rate of 13.5 MHz for each channel is termed the 4:4:4 mode of operation, and it yields 720 active samples per line for both 525/60 and 625/50 standards. This mode is frequently used for postproduction. If a (full-bandwidth) key signal is also required to be carried with the video, this combination is known as a 4:4:4:4 signal.

1.9.2. 4:2:2 Mode. More frequently used for distribution is the 4:2:2 mode, where Y is sampled at 13.5 MHz, and the color difference signals are sampled at 6.25 MHz rate, corresponding to 360 active samples per line.

1.9.3. 4:1:1 Mode. The 4:1:1 mode is used where bandwidth is at a premium, and the color difference signals are each sampled at 3.75 MHz rate, corresponding to 180 samples per line.

1.9.4. 4:2:0 Mode. A further alternative, 4:2:0 mode, whose structure is not self-evident, is derived from a 4:2:2 sampling structure but reduces the vertical resolution of the color difference information by 2:1 to match the reduced color difference horizontal resolution. Four line (and field sequential if interlaced) co-sited C_b , C_r samples are vertically interpolated weighted toward the closest samples, and the resultant sample is located in between two adjacent scanning lines. This mode is used in MPEG bit-rate reduced digital signal distribution formats, and hence in the ATSC digital television standard.

The above four modes are illustrated in Table 6.

2. ADVANCED TELEVISION SYSTEMS, CURRENT AND FUTURE

2.1. ATSC Digital Television Standard

2.1.1. Overview. The Advisory Committee on Advanced Television Service (ACATS) to the Federal Communications Commission, with support from Canada and Mexico, from 1987 to 1995 developed a recommendation for an Advanced Television Service for North America. The ACATS enlisted the cooperation of the best minds in the television industry, manufacturers, broadcasters, cable industry, film industry, and federal regulators in its organization to develop an advanced television system that would produce a substantial improvement in video images and in audio performance over the existing NTSC, 525-line system. The primary video goal was at least a

doubling of horizontal and vertical resolution with a widening in picture aspect ratio from current 4 (W) \times 3 (H) to 16 (W) \times 9 (H), and this was named "high-definition television." Also included was a digital audio system consisting of five channels plus a low-frequency channel (5.1).

Twenty-one proposals were made for terrestrial transmission systems for extended-definition television (EDTV) or high-definition television (HDTV), using varying amounts of RF spectrum. Some systems augmented the existing NTSC system, with an additional channel of 3 MHz or 6 MHz, some used a separate simulcast channel of 6 MHz or 9 MHz bandwidth, and all of the early systems used hybrid analog/digital technology in the signal processing with an analog RF transmission system. Later proposals changed the RF transmission system to digital along with all-digital signal processing.

It was also decided that the signal would be transmitted in a 6 MHz RF channel, one for each current broadcaster of the (6 MHz channel) NTSC system, and that this new channel would eventually replace the NTSC channels. The additional channels were created within the existing UHF spectrum by improved design of TV receivers so that the previously taboo channels, of which there were many, could now be used.

In parallel with this effort, the Advanced Television Systems Committee (ATSC) documented and developed the standard known as the ATSC Digital Television Standard, and it is subsequently developing related implementation standards.

In countries currently using 625-line, 4:3 aspect ratio television systems, plans are being developed to eventually use a 1250-line, 16:9 aspect ratio system, and the ITU-R has worked successfully on harmonizing and providing interoperability between the ATSC and 1250-line systems.

Figure 20 shows the choices by which the signals of the various television standards will reach the consumer. Other articles detail satellite, cable TV, and asynchronous transfer mode (ATM) common carrier networks.

The ATSC and the ITU-R have agreed on a digital terrestrial broadcasting model, which is shown in Fig. 21. Video and audio sources are coded and compressed in separate video and audio subsystems. The compressed video and audio are then combined with ancillary data and control data in a service multiplex and transport, in which form the combined signals are distributed to the terrestrial transmitter. The signal is then channel-coded, modulated, and fed at appropriate power to the transmission antenna. The receiver reverses the process, demodulating the RF signal to the transport stream, and then demultiplexing the audio, video, ancillary, and control data into their separate but compressed modes; and the individual subsystems then decompress the bit streams into video and audio signals that are fed to display screen and speakers, and the ancillary and control data are used if and as appropriate within the receiver.

2.1.2. Information Service Multiplex and Transport System. These subsystems provide the foundation for the digital communication system. The raw digital data are first formatted into *elementary bit streams*, representing image data, sound data, and ancillary data. The elementary

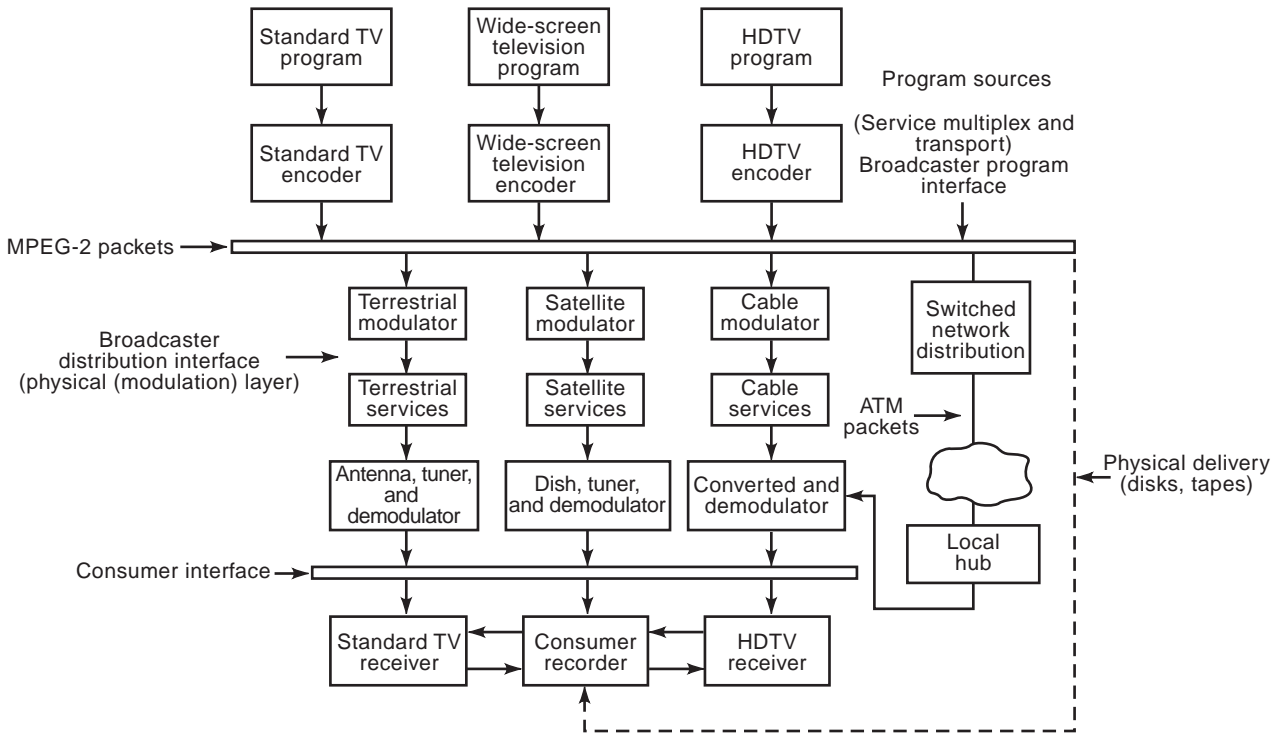

Figure 20. Television service model.

bit streams are then formed into manageable packets of information (*packetized elementary stream, PES*), and a mechanism is provided to indicate the start of a packet (synchronization) and assign an appropriate identification code (*packet identifier, PID*) within a header to each packet. The packetized data are then multiplexed into a *program transport stream* that contains all the information for a single (television) program. Multiple program transport streams may then be multiplexed to form a *system level multiplex transport stream*.

Figure 22 illustrates the functions of the multiplex and transport system and shows its location between the application (e.g., audio or video) encoding function and the

transmission subsystem. The transport and demultiplex subsystem functions in the receiver in the reverse manner, being situated between the RF modem and the individual application decoders.

2.1.2.1. Fixed-Length Packets. The transport system employs the fixed-length transportation stream packetization approach defined by the Moving Picture Experts Group (MPEG), which is well suited to the needs of terrestrial broadcast and cable television transmission of digital television. The use of moderately long, fixed-length packets matches well with the needs for error protection, and it provides great flexibility for initial needs of the ser-

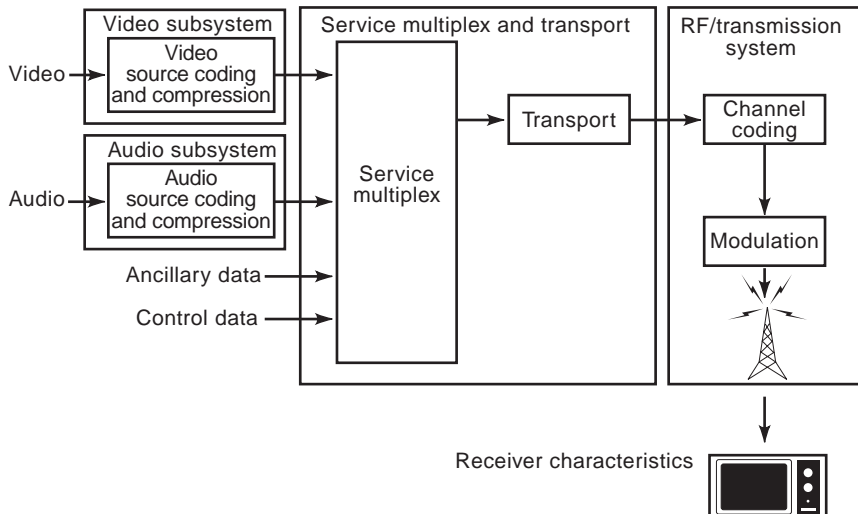

Figure 21. Block diagram showing ATSC and ITU-R terrestrial television broadcasting model.

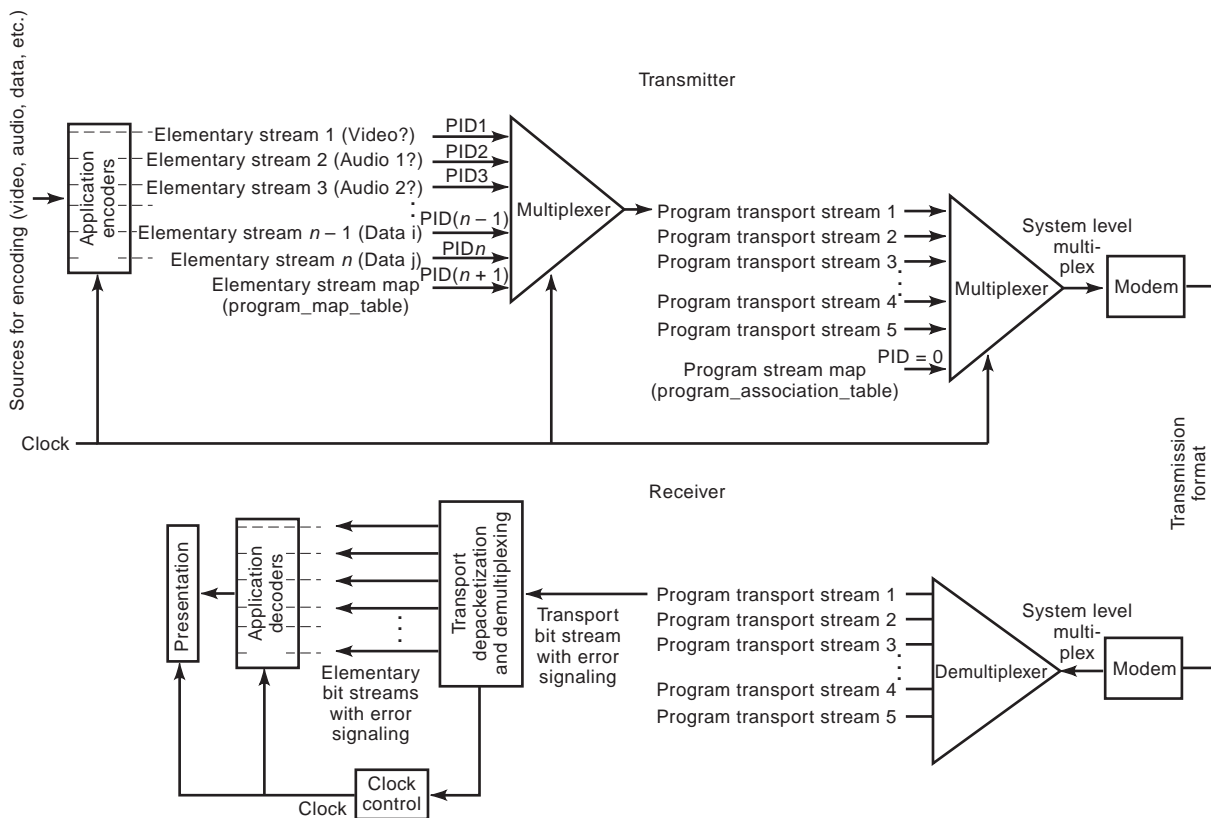

Figure 22. Organization of functionality within a transport system for digital TV programs.

vice to multiplex audio, video, and data, while providing backward compatibility for the future and maximum interoperability with other media (MPEG-based).

2.1.2.2. Packet Identifier. The use of a PID in each packet header to identify the bit stream makes it possible to have a mix of audio, video, and auxiliary data that is not specified in advance.

2.1.2.3. Scalability and Extensibility. The transport format is scalable in that more elementary bit streams may be added at the input of the multiplexer, or at a second

multiplexer. Extensibility for the future could be achieved with no hardware modification by assigning new PIDs for additional elementary bit streams.

2.1.2.4. Robustness. After detecting errors during transmission, the data bit stream is recovered starting with the first good packet. This approach ensures that recovery is independent of the properties of each elementary bit stream.

2.1.2.5. Transport Packet Format. The data transport packet format, as shown in Fig. 23, is based on fixed

Figure 23. Transport packet format.

Figure 24. Structural overview of packetized elementary stream (PES) packet.

Figure 25. Variable-length PES packets and fixed-length transport packets.

length packets (188 bytes) identified by a variable-length header including a sync byte and the PID. Each header identifies a particular application bit stream (elementary bit stream) that forms the payload of the packet. Applications include audio, video, auxiliary data, program and system control information, and so on.

2.1.2.6. PES Packet Format. The elementary bit streams are themselves wrapped in a variable-length packet structure called the packetized elementary stream (PES) before transport processing. See Fig. 24. Each PES packet for a particular elementary bit stream then occupies a variable number of transport packets, and data from the various elementary bit streams are interleaved with each other at the (fixed length) transport packet layer. New PES packets always start a new transport packet, and stuffing bytes (i.e., null bytes) are used to fill partially filled transport packets.

2.1.2.7. Channel Capacity Allocation. The entire channel capacity can be reallocated to meet immediate service needs. As an example, ancillary data can be assigned fixed amounts depending on a decision made as to how much to allocate to video; or if the data transmission time is not

critical, then it can be sent as *opportunistic data* during periods when the video channel is not fully loaded.

Figure 25 illustrates how the variable-length PES packets relate to the fixed-length transport packets.

The transport system provides other features, including decoder synchronization, conditional access, and local program insertion. Also, issues relating to the storage and playback of programs are addressed, and the appropriate hooks are provided to support the design of consumer digital products based on recording and playback of these bitstreams, including the use of “trick modes” such as slow motion and still frame, typical of current analog video cassette recorders (VCRs).

2.1.2.8. Local Program Insertion. This feature is extremely important to permit local broadcast stations to insert video, audio, or data that is unique to that station. As shown in Fig. 26 to splice local programs, it is necessary to extract (by demultiplexing) the transport packets, identified by the PIDs of the individual elementary bit streams, which make up the program that is to be replaced, including the *program map table*, which identifies the individual bit streams that make up the program. Program insertion can then take place on an individual PID basis, using the fixed-length transport packets.

2.1.2.9. Presentation Time Stamp and Decoding Time Stamp. These time stamps both occur within the header of the PES packet, and they are used to determine when the data within the packet should be read out of the decoder. This process ensures the correct relative timing of the various elementary streams at the decoder relative to the timing at which they were encoded.

2.1.2.10. Interoperability With ATM. The MPEG-2 transport packet size (188 bytes) is such that it can easily be partitioned for transfer in a link layer, which supports asynchronous transfer mode (ATM) transmission (53 bytes per cell). The MPEG-2 transport layer solves MPEG-2 presentation problems and performs the multimedia multiplexing function, whereas the ATM layer solves switching and network adaptation problems.

2.1.3. Video Systems

2.1.3.1. Compressed Video. Compression in a digital HDTV system is required because the bit rate required for an uncompressed HDTV signal approximates 1 Gbps (with the luminance/chrominance sampling already compressed to 4:2:2 mode). The total transmitted data rate in the ATSC digital television standard over a 6 MHz channel is approximately 19.4 Mbps. A compression ratio of 50:1 or greater is therefore required.

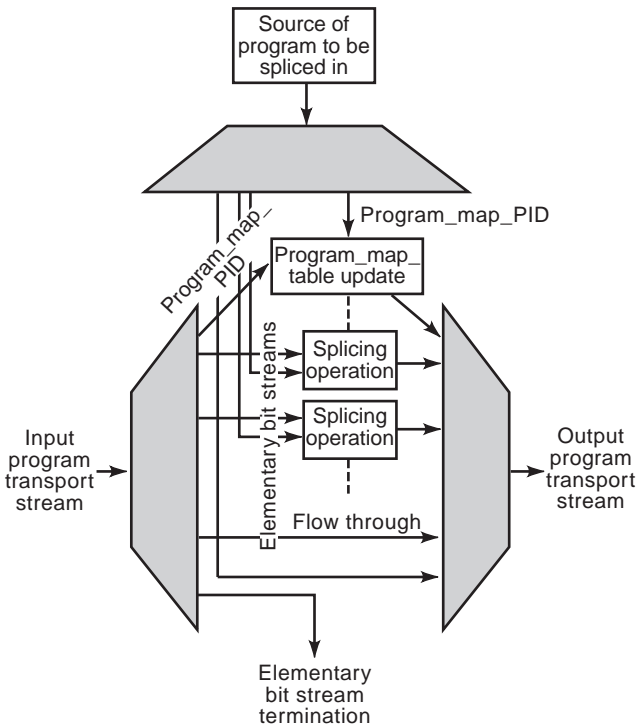

Figure 26. Example of program insertion architecture.

The ATSC Digital Television Standard specifies video compression using a combination of compression techniques that for compatibility conform to the algorithms of MPEG-2 Main Profile, High Level.

The goal of the compression and decompression process is to produce an approximate version of the original image sequence, such that the reconstructed approximation is imperceptibly different from the original for most viewers, for most images, and for most of the time.

2.1.3.2. Production Formats. A range of production format video inputs may be used. These include the current NTSC format of 483 active lines, 720 active samples/line, 60 fields, 2:1 interlaced scan (60I), the Standard Definition format of 480 active lines, 720 active samples/line, 60 frames progressive scan (60P), and high-definition formats of 720 active lines, 1280 active samples/line, 60P, or 1080 active lines, 1920 active samples/line, 60I.

2.1.3.3. Compression Formats. A large range of 18 compression formats is included to accommodate all of the above production formats. The 30P and 24P formats are included primarily to provide efficient transmission of film images, associated with the above production formats. The VGA graphics format is also included at 480 lines and 640 pixels (see below for pixel definition). Details of these compression formats are found in Table 7.

2.1.3.4. Colorimetry. The Digital Television Standard specifies SMPTE 274 M colorimetry (same as ITU-R BT.709, 1990) as the default, and preferred, colorimetry. This defines the color primaries, transfer characteristics, and matrix coefficients.

2.1.3.5. Sample Precision. After preprocessing, the various luminance and chrominance samples will typically be represented using 8 bits per sample of each component.

2.1.3.6. Film Mode. In the case of 24 fps film that is sent at 60 Hz rate using a 3:2 pull-down operation, the processor may detect the sequences of three nearly identical pictures followed by two nearly identical pictures and may only encode the 24 unique pictures per second that existed in the original film sequence. This avoids sending redundant information and permits higher quality transmission. The processor may detect similar sequencing for

30 fps film and may only encode the 30 unique pictures per second.

2.1.3.7. Color Component Separation and Processing. The input video source to the video compression system is in the form of RGB components matrixed into luminance (Y) (intensity or black-and-white picture) and chrominance (C_b and C_r) color-difference components, using a linear transformation. The Y, C_b , and C_r signals have less correlation with each other than R, G, and B and are thus easier to code. The human visual system is less sensitive to high frequencies in the chrominance components than in the luminance components. The chrominance components are lowpass-filtered and subsampled by a factor of two in both horizontal and vertical dimensions (4:2:0 mode) (see Section 1.9).

2.1.3.8. Representation of Picture Data. Digital television uses digital representation of the image data. The process of digitization involves sampling of the analog signals and their components, in a sequence corresponding to the scanning raster of the television format, representing each sample with a digital code.

2.1.3.9. Pixels. The individual samples of digital data are referred to as picture elements, or “pixels” or “pels.” When the ratio of active pixels per line to active pixels per frame is the same as the aspect ratio, the format is said to have “square pixels.” The term refers to the spacing of samples, not to the shape of the pixel.

2.1.3.10. Blocks, Macroblocks, and Slices. For further processing, pixels are organized into blocks of 8×8 , representing either luminance or chrominance information. Macroblocks consist of four blocks of luminance (Y) and one each of C_b and C_r . Slices consist of one or more macroblocks in the same row, and they begin with a slice start code. The number of slices affects compression efficiency; a larger number of slices provides for better error recovery but uses bits that could otherwise be used to improve picture quality. The slice is the minimum unit for resynchronization after an error.

2.1.4. Removal of Temporal Information Redundancy: Motion Estimation and Compensation. A video sequence is a series of still pictures shown in rapid succession to give

Table 7. ATSC Compression Formats: A Hierarchy of Pixels and Bits

Active Lines	Pixels per Line	Total Pixels per Frame	Uncompressed Payload Bit Rate in Mbps (8-bit 4:2:2 sampling) at Picture (Frame) Rate				Aspect Ratio and Notes
			60P	60I	30P	24P	
1080	1920	2,073,600	Future	995	995	796	16:9 only
720	1280	921,600	885	—	442	334	16:9 only
480	704	337,920	324	162	162	130	16:9 & 4:3
480	640	307,200	295	148	148	118	4:3 only (VGA)
Vertical Resolution	Horizontal Resolution	Higher	← → Temporal Resolution		Lower

Figure 27. Video frame order, group of pictures, and typical I-frames, P-frames, and B-frames.

the impression of continuous motion. This usually results in much temporal redundancy (picture sameness) among the adjacent pictures. Motion compensation attempts to delete this temporal redundancy from the information transmitted. In the standard, the current picture is predicted from the previously encoded picture, estimating the motion between the two adjacent pictures and compensating for the motion. This “motion-compensated residual” is encoded rather than the complete picture, eliminating repetition of the redundant information.

2.1.4.1. Pictures, Groups of Pictures, and Sequences. The primary coding unit of a video sequence is the individual video frame or picture, which consists of the collection of slices constituting the active picture area. A video sequence consists of one or more consecutive pictures, and it commences with a sequence header, which can serve as an entry point.

One or more pictures or frames in sequence may be combined into a group of pictures (GOP), optional within MPEG-2 and the ATSC Standard, to provide boundaries for interpicture coding and registration of time code.

Figure 27 illustrates a time sequence of video frames consisting of intracoded pictures (I-frames), predictive coded pictures (P-frames), and bidirectionally predictive coded pictures (B-frames).

2.1.4.2. I-, P-, and B-Frames. Frames that do not use any interframe coding are referred to as I-frames (where I

Figure 28. Video structure hierarchy.

denotes intraframe coded). All the information for a complete image is contained within an I-frame, and the image can be displayed without reference to any other frame. (The preceding frames may not be present or complete for initialization or acquisition, and the preceding or following frames may not be present or complete when noncorrectable channel errors occur.)

P-frames (where P denotes predicted) are frames where the temporal prediction is in the forward direction only (formed only from pixels in the most recently decoded I- or P-frame). Interframe coding techniques improve the overall compression efficiency and picture quality. P-frames may include portions that are only intraframe-coded.

B-frames (where B denotes bidirectionally predicted) include prediction from a future frame as well as from a previous frame (always I- or P-frames). Some of the consequences of using future frames in the prediction are as follows: The transmission order of frames is different from the displayed order of frames, and the encoder and decoder must reorder the video frames, thus increasing the total latency. B-frames are used for increasing compression efficiency and perceived picture quality.

Figure 28 illustrates the components of pictures as discussed above.

2.1.5. Removal of Spatial Information Redundancy: The Discrete Cosine Transform. As shown in Fig. 29, 8 × 8 blocks of spatial intensity showing variations of luminance and chrominance pel information are converted

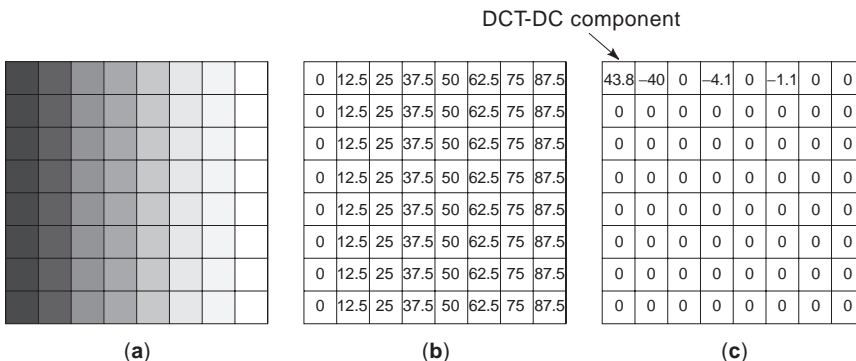

Figure 29. Discrete cosine transform.

into 8×8 arrays of coefficients relating to the spatial frequency content of the original intensity information. The transformation method used is the discrete cosine transform (DCT).

As an example, in Fig. 29(a), an 8×8 pel array representing a black-to-white transition is shown as increasing levels of a gray scale. In Fig. 29(b), the gray-scale steps have been digitized and are represented by pel amplitude numerical values. In Fig. 29(c), the gray-scale block is represented by its frequency transformation coefficients, appropriately scaled. The DCT compacts most of the energy into only a small number of the transform coefficients. To achieve a higher decorrelation of the picture content, two-dimensional (along two axes) DCT coding is applied. The (0,0) array position (top left) represents the DC coefficient or average value of the array.

2.1.6. Quantizing the Coefficients. The goal of video compression is to maximize the video quality for a given bit rate. Quantization is a process of dividing the coefficients by a value of N , which is greater than 1, and rounding the answer to the nearest integer value. This allows scaling the coefficient values according to their importance in the overall image. Thus high-resolution detail to which the human eye is less sensitive may be more heavily scaled (coarsely coded). The quantizer may also include a dead zone (enlarged interval around zero) to core to zero small noise-like perturbations of the element value. Quantization in the compression algorithm is a lossy step (information is discarded that cannot be recovered).

2.1.7. Variable Length Coding, Codeword Assignment. The quantized values could be represented using fixed-length codewords. However, greater efficiency can be achieved in terms of bit rate, by employing what is known as entropy coding. This attempts to exploit the statistical properties of the signal to be encoded. It is possible to assign a shorter codeword to those values occurring more frequently and a longer codeword to those occurring less frequently. The Morse code is an example of this method.

One optimal codeword design method, the Huffman Code, is used in the Standard. It will be noted that many zero-value coefficients are produced, and these may be prioritized into long runs of zeros by zigzag scanning or a similar method.

2.1.8. Channel Buffer. Motion compensation, adaptive quantization, and variable-length coding produce highly variable amounts of compressed video data as a function of time. A buffer is used to regulate the variable-input bit rate into a fixed-output bit rate for transmission. The fullness of the buffer is controlled by adjusting the amount of quantization error in each image block (a rate controller driven by a buffer state sensor adjusts the quantization level). Buffer size is constrained by maximum tolerable delay through the system and by cost.

2.1.9. Audio

2.1.9.1. System Overview. The audio subsystem used in the ATSC Digital Television Standard is based on the AC-3 digital audio compression standard. The subsystem can encode from one to six channels of source audio from a pulse-code modulation (PCM) representation (requiring 5.184 Mbps for the 5.1 channel mode) into a serial bit stream at a normal data rate of 384 kbps. The 5.1 channels are left (front), center (front), right (front), left surround (rear), right surround (rear) (all 3 Hz to 20 kHz), and low-frequency subwoofer (normally placed centrally) (which represents the 0.1 channel, 3 Hz to 120 Hz). The system conveys digital audio sampled at a frequency of 48 kHz, locked to the 27 MHz system clock.

In addition to the 5.1 channel input, monophonic and stereophonic inputs and outputs can be handled. Monophonic and stereophonic outputs can also be derived from a 5.1 channel input, permitting backward compatibility.

The audio subsystem, as illustrated in Fig. 30, comprises the audio encoding/decoding function and resides between the audio inputs/outputs and the transport system. The audio encoder(s) is (are) responsible

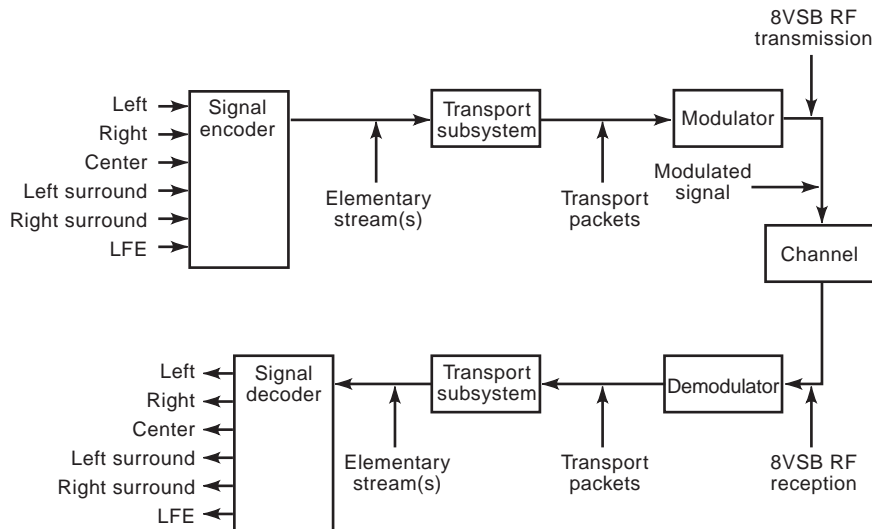

Figure 30. Audio subsystem within the digital television system.

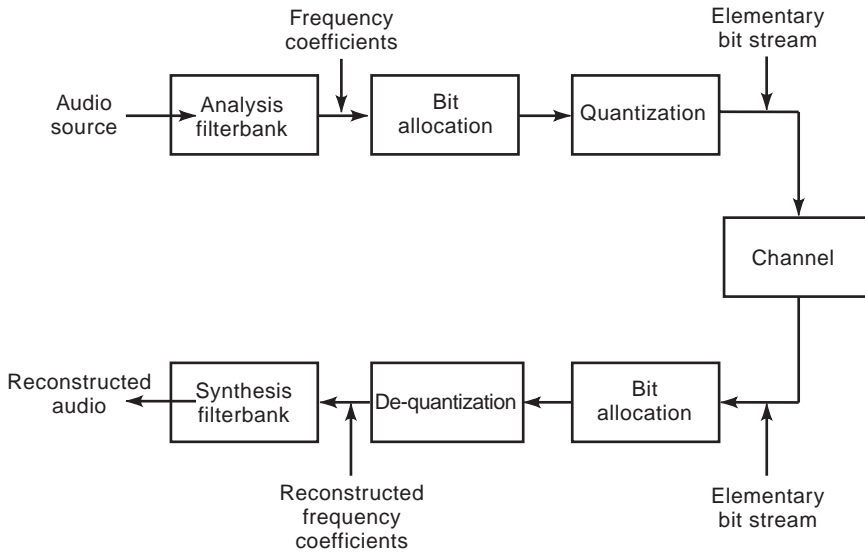

Figure 31. Overview of audio compression system.

for generating the *audio elementary stream(s)*, which are encoded representations of the baseband audio input signals.

The transport subsystem packetizes the audio data into PES packets that are then further packetized into (fixed length) transport packets. The transmission subsystem converts the transport packets into a modulated RF signal for transmission to the receiver. Transport system flexibility allows multiple audio elementary streams to be transmitted.

In the receiver, the encoding, packetization, and modulation process is reversed to produce reconstructed audio.

2.1.9.2. Audio Compression. Two mechanisms are available for reducing the bit rate of sound signals. The first uses statistical correlation to remove redundancy from the bit stream. The second uses the psychoacoustical characteristics of the human hearing system such as spectral and temporal masking to reduce the number of bits required to recreate the original sounds.

The audio compression system consists of three basic operations, as shown in Fig. 31. In the first stage, the representation of the audio signal is changed from the time domain to the frequency domain, which is more efficient in order to perform psychoacoustically based audio compression. The frequency domain coefficients may be coarsely quantized because the resulting quantizing noise will be at the same frequency as the audio signal, and relatively low signal-to-noise ratios (SNRs) are acceptable due to the phenomena of psychoacoustic masking. The bit allocation operation determines what actual SNR is acceptable for each individual frequency coefficient. Finally, the frequency coefficients are coarsely quantized to the necessary precision and formatted into the audio elementary stream.

The basic unit of encoded audio is the AC-3 sync frame, which represents six audio blocks of 256 frequency coefficient samples (derived from 512 time samples), a total of 1536 samples. The AC-3 bit stream is a sequence of AC-3 sync frames.

2.1.9.3. Additional Audio Services. Additional features are provided by the AC-3 subsystem. These include loudness normalization, dynamic range compression with an override for the listener, and several associated services, namely, dialogue, commentary, emergency, voice-over, help for the visually impaired and hearing-impaired (captioning), and multiple languages. Some of these services are mutually exclusive, and multilanguage service requires up to an extra full 5.1 channel service for each language (up to an additional 384 kbps).

2.2. Ancillary Data Services

Several data services have been included in the ATSC Standard. Other services can be added in the future. Currently included are program subtitles (similar to closed captioning in NTSC), emergency messages (mixed into baseband video in NTSC), and program guide information.

2.2.1. Possible Future Data Services. Information data related to the following may be desired: conditional access, picture structure, colorimetry, scene changes, local program insertion, field/frame rate and film pull-down, pan/scan, multiprogram, and stereoscopic image.

Figure 32. Vestigial sideband (VSB) in 6 MHz channel for digital transmission.

2.2.2. Transmission Characteristics. The transmission subsystem uses a vestigial sideband (VSB) method: (1) 8-VSB for simulcast terrestrial broadcast mode and (2) a 16-VSB high data rate mode. VSB includes a small part of the lower sideband with the full upper sideband. Sloped filtering at the transmitter and/or the receiver attenuates the lower end of the band. The 8-VSB coding maps three bits into one of eight signal levels. The system uses a symbol rate of 10.76 Msymbols/s, capable of supporting a data stream payload of 19.39 Mbits/s. See Fig. 32 VSB in 6-MHz channel.

Modulation techniques for some other planned broadcast systems use orthogonal frequency division multiplexing (OFDM) or coded OFDM (COFDM), which is a form of multicarrier modulation where the carrier spacing is selected, so that each subcarrier within the channel is orthogonal to the other subcarriers, which mathematically ensures that during the sampling time for one carrier, all other carriers are at a zero point.

The 8-VSB subsystem takes advantage of a pilot, segment sync, and a training sequence for robust acquisition and operation. In order to maximize service area, an NTSC rejection filter (in the receiver) and trellis coding are used. The system can operate in a signal-to-additive-white-Gaussian noise (S/N) environment of 14.9 dB. The transient peak power to average power ratio as measured on a low-power transmitted signal with no nonlinearities is no more than 6.3 dB for 99.9% of the time.

A block diagram of a generic transmitter subsystem is shown in Fig. 33. The incoming data (19.39 MB/s) are randomized and then processed for forward error correction (FEC) in the form of Reed–Solomon coding (20 RS parity bits are added to each packet, known as outer error correction). Data interleaving, to reorganize the data stream so that it is less vulnerable to bursts of errors, then interleaves to a depth of about one sixth of a data field (4 ms deep).

The second stage, called inner error correction, consists of a two-thirds rate trellis coding. This encodes one bit of a two-bit pair into two output bits, using a one-half convolutional code, whereas the other input bit is retained as precoded. Along with the Trellis Encoder, the data packets are precoded into data frames and mapped into a signaling waveform using an 8-level (3 bit), one-dimensional constellation (8 VSB). Data Segment Sync (4 symbols = 1 byte) at the beginning of a segment of 828 data

plus parity symbols, and Data Field Sync at the beginning of a data field of 313 segments (24.2 ms), are then added. Data Field Sync includes the training signal, used for setting the receiver equalizer.

A small in-phase pilot is then added to the data signal at a power of 11.3 dB below the average data signal power. The data is then modulated onto an IF carrier, which is the same frequency for all channels. The RF Up-Converter then translates the filtered, flat IF data signal spectrum to the desired RF channel. It is then amplified to the appropriate power for the transmitting antenna.

For the same approximate coverage as an NTSC transmitter (at the same frequency), the average power of the ATV signal is approximately 12 dB less than the NTSC peak sync power.

The frequency of the RF upconverter oscillator will typically be the same as for NTSC (except for offsets). For extreme co-channel situations, precise RF carrier frequency offsets with respect to the NTSC co-channel carrier may be used to reduce interference into the ATV signal. The ATV signal is noise-like, and its interference into NTSC does not change with precise offset.

The ATV co-channel pilot should be offset in the RF upconverter from the dominant NTSC picture carrier by an odd multiple of half the data segment rate. An additional offset of 0, +10 kHz, or –10 kHz is required to track the principal NTSC interferer.

For ATV-into-ATV co-channel interference, precise carrier offset prevents the adaptive equalizer from misinterpreting the interference as a ghost.

2.3. The Japanese High-Definition Television Production System

This television production system was developed by the Japanese Broadcasting Corporation (NHK). It was standardized in 1987 by the Broadcast Technology Association (BTA), now renamed the Association of Radio Industries and Business (ARIB), in Japan and in the United States by SMPTE (240 M and 260 M Standards). It uses a total of 1125 lines (1035 active lines), is interlaced at a field rate of 60 Hz, and has an aspect ratio of 16:9. It requires a bandwidth of 30 MHz for the luminance signal (Y), and 15 MHz for each of the two color difference signals (P_B and P_R). When digitized at 8 bits per sample, it uses 1920 pixels per

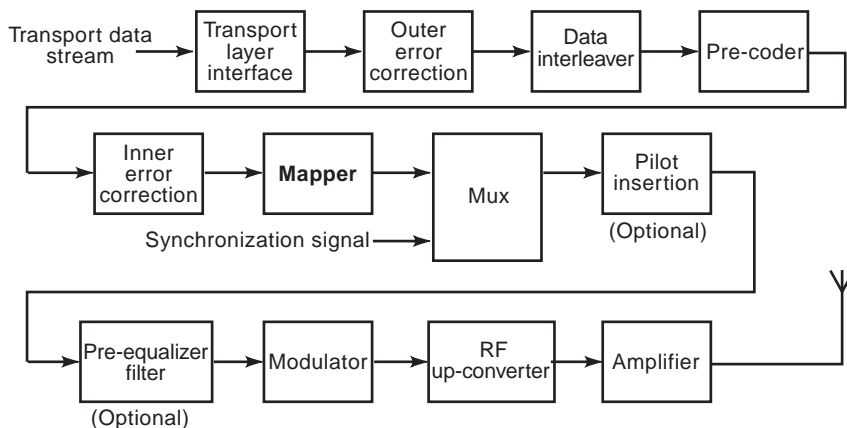

Figure 33. 8-VSB transmitter subsystem block diagram.

Table 8. MUSE Transmission Systems

Transmission System	Type of Transmission	Bandwidth	Channel Compatible	Compatible with NTSC
MUSE	Direct Broadcast by Satellite (DBS)	8.1 MHz	NA	No
MUSE-T	Satellite	16.2 MHz	NA	No
MUSE-6	Terrestrial Broadcast	6 MHz	Yes	Yes
MUSE-9	Terrestrial Broadcast	6 + 3 MHz Augmentation	Yes, with 2nd 3 MHz channel	Yes
MUSE-E	Terrestrial Broadcast	8.1 MHz	No	No

line and it requires a total bit rate of 1.2 Gbps. Note that this production system is similar to the interlaced system used in the ATSC standard, except that the latter uses 1080 active lines.

2.4. Japanese MUSE Transmission Systems

A range of transmission systems were developed by NHK based on the Multiple Sub-Nyquist Encoding (MUSE) transmission scheme (see Table 8). MUSE (8.1 MHz bandwidth) was developed for DBS broadcasting and MUSE-T (16.2 MHz bandwidth) was developed for satellite transmission. MUSE-6 was designed to be compatible with a 6 MHz channel and NTSC receivers. MUSE-9 uses a 3 MHz augmentation channel in addition to the standard 6 MHz channel and is NTSC receiver-compatible.

2.5. Japanese Hi-Vision System

This system incorporates the 1920×1035 television production system and the MUSE-E transmission system. MUSE-E uses an 8.1 MHz bandwidth and is incompatible with standard NTSC receivers and channel allocations. Four audio channels are time-division-multiplexed with the video signals, in the blanking intervals. The encoding and decoding processes are both very complex and require many very large-scale integration (VLSI) chips. This system requires a MUSE-E receiver, or a set-top box equipped with a MUSE decoder feeding either a 16:9 display or a 4:3 aspect ratio conventional receiver. In the near-term, NHK will use simultaneous Hi-Vision/NTSC program production.

The MUSE systems are not receiver-compatible with either the North-American ATSC system or the European DVB system (see below).

2.6. The Japanese Enhanced Definition Television System (EDTV-II)

EDTV-II is an NTSC-compatible letter-box analog transmission system standardized by the ARIB in Japan. The input signal is 525-line, 60-frame progressive scan (525P) with 16:9 aspect ratio. 525-line, 30-frame interlaced scan (525I) can be upconverted as an input signal. Note that the 525P signal is one of the SDTV signal formats defined in the ATSC Standard (720×480 at 60P). It is also defined as a production format in SMPTE 293 M and SMPTE 294 M standards documents.

Compared with the current 525I standard, the frame rate has been doubled from 30 to 60. The sampling frequency in the format has been doubled to 27 MHz, compared with 525I, and the aspect ratio has been changed from 4:3 to 16:9. This increase of sampling frequency permits comparable resolution in H and V axes to be maintained. The production system is effectively an 8:4:4 digital system with production interfaces at 540 Mbps. 4:2:0 can also be used in production and would require interfacing at 360 Mbps. Horizontal blanking is shrunk to achieve this bit rate.

The EDTV-II analog transmission system is used for both terrestrial and satellite broadcasting. It requires the same bandwidth as the NTSC system, and no changes are needed in transmitter implementations. The image is displayed on an EDTV-II receiver in a progressive manner with 480 lines and a 16:9 aspect ratio. It is compatible with existing NTSC receivers, except that the display image is a 16:9 aspect ratio and so appears in a letter-box format with black bars at top and bottom. The 525P signal requires a video bandwidth of approximately 6.2 MHz. The EDTV-II system creates three enhancement signals in addition to an NTSC signal, with which they are then frequency-domain-multiplexed.

2.6.1. Main Picture (MP). The 525P 16:9 signal is reduced from 6.2 MHz to 4.2 MHz bandwidth, and the 480 lines are decimated to 360 lines to produce a letter-box display on the NTSC 4:3 receiver. Black bars, at top and bottom, are each 60 lines wide. Thus, horizontal and vertical resolution are reduced to conform to the NTSC format, but to maintain the 16:9 aspect ratio.

2.6.2. Horizontal High (HH 4.2 MHz to 6.2 MHz). A frequency enhancement signal is extracted from the original 525P image and is multiplexed into the MP signal to increase the horizontal bandwidth to 6.2 MHz in the EDTV-II receiver. For transmission, the HH signal is downshifted to 2 to 4 MHz and frequency-division-multiplexed into an unused vertical temporal frequency domain in the conventional NTSC system called the Fukinuki hole. The Fukinuki hole may only be used for correlated video information, which applies in this case.

In the EDTV-II receiver, a motion detector multiplexes the HH signal only onto the still parts of the picture where there is more need for high resolution to satisfy human vision characteristics. Two enhancement signals are frequency-division-multiplexed together into the top and

bottom panels, which together occupy one third as much area as the main picture. As these are generated in a 360-line format, they must be compressed by a 3 to 1 pixel downsampling decimation process to fit into the 120 lines of the top and bottom panels.

2.6.3. Vertical High Frequency (VH). The VH signal enhances the vertical still picture resolution back up to 480 lines. The signal is transmitted only for stationary areas of the image, and temporal averaging is applied.

2.6.4. Vertical Temporal Frequency (VT). The VT enhancement signal is derived from the progressive-to-interlace scan conversion at the encoder and improves the interlace-to-progressive scan (360/2:1 to 360/1:1) conversion in the receiver.

The EDTV-II receiver performs the reverse of the encoding process. The NTSC receiver uses the MP signal directly.

2.7. The European DVB System

The Digital Video Broadcast (DVB) system has been designed for MPEG-2-based digital delivery systems for satellite, cable, community cable, multichannel multipoint distribution (MMDS), and terrestrial broadcasting. Service information, conditional access, and teletext functions are also available. All DVB systems are compatible.

DVB-T, the terrestrial broadcasting standard, is similar in many respects to the ATSC standard. However, there are several significant differences. DVB-T uses Coded Orthogonal Frequency Division Multiplexing (COFDM). This technique is already being used for Direct Audio Broadcast (DAB). A total of 1704 (2k) or 6816 (8k) individual carriers may be used. The 8k system is more robust, but increases receiver complexity and cost. Some broadcasters have already adopted the 2k system, although it will not be compatible with the 8k system. DVB-T uses the MPEG-2 Layer II Musicam audio standard, a 50 Hz frame rate, and aspect ratios of 4:3, 16:9, or 20:9.

2.8. The European PALplus System

This is an analog delivery system that uses a current TV channel to transmit an enhanced widescreen version of the PAL signal. A conventional receiver displays the PALplus picture as a letter-box in a 4:3 aspect ratio. A widescreen receiver shows the same transmitted picture in a 16:9 format with higher resolution. European broadcasters are divided on whether to use this format. The PALplus concept is closely similar to the Japanese EDTV-II format, described above.

represent a fusion of ones commonly used in each realm, thus allowing the possibility to take the best of both. This common feature appears time and again in the Terahertz domain where technologists selectively adopt concepts from the optical community and use them alongside those taken from the microwave world.

Since we have become accustomed to think of waves of electrical energy and light waves as forming parts of a common spectrum, the attempt has often been made to extend our knowledge over the wide region which has separated the two phenomena, and to bring them closer together... [1]

This seminal statement characterizes precisely a revolution that is taking place now, more than 100 years after the recognition by Rubens and Nichols of a fundamental quandary [2]: Electromagnetic waves form a continuous spectrum, starting at the microwave region through the optical, ultraviolet, and X-ray region. Nevertheless, our possibilities to access certain regions of this spectrum are limited by fundamental and technological reasons, which leads to “gaps,” i.e., restrictions, for the widespread and practical use of radiation with certain frequencies. One such breach is associated with the transition region from microwave to optics, now recognized as the Terahertz region.

This long-standing gap in the spectrum is loosely defined as that between 100 GHz and 10 THz, which is equivalent to radiation with a wavelength of 30–3000 μm, associated with energies in the range of 0.4–40 meV. In this region of the electromagnetic spectrum, a fundamental change occurs in the way electromagnetic waves are generated and detected.

Electromagnetic radiation is associated with coupled and temporally varying electric $\vec{E}(t)$ and magnetic fields $\vec{H}(t)$. Analyzing Maxwell’s second equation, i.e., Ampere’s law [3]:

$$\nabla \times \vec{H} = \vec{j} + \frac{\partial \vec{D}}{\partial t}, \quad (1)$$

it can be seen that temporally varying magnetic fields can only be driven by two types of fundamentally different source terms, as evident from the two right-hand terms, which are the electric current density \vec{j} and the electric displacement \vec{D} . They represent different approaches to the generation of electromagnetic radiation. The first term is the dominant approach used at low “microwave” frequencies using the motion of electronic charges to generate radiation. This method was adopted already in the early days of electromagnetism [4]. By creating temporally varying currents, it was possible to produce the emission of electromagnetic radiation. Alternatively, at optical and infrared wavelengths, sources of radiation are associated with dipolar transitions [5], specifically electronic transitions, occurring within atoms or molecules. In modern times, interest in Terahertz photonics has increased, because inverted dipolar transitions make stimulated emission possible and so allow amplification of optical radiation, which, in turn, leads to the realization of coherent electromagnetic sources or, as they are better known, lasers [6].

These two fundamentally different approaches to the generation of electromagnetic radiation have led to

Terahertz (THz), or 10^{12} Hz electromagnetic radiation lies between the infrared and microwave regions of the electromagnetic spectrum. The THz domain comprised the millimeter wave, submillimeter wave, and far infrared regions. Because this frequency range falls in between the more established domains of microwave and optics, the technologies used to access the THz frequency range

mature technology for diverse applications at both microwave (electrical) and infrared (optical) frequencies; however, both encounter fundamental difficulties when accessing the Terahertz range of the electromagnetic spectrum.

From the microwave perspective, the generation of high-frequency time-varying currents becomes difficult to control because of the parasitic effects of the miniature circuit structures combined with the exponential increase in electrical loss as the electrical current becomes restricted to the skin depth. For Terahertz circuitry to operate successfully, a simple rule holds true. As the frequency is increased, the area of the circuit must decrease as the square of the increase in frequency and the cube in volume. Consequently, from a power perspective, levels available rapidly drop with the increase in frequency from watts in the millimeter region to milliwatts in the Terahertz region.

Fortunately, this rule of thumb does not affect detector sensitivity to the same extent. In general, the size of the intrinsic detector is small compared with the wavelength of operation, and only small currents exist within the device. As a result, a relatively moderate degradation is experienced with increasing frequency.

In spite of the difficulties encountered in realizing microwave Terahertz circuits, many advances have recently occurred, which have been mainly achieved with the adoption of improved semiconductor processing capability, use of accurate design tools, and novel Micro-Electro-Mechanical Systems (MEMS) circuit engineering. As a result, increasing levels of power and bandwidth have been achieved from solid-state sources. Similarly, broad-band, very high sensitivity detectors have been demonstrated by a number of workers.

From the optical viewpoint, efficient sources of radiation are traditionally associated with solid-state lasers, which require the population inversion of an electronic transition, i.e., more electrons in an upper state than in a lower lying state of a dipolar transition. For Terahertz wavelengths, where a comparatively small energy spacing exists between lasing transitions, inversion is much harder to achieve. It is therefore difficult to realize Terahertz lasers and alternative methods to generate Terahertz radiation by optical means, like photomixing, have been necessary to circumvent this problem. Recently, however, the first quantum cascade lasers operating in the Terahertz frequency range have been realized but only at low temperatures. Complex materials processing (molecular beam epitaxy) is required to manufacture the artificial bandgap structures required to achieve population inversion. Although the fabrication process is complex, it provides many degrees of freedom for optimization, and rapid progress is to be expected.

As a result of these and other breakthroughs in technology, the Terahertz region is finally finding applications outside the traditional heartland of remote sensing and radio astronomy. Extensive research in the last few years has identified many attractive new application areas (see Fig. 1) and paved the technological path toward broadly usable Terahertz systems for everyday applications. Consequently, the Terahertz gap may be close to being bridged.

1. DRIVING FORCE

Research has been carried out in the Terahertz region for several decades (for an historical overview see [2]). However, until recently, work was limited to basic research or applications such as radio astronomy, planetary/cometary science, and atmospheric science. In the terrestrial domain, plasma diagnostics provided a thrust. In fact, without these driving influences, it is unlikely that many of the recent technological breakthroughs would have occurred.

Astronomy and remote sensing of the earth's atmosphere has provided a powerful incentive for the development of Terahertz technology. The photon energy level associated with Terahertz radiation is low when compared with optical photons. Optical photons are emitted when electrons change energy states during relaxation, e.g., from a conduction band to a valence band in a semiconductor or between atomic states in atoms. By comparison, Terahertz photons are emitted when a molecule change its thermal, rotational, or bending state. Correspondingly, the energies involved are 100–1500 times smaller, making their detection that much more difficult. However, although optical spectroscopy provides information as to the atomic composition of materials, Terahertz spectroscopy provides information regarding the molecular concentration as well as its physical condition, i.e., heat, pressure, speed, etc., in the region being measured. It is for this reason that radio astronomers, planetologists, and atmospheric scientists have undertaken so much work. By studying the Terahertz radiation emitted or absorbed by a gaseous region, it is possible to investigate chemical and physical processes in places where instrumentation cannot be sent and thereby obtain valuable insight into the processes and mechanisms involved.

Although space-based remote sensing still remains the dominant scientific application, Terahertz technology is also now expanding its usage into more everyday areas. Extensive research in the last years has identified numerous potential applications, and this paved the technological path toward more readily usable Terahertz systems.

2. APPLICATIONS PAST AND PRESENT

2.1. Space Applications

The requirements of the radiometric measurements desired for astronomy and remote environmental sensing has, in general, meant that space instrumentation has pushed technology toward operation at the highest frequencies and sensitivities. It is therefore sensible to start the applications sections with an overview of space-related developments.

Several Earth observation and space science missions, employing Terahertz frequency instruments, have been developed in the past and many more are planned for the future [13,14]. These instruments have many commonal-

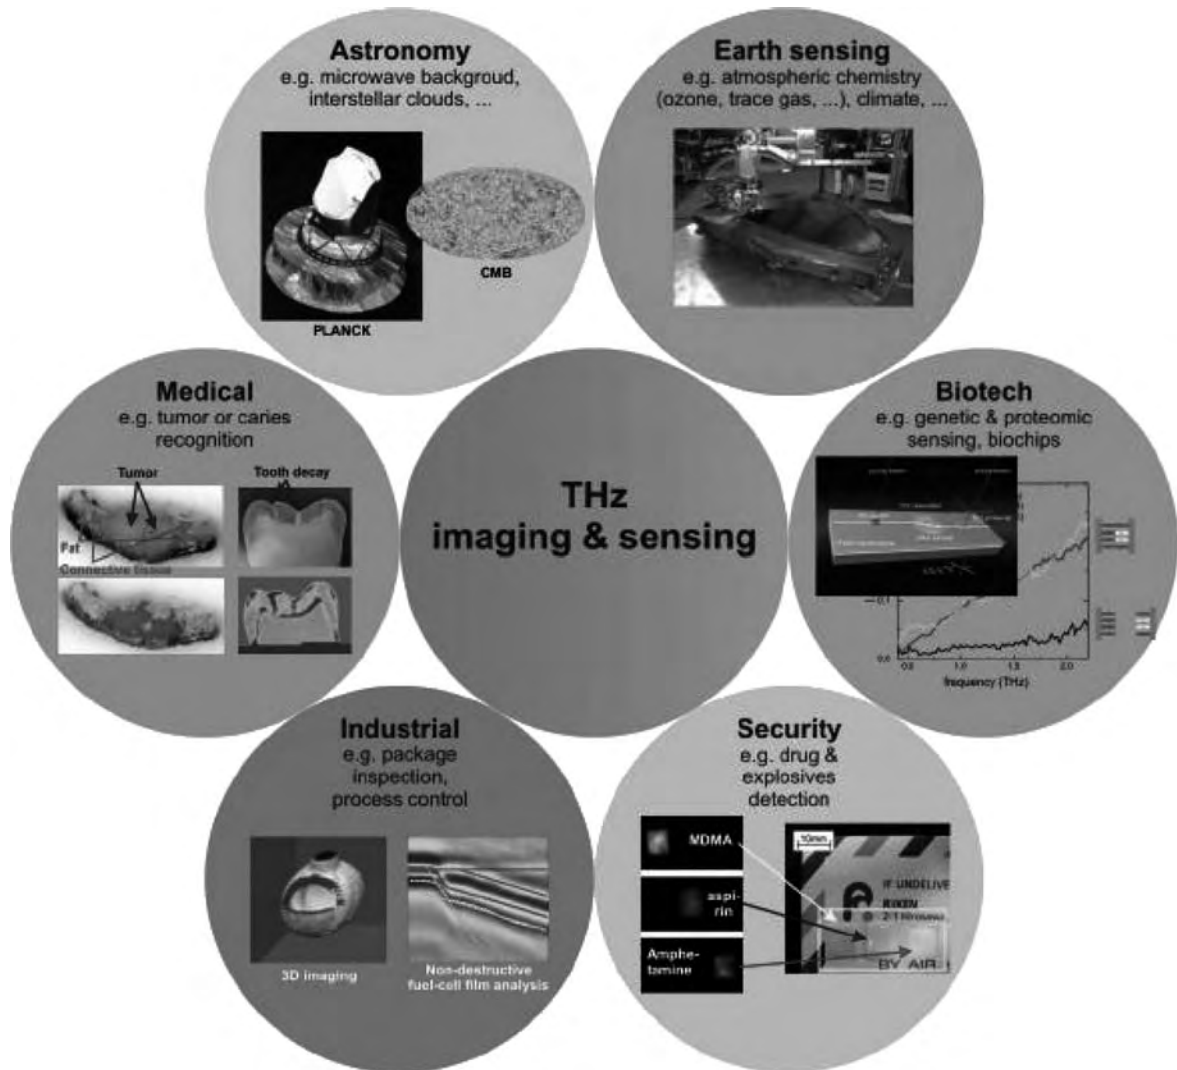

Figure 1. Illustration of some exemplary applications of Terahertz radiation. Illustrations taken from work performed at European Space Agency (astronomy and earth sensing), at Univ. of Frankfurt and Teraview Ltd. [7,8], RWTH Aachen and Rensselaer Polytechnic Inst. (industrial; [9,10]), Riken (security;[11]) and RWTH Aachen [12]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

ities in their design and construction techniques, and they all make use of state-of-the-art Terahertz technology to achieve the ambitious goals of future missions in terms of resolution, sensitivity, and frequency of operation. Added to this is the requirement for low mass, power, and reliability.

Although the basic architectures of the instruments are similar, applications and status of technologies vary widely over the frequency range: The lower end of the spectrum is routinely used for communications, including satellite communications, and several commercial and military (terrestrial) applications have emerged at millimeter waves up to 100 GHz. In contrast, the highest frequencies are used mainly for scientific programs, in both space and terrestrial applications.

As a consequence, the maturity and availability of technologies in this frequency range decreases directly with the wavelength.

As a result of the potential commercial applications at lower Terahertz frequencies, all the technological ingredients are rapidly becoming available, and cost effectiveness becomes a driver. This is in contrast to the higher frequencies, where many of the technology elements may be missing or immature.

The emergence of large-volume markets (such as secure communications links, radars, anticollision car radars, short-distance radiolinks, and wireless local area networks) has provided the market pull for the development of mm-wave electronics. Although their suitability for space applications still needs to be demonstrated,

semiconductor devices and MMICs are commercially available at frequencies below 100 GHz, which can be considered today as the upper frequency limit of “commercial” microwave electronics.

However, changes will occur in the near future because of technology needs of optical communications. Globally, an ever-increasing need exists for more bandwidth. Even during the present slowdown in the telecommunications markets, Internet traffic is growing by 100% per year. This need for bandwidth can be satisfied with optical fiber in fixed networks. A single fiber can carry a bandwidth of over 1 THz (using Wavelength-Division Multiplex), but the bandwidth of the electronic interface creates the bottleneck. Consequently, faster mm-wave circuits are being developed. Optical systems at 40 Gbit/s are commercially available, 80 Gbit/s systems are under development, and 160 Gbit/s systems are being planned. As a result, this development will drive mm-wave technologies, including semiconductor devices, to frequencies well above 100 GHz, offering new prospects also for the space applications of millimeter-wave electronics.

Radio astronomy has also been a major driver for the development of Terahertz technology [15–18]. Here, however, the absolute requirement for the lowest noise receivers has led to the development of superconducting systems. Observations over the whole electromagnetic spectrum are required, e.g., in order to test different cosmological theories of the evolution of the Universe (see Fig. 2). As a result of the masking effect of the atmosphere, space observatories are considered as being of prime importance. Future planned instruments will open up this virtually unexplored part of the spectrum that cannot be observed from the ground.

Another space application for Terahertz sensors is in planetary and small-body (asteroids, moons, and comets) observations. To date, little heritage in planetary and cometary instruments and space-based observations utilizing (sub)millimeter-wave frequencies exists. However, planetary and cometary targets have been identified for which this type of instrument offers the opportunity for

significant scientific progress in the medium term. Surface-based (landers) or orbital remote sensing observations of gaseous species in the Venutian, Martian, and Jovian atmospheres, as well as around Europa and Titan, have all been proposed. The instruments should be able to provide information on composition, temperature, pressure, and gas velocity (winds) that will provide a wealth of information.

It has also resulted in the first such instrument: MIRO (Microwave Instrument for the Rosetta Orbiter) [19], launched on the ESA cornerstone mission Rosetta [20] in March 2004, and scheduled to reach its target comet (Churyumov–Gerasimenko) nucleus and of the cruise target asteroids in 2014.

In Earth observation, Terahertz instruments are often used in synergy with optical and infrared sensors. Vertical profiles of temperature and humidity of the atmosphere are conveniently determined from meteorological satellites using passive millimeter-wave sounders operating at specific spectral lines of high atmospheric attenuation (e.g., at 60 and 183 GHz). Remote sensing of the surface of the Earth is possible from a satellite even under cloudy or foggy conditions at window frequencies, which are not affected by the atmosphere or adverse weather conditions. Millimeter waves are especially useful for the imaging of ocean winds, sea ice, and snow, whereas ice clouds are best observed with sub-mm instruments.

Furthermore, there are several very important processes taking place in the atmosphere, [21,22] such as the greenhouse effect and ozone depletion. A growing need exists to better understand the possible detrimental effects of man’s activities on climate. The most effective way to correlate these interactions is to perform high-precision spaceborne global measurements of the composition of the atmosphere. Spectral lines at millimeter and sub-millimeter frequencies allow the use of radiometers for the determination of concentrations of, e.g., Ozone and other trace gases, such as CFCs, that are affecting its concentration.

Figure 2. Terahertz space applications for the observation of the cosmic microwave background.

2.2. Plasma Diagnostics

Since the early days of fusion research in the late 1950s, intense efforts were devoted to the precise monitoring of a plasma, because an accurate determination of the spatial density and temperature profile of a hot and dense plasma is critical to enable a stable plasma confinement and steady operation conditions in a fusion reactor. Initially, the cyclotron emission was observed, like, e.g., experiments of the hot plasma emission in the wavelength range from 100 μm –1.6 mm (i.e., 0.18–3 THz) [23]. These experiments were conducted as early as 1961 in the framework of the first British fusion device attempt termed ZETA (Zero Energy Thermonuclear Assembly). Meanwhile, several nonperturbing techniques for measuring the electron density distribution of a hot plasma have been developed based on Thomson scattering, interferometry, or reflectometry. Most of the techniques operate at the low-frequency end of the Terahertz spectrum. Actually, complex heterodyne imaging and spectroscopy systems have been developed that allow monitoring and resolution in two and potentially even in three dimensions, the relevant properties of the plasma, in order to observe, e.g., plasma profiles, turbulence, and/or fluctuations [24–26]. In fact, it is accepted in the plasma community that these or similar measurement techniques will certainly be necessary for the next generation prototype fusion reactor device ITER. Apart from plasma diagnostics, high-power gyrotrons operating at the low-frequency edge of the Terahertz frequency are regularly used for RF-plasma production, heating, noninductive current drive, and plasma stabilization [27]. Ample efforts targeting high-power Terahertz sources were mainly determined by this application area.

2.3. Medical Imaging

Terahertz technology in the medical imaging field is currently in a crucial phase and may soon expand our ana-

lytic capabilities. Here, interest in Terahertz imaging comes from a combination of two intrinsic characteristics of Terahertz radiation. First, Terahertz radiation is non-ionizing and therefore intrinsically safe for biomedical sensing and imaging. Given the increasing awareness of the damaging effects of ionizing radiation, an intense interest in alternative techniques to X-ray diagnosis exists. Secondly, Terahertz analysis has indicated to be able to distinguish cancerous tissue from normal tissue (see Fig. 3, [28]). Although the precise reason for the observed different Terahertz response from healthy tissue and tumors is still unknown, it appears extremely attractive to have a nonionizing spectroscopic imaging technique that can directly identify and localize tumors.

Despite of a limited penetration depth for Terahertz waves in tissue on the order of several millimeters to a centimeter, a great interest in the technique for medical applications has emerged. Another potential medical application is checking how injuries are healing underneath surgical bandages without the need of taking off the bandage. A related imaging application also appears particularly suitable in the field of dental imaging (see Fig. 3). Here, a high interest in nonionizing radiation imaging also exists, and several analyses have demonstrated the capabilities of Terahertz radiation to image teeth and to identify early stages of caries or to monitor dental enamel thickness, which is necessary to quantify problems associated with enamel erosion [30].

2.4. Molecular Sensing for Environmental, Biotechnological, and Pharmaceutical Applications

Further sensing applications develop from the fact that specific molecular rotations, vibrations, or librations of molecules and molecular aggregates occur in this frequency range, which enables a large variety of applications for the detection and/or identification of molecules in diverse areas.

Figure 3. Exemplary Terahertz medical applications, illustrating the potential capability to distinguish tumors (left) and the early diagnosis of tooth decay (right). Figures from [7,29]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

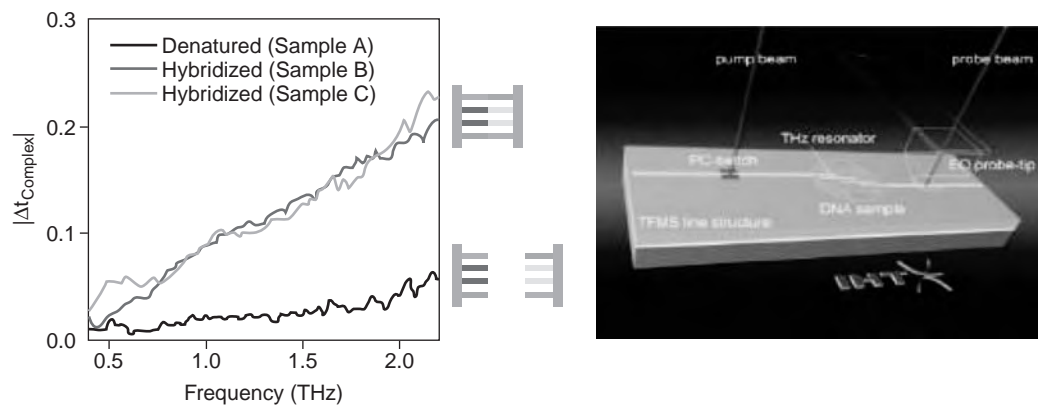

Figure 4. Exemplary illustration of Terahertz sensing of genes. The left figure illustrates spectral distinction of genes via binding state dependencies (adapted from [35]), and an integrated biosensing system (adapted from [37]). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

For environmental sensing, it appears very attractive that the rotational transitions of gases are highly dependent on the particular gas species. Broad-band Terahertz analysis can therefore trace complete gas compositions simultaneously with one device. Related applications for gas sensing are, e.g., monitoring of combustion processes [31,32], or plasma sensing [33], e.g., to control plasma etching processes.

Numerous applications in the field of biomolecular sensing are emerging. Here, a direct resonant probing of biomolecules of biomolecular binding events is crucial to detect and understand the function of biomolecules. Usual approaches are based on indirect probing by labeling the analyzed biomolecules, which is an additional costly process and also has a detrimental effect on the quality of the analysis.

A huge interest in label-free direct probing of biomolecules and their interactions exists. Terahertz spectroscopy has demonstrated that it allows to sense biomolecules like DNA and proteins [34–36] directly, without requiring labels. These basic observations are now being brought closer to application by the development of integrated Terahertz biochips (Fig. 4, [37], [38]). Many more molecular sensing applications have been identified, e.g., for monitoring chemicals or active ingredients in medicine during pharmaceutical manufacturing [39] or sensing chemical spatial distributions in objects [40].

2.5. Security

A great interest in the detection of drugs and explosives by Terahertz techniques has emerged, given the currently higher critical perception of security issues. Here, Terahertz techniques could also have a high potential, as resonant states seem to allow the spectroscopic distinction of explosives [41] and drugs [11]. One of the unique properties of longer wavelength Terahertz radiation is its ability to pass through many materials that are opaque in the visible region. Materials such as clothing, plastics, glass, and paper are transparent or have relatively low loss to frequencies as high as 1 THz. Above 1 THz,

most materials are relatively absorptive but can nevertheless be imaged through using active techniques. Below 1 THz, it becomes possible to image hidden objects through clothing passively [42] or to sense their corresponding molecules spectroscopically. Consequently, much interest at present exists in the use of Terahertz imagery and sensing for security purposes. Applications include intercepting foreign objects hidden within mail (see Fig. 5) and concealed weapons (see Fig. 6) at airports. Both applications are in their infancy and have yet to prove their superiority over existing techniques.

Work has also been undertaken to investigate the possibility of remotely detecting chemical and biological agents [43]. This problem has many challenges to overcome, but initial results show it to be possible.

2.6. Material Inspection and Quality Control

Already, from the early days of Terahertz technology, it was clearly recognized that Terahertz radiation could find applications in materials analysis and quality control, particularly for electronic materials (see Fig. 7). Wide-ranging demonstrations of these capabilities have been

Figure 5. Exemplary illustration of Terahertz identification of drugs (adapted from [11]), using multispectral transillumination and component spatial pattern analysis. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 6. Exemplary illustration of Terahertz identification of concealed weapons (adapted from [42]).

performed to date, starting from the simple analysis of dielectrics and semiconductors [45,46]. Important work has been performed for the analysis of superconductors [47], including imaging at low temperatures [48]. Other examples of analyzed materials are ceramic materials for solid-oxide fuel cells (Fig. 8, [9]), manganites relevant for spintronics [49], and many more materials, like ferroelectrics, incommensurate crystals, dielectrics, magnets, low-

Figure 7. Terahertz image through a semiconductor chip (from [44]).

dimensional conductors and superconductors (for an overview, see [50]). Recent work in the field has been directed particularly to analysis in nanostructures that play a vital role for future photonic and electronic components (see, e.g., [51]).

Terahertz technology has a broad application perspective in this field. First commercial systems (e.g., Nikon) are emerging precisely in this field.

A further interesting application field of Terahertz technology is based on the long wavelength of this type of radiation in comparison with optics. The longer wavelength implies that Terahertz waves exhibit less scattering in comparison with optics. Imaging and vision systems in this frequency range can therefore tolerate harsh environmental conditions that are necessary in diverse application areas, like, e.g., package inspection [52] or industrial process monitoring [7]. Here, a higher resolution than what is available with conventional millimeter-wave imaging systems is often desired, while at the same time, optical imaging cannot provide a solution because of scattering.

3. BASIC TECHNOLOGY

3.1. Microwave Terahertz Detectors, Sources, and Systems

Whereas photonic-based Terahertz systems appeared relatively suddenly, quickly demonstrating their usefulness in the applications described previously, microwave

Figure 8. Material inspection analysis with Terahertz waves. Here, tomographic imaging allows cross sections and determines deposited film thickness of the active layers of solid-oxide fuel cells (adapted from [9]). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 9. ADMIRALS (a) Artist view of the ADMIRALS antenna. (b) CFRP face skin manufacturing of the ADMIRALS antenna breadboard.

Terahertz systems evolved slowly over several decades. The broad-band solid-state radiometers used on current space missions and quantum noise limited cryogenic receivers used on ground and spaced-based radio telescopes find their origin in the humble cat's whisker detector [53] used in the earliest radios. The design rules governing the performance of microwave Terahertz detectors, sources, and systems have been understood for many years, and apart from the development of certain types of cooled detector progress, no groundbreaking discoveries have occurred since the Gunn diode [54]. Consequently, workers have resorted to better system engineering, new materials, and refining their design tools and manufacturing techniques to simultaneously improve performance and achieve operation at ever-higher frequencies. This section attempts to describe some of the techniques and technologies that have been developed for realizing the “microwave” instruments that operate in the Terahertz frequency range today. Such instruments have some commonalities. First, the basic building blocks are common: antenna, reflectors, waveguide and feed-systems, and receiver and the corresponding sub-systems. Second, semiconductor devices and device technologies are a key element for the construction of any (sub)millimeter-wave instrument.

These building blocks are discussed in the following sections and are categorized according to the way sub-systems would be positioned in a typical system, i.e., from the top down (antenna, feed, receiver, etc.).

3.1.1. Microwave Terahertz Technology: Antenna and Feed Systems. The antenna sub-system is a key element for most Terahertz instruments. In order to image or analyze the information gathered by a remote sensing instrument, knowledge of the instruments “field of view” is vital. Consequently, the instrument’s antenna performance is critical because it largely determines the resolution and accuracy with which, e.g., the concentration profiles of atmospheric species can be retrieved. Antenna performance is also of prime concern for astronomical and planetary missions. For pointed observatories, which seek to map point-like or not very extended objects, the emphasis is on beam efficiency and the control of main beam

shapes. For survey missions, the level of far side lobes also becomes very important, and in some cases (such as the PLANCK mission [15,16]) this exerts a critical influence on the success of the mission.

Terahertz reflectors and the corresponding sub-systems relevant to ambitious scientific and earth observation satellite programs lead to high-precision, stable reflectors, high-performance lightweight materials, and low-loss RF components [55,56]. The requirements of future missions outrange those of more classical telescopes working in the microwave frequency range by a few orders of magnitude in terms of surface accuracy and stability. Furthermore, the tolerances on relative positioning lead to near optical accuracies. In addition, the temperature range that the instruments must work reliably over add system complexity to the manufacturing, integration, and testing. Considerable effort has been taken to ensure antenna performance, and dedicated Terahertz antenna technology studies have been performed (e.g., the ADMIRALS activity [13]: Antenna Development in Millimeter/sub-millimeter-wave Range for Astronomy and Limb Sounding, Fig. 9).

Figure 10. Breadboarded 5-frequency quasioptical demultiplexer.

Over the past years, several activities have been started in the field of quasi-optical feed systems (Fig. 10, [57]) in terms of controlling the observed signals, which has led to low-loss compact systems. Low-loss frequency selective structures (FSS) [58] are being considered because present receiver systems are limited by losses. Significant losses in high-Q multilayer beamsplitters occur because of the absorption in the substrate material that is required to support the individual printed arrays of resonant FSS elements. A radical approach for improvement is the removal of the dielectric backing and interlayer spacer material to form air-spaced self-supporting FSS structures [59].

Most of the instruments that have been mentioned in the previous sections have receivers that utilize waveguide horn antennas as the initial receiving elements. They have traditionally been the most common microwave antenna feed types and although the attenuation of fundamental-mode waveguides at (sub)millimeter-wave frequencies is high and both the effect of metal tolerances and misalignments becomes more severe, horns and waveguides have been produced for these wavelengths with great success [60].

However, the small size can be turned into an advantage when the dimensions and tolerances required become compatible with those achieved by lithography or micromachining. In recent years, the advancement of photolithographic and micromachining techniques has resulted in a very reliable and repeatable process for creating structures on dielectric substrates, and the fabrication of complex electronic structures with a high yield is now

possible, which means that a viable alternative for waveguide-based front ends has emerged.

An important advantage of the integrated planar technology [61] is that the antenna, mixer, local oscillator, and all peripheral circuitry can be realized on a single substrate, thereby eliminating the transmission lines between the separate devices (see Fig. 11, [62]).

However, some problems related to planar antennas may exist because of efficiency problems associated with the dielectric substrates on which these antennas are fabricated. If the dielectric is thick in terms of wavelength, substrate and surface wavemodes can be excited. Two basic approaches have been used to increase the efficiency; dielectric lenses or electromagnetic bandgap crystals (EBG) [63,64].

The electromagnetic bandgap antenna is still a relatively new concept, and with respect to the antenna performance, the EBG technology is still in an experimental stage [65]. On the contrary, research on integrated lens antennas has already shown that the radiation characteristics are very promising and the integrated lens designs have already reached some level of maturity. Several activities on the above technologies have been initiated with very good results [66,67].

Although this approach has offered competing performance, micromachining in a general sense is not restricted to planar structures. It is also possible to manufacture more traditional “waveguide-like” structures. The advantages of these come from the fact that it is possible to form a waveguide section in which the active semiconductor can be integrated directly into it, which allows more familiar design approaches to be applied [68].

Also, in the world of filters and windows (see Fig. 12) for submillimeter and Terahertz direct detection instruments, much work is being performed [69]. Metal mesh filter technology [70] has become the prime source of Terahertz filters for most space and sub-orbital instruments in both the astronomical and Earth Observation communities. These filters can be either embedded in a dielectric (hot-pressed filters [71]) or as airgap devices [72].

Figure 11. Integrated antenna with peripheral circuitry.

Figure 12. Metal mesh and dielectric filters.

The successful development of broad-band antireflection coatings [73] for high refractive index dielectrics (germanium, sapphire, silicon, quartz) serves as an enabling technology for the development of refracting optics for instruments operating at Terahertz wavelengths. Excellent performance of these coatings with low reflective losses has recently been demonstrated in windows, filters in windows, and filters at these wavelengths.

3.1.2. Microwave Terahertz Technology: Superconducting Detectors. One of the most powerful characteristics of the microwave Terahertz approach is the ability to realize sensors that are so sensitive they can detect the naturally occurring background Terahertz radiation. At this present time, an equivalent photonic technique that can achieve the required sensitivity without the use of an external signal seemingly does not exist. For certain applications, like radio astronomy and atmospheric sensing, the main aim is to observe the naturally occurring radiation purely by passive means. Consequently, the technology developed for this purpose follows a completely different path to the photonic route.

To an astronomer, detector performance is the main priority. Capturing an image of a distant extended source, such as a nebula, can take hours, days, or even weeks. The smallest signal that can be detected is directly proportional to the receiver noise temperature and inversely proportional to the square root of the product of the bandwidth of the radiometer and the time spent viewing the object. Observing time on the few radio telescopes that can operate up to 1 THz is very limited, and so astronomers want to make the most of the time they have. They will, therefore, go to extraordinary lengths to build radio receivers with sensitivities that approach to quantum limit. For the systems they use, two predominant methods of detection exist; direct and heterodyne detection.

Direct detection generally involves a bolometric device. This device acts like a very sensitive thermometer. The signal is coupled to the device and either the resistance, charge, or current of the device is monitored, and any observed change indicates that the incident power has varied. Such bolometers have traditionally been fabricated from InSb [74]. To achieve ultimate performance, such bolometers are generally actively cooled using a cryostat operating at a few tens of milliKelvin. The main advantage of the bolometer is that it is an intrinsically simple structure. This device, coupled with recent advances in MEMs-derived fabrication techniques, has provided the means to accurately control the thermal environment of the bolometer, increasing its sensitivity and speed while simultaneously providing the means to assemble large imaging arrays of uniform devices, which provides the means to dramatically reduce the time required to observe. Examples of such arrays are SCUBA [72], used on the James Clerk Maxwell Telescope in Hawaii, or BOLOCAM (Fig. 13 [75]).

With such arrays it is possible to detect the presence of planets around stars, hence the interest. Future bolometric arrays will have sensitivities that are two orders of magnitude higher, allowing images to be captured in minutes that would have taken weeks before. A new type of

Figure 13. BOLOCAM Bolometer array.

bolometer, the transition edge bolometer [76] is potentially offering superior performance compared with previous devices, and the next generation of arrays could be implementing this emerging technology.

One disadvantage of such direct detection methods is the fact that the detector will also respond to power from signals at wavelengths other than those desired. Band-pass filters are therefore required to block unwanted signals, and the finesse of these filters effectively dictates the frequency being observed.

As the spectral resolution of bolometers is limited, a technique known as heterodyne mixing is used to provide spectral information. In heterodyne mixing, detection of the signal occurs when it is coupled into a nonlinear device and combined or “mixed” with a coherent spectrally pure second signal, the Local Oscillator, or LO. The LO is arranged so that it is close in frequency to the signal being observed. As the detection device is nonlinear, new signals are generated at various frequencies. One of these signals is the difference frequency (or intermediate frequency, IF), which is sufficiently low in frequency that it can then be amplified and detected using conventional low-frequency “base-band” electronics.

For radio astronomy, in order to add as little noise to the signal to be detected as possible, a very sensitive superconducting device known as an SIS (superconductor insulator superconductor) junction [76] is used as the mixing detector. This device is cooled to below its superconducting transition temperature. Most radio astronomy heterodyne systems use SIS mixers, but at around 1 THz the sensitivity, the SIS detector degrades. Above this frequency the energy of the received photons is above the bandgap of the superconducting material, and the losses within the junction become high. Consequently, the performance drops rapidly. In response to this fundamental problem, a relatively new device that operates using a combination of the bolometric and mixer effect has been developed. This device is known as the

Figure 14. (a) 2.5 THz Nb HEB device. (b) Zoom of the 60 nm microbridge.

Hot Electron Bolometer (see Fig. 14), or HEB [77]. The HEB consists of a very small length of superconducting metal sandwiched between two normal metal electrodes. The device still needs to be cooled below the transition temperature, but unlike a conventional bolometer, the HEB temperature can be modulated very quickly. Like the SIS junction, an LO signal (at least an order of magnitude lower) is introduced, which is mixed with the signal to be observed and again an IF signal is created. However, in case of the HEB, it is the junction temperature that is modulated at the IF frequency. As a result of the fast cooling mechanisms involved, the responsivity of the HEB device is in the picosecond range [78].

3.1.3. Microwave Terahertz Technology: Room Temperature Detectors. The detectors described in Section 3.1.2 probably provide the highest sensitivity, but they have one serious disadvantage: they need to be cooled to very low temperatures. Some applications do not require maximum sensitivity but need to provide solutions at a reduced cost and complexity or are required to operate in hostile environments such as aircraft or satellites for extended periods. The measurements of interest may require an IF bandwidth much higher than can be achieved by superconducting receivers. Consequently, when weight, power, and longevity are paramount parameters, then room temperature Schottky-based heterodyne mixers [79] have been deployed.

By arranging Schottky diodes in particular configurations, the system complexity can be further simplified. One favored arrangement is the antiparallel configuration [80]. By arranging the diodes in this way, the mixer is able to operate in subharmonic mode [81], for which the LO can be at approximately half the signal frequency, which becomes evermore important as the available LO power drops at higher frequencies. Other benefits of the antiparallel configuration include increased RF and IF bandwidth, inherent amplitude noise immunity, and finally allows the LO signal to be fed into the mixer by a completely separate port to the signal, which greatly simplifies the system as a diplexer to combine the signal with the LO frequency, which is no longer required. It is for these reasons that the

subharmonic mixer has become the favorite solution for heterodyne detection on space- or aircraft-based remote sensing instruments [82].

The only real disadvantage of the subharmonic mixer is that it typically requires 2–3 mW of LO power. Consequently, as the signal frequency encroaches 1 THz, current source technology is unable to meet the LO requirement. At this point, the only option for room temperature heterodyne detection is the fundamental Schottky mixer [83] that typically requires only 0.5–1 mW of LO power, albeit at the signal frequency. These have been successfully demonstrated up to 2.5 THz using FIR gas lasers as the LO source [84]. An example of the kind of circuitry required to operate at these wavelengths is shown in Fig. 15.

At this frequency, the circuit dimensions that are required become truly microscopic in order to avoid the parasitic capacitances and inductances that are generated by the tiniest physical features. These can effectively short out the signal if the circuit is not designed carefully. Consequently, novel techniques have been developed to minimize circuit parasitics such

Figure 15. The internal Terahertz circuitry of a 2.5 THz mixer.

as the use of airbridged contacting fingers and substrate removal [85].

3.1.4. Microwave Terahertz Technology: Generation of Terahertz Waves. Detector technology has moved to a sufficient level of maturity that most future advances will come from improved engineering rather than new breakthroughs. In contrast, solid-state generation of sufficient Terahertz power is still a largely unsolved problem. To date, an efficient broad-band room temperature 1 THz (or above) source has eluded workers.

Vacuum devices have been demonstrated up to 1 THz in the form of Backward Wave Oscillators [86], but these have a number of disadvantages for most applications. Primarily they are expensive, require high power, are inefficient, and lifetime is also an issue.

This lack of a simple source is currently impeding commercialization of the Terahertz region. At lower microwave frequencies, complex applications have emerged such as radar and communications. Similar systems could be realized at Terahertz frequencies were a suitable source available.

FIR gas lasers can provide high powers and have recently demonstrated the required reliability, lifetime, and efficiency to fly on a space mission [87]. However, they are still far from ideal.

At present, the most convenient source of RF power at the lower end of the Terahertz region is the indium phosphide (InP) Gunn oscillator. Excellent performance has been demonstrated at room temperature to 150 GHz [88]. More importantly, the InP Gunn oscillator has a very modest DC power requirement of a few Watts. To obtain higher output power levels (several Watts), around 100 GHz power combining power amplifiers, which are now becoming available, have been used [89].

Although sufficient LO power levels for most applications is available to approximately 150 GHz to obtain LO at higher frequencies, it is necessary to frequency multiply, which is achieved by using a nonlinear element to generate higher order harmonics from a pump source. Whereas in a heterodyne mixer, a nonlinear resistance is used to mix frequencies, a frequency multiplier uses a nonlinear capacitance or varactor to generate higher harmonics of the pump frequency. These multipliers generally take the form of doublers (X2) or triplers (X3), or combinations with secondary multipliers to achieve higher multiplication factors. Again, various configurations of diodes are used to realize balanced multipliers. Frequency multipliers have moved forward rapidly recently with the adoption of MEMS-like circuits [90] and the implementation of accurate design tools. The result is that fixed tuned multipliers are now able to provide the LO requirement for SIS and HEB receivers up to 1.5 THz. Unfortunately, it may be some time before they can provide the LO requirement for a Schottky-based system, which would open up true commercialization possibilities with the eradication of the cooling requirement. The reason for the dropoff in performance is because of a fundamental problem in the frequency multiplication process. With each multiplication step, a low efficiency of conversion exists (typically 5–30% [91]), and consequently, power

Figure 16. Close-up of an HBV device.

levels drop exponentially with the increase in frequency. An increase in pump power can be considered but power handling and thermal issues must then be considered. The standard route is to use balanced doublers that share the input power between several diodes. These devices have shown efficiencies in excess of 50% [92], but the low multiplication factor requires a number of stages before 1 THz is reached. The complex matching requirement between successive stages effectively limits the bandwidth of the complete chain.

A relatively new type of nonlinear element, the Heterostructure barrier varactor (see Fig. 16), or HBV, has demonstrated excellent performance [93]. As they have a symmetrical CV characteristic, these devices can greatly simplify the circuit design by canceling even harmonics and thus allowing higher harmonics, such as the 5th and 7th to be generated, which is achieved at the expense of complex material processing. The HBV provides an additional degree of freedom over the varactor because it can be tailored to handle high powers. Heating of the device again can become a problem, so that integral heatsinks and careful material engineering is required.

A Gunn or Transferred Electron Oscillator (TEO) device manufactured from new materials such as GaN has been shown theoretically to offer high powers at frequencies approaching 1 THz [94]. However, there are many manufacturing and design issues to overcome before such devices are realized.

3.1.5. Microwave Terahertz Technology: Integration Technologies. An area that has advanced rapidly is that of Terahertz circuit architecture. Deep lithographic techniques developed for the MEMS industry now offer an alternative to conventional machining of the low-loss waveguide cavities [95]. These techniques offer not only greatly reduced cost but also allow more complex systems to be realized. An example of such technology is shown in Fig. 17.

The image on the left shows the internal features of a 500 GHz subharmonic mixer. The image on the right gives an idea of scale with the finger tips shown holding the

Figure 17. A 500 GHz micromachined sub-harmonic mixer.

complete mixer. The rectangular aperture is the LO input waveguide, which is approximately 800×400 microns in dimension; the signal waveguide is approximately half this size. A recent trend for Terahertz components is to remove as much of the dielectric material from the circuit as possible, which not only provides lower loss but also allows larger circuits to be implemented for the same frequency without the corresponding increase in parasitics. As the circuits have such little mass, it is usually possible to integrate supporting leads into the microstrip or coplanar waveguide circuit [96]. This approach greatly aids assembly, which can become challenging as the frequency increases.

3.1.6. Microwave Terahertz Technology: Design Tools. In the development of components and systems for high millimeter and sub-millimeter waves, the design tools have to cover both quasioptical and “microwave-like” components. This frequency range falls in between the more established domains of microwave and optical design, and considerable debate still exists as to which of the many electromagnetic analysis techniques and physical assumptions should be used for the correct design and analysis. Also, considerable effort is placed on speeding up calculation of large structures using quasioptical techniques while preserving accuracy.

Specific modelling efforts are needed for periodic structures [FSS, EBG, left-handed materials (LHM)] and sub-millimeter components like wiregrids and polarizers. More importantly, however, specific problems exist associated with modeling the complex interactions of these components and little measured data exist to date. To address this deficiency, validation becomes of prime importance.

A similar problem exists in the modeling of active devices. Linear and nonlinear simulation methods for active circuits and MMICs are fairly well established at microwave frequencies. Accurate modeling becomes more difficult with increasing frequency, and the upper frequency limit, where models can be validated, is determined by the available measurement equipment, currently 110 GHz or less. Development of MMICs for frequencies above 110 GHz will require considerable modeling efforts, not only with active devices, but also in constructing and validating the models for passive components, including transmission lines and their discontinuities.

The need for accurate design tools grows with the level of integration. The change from whiskered devices to pla-

nar discrete components creates a “generation gap,” as the change is more fundamental than simply replacing one component with another, and requires a change in the whole design process. A similar gap is encountered in the change from hybrid structures (that use discrete components) to monolithic circuits. Bridging the gap and taking full benefit of the potentials of a new technology requires that the CAD tools develop at a similar pace. For example, circuits at high mm and sub-mm wave frequencies have traditionally suffered from relatively narrow bandwidth, because of the largely empirical design and tuning approach used in their development. Monolithic structures allow broad-band, “tuner-less” operation, but only if a CAD tool is available that can analyze the complete structure, and if the models are valid and sufficiently accurate. A number of commercially available finite element simulation tools are presently on the market, and comparison between simulations and measurements have shown them to have some degree of accuracy providing the exact geometry is known along with the material properties being simulated. As more and more complex Terahertz systems are required, such tools will naturally evolve to fill the need.

3.2. Photonic Terahertz Technologies

Photonic Terahertz technologies have emerged since the late 1980s and are currently the most adaptable and broad-band-based approach to develop active Terahertz systems. The ample capabilities of photonic Terahertz technologies have resulted in a rapid proliferation of this technique from a handful of laser experts to a wide variety of researchers in various disciplines and to the emergence of first commercial systems based on these technologies. Several dedicated overviews have been published on photonic Terahertz technologies [44,97,98] so that only a very condensed summary of this approach is presented here. Although microwave Terahertz technologies clearly evolved from space application oriented device developments (for an overview, see [99]), photonic Terahertz technologies emerged independently as a research tool for the spectroscopic investigation of materials, trying to extend the analytic observation window of existing techniques like Fourier-Transform Infrared (FTIR) spectroscopy to longer and longer wavelengths. At the same time, an important motivator for these developments was the wish to

Figure 18. Scheme of the basic operation principle of an impulsive optical or time-domain Terahertz system.

provide broad-band photonic-based analytical tools for high-frequency electronic developments.

To date, most photonic Terahertz technologies are based on impulsive optical approaches for the generation and detection of electromagnetic radiation in the Terahertz frequency range (see Fig. 18). The general idea of this “time-domain THz spectroscopy” was to make use of ultrafast laser pulses, with a duration of typically less than 100 femtoseconds ($1 \text{ fs} = 10^{-15} \text{ s}$), to enable the optoelectronic activation of emitters and detectors of radiation for a brief moment in time. This concept hence allows sensing or “scanning” the real-time evolution of Terahertz waves by delaying the time-point of the detection event relative to that of the emission, which is easily done by delaying the respective optical laser pulses. This approach facilitates the implementation of coherent (phase-sensitive) detection schemes, which is relevant in terms of noise reduction in order to automatically suppress the unwanted thermal background radiation. Coherence also opens the way to a full range of appealing possibilities, as direct temporal or material thickness information can be derived from measured Terahertz transients, and modern image and object reconstruction algorithms can be implemented.

Two main principles (see Fig. 19) are currently used for the optoelectronic impulsive generation or detection of Terahertz waves. The first approach is based on using photoconductive structures in semiconductors to generate rapid current pulses to emit radiation or to sense Terahertz fields. This concept was initially demonstrated in [100] and allows generation of subpicosecond pulses of radiation with a very broad spectrum and coherent detec-

tion by converting impinging field amplitudes to currents at the time-point the detecting photoconductive structures are activated by a second femtosecond laser. The second concept is based on using nonlinear optical effects to mix electromagnetic fields. This concept was initially derived from Cerenkov radiation experiments and evolved to a first sub-picosecond system [101]. Since these early days, a significant improvement of these more or less “standard” femtosecond (fs) laser-based approaches has been achieved. Although detection efficiency is excellent, much research and improvement is dedicated to increase the efficiency of the emission process (see, e.g., [102]). Time-averaged power levels on the order of $40 \mu\text{W}$ and 1 mW are achieved by using appropriately conceived photoconductive structures with standard fs lasers [103], or amplified fs-laser systems, respectively [2]. Huge bandwidths have been demonstrated with exceptional achievements showing an emission and detection bandwidth extending from a few hundred Gigahertz up to 120 THz [103]. Broad-band analytic systems with a dynamic range of 110 dB in 20 ms have been reported by Brodschelm et al. [104], as well as systems with a 90 dB resolution [105].

Impulsive optical Terahertz technology has given rise to numerous system developments. Specifically, it has allowed the development of active Terahertz imaging systems [52], which have attracted great attention in diverse application fields. Currently, this development has reached a maturity that facilitates the increase in the complexity of Terahertz imaging in diverse areas. Major developments have been directed to enable 3-D spatially resolved analysis [106], and to adapt more sophisticated imaging concepts known from optical imaging, like near-field imaging [107], dark-field imaging [7], microscopic imaging [108] and synthetic phased arrays to increase resolution [109].

Despite the attraction of the developed time-domain Terahertz systems, significant developments have still to be made before video-rate systems for everyday applications can be provided by photonic Terahertz technologies. The essential problem of this approach is the high cost and significant complexity of the underlying femtosecond optical lasers that are used to drive these systems. Several approaches are therefore studied to develop alternatives to standard femtosecond laser-based systems. One evident approach is to minimize the complexity of femtosecond lasers used to drive Terahertz systems. Such approaches are

Figure 19. Schematic of a photoconductive Terahertz emitter/detector structure consisting of a dipole with an integrated metal-semiconductor-metal contact (Auston switch), coplanar waveguides, and contact pads. The left part of the figure depicts a cross section of the Auston switch, when the antenna is operated as a Terahertz emitter.

followed by industry and academia and are either directed at fabricating more compact femtosecond laser systems, or to increase the power output of fiber laser-based concepts.

Another photonic Terahertz technology alternative is to mix two continuous wave (cw) lasers to generate narrow, tunable Terahertz radiation. This approach adopted, e.g., in [110], has reached a remarkable complexity by demonstrating even cw-imaging systems (for an overview, see, e.g., [7]). It is highly attractive to follow this cw-photomixing route, as this concept can be transferred to use standard optical laser diodes, which have a high performance at low costs. Nevertheless, complex stabilization procedures of one laser wavelength with respect to the other have to be implemented to maintain and tune the generated and detected Terahertz radiation. Significant room for improvement in this area still exists, especially in view of the restricted power output of photonic cw-Terahertz sources, as typically more than an order of magnitude less power output is observed in comparison with pulsed sources. Improvements with regard to improved heat dissipation and prevention of charge carrier accumulation by heterostructures appear promising.

Another field that has matured is the development of optical parametric oscillators (OPOs) operating at Terahertz frequencies. Here, the traditional problem is the significant Terahertz absorption of adequate mixing crystals and the difficulty of achieving phase matching over extended crystal lengths. Nevertheless, using nanosecond high-power pulses at low repetition rates, OPOs with remarkable characteristics have been demonstrated [111]. Using parametric oscillation of LiNbO_3 crystals pumped by Q-switched Nd:YAG lasers, widely tunable coherent Terahertz sources in the range between 0.7 and 3 THz with output power levels in the range of 0.9 nJ/pulse have been realized.

A focus of attention in the recent past is the development of solid-state Terahertz lasers based on quantum cascade laser (QCL) approaches (Fig. 20). The initial demonstration of a Terahertz QCL is very recent [112], nevertheless extraordinarily rapid improvements of this technology have been achieved. The most recent progress

in this field is a 3.8 THz QCL working at a temperature of 137 K [113]. Such a high-temperature operation only 2 years after the first realization of Terahertz QCL was not foreseen and gives substantial hope that operation close to room temperature can be achieved. It is interesting to note that the first photonic Terahertz detectors have been demonstrated, inverting the operation regime of similar QCL structures [114].

4. REQUIREMENTS FOR FUTURE APPLICATIONS

4.1. General Requirements of Future Space Applications

The first part of this section identifies the “market pull,” for (sub)millimeter-wave technologies, generated by the future Earth observation and space science missions.

In the area of Earth observation, operational and atmospheric composition missions can be identified, with different levels of certainty.

For the operational missions like Post-EUMETSAT Polar System (Post-EPS) and Post-Meteosat Second Generation (Post-MSG), it seems clear that continuity of the observation data will be required, i.e., the new generation of instruments on polar orbit will cover at least the same frequencies (up to approximately 200 GHz), with a probable extension to higher frequencies.

The main function of current atmospheric sounders is the measurement of the vertical profiles of temperature and water vapor in the troposphere using multiple receivers around the spectral lines of oxygen and water vapor.

Sub-millimeter-wave imagers up to 875 GHz are considered as a potential part of the payload of the follow-up satellites. The main task of these instruments will be the observation of clouds, in particular cirrus clouds, which are one of the major unknowns in the radiative balance of the Earth’s atmosphere.

Atmospheric sounders and imagers will require low-noise instruments operating at multiple frequencies. Increased resolution will lead to the need for low-mass large-diameter reflector systems. The most important change in receiver technology with respect to the first generation sounders is that low-noise amplifiers and MMICs will become available in the near future for frequencies up to 220 GHz.

As low-noise amplifiers are not expected to be available for sub-millimeter-wave frequencies in the near future, heterodyne receivers will be needed. High-performance Schottky mixers operating at or close to room temperature and local oscillators (LO) are required.

Further requirements for sub-millimeter-wave instruments originate from the need to better understand the long-term climatological effects of the chemistry of the atmosphere. It seems likely that future Earth observation missions will include instruments for measuring the various trace gases that have spectral lines at sub-mm-wave frequencies up to 3.5 THz. Device technologies become very critical in low-noise receivers for Terahertz frequencies, especially in the LO generation.

With respect to space science, the most likely sub-millimeter-wave missions are Post-Herschel and Post-Planck.

Figure 20. Semiconductor heterostructure and electronic wave-functions of the first electrically driven quantum cascade laser operating in the Terahertz frequency range [111]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

It can be expected that a follow-up mission to Planck will occur, because of the key role the observations of Cosmic Microwave Background (CMB) has in increasing our understanding of the evolution of the universe. Such follow up would require measurement of the polarization properties of CMB radiation, requiring significant improvements in polarimetric antenna architectures and receivers, because of the extremely low level of the polarized signals.

Herschel has been an important driver for the development of sub-millimeter technologies for over 15 years, both in Europe and in the United States. Significant advances in superconducting device technologies (SIS, HEB) have allowed the development of sensitive heterodyne receivers for frequencies up to 1.9 THz. This development work also allows identification of the LO chain as the critical area where continuing efforts are essential for any future mission involving sub-mm receivers.

American and European astronomers are presently considering options for future Terahertz wavespace astronomy missions. Extrapolating from the past and present projects (space, airborne, and ground-based), and taking into account the still missing areas in observing capabilities (spectral, spatial, and imaging), several model missions have been proposed. Submillimeter-wave polarimetry, interferometry, and imaging systems will be reviewed for their scientific merits, feasibility status, and technical development needs in the frame of post-Planck and Post-Herschel.

The identified technology needs of future missions, and the foreseen missions themselves, are often extrapolations of the existing status, and thus represent “incremental” improvements. It is also important to follow the emergence of new breakthrough technologies (technology push), which may allow completely new solutions. Some candidates for such technologies, ranging from system-level solutions down to novel devices, are listed in the following:

- Interferometry allows resolution essentially better than that achievable by a single aperture. A commendable long-range goal is to achieve Hubble Space Telescope-class resolution in the sub-millimeter-wave range, which would require an imaging interferometer with at least 1 km maximum baseline.
- Imaging arrays are of great interest for space astronomy and for atmospheric research. In astronomy, most of the spectral line emitting regions are usually spatially extended over many observing beams in the sky, and mapping is required to astrophysically understand the regions under study. In atmospheric research, multiple beams would allow push-broom measurements, e.g., in-limb scanning experiments.
- Large arrays of superconducting bolometers (100 × 100 pixels).
- Improve LO power to sufficiently drive mixers.
- Novel artificial materials (EBG, metamaterials) are emerging, and initial studies have shown very promising results. EBG and LHM technology offers promising alternatives to overcome the limitations of the

current technology, and it is envisaged that many new structures will evolve.

- Micro-System Technologies and specifically RF MEMS will allow developing innovative functional concepts to demonstrate adjustability and tunability, which may represent a fundamental change in the way systems are being designed today when the design itself (and the technology) will probably allow compensation for design and fabrication process inaccuracy by the addition of MEMS devices to optimize the structure geometry and therefore its parameters.

4.2. Everyday Applications

In analogy to space applications, also for the everyday use of Terahertz technology, a “market pull” and “technology push” situation is observed.

Starting with the “market pull” emphasis on the application areas identified is given by the intrinsic benefits of Terahertz radiation. Interest is high, especially for imaging and sensing applications in niches where traditional analytic methods have difficulties, although no broad market exists to date. Some of the Terahertz sensing and imaging applications identified by exploratory work are:

- Gas sensing for environmental sensing or combustion/plasma process control [115,116].
- Material characterization, for example, analysis of dielectrics, semiconductors, metals, and – more exotic materials like superconductors [45,47].
- Biomolecular sensing chips for biotechnology and pharmaceutical research [36,37].
- Monitoring chemical content or composition, e.g., during medicament production [39].
- Process monitoring and quality control, e.g., for steel manufacturing [117].
- Imaging through packages or clothes for security issues and drug detection [11].
- Medical imaging, e.g., for early carcinoma detection [28].
- Cellular level imaging, e.g., for analysis of metabolic processes [108].
- Nonionizing dental imaging [29].
- Tomographic imaging, surface reconstruction [10,118].

In general, the fields where Terahertz technology has generated interests are very wide. However, it must be emphasized that many of these applications are currently still at the proof of principle stage and that they still have to meet market-relevant criteria such as cost, reliability, integration, etc., before a broad market penetration can be expected. In contrast to space applications, where Terahertz techniques are regularly used and it is widely accepted that most future scientific breakthroughs in astronomy will stem from Terahertz missions, Terahertz technology for everyday applications has still to meet technological issues before wider acceptance is achieved. Therefore, the “technology push” for everyday applica-

tions is not only a way to optimize or expand solutions, as is the case for space missions. For everyday applications it is imperative and obligatory to enhance the performance, lower the cost, and increase the integration of existing Terahertz technologies to meet the broad market expectations. Areas where crucial technological improvement is expected and required are:

- Compact and efficient Terahertz sources, like quantum cascade Terahertz lasers and quantum optoelectronic cw sources. Here efficiency increase has a two-fold positive implication: Higher efficiency enables the higher output powers that are required for fast high-throughput imaging and sensing solutions. Higher efficiency also enables more compact pump lasers or electronics, which reduce the cost and size of systems solutions.
- Room temperature sensitive detectors are necessary to cope with compact and cost efficient solutions in everyday applications.
- Detection arrays are decisive to enable fast imaging systems in various fields like security scanning, medical imaging, etc.
- Terahertz sensors and sensing elements, e.g., for biomolecular detection, are scarcely available, but necessary in order to realize integrated sensing systems like biochips.

Fundamental system integration technologies need improvement. Here, a close connection to the achieved advances and future expectations of space Terahertz technologies is given, including e.g., interest in emerging artificial materials (EBG, LHM) or the implementation of RF-MEMS.

At the system level, engineering improvements and data acquisition and processing improvements are desired to enable high-throughput sensing and imaging systems. For this purpose also, efficient parallel detection concepts seem promising.

5. SUMMARY/FUTURE

The Terahertz gap appears close to being bridged, which has come about through combined effort from both sides, the photonic side coming down in frequency and the microwave side going up. There is now little to stop Terahertz technology reaching the commercial sector. Many of the key technology requirements are now in place. High-sensitivity detectors exist in both cooled and room temperature form. The mass manufacturability fabrication technology is in place and the design tools necessary for more complex system integration are becoming commercially available. The main missing element is a convenient source of Terahertz power. Cooled lasers have been demonstrated and room temperature solid-state sources have been demonstrated to 1.4 THz, but relatively low powers have been achieved. To some extent, further progress may be realized by scaling up existing technology, but a quantum breakthrough is required before a practical solid-state Terahertz source is realized. The importance of this final step cannot be

understated, the arrival of the Gunn oscillator into the microwave allowed the rapid commercialization of the many applications, and such a simple solution for the Terahertz region would have a similar effect.

1. TRENDS AND NEEDS IN THERMAL MANAGEMENT

1.1. Thermal Packaging Roadmaps

The challenges posed by high chip heat fluxes and ever more stringent performance and reliability constraints make thermal management a key enabling technology in the development of microelectronic systems for the

Table 1. SIA/NEMI Roadmap Product Categories

Product	Description
Low cost— <\$300	Commodity consumer products, disk drives, displays, and microcontrollers
Hand held— <\$1000	Battery-powered products, PDAs, and cellular telephones
Cost/performance— <\$3000	Notebooks, desktop computers, and telecommunications
High performance— >\$3000	High-end workstations, servers, and supercomputers
Harsh environments	Under-the-hood automotive, mining, and resource exploration
Memory	DRAMs and SRAMs

twenty-first century. Thus, thermal packaging efforts must be performed in the context of the salient trends and parameters that characterize the IC technology and the electronic products industry.

Recent road-mapping efforts, including the Semiconductor Industry Association's (SIAs) National Technology Roadmap for Semiconductors [1] and NEMI's National Electronics Manufacturing Technology Roadmap [2], have affirmed the expectation that improvements in CMOS semiconductor technology will continue unabated into the early part of the twenty-first century. Exploiting the potential of this IC technology, with the attendant increase in chip size, switching speed, and transistor density, will necessitate significant improvements in packaging technology. Furthermore, under the influence of growing product complexity, packaging is evolving from an IC technology enabler to a primary electronic product/system differentiator. Consequently, future packaging technology may well be driven primarily by market application requirements, with reduced cost per function providing the major technology development and execution challenges.

The SIA and NEMI roadmaps recognize the six categories of market applications listed in Table 1. Together these categories encompass the majority of the product stream of the semiconductor industry. It is anticipated that system costs will remain fixed in each of these categories, despite ever increasing functionality. It is also assumed that power, voltage, operating, and chip junction temperatures, as well as package thickness, will be determined by market requirements, whereas all other needs are derived from scaling laws or physics-based extrapolations.

Table 2 summarizes the range expected to prevail in the salient IC device characteristics, across the six categories. As may be seen in Table 2, by the year 2006, at the leading edge, chip frequency is expected to reach 1250 MHz with a chip size of 900 mm² and a chip power 140 W. In assessing the technology needed for each of these categories, emphasis was placed on the revenue "center-of-gravity."

Based on these considerations, the NEMI Packaging Working Group determined that the following research and development issues needed to be addressed:

- Arriving innovation with aggressive cost-reduction targets, for all but the Cost-Performance segment
- Achieving the breakthroughs needed for 0.2mm chip thinning and handling
- EMI and noise margin management, for high-speed, low-voltage applications

Integration of design, chip fabrication, assembly and packaging, and test technologies beyond 2001

Anticipation of an accelerating shift from peripheral to area array chip interconnects

The NEMI Working Groups also concluded that significant improvements in thermal management are required to support power-cost targets and that automotive needs ($T_j > 185^\circ\text{C}$) will require new quality and reliability techniques and packaging.

It may thus be seen that the challenges posed by high chip heat fluxes and ever more stringent performance and reliability constraints make thermal management one of the key enabling technologies for microelectronic systems in the twenty-first century. Focusing more specifically on cooling needs, the NEMI Working Groups proposed the following topology for thermal packaging technology:

Commodity products—natural convection

Handheld products—natural convection with heat spreaders

Cost and performance products—forced convection with heatsinks

High-performance products—forced convection, aggressive heatsinking, heat pipes, impingement cooling, and liquid cooling

1.2. Thermal packaging options

When the heat flux is dissipated by an electronic component, device, or assembly and the local ambient temperatures are known and the allowable temperature is specified, the equations of the following sections can be used to determine which heat transfer process or combination of processes (if any) can be employed to meet the desired performance goals. Figure 1 shows the variation of

Table 2. SIA National Technology Roadmap—Parameter Range for 2006

Parameter	Value
Chip frequency	300 to 1250 MHz
Chip size	75 to 900 mm ²
Package inputs/outputs	400 to 2200
Chip power	1 to 28 to 140 W
Junction temperature	100 to 195°C
Ambient temperature	45 to 170°C
Voltage	0.90 to 3.30 V

Figure 1. Temperature differences attainable as a function of heat flux for various heat transfer modes and various coolant fluids [3].

attainable temperature differences with surface heat flux for a variety of heat transfer modes and coolant fluids.

Examination of Fig. 1 reveals that for a typical allowable temperature difference of 60°C between the component surface and the ambient, natural cooling in air, relying on both free convection and radiation, is effective only for heat fluxes below approximately 0.05 W/cm^2 . Although forced convection cooling in air offers approximately an order-of-magnitude improvement in the heat transfer coefficient, this thermal configuration is unlikely to provide heat removal capability in excess of 1 W/cm^2 even at an allowable temperature difference of 100°C .

To facilitate the transfer of moderate and high heat fluxes from component surfaces, the thermal designer must choose between the use of finned air-cooled heatsinks and direct or indirect liquid cooling. Finned arrays and sophisticated techniques for improving convective heat transfer coefficients can extend the effectiveness of air cooling to progressively higher component heat fluxes but often at ever-increasing weight, cost, and volume penalties. Alternatively, reliance on heat transfer to liquids flowing at high velocity through so-called cold plates can offer a dramatic improvement in the transferrable heat flux even at temperature differences as low as 10°C , when the conduction resistance in the cold plate wall is negligible.

A similarly high heat flux capability is offered by boiling heat transfer to fluorochemical liquids. The high dielectric properties of these liquids make it possible to immerse most components. This direct liquid contact allows the removal of component heat fluxes in excess of 10 W/cm^2 with saturated pool boiling at temperature differences typically less than 20°C . Immersion cooling can also offer significant advantages and, as seen in Fig. 1 [3],

serves to bridge the gap between direct air cooling and cold plate technology.

Unfortunately, when addressed within stringent cost targets, the cooling requirements of twenty-first century microelectronic components cannot be met by today's thermal packaging technology. Rather, ways must be sought to improve on currently available technology, to leverage and combine the best features of existing thermal packaging hardware, and to introduce unconventional, perhaps even radical, thermal solutions into the electronic product family. In so doing, attention must be devoted to three primary issues:

1. *Highly Effective Air Cooling.* Removing dissipated power from one or several advanced chips within minimal volumes and with low air-side pressure drops.
2. *Heat Spreading.* Transporting heat from a relatively small area contiguous with the chip to a relatively large heatsink or cold plate base.
3. *Interfacial Heat Transfer.* Thermal resistances between the chip and the next level of thermal packaging.

Attention now turns to a detailed discussion of basic heat transfer and the determination of the various types of thermal resistances often encountered in electronic equipment.

2. THERMAL MODELING

To determine the temperature differences encountered in the flow of heat within electronic systems, it is necessary

to recognize the relevant heat transfer mechanisms and their governing relations. In a typical system, heat removal from the active regions of the microcircuit(s) or chip(s) may require the use of several mechanisms, some operating in series and others in parallel, to transport the generated heat to the coolant or ultimate heatsink. Practitioners of the thermal arts and sciences generally deal with four basic thermal transport modes: conduction, convection, phase change, and radiation.

2.1. Conduction Heat Transfer

2.1.1. One-dimensional Conduction. Steady thermal transport through solids is governed by the Fourier equation, which, in one-dimensional form, is expressible as

$$q = -kA \frac{dT}{dx} \quad (1)$$

where q is the heat flow, k is the thermal conductivity of the medium, A is the cross-sectional area for the heat-flow, and dT/dx is the temperature gradient. As depicted in Fig. 2 [4], heat-flow produced by a negative temperature gradient is considered positive. This convention requires the insertion of the minus sign in Eq. (1) to assure a positive heat flow, q . The temperature difference resulting from the steady-state diffusion of heat is thus related to the thermal conductivity of the material, the cross-sectional area, and the path length, L , according to

$$(T_1 - T_2)_{cd} = q \frac{L}{kA} \quad (2)$$

The form of Eq. (2) suggests that, by analogy to Ohm's Law governing electric current flow through a resistance, it is possible to define a thermal resistance for conduction, R_{cd} , as

$$R_{cd} \equiv \frac{(T_1 - T_2)}{q} = \frac{L}{kA}$$

Figure 2. One-dimensional conduction through a slab [4].

2.1.2. One-Dimensional Conduction with Internal Heat Generation. Situations in which a solid experiences internal heat generation, such as that produced by the flow of an electric current, give rise to more complex governing equations and require greater care in obtaining the appropriate temperature differences. The axial temperature variation in a slim, internally heated conductor subjected to a constant and uniform internal heat generation and whose edges (ends) are held at a temperature T_0 , is found to equal

$$T = T_0 + q_g \frac{L^2}{2k} \left[\left(\frac{x}{L} \right) - \left(\frac{x}{L} \right)^2 \right]$$

When the volumetric heat generation rate, q_g , in watts per cubic meter, is uniform throughout, the peak temperature is developed at the center of the solid and is given by

$$T_{\max} = T_0 + q_g \frac{L^2}{8k}$$

Alternatively, because q_g is the volumetric heat generation, $q_g = q/LW\delta$, the center-edge temperature difference can be expressed as

$$T_{\max} - T_0 = q \frac{L^2}{8kLW\delta} = q \frac{L}{8kA} \quad (3)$$

where the cross-sectional area, A , is the product of the width, W , and the thickness, δ . An examination of Eq. (3) reveals that the thermal resistance of a conductor with a distributed heat input is only one quarter that of a structure in which all of the heat is generated at the center.

In the design of airborne electronic systems and equipment to be operated in a corrosive or damaging environment, it is often necessary to conduct the heat dissipated by the components down into the substrate or printed circuit board (PCB) and, as shown in Fig. 3, across the substrate-PCB to a cold plate or sealed heat exchanger. For a symmetrically cooled substrate-PCB with approximately uniform heat dissipation on the surface, a first estimate of the peak temperature at the center of the board can be obtained by use of Eq. (3).

This relation can be used effectively in the determination of the temperatures experienced by conductively cooled substrates and conventional PCBs, as well as PCB's with copper lattices on the surface, metal cores, or heatsink plates in the center. In each case, it is necessary to evaluate or obtain the effective thermal conductivity of the conducting layer. As an example, consider an alumina substrate, 0.20 m long, 0.15 m wide, and 0.005 m thick with a thermal conductivity of 20 W/mK, whose edges are cooled to 35°C by a cold plate. Assuming that the substrate is populated by 30 components, each dissipating 1 W, the substrate center temperature will equal 85°C when calculated using Eq. (3).

2.1.3. Spreading Resistance. In chip packages that provide for lateral spreading of the heat generated in the chip, the increasing cross-sectional area for heat flow at

Figure 3. Edge-cooled printed circuit board populated with components [4].

successive layers below the chip reduces the internal thermal resistance. Unfortunately, however, there is an additional resistance associated with this lateral flow of heat. This, of course, must be taken into account in the determination of the overall chip package temperature difference.

For the circular and square geometries common in microelectronic applications, Negus et al. [5] provided an engineering approximation for the spreading resistance for a small heatsource on a thick substrate or heat spreader (required to be three to five times thicker than the square root of the heatsource area) can be expressed as

$$R_{sp} = \frac{0.475 - 0.62\varepsilon + 0.13\varepsilon^2}{k\sqrt{A_c}} \quad (4)$$

where ε is the ratio of the heatsource area to the substrate area, k is the thermal conductivity of the substrate, and A_c is the area of the heatsource.

For relatively thin layers on thicker substrates, such as encountered in the use of thin lead frames, or heat spreaders interposed between the chip and substrate, Eq. (4) cannot provide an acceptable prediction of R_{sp} . Instead, use can be made of the numerical results plotted in Fig. 4 to obtain the requisite value of the spreading resistance.

2.1.4. Interface and Contact Resistance. Heat transfer across the interface between two solids is generally accompanied by a measurable temperature difference, which can be ascribed to a contact or interface thermal resistance. For perfectly adhering solids, geometrical differences in the crystal structure (lattice mismatch) can impede the flow of phonons and electrons across the interface, but this resistance is generally negligible in engineering design. When dealing with real interfaces, the asperities present on each of the surfaces, as shown in an artist's conception in Fig. 5, limit actual contact between the two solids to a very small fraction of the apparent interface area. The flow of heat across the gap between two solids in nominal contact is, thus, seen to involve solid conduction in the areas of actual contact and fluid conduction across the open spaces. Radiation across the gap is of increasing importance for elevated surface temperatures and in a vacuum environment when convective and conductive mechanisms are suppressed.

The total contact conductance, h_{co} , is taken as the sum of the solid-to-solid conductance, h_c , and the gap conductance, h_g

$$h_{co} = h_c + h_g \quad (5)$$

Figure 4. The thermal resistance for a circular heatsource on a two-layer substrate [6].

Figure 5. Physical contact between two nonideal surfaces [4].

and the contact resistance based on the apparent contact area, A_a may be defined as

$$R_{co} \equiv \frac{1}{h_{co}A_a} \quad (6)$$

In Eq. (5), h_c is given by Yovanovich and Antonetti [6] as

$$h_c = 1.25k_s \left(\frac{m}{\sigma} \right) \left(\frac{P}{H} \right)^{0.95} \quad (7)$$

where P is the contact pressure and H is the microhardness of the softer material (both in Pa), k_s is the harmonic mean thermal conductivity for the two solids with thermal conductivities, k_1 and k_2 ,

$$k_s = \frac{2k_1k_2}{k_1 + k_2}$$

σ is the effective rms surface roughness developed from the surface roughnesses of the two materials, σ_1 and σ_2 ,

$$\sigma = \sqrt{\sigma_1^2 + \sigma_2^2}$$

and m is the effective absolute surface slope composed of the individual slopes of the two materials, m_1 and m_2 ,

$$m = \sqrt{m_1^2 + m_2^2}$$

In the absence of detailed information, the σ/m ratio can be taken equal to 5–9 μm for relatively smooth surfaces [7].

For normal interstitial gases near atmospheric pressure, h_g in Eq. (5) is given by

$$h_g = \frac{k_g}{Y} \quad (8)$$

where k_g is the thermal conductivity of the gap fluid and Y is the distance between the mean planes given by

$$Y = 1.185 \left[-\ln \left(3.132 \frac{P}{H} \right) \right]^{0.547} \sigma$$

Equations (7) and (8) can be added and, in accordance with Eq. (6), the total contact resistance becomes

$$R_{co} = \left\{ \left[1.25k_s \left(\frac{m}{\sigma} \right) \left(\frac{P}{H} \right)^{0.95} + \frac{k_g}{Y} \right] A_a \right\}^{-1} \quad (9)$$

2.1.5. Transient Heating or Cooling. An internally heated solid, of relatively high thermal conductivity, which is experiencing no external cooling, will undergo a constant rise in temperature according to

$$\frac{dT}{dx} = \frac{q}{mc} \quad (10)$$

where q is the rate of internal heat generation, m is the mass of the solid, and c is the specific heat of the solid. Equation (10) assumes that all of the mass can be represented by a single temperature, and this relation is frequently termed the *lumped capacity* solution for transient heating.

Expanding on the analogy between thermal and electric resistances, the product of mass and specific heat can be viewed as analagous to electric capacitance and thus to constitute the thermal capacitance.

When the same solid is externally cooled, the temperature rises asymptotically toward the steady-state temperature, which is itself determined by the external resistance to the heat flow, R_{ex} . Consequently, the time variation of the temperature of the solid is expressible as

$$T(t) = T(t-0) + qR_{ex}[1 - e^{-t/mcR_{ex}}]$$

The lumped capacitance model is accurate when the ratio of the internal conduction resistance of a solid to the external thermal resistance is small. This ratio is represented by the Biot number (Bi), and the criterion for applicability of the lumped capacitance model is typically given as

$$\text{Bi} = \frac{hL_c}{k} < 0.1$$

where the characteristic length, L_c , is typically defined as the ratio of the solid's volume to its surface area. More generally, L_c should be taken as the distance over

which the solid experiences its maximum temperature difference [8].

2.2. Convective Heat Transfer

2.2.1. The Heat Transfer Coefficient. Convective thermal transport from a surface to a fluid in motion can be related to the heat transfer coefficient, h , the surface-to-fluid temperature difference, and the wetted surface area, S , in the form

$$q = hS(T_s - T_{fl}) \quad (11)$$

The differences among convection to a rapidly moving fluid, a slowly flowing or stagnant fluid, and variations in the convective heat transfer rate for various fluids are reflected in the values of h . For a particular geometry and flow regime, h may be found from available empirical correlations and/or theoretical relations. Use of Eq. (11) makes it possible to define the convective thermal resistance as

$$R_{cv} \equiv \frac{1}{hS}$$

2.2.2. Dimensionless Parameters. Common dimensionless quantities that are used in the correlation of heat transfer data are the *Nusselt number*, Nu , which relates the convective heat transfer coefficient to the conduction in the fluid where the subscript, fl , pertains to a fluid property,

$$Nu \equiv \frac{h}{k_{fl}/L} = \frac{hL}{k_{fl}}$$

the *Prandtl number*, Pr , which is a fluid property parameter relating the diffusion of momentum to the conduction of heat,

$$Pr \equiv \frac{c_p \mu}{k_{fl}}$$

the *Grashof number*, Gr , which accounts for the buoyancy effect produced by the volumetric expansion of the fluid,

$$Gr \equiv \frac{\rho^2 \beta g L^3 \Delta T}{\mu^2}$$

and the *Reynolds number*, Re , which relates the momentum in the flow to the viscous dissipation,

$$Re \equiv \frac{\rho VL}{\mu}$$

2.2.3. Natural Convection. Despite increasing performance demands and advances in thermal management technology, direct air-cooling of electronic equipments continues to command substantial attention. Natural convection is the quietest, least expensive, and most reliable

implementation of direct fluid cooling. In more demanding systems, natural convection cooling with air is often investigated as a baseline design to justify the application of more sophisticated techniques.

In natural convection, fluid motion is induced by density differences resulting from temperature gradients in the fluid. The heat transfer coefficient for this regime can be related to the buoyancy and the thermal properties of the fluid through the *Rayleigh number*, Ra , which is the product of the Grashof and Prandtl numbers,

$$Ra = \frac{\rho^2 \beta g c_p}{\mu k_{fl}} L^3 \Delta T$$

where the fluid properties, ρ , β , c_p , μ , and k , are evaluated at the fluid bulk temperature, and ΔT is the temperature difference between the surface and the fluid.

Empirical correlations for the natural convection heat transfer coefficient generally take the form

$$Nu \equiv C(Ra)^n$$

where n is found to be approximately 0.25 for $10^3 < Ra < 10^9$, representing laminar flow, 0.33 for $10^9 < Ra < 10^{12}$, the region associated with the transition to turbulent flow, and 0.4 for $Ra > 10^{12}$, when strong turbulent flow prevails. The precise value of the correlating coefficient, C , depends on fluid, the geometry of the surface, and the Rayleigh number range. Nevertheless, for common plate, cylinder, and sphere configurations, it has been found to vary in the relatively narrow range of 0.45 to 0.65 for laminar flow and 0.11 to 0.15 for turbulent flow past the heated surface [3].

2.2.4. Vertical Channels. Vertical channels formed by parallel PCBs or longitudinal fins are a frequently encountered configuration in natural convection cooling of electronic equipment. The historical work of Elenbaas [9], a milestone of experimental results and empirical correlations, was the first to document a detailed study of natural convection in smooth, isothermal parallel plate channels. In subsequent years, this work was confirmed and expanded both experimentally and numerically by a number of researchers, including Bodia and Osterle [10], Sobel et al. [11], Aung [12], Aung et al. [13], Miyatake and Fujii [14], and Miyatake et al. [15].

These studies have revealed that the value of the Nusselt number lies between two extremes associated with the separation between the plates or the channel width. For wide spacing, the plates appear to have little influence on one another and the Nusselt number in this case achieves its *isolated plate limit*. On the other hand, for closely spaced plates or for relatively long channels, the fluid attains its *fully developed* value and the Nusselt number reaches its *fully developed limit*. Intermediate values of the Nusselt number can be obtained from a composite expression for smoothly varying processes and have been verified by the detailed experimental and numerical studies of BarCohen and Rohsenow [16].

For an isothermal channel, at the fully developed limit, the Nusselt number takes the form

$$\text{Nu} = \frac{\text{El}}{C_1 \mathcal{A}} \quad (12)$$

where El is the Elenbaas number, defined as

$$\text{El} \equiv \frac{c_p \rho^2 g \beta (T_w - T_{\text{amb}}) H^4}{\mu k l}$$

where H is the channel spacing, l is the channel length, and $(T_w - T_{\text{amb}})$ is the temperature difference between the channel wall and the ambient, or channel, inlet. For an asymmetric channel, or one in which one wall is heated and the other is insulated, the appropriate value of C_1 is 12, whereas for a symmetrically heated channel, $C_1 = 24$.

For an isoflux channel, at the fully developed limit, the Nusselt number has been shown to take the form

$$\text{Nu} = \sqrt{\frac{\text{El}'}{C_1}} \quad (13)$$

where the modified Elenbaas number, El' , is defined as

$$\text{El}' \equiv \frac{c_p \rho^2 g \beta q'' H^5}{\mu K^2 l}$$

where q'' is the heat flux leaving the channel wall(s). When this Nusselt number is based on the maximum wall temperature ($x=l$), the appropriate values of C_1 are 24 and 48 for the asymmetric and symmetric cases, respectively. When based on the midheight ($x=l/2$) wall temperature, the asymmetric and symmetric C_1 values are 6 and 12, respectively.

In the limit where the channel spacing is very large, the opposing channel walls do not influence each other either hydrodynamically or thermally. This situation may be accurately modeled as heat transfer from an isolated vertical surface in an infinite medium. Natural convection from an isothermal plate can be expressed as

$$\text{Nu} = C_2 \text{El}^{1/4} \quad (14)$$

where McAdams [17] suggests a C_2 value of 0.59. Natural convection from an isoflux plate is typically expressed as

$$\text{Nu} = C_2 \text{El}^{1/5} \quad (15)$$

with a leading coefficient of 0.631 when the Nusselt number is based on the maximum ($x=l$) wall temperature and 0.73 when the Nusselt number is based on the midheight ($x=l/2$) wall temperature.

2.2.5. Composite Equations. When a function is expected to vary smoothly between two limiting expressions, which are themselves well defined, and when intermediate values are difficult to obtain, an approximate composite relation can be obtained by appropriately summing the

two limiting expressions. Using the Churchill and Usagi [18] method, BarCohen and Rohsenow [19] developed composite Nusselt number relations for natural convection in parallel plate channels of the form

$$\text{Nu} = [(\text{Nu}_{\text{fd}})^{-n} + (\text{Nu}_{\text{ip}})^{-n}]^{-1/n} \quad (16)$$

where Nu_{fd} and Nu_{ip} are Nusselt numbers for the fully developed and isolated plate limits, respectively. The correlating exponent n was given a value of 2 to offer good agreement with Elenbaas's [9] experimental results.

For an isothermal channel, combining Eqs. (12) and (14) yields a composite relation of the form

$$\text{Nu}_{\text{comp}} = \left[\frac{C_3}{\text{El}^2} + \frac{C_4}{\sqrt{\text{El}}} \right]^{-1/2} \quad (17)$$

whereas for an isoflux channel, Eqs. (13) and (15) yield a result of the form

$$\text{Nu}_{\text{comp}} = \left[\frac{C_3}{\text{El}'} + \frac{C_4}{\text{El}'^{2/5}} \right]^{-1/2} \quad (18)$$

Values of the coefficients C_3 and C_4 appropriate to various cases of interest appear in Table 3.

In electronic cooling applications where volumetric concerns are not an issue, it is desirable to space the PCBs far enough apart that the isolated plate Nusselt number prevails along the surface. In lieu of choosing an infinite plate spacing, the composite Nusselt number may be set equal to 99%, or some other high fraction, of its associated isolated plate value. The composite Nusselt number relation may then be solved for the appropriate channel spacing.

For an isothermal channel, the channel spacing that maximizes the rate of heat transfer from individual PCBs takes the form

$$H_{\text{max}} = \frac{C_5}{P^{1/4}} \quad (19)$$

where

$$P = \frac{c_p \rho^2 g \beta (T_w - T_{\text{amb}})}{\mu k l} = \frac{\text{El}}{H^4}$$

whereas for an isoflux channel, the channel spacing that minimizes the PCB temperature for a given heat flux takes the form

$$H_{\text{max}} = \frac{C_5}{R^{1/5}} \quad (20)$$

where

$$R = \frac{c_p \rho^2 g \beta q''}{\mu k^2 l} = \frac{\text{El}'}{H^5}$$

Values of the coefficient C_5 appropriate to various cases of interest appear in Table 3.

Table 3. Appropriate Values of the C_i Coefficients Appearing in Eqs. (12)–(25)

Case	C_1	C_2	C_3	C_4	C_5	C_6	C_7
<i>Isothermal</i>							
In general	X	Y	X^2	Y^{-2}	$\left(\frac{X^2Y^2(0.99)^2}{1 - (0.99)^2}\right)^{1/6}$	$\frac{1}{(XY)^2}$	$(\sqrt{2XY})^{1/3}$
Symmetric heating	24	0.59	576	2.87	4.63	0.0050	2.72
Asymmetric heating	12	0.59	144	2.87	3.68	0.0199	2.16
<i>Isoflux</i>							
In general	X	Y	X	Y^{-2}	$\left(\frac{XY^2(0.99)^2}{1 - (0.99)^2}\right)^{1/3}$	$\frac{2}{(XY)^2}$	$\left(\frac{XY^2}{2}\right)^{1/3}$
Symmetric heating							
maximum temp.	48	0.63	48	2.52	9.79	0.105	2.12
midheight temp.	12	0.73	12	1.88	6.80	0.313	1.47
Asymmetric heating							
maximum temp.	24	0.63	24	2.52	7.77	0.210	1.68
midheight temp.	6	0.73	6	1.88	5.40	0.626	1.17

2.2.6. Optimum Spacing. In addition to being used to predict heat transfer coefficients, the composite relations presented may be used in optimizing the spacing between PCBs. For isothermal arrays, the optimum spacing maximizes the total heat transfer from a given base area or the volume assigned to an array of PCBs. In the case of isoflux parallel plate arrays, the total array heat transfer for a given base area may be maximized by increasing the number of plates indefinitely. Thus, it is more practical to define the optimum channel spacing for an array of isoflux plates as that spacing that will yield the maximum volumetric heat dissipation rate per unit temperature difference. Despite this distinction, the optimum spacing is found in the same manner.

The total heat transfer rate from an array of vertical, single-sided plates can be written as

$$\frac{Q_T}{l_s W k \Delta T} = \left(\frac{Nu}{H(H+d)} \right) \tag{21}$$

where the number of plates, $m = W/(H+d)$, d is the plate thickness, W is the width of the entire array, and s is the depth of the channel. The optimum spacing may be found by substituting the appropriate composite Nusselt number equation into Eq. (21), taking the derivative of the resulting expression with respect to H , and setting the result equal to zero. Use of the isothermal composite Nusselt number of Eq. (21) yields a relation of the form

$$(2b + 3d - C_6 P^{3/2} b^7)_{opt} = 0 \tag{22}$$

or

$$b_{opt} = \frac{C_7}{P^{1/4}} \tag{23}$$

when d , the PCB thickness, is negligible. Use of an isoflux composite Nusselt number yields

$$(b + 3d - C_6 R^{3/5} b^4)_{opt} = 0 \tag{24}$$

or

$$b_{opt} = \frac{C_7}{R^{1/5}} \quad (d=0) \tag{25}$$

Values of the coefficients C_6 and C_7 appropriate to various cases of interest appear in Table 3.

2.2.7. Limitations. These smooth plate relations have proven useful in a wide variety of applications and have been shown to yield very good agreement with measured empirical results for heat transfer from arrays of PCBs. However, when applied to closely spaced PCBs, these equations tend to underpredict heat transfer in the channel because of the presence of between-package wall flow and the nonsmooth nature of the channel surfaces [20].

2.2.8. Forced Convection. For forced laminar flow in long, or very narrow, parallel-plate channels, the heat transfer coefficient attains an asymptotic value (a fully developed limit), which for symmetrically heated channel surfaces is equal approximately to

$$h = \frac{4k_f}{d_e}$$

where d_e is the *hydraulic diameter* defined in terms of the flow area, A , and the wetted perimeter of the channel, P_w

$$d_e \equiv \frac{4A}{P_w}$$

In the inlet zones of such parallel-plate channels and along isolated plates, the heat transfer coefficient varies with the distance from the leading edge. The low-velocity or laminar flow average convective heat transfer coefficient for $Re < 2 \times 10^5$ is given by [3]

$$h = 0.664 \left(\frac{k}{L} \right) Re^{1/2} Pr^{1/3} \tag{26}$$

where k is the fluid thermal conductivity and L is the characteristic dimension of the surface.

A similar relation applies to flow in tubes, pipes, ducts, channels, and/or annuli with the equivalent diameter, d_e , serving as the characteristic dimension in both the Nusselt and Reynolds numbers. For laminar flow, $Re \leq 2100$

$$\frac{hd_e}{k} = 1.86 \left[\text{Re Pr} \left(\frac{d_e}{L} \right) \right]^{1/3} \left(\frac{\mu}{\mu_w} \right)$$

which is attributed to Sieder and Tate [21] and where μ_w is the viscosity of the convective medium at the wall temperature. Observe that this relationship shows that the heat transfer coefficient attains its maximum value for short channels and decreases as L increases.

In higher velocity turbulent flow, the dependence of the convective heat transfer coefficient on the Reynolds number increases and, in the range $Re \geq 3 \times 10^5$, is typically given by [3]

$$h = 0.036 \left(\frac{k}{L} \right) (\text{Re})^{0.80} (\text{Pr})^{1/3} \quad (27)$$

In pipes, tubes, channels, ducts, and/or annuli, turbulent flow occurs at an equivalent diameter based Reynolds number of 10,000 with the flow regime bracketed by

$$2110 \leq \text{Re} \leq 10,000$$

usually referred to as the transition region. Hausen [22] has provided the correlation

$$\frac{hd_e}{k} = 0.116[\text{Re} - 125](\text{Pr})^{1/3} \left(1 + \frac{d_e}{L} \right)^{2/3} \left(\frac{\mu}{\mu_w} \right)$$

and Sieder and Tate [21] give for turbulent flow

$$\frac{hd_e}{k} = 0.23(\text{Re})^{0.80} (\text{Pr})^{1/3} \left(\frac{\mu}{\mu_w} \right)$$

Additional correlations for the coefficient of heat transfer in forced convection for various configurations may be found in the heat transfer textbooks [8,23–25].

2.2.9. Phase Change Heat Transfer. When heat exchange is accompanied by evaporation of a liquid or condensation of a vapor, the resulting flow of vapor toward or away from the heat transfer surface and the high rates of thermal transport associated with the latent heat of the fluid can provide significantly higher heat transfer rates than single phase heat transfer alone.

2.2.10. Boiling. Boiling heat transfer displays a complex dependence on the temperature difference between the heated surface and the saturation temperature (boiling point) of the liquid. In nucleate boiling, the primary region of interest, the ebullient heat transfer rate is typically expressed in the form of the Rohsenow [26] equation

$$q = \mu_f h_{fg} \sqrt{\frac{g(\rho_f - \rho_g)}{\sigma}} \left[\frac{c_{pf}}{C_{sf} \text{Pr}_f^{1.7} h_{fg}} \right]^{1/r} (T_s - T_{\text{sat}})^{1/r} \quad (28)$$

where $1/r$ is typically correlated with a value of three, and C_{sf} is a function of characteristics of the surface–fluid combination. Rohsenow recommended that the fluid properties in Eq. (28) be evaluated at the liquid saturation temperature.

For pool boiling of the dielectric liquid FC-72 ($T_{\text{sat}} = 56^\circ\text{C}$ at 101.3 kPa) on a plastic-pin-grid-array (PPGA) chip package, Watwe [27] obtained values of 7.47 for $1/r$ and 0.0075 for C_{sf} . At a surface heat flux of 10 W/cm^2 , the wall superheat at 101.3 kPa is nearly 30°C , corresponding to a average surface temperature of approximately 86°C .

The departure from nucleate boiling, or critical heat flux (CHF), places an upper limit on the use of the highly efficient boiling heat transfer mechanism. CHF can be significantly influenced by system parameters such as pressure, subcooling, heater thickness and properties, and dissolved gas content. Watwe et al. [28] presented the following equation to predict the pool boiling critical heat flux of dielectric coolants on a horizontal surface and under a variety of parametric conditions.

$$\begin{aligned} \text{CHF} = & \left\{ \frac{\pi}{24} h_{fg} \sqrt{\rho_g} [\sigma_f g (\rho_f - \rho_g)]^{1/4} \right\} \left(\frac{\delta \sqrt{\rho_h c_{ph} k_h}}{\delta \sqrt{\rho_h c_{ph} k_h} + 0.1} \right) \\ & \times \{ 1 + [0.3014 - 0.01507L/P] \} \\ & \times \left\{ 1 + 0.03 \left[\left(\frac{\rho/f}{\rho/g} \right)^{0.75} \frac{c_{pf}}{h_{fg}} \Delta T_{\text{sub}} \right] \right\} \quad (29) \end{aligned}$$

The first term on the right-hand side of Eq. (29) is the classical Kutateladze–Zuber prediction, which is in the upper limit on the saturation value of CHF on very large heaters. The second term represents the effects of heater thickness and thermal properties on the critical heat flux. The third term in Eq. (29) accounts for the influence of the length scale. The last term is an equation representing the best-fit line through the experimental data of Watwe et al. [28] and represents the influence of subcooling on CHF. The pressure effect on CHF is embodied in the Kutateladze–Zuber and the subcooling model predictions, which make up Eq. (29), via the thermophysical properties. Thus, it can be used to estimate the combined influences of various system and heater parameters on CHF. The critical heat flux, under saturation conditions at atmospheric pressure, for a typical dielectric coolant like FC-72 is approximately 17 W/cm^2 .

2.2.11. Condensation. Closed systems involving an evaporative process must also include some capability for vapor condensation. Gerstmann and Griffith [29] correlated film condensation on a downward-facing flat plate as

$$\text{Nu} = 0.81 \text{Ra}^{0.193} \quad 10^{10} > \text{Ra} > 10^8$$

$$\text{Nu} = 0.69 \text{Ra}^{0.20} \quad 10^8 > \text{Ra} > 10^6$$

where

$$\text{Nu} \equiv \frac{h}{k} \left(\frac{\sigma}{g(\rho_f - \rho_g)} \right)^{1/2}$$

$$\text{Ra} \equiv \frac{g\rho_f(\rho_f - \rho_g)h_{fg}}{k\mu\Delta T} \left(\frac{\sigma}{g(\rho_f - \rho_g)} \right)^{3/2}$$

The Nusselt number for laminar film condensation on vertical surfaces was correlated by Nusselt [30] and later modified by Sadasivan and Lienhard [31] as

$$\text{Nu} = \frac{hL}{k_f} = 0.943 \left[\frac{g\Delta\rho_{fg}L^3h'_{fg}}{k_f\nu_f(T_{\text{sat}} - T_c)} \right]^{1/4}$$

where

$$h'_{fg} = h_{fg}(1 + C_c Ja)$$

$$C_c = 0.683 - \frac{0.228}{\text{Pr}_l}$$

$$Ja = \frac{c_{\text{pf}}(T_{\text{sat}} - T_c)}{h_{fg}}$$

2.2.12. Flow Resistance. The transfer of heat to a flowing gas or liquid that is not undergoing a phase change results in an increase in the coolant temperature from an inlet temperature of T_{in} to an outlet temperature of T_{out} , according to

$$T_{\text{out}} - T_{\text{in}} = \frac{q}{\dot{m}c_p}$$

To facilitate the use of a resistance network representation for the analysis of convectively cooled packaging configurations, it is possible to use the above equation to define an effective flow resistance, R_{f1} , as

$$R_{f1} \equiv \frac{1}{\dot{m}c_p} \quad (30)$$

where \dot{m} , the mass flowrate, is given in kilograms per second.

In multicomponent systems, determination of individual component temperatures requires knowledge of the fluid temperature adjacent to the component. The rise in fluid temperature relative to the inlet value can be expressed in a flow thermal resistance, as in Eq. (30). When the coolant flow path traverses many individual components, care must be taken to use R_{f1} with the total heat absorbed by the coolant along its path, rather than the heat dissipated by an individual component. For system-level calculations aimed at determining the average component temperature, it is common to base the flow resistance on the average rise in fluid temperature, that is, one-half the value indicated by Eq. (30).

2.3. Radiative Heat Transfer

Unlike conduction and convection, radiative heat transfer between two surfaces or between a surface and its

surroundings is not linearly dependent on the temperature difference and is expressed instead as

$$q = \sigma S \mathcal{F} (T_1^4 - T_2^4)$$

where \mathcal{F} includes the effects of surface properties and geometry and σ is the Stefan–Boltzmann constant, $\sigma = 5.67 \times 10^{-8} \text{ W/m}^2 \cdot \text{K}^4$. For modest temperature differences, this equation can be linearized to the form

$$q = h_r S (T_1 - T_2) \quad (31)$$

where h_r is the effective radiation heat transfer coefficient

$$h_r = \sigma \mathcal{F} (T_1^2 + T_2^2)(T_1 + T_2)$$

and, for small $\Delta T = T_1 - T_2$, h_r is approximately equal to

$$h_r = 4\sigma \mathcal{F} (T_1 T_2)^{3/2}$$

It is of interest to note that for temperature differences of the order of 10 K with absolute temperatures around room temperature, the radiative heat transfer coefficient, h_r , for an ideal (or black) surface in an absorbing environment, is approximately equal to the heat transfer coefficient in natural convection of air.

Noting the form of Eq. (31), the radiation thermal resistance, analogous to the convective resistance, is seen to equal

$$R_r = \frac{1}{h_r S}$$

3. THERMAL RESISTANCE NETWORKS

The expression of the governing heat transfer relations in the form of thermal resistances greatly simplifies the first-order thermal analysis of electronic systems. Following the established rules for resistance networks, thermal resistances that occur sequentially along a thermal path can be simply summed to establish the overall thermal resistance for that path. In similar fashion, the reciprocal of the effective overall resistance of several parallel heat transfer paths can be found by summing the reciprocals of the individual resistances. In refining the thermal design of an electronic system, prime attention should be devoted to reducing the largest resistances along a specified thermal path and/or providing parallel paths for heat removal from a critical area.

Although the thermal resistances associated with various paths and thermal transport mechanisms constitute the building blocks in performing a detailed thermal analysis, they have also found widespread application as figures of merit in evaluating and comparing the thermal efficacy of various packaging techniques and thermal management strategies.

3.1. Chip Module Thermal Resistances

3.1.1. Definition. The thermal performance of alternative chip and packaging techniques is commonly compared on the basis of the overall (junction-to-coolant) thermal resistance, R_T . This packaging figure-of-merit is generally defined in a purely empirical fashion,

$$R_T \equiv \frac{T_j - T_{f1}}{q_c}$$

where T_j and T_{f1} are the junction and coolant (fluid) temperatures, respectively, and q_c is the chip heat dissipation.

Unfortunately, however, most measurement techniques are incapable of detecting the actual junction temperature, that is, the temperature of the small volume at the interface of p -type and n -type semiconductors. Hence, this term generally refers to the average temperature or a representative temperature on the chip.

Examination of various packaging techniques reveals that the junction-to-coolant thermal resistance is, in fact, composed of an internal, largely conductive, resistance and an external, primarily convective, resistance. As shown in Fig. 6, the internal resistance, R_{jc} , is encountered in the flow of dissipated heat from the active chip surface through the materials used to support and bond the chip and onto the case of the integrated circuit package. The flow of heat from the case directly to the coolant, or indirectly through a fin structure and then to the coolant, must overcome the external resistance, R_{ex} .

3.1.2. Internal Thermal Resistance. As previously discussed, conductive thermal transport is governed by the Fourier equation, which can be used to define a conduction thermal resistance, as in Eq. (3). In flowing from the chip to the package surface or case, the heat encounters a series of resistances associated with individual layers of materials such as silicon, solder, copper, alumina, and epoxy, as well as the contact resistances that occur at the interfaces between pairs of materials. Although the actual

heat-flow paths within a chip package are rather complex and may shift to accommodate varying external cooling situations, it is possible to obtain a first-order estimate of the internal resistance by assuming that power is dissipated uniformly across the chip surface and that heat flow is largely one-dimensional. To the accuracy of these assumptions, Eq. (32)

$$R_{jc} = \frac{T_j - T_c}{q_c} = \sum \frac{x}{kA} \tag{32}$$

can be used to determine the internal chip module resistance, where the summed terms represent the conduction thermal resistances posed by the individual layers, each with thickness x . As the thickness of each layer decreases and/or the thermal conductivity and cross-sectional area increase, the resistance of the individual layers decreases. Values of R_{cd} for packaging materials with typical dimensions can be found using Eq. (32) or Fig. 7, to range from 2 K/W for a 1000 mm² by 1 mm thick layer of epoxy encapsulant to 0.0006 K/W for a 100 mm² by 25 μm (1 mil) thick layer of copper. Similarly, the values of conduction resistance for typical soft bonding materials are found to lie in the range of approximately 0.1 K/W for solders and 1 K/W–3 K/W for epoxies and thermal pastes for typical x/A ratios of 0.25 to 1.0.

Comparison of theoretical and experimental values of R_{jc} reveals that the resistances associated with compliant, low thermal conductivity bonding materials, and the spreading resistances, as well as the contact resistances at the lightly loaded interfaces within the package, often dominate the internal thermal resistance of the chip package. Thus, it is not only necessary to correctly determine the bond resistance but to also add the values of R_{sp} , obtained from Eq. (4) and/or Fig. 4, and R_{co} from Eqs. (6) or (9) to the junction-to-case resistance calculated from Eq. (32). Unfortunately, the absence of detailed information on the void in the die-bonding and heatsink attach layers and the present inability to determine, with precision,

Figure 6. Primary thermal resistances in a single-chip package [4].

Figure 7. Conductive thermal resistances for packaging materials [4].

the contact pressure at the relevant interfaces, conspire to limit the accuracy of this calculation.

3.1.3. External Resistance. An application of Eqs. (26) or (27) to the transfer of heat from the case of a chip module to the coolant shows that the external resistance, $R_{ex} = 1/hS$, is inversely proportional to the wetted surface area and to the coolant velocity to the 0.5 to 0.8 power and directly proportional to the length scale in the flow direction to the 0.5 to 0.2 power. It may, thus, be observed that the external resistance can be strongly influenced by the fluid velocity and package dimensions and that these factors must be addressed in any meaningful evaluation of the external thermal resistances offered by various packaging technologies.

Values of the external resistance, for a variety of coolants and heat transfer mechanisms, are shown in Fig. 8 for a typical component wetted area of 10cm^2 and a velocity range of 2m/s to 8m/s. They are seen to vary from a nominal 100 K/W for natural convection in air, to 33 K/W for forced convection in air, to 1 K/W in fluorocarbon liquid forced convection, and to less than 0.5 K/W for boiling in fluorocarbon liquids. Clearly, larger chip packages will experience proportionately lower external resistances than the displayed values. Moreover, conduction of heat through the leads and package base into the PCB or substrate will serve to further reduce the effective thermal resistance.

Figure 8. Typical external (convective) thermal resistances for various coolants and cooling modes [4].

In the event that the direct cooling of the package surface is inadequate to maintain the desired chip temperature, it is common to attach finned heatsinks, or compact heat exchangers, to the chip package. These heatsinks can considerably increase the wetted surface area but may act to reduce the convective heat transfer coefficient by obstructing the flow channel. Similarly, the attachment of a heatsink to the package can be expected to introduce additional conductive resistances in the adhesive used to bond the heatsink and in the body of the heatsink. Typical air-cooled heatsinks can reduce the external resistance to approximately 10 K/W to 15 K/W in natural convection and to as low as 3 K/W to 5 K/W for moderate forced convection velocities.

When a heatsink or compact heat exchanger is attached to the package, the external resistance accounting for the bond-layer conduction and the total resistance of the heatsink, R_{sk} , can be expressed as

$$R_{ex} = \frac{T_c - T_{fl}}{q_c} = \sum \left(\frac{x}{kA} \right)_b + R_{sk} \quad (33)$$

where R_{sk}

$$R_{sk} = \left[\frac{1}{nhS_f\eta} + \frac{1}{h_bS_b} \right]^{-1}$$

is the parallel combination of the resistance of the n fins

$$R_f = \frac{1}{nhS_f\eta}$$

and the *bare* or base surface not occupied by the fins

$$R_b = \frac{1}{h_bS_b}$$

Here, the base surface is $S_b = S - S_f$ and the heat transfer coefficient, h_b , is used because the heat transfer coefficient that is applied to the base surfaces is not necessarily equal to that applied to the fins.

An alternative expression for R_{sk} involves an *overall surface efficiency*, η_0 , defined by

$$\eta_0 = 1 - \frac{nS_f}{S}(1 - \eta)$$

where S is the total surface composed of the base surface and the finned surfaces of n fins

$$S = S_b + nS_f$$

In this case, it is presumed that $h_b = h$, so that

$$R_{sk} = \frac{1}{h\eta_0S}$$

In an optimally designed fin structure, η can be expected to fall in the range of 0.50 to 0.70 [4]. Relatively thick fins in a low velocity flow of gas are likely to yield fin

efficiencies approaching unity. This same unity value would be appropriate, as well, for an unfinned surface and, thus, serve to generalize the use of Eq. (33) to all package configurations.

3.1.4. Total Resistance of Single-Chip Packages. To the accuracy of the assumptions employed in the preceding development, the overall single-chip package resistance, relating the chip temperature to the inlet temperature of the coolant, can be found by summing the internal, external, and flow resistances to yield

$$\begin{aligned} R_T &= R_{jc} + R_{ex} + R_{fl} \\ &= \sum \frac{x}{kA} + R_{int} + R_{sp} \frac{1}{\eta h A} + \left(\frac{Q}{q} \right) \left(\frac{1}{2\rho Q c_p} \right) \end{aligned} \quad (34)$$

In evaluating the thermal resistance by this relationship, care must be taken to determine the effective cross-sectional area for heat flow at each layer in the module and to consider possible voids in any solder and adhesive layers.

As previously noted in the development of the relationships for the external and internal resistances, Eq. (34) shows R_T to be a strong function of the convective heat transfer coefficient, the flowing heat capacity of the coolant, and their geometric parameters (thickness and cross-sectional area of each layer). Thus, the introduction of a superior coolant, use of thermal enhancement techniques that increase the local heat transfer coefficient, or selection of a heat transfer mode with inherently high heat transfer coefficients (boiling, for example) will all be reflected in appropriately lower external and total thermal resistances. Similarly, improvements in the thermal conductivity and reduction in the thickness of the relatively low conductivity bonding materials (such as soft solder, epoxy, or silicone) would act to reduce the internal and total thermal resistances.

3.1.5. Applications of R_{jc} . The commonly used junction-to-case thermal resistance, relying on just a single case temperature, can be used with confidence only in the relatively unlikely circumstance that the package case is isothermal. In a more typical packaging configuration, when substantial temperature variations are encountered among and along the external surfaces of the package, Andrews [32], Furkay [33], and Wilson [34], among others, showed that the use of the reported R_{jc} can lead to grossly erroneous chip temperature predictions, which is especially of concern in the analysis and design of plastic chip packages, because of the inherently high thermal resistance of the plastic encapsulant and the package anisotropies introduced by the large differences in the conductivity and the resulting conductance between the lead frame and/or heat spreader and the plastic encapsulant. Although the use of R_{ja} is best suited to the determination of the actual chip temperature, not only does it contain the drawbacks of R_{jc} , but the variability of the convective (external) component in R_{ja} makes this an inappropriate parameter for the thermal characterization of the chip package itself.

Despite these limitations, the persistent demand for chip temperature prediction and control has sustained the use of the R_{ja} and R_{jc} metrics in the thermal characterization of chip packages. As an alternative, it is possible to model a chip package with a resistor network, in which each of the primary thermal paths is represented by a single thermal resistor, typically connecting the chip to one of the external package surfaces. This compact model approach was discussed and illustrated by Krueger and Bar-Cohen [35] and Bar-Cohen and Krueger [36] and was implemented by the French Telecom Research Centre (CNET) in creating a databank for thermal characteristics of electronic components used in the telecommunication industry [37]. When calibrated with empirical data, such a resistor network model could provide a universal thermal representation of a chip package, which is nearly independent of the package attachment and cooling configuration. Using this model, the design engineer could then determine the chip temperature as a function of known temperatures and/or heat transfer relations at each of the exposed surfaces.

Recognition of the popularity and longevity of the single-valued, junction-to-case thermal resistance leads to a recasting of the chip package thermal network model in the form of surface-weighting factors, which could be used to obtain the appropriate average case temperature for various thermal packaging configurations. This approach makes it possible to extend the use of the conventional R_{jc} to situations in which the exterior case is highly nonisothermal, including thermal insulation of one or more surfaces.

3.2. R_{jc} with Weighted Average Case Temperature

As R_{jc} is strictly valid only for an isothermal package surface, a method must be found to address the individual contributions of the various surface segments according to their influence on the junction temperature. In Section 3.2.1., the theory and assumptions underpinning this approach and the derivation of the relevant “thermal

influence coefficients” as well as evaluation of the accuracy attained will be presented. It will be shown that the use of the junction-to-case thermal resistance can be extended to nonisothermal packages by defining an appropriately weighted, average surface temperature based on numerically derived thermal influence coefficients for each package surface (or segment) of interest.

3.2.1. Expanded R_{jc} Methodology. It is convenient to introduce the expanded R_{jc} methodology with a thermal model of a chip package that can be approximated by a network of three thermal resistances connected in parallel from the chip to the top, sides, and bottom of the package, respectively. This type of compact model is commonly referred to as a star network and, in this model, the heat flow from the chip is

$$q = q_1 + q_2 + q_3$$

or

$$q = \frac{T_j - T_1}{R_1} + \frac{T_j - T_2}{R_2} + \frac{T_j - T_3}{R_3} \tag{35}$$

This compact model of an electronic device is shown schematically in Fig. 9.

Equation (35) can be rearranged to yield the dependence of the chip (or junction) temperature on the temperature of the three surface segments as

$$T_j = \left(\frac{R_2 R_3}{R_s}\right) T_1 + \left(\frac{R_3 R_1}{R_s}\right) T_2 + \left(\frac{R_1 R_2}{R_s}\right) T_3 + \left(\frac{R_1 R_2 R_3}{R_s}\right) q \tag{36}$$

where $R_s = R_1 R_2 + R_1 R_3 + R_2 R_3$

Figure 9. Geometry of a 28-lead PLCC device. (a) The compact model schematic and (b) the actual device cross section [37].

Equation (36) may be generalized to admit n distinct elements along the package surface, or

$$T_j = \sum_{k=1}^n A_k T_k + A_{n+1} q \quad (37)$$

A comparison of Eqs. (36) and (37) shows that the coefficients of the specified surface temperatures, the A_k 's, are totally determined by the internal resistances of the chip package

$$A_1 = \frac{R_2 R_3}{R_s} \quad A_2 = \frac{R_3 R_1}{R_s}$$

$$A_3 = \frac{R_1 R_2}{R_s} \quad A_4 = \frac{R_1 R_2 R_3}{R_s}$$

The temperature coefficients needed to generate a junction temperature relation of the form shown in Eq. (37) can thus be determined from previously calculated internal resistances or, in the absence of such values, by extraction from empirical data or numerical results for the junction temperature. Furthermore, inspection of Eq. (36) reveals that the sum of the coefficients of the various surface temperatures, whether expressed in terms of the directional, internal resistances, as in Eq. (36), or in terms of influence coefficients, as in Eq. (37), is identically equal to unity for all boundary conditions. Alternatively, as shown by Furkay [33], the power dissipation coefficient, $A_{n+1} q$, is, in fact, the familiar R_{jc} , the isothermal, junction-to-case thermal resistance. Consequently, Eq. (37) may be rewritten as

$$T_j = \sum_{k=1}^n A_k T_k + R_{jc} q \quad (38)$$

or, returning to R_{jc}

$$R_{jc} = T_j - \frac{\sum_{k=1}^n A_k T_k}{q} = \frac{T_j - \bar{T}_c}{q} \quad (39)$$

where \bar{T}_c is the average case temperature

$$\bar{T}_c = \frac{\sum_{k=1}^n S_k}{S_T} T_k \quad (40)$$

where S_k is the surface area of the k th surface and S_T is the surface area of the entire package.

Equation (39) can be viewed as a generalized and expanded junction-to-case thermal resistance, based on an appropriately weighted, average case temperature. As previously noted, several different approaches may be taken in determining the average temperature of a nonisothermal chip package or case. The most basic approach involves calculating a simple average of, for example, the top, bottom, and fourside surface temperature. A somewhat better value can be found by surface area averaging of these temperatures in accordance with Eq. (40).

In a package with anisotropic conduction, the simple average and area average approaches yield an erroneous

case temperature by neglecting the variation in resistance to heat flow from the chip to the surface element. This shortcoming is addressed by this approach, which provides an improved weighted average temperature based on the importance to heat transfer of the various package surfaces. The average case temperature should be found in the prescribed manner, that is, by

$$\bar{T}_c = \sum_{k=1}^n A_k T_{k,1} \quad (41)$$

With this particular value of \bar{T}_c , the conventional R_{jc} , obtained empirically or numerically from isothermal case results, can be used to find T_j for all operating conditions, subject to the assumption that each surface segment is itself isothermal. When necessary, a single surface may be divided into several zones, each of which is more nearly isothermal than the entire surface and is recognized with its own index in Eq. (41). It should be noted that the weighting imposed by this equation on the average case temperature addresses variations in the size of the surface segments, as well as variations in the internal thermal paths between the chip and each of the surface elements.

3.2.2. The Insulated Surface. In many applications, chip packages are cooled selectively along particular exposed surfaces. One such example is a package cooled from the top and side surfaces while the bottom surface is insulated. The thermally active surfaces may vary from application to application, and the thermal analyst needs to quantify the effect of thermally insulating one or more areas on a package of known thermal resistance. For the assumptions used in the development of the expanded R_{jc} model, insulation of surface m results in zero heat flow through resistance, R_m . This causes the temperature of surface m to equal the chip temperature. With this in mind, the junction temperature for a package with a single insulated surface given by Eq. (38) is found to equal

$$T_j = \sum_{k \neq m} \left(\frac{A_k}{1 - A_m} \right) T_k + (R_{jc}^*) q \quad (42)$$

The weighted-average case temperature for this thermal configuration is found to equal

$$\bar{T}_c = \sum_{k \neq m} \left(\frac{A_k}{1 - A_m} \right) T_k \quad (43)$$

and the modified junction to case resistance, R_{jc}^* is

$$R_{jc}^* = \frac{R_{jc}}{1 - A_m} \quad (44)$$

3.2.3. Implementation. To thermally characterize any electronic package by relations of the form of Eqs. (40) and (42), it is necessary to compute or measure the relevant influence coefficients or the equivalent set of internal

resistances. Several difficult issues will develop undertaking such an effort. Fundamentally, a strictly experimental approach to thermal characterization of electronic devices would suffer from measurement errors and nonlinearities. Even more esoteric, is a precise experimental definition of what temperatures must be measured on the electronic component. Precise measurement of the p - n junction operating temperature is usually not practical. Approximations using signal characteristics, or implanted temperature sensors are generally used for experimental purposes.

Numerical simulation of the thermal behavior of a finite element (or finite difference) model of a chip package can provide the necessary temperatures and heat flows for a variety of operating conditions. Such a model can properly represent the conduction temperature field in each of the solid elements constituting the package but unfortunately cannot yet faithfully reproduce the thermal resistances at the interfaces (the so-called contact thermal resistances) between these elements. Regrettably, these contact resistances, and especially the values along the chip surfaces where the heat fluxes are highest, can account for a significant fraction of the package resistance [38]. Thus, in the near term, empirical contact resistance data must be used in generating an accurate finite element or finite difference thermal model of an integrated circuit package. For typical contact resistance values, the reader is referred to Refs. 6 and 30.

4. ADVANCED TOPICS

4.1. Convection Between Populated Printed Circuit Boards

The relations presented previously for natural convection in vertical channels have proved useful in a wide variety of applications and have been shown to yield very good agreement with measured empirical results for heat transfer from arrays of PCBs. However, these traditional models, employing smooth-walled channel relations and based on the free channel spacing, underestimate heat transfer for narrowly spaced PCB configurations and overestimate optimum PCB spacings. Furthermore, when an attempt is made to maximize volumetric heat dissipation in an array of PCBs, the optimum PCB spacing is overestimated and, as a result, the maximum array dissipation is underestimated.

Teertstra et al. [39] proposed an analytical friction factor correlation for fully developed flow through an idealized array of uniformly sized and spaced cuboid blocks on one side of a parallel-plate channel.

$$f_{2H} = \left[\left(\frac{96\mathcal{A}}{Re_{2H}} \right)^3 + \left(\frac{0.347\mathcal{B}}{Re_{2H}^{1/4}} \right)^3 \right]^{1/3} \quad (45)$$

This composite equation connects the laminar and turbulent limiting cases and is applicable for a full range of Reynolds numbers, $1 \leq Re_{2H} = 2HV/v \leq 100000$.

The \mathcal{A} and \mathcal{B} factors appearing in Eq. (45) are expressed solely in terms of the component array geometry

$$\mathcal{A} = \frac{\gamma^2}{\zeta^3 \chi} \quad (46)$$

$$\mathcal{B} = \frac{\gamma^{5/4}}{\zeta^3 \xi} \quad (47)$$

where

$$\gamma = \left[1 + \frac{B}{H} \frac{H}{L} \frac{1}{1+S/L} \right] \quad (48)$$

$$\zeta = \left[1 - \frac{B}{H} \frac{1}{1+S/L} \right] \quad (49)$$

$$\chi = \left[\frac{B}{H} + \left(1 - \frac{B}{H} \right) \left(1 + \frac{2B}{H} \frac{H}{L} \frac{1}{1+S/L} \right) \right] \quad (50)$$

and

$$\xi = \left[\frac{B}{H} + \left(1 - \frac{B}{H} \right) \frac{1}{1+S/L} \right] \quad (51)$$

Figure 10 illustrates the definitions of the geometrical parameters B , H , S , and L appearing in Eqs. (48)–(51). The groupings B/H and S/L represent the nondimensional package array height and spacing, respectively, where H/L provides the needed link between them.

Despite the complexity of the dependence, it is clear that as the package size shrinks (i.e., $B/H \rightarrow 0$) and/or as the spacing increases (i.e., $S/L \rightarrow \infty$) \mathcal{A} and \mathcal{B} approach unity, and the associated laminar and turbulent friction factors reduce to appropriate smooth plate values. With finite package size, however, \mathcal{A} and \mathcal{B} increase steeply with increasing package size. As \mathcal{A} and \mathcal{B} increase, the friction factor associated with the channel also increases, leading to deteriorated channel flow with increased protuberance size. Thus, by representing the actual populated PCB by

Figure 10. Definition of the various geometrical parameters used in Eqs. (48) through (51).

an equivalent array of cuboid blocks mounted on a flat plate, the package-corrected friction factor for the PCB channel may be predicted using Eq. (45).

Knowledge of the friction factor may be used to calculate the pressure loss and flowrate in the channel.

$$\left. \frac{\partial P}{\partial x} \right|_{\text{loss}} = \frac{-f_{2H} \rho Re_{2H}^2 v^2}{16H^3} \quad (52)$$

This flowrate may then be used in standard forced convection correlations to obtain a heat transfer coefficient.

In an approach to a real situation, the deviation of the friction factor characteristics of an actual PCB channel from that of an idealized smooth channel could be obtained and used to more accurately predict the flowrate and thus the convective heat transfer in the channel.

4.2. Air-Cooled Heatsinks

The simplicity and cost effectiveness of air-cooled heatsinks continue to expand the design space for this most ubiquitous of all thermal management hardware in the electronic industry. When attached to modules, chip packages, or directly to chips, heatsinks can enhance both the reliability and functional performance of electronic, telecommunication, and power conversion systems. However, rapidly increasing chip power dissipation and concerns over weight, cost, acoustic noise, and time-to-market are constraining the successful application of these thermal devices. Greater attention to the underlying thermal, fluid, and structural interactions, as well as an appreciation for the cost and limits of available materials and fabrication processes, will be needed to maintain the viability of this cooling technique.

Extended surface heat transfer relations, which describe the thermal performance of individual fins and fin arrays, can be manipulated to provide criteria for the selection of fin geometries that will minimize the volume and mass required to meet a target dissipation. Attention must also be devoted to the impact of the fluid dynamic design on the pressure drop, dissipated pumping power, and acoustic noise generated by the heatsink. All three of these penalty quantities vary non-linearly with velocity, and a desire for quiet operation may lead to the selection of higher airflow rates at lower pressures.

Use of a large, high-performance heatsink to cool a single chip requires that the base of the heatsink serve as a heat spreader. The tradeoffs involved in optimizing the base in terms of volume, mass, and performance suggest that one consider the use of new, engineered materials, such as ceramics, composite materials, and embedded heat pipes.

Although the use of a heatsink is intended to improve the reliability of an individual electronic component, potential failure modes of the material layer or coating used to attach the heatsink may compromise this goal. Thermally induced stresses may lead to cracking, delamination, and rupture of the heatsink bond. Unfortunately, although thermal stress considerations favor a relatively thick interfacial layer, thermal performance demands that this low thermal conductivity layer be as thin as possible.

In the design and selection of high-performance, compact heatsinks, attention must be paid to the immediate physical surroundings. Neglecting the potential for air-flow bypassing the heatsink and leaking out can lead to serious overpredictions in heatsink performance. Moreover, care must often be taken to minimize the volume occupied by the thermal solution and its impact on the form and shape of the packaged product. Although analysis and testing can provide guidelines for dealing with these issues, today's commercial computational fluid dynamics (CFD) software is most effective in identifying solutions and optimization opportunities early in the design cycle and can be used successfully to tailor the thermal solution to the specified physical and performance envelope.

Air-cooled, least-material optimum fin arrays are typically characterized by large aspect ratio fins and interfin spacings that are beyond the range of conventional casting, extrusion, and machining operations. The design of cost-effective heatsinks requires that attention be devoted to manufacturing considerations. The performance and manufacturing costs of various suboptimal (thermal) configurations must be sufficiently well understood to perform a more generalized optimization.

Using the present as prologue, it appears clear that future heatsink design will need to address the myriad of concerns and constraints that define the electronic product envelope. In the coming era, the limits on heatsink performance will be established not by thermal performance alone but by the cost effectiveness of the thermal design, including material and manufacturing/fabrication costs, as well as the less visible costs of reliability, acoustic noise, space utilization, and time-to-market. To assist in this multidimensional design process, it can be expected that, in the future, automated design will play a far greater role in heatsink development. Such second-generation CAD tools can be expected to provide sophisticated inverse-design capability, which will help define the optimal configurations to offer virtual reality displays—this will aid the designer in tailoring the heatsink to the size and shape of the available space and to afford easy access to rapid prototyping tools that generate heatsink samples for rapid evaluation of proposed solutions.

For a thorough treatment of heatsink design and analysis, the reader is referred to Ref. 4.

4.3. Passive Immersion Modules

The challenges posed by high chip heat fluxes make direct liquid cooling a leading candidate for future thermal packaging systems. Passive immersion modules (PIMs) consist of active microelectronic components encapsulated in a liquid-filled enclosure. The dielectric liquid wets the surface of the component, and heat is removed by convection and/or boiling. As liquid circulates within the enclosure, heat is spread to the module walls. The external surfaces of the module are then cooled by the ambient air. The module walls may be internally finned, externally finned, or both [40].

The circulation of the liquid within a PIM, including the formation, collapse, and additional buoyancy of vapor bubbles generated through boiling, may be used to

overcome the barriers posed by thermal conduction through solids and across solid-to-solid interfaces (a dominant concern in the application of conventional heatsink technology). Although high-velocity-flow boiling, liquid jet impingement, and liquid sprays could all be used to cool the anticipated high flux chips of 2006, the SIA/NEMI cost constraints appear to favor development of modules that passively reject the generated heat to air.

A PIM consists of heat-dissipating microelectronics enclosed in a liquid-filled module. In such PIMs, high heat fluxes may lead to boiling on the component surfaces. Vapor bubbles generated in the module rise, coalesce, and condense in the liquid, inducing considerable circulation and bubble pumped convection along the module walls that serve as submerged condensers. The thermal performance of such a PIM is constrained by the departure from nucleate boiling or critical heat flux (CHF) on the surface of the components and the maximum attainable heat transfer rate at the submerged condenser surfaces.

Markowitz and Bergles [41] proposed that the complex phenomena occurring within a PIM could be effectively represented in a performance map, similar to that depicted in Fig. 11, relating the heat dissipation, Q , to the temperature difference, ΔT_{hc} , between the chips (heaters) and the condenser. In creating a theoretical performance map for a PIM, the lower bound of the performance envelope is defined by natural convection on both the chip and condenser surfaces. In modules in which the condenser surface is at the top of the module where vapor can collect, the upper bound for the performance envelope is vapor-space condensation. However, for tall, narrow modules in which the majority of the heat is removed from side-wall submerged condenser, vapor-space condensation does not represent a realistic upper limit for the performance of the condenser. A more realistic upper bound may be that of bubble pumped convection with noncondensing bubbles. A semi-empirical correlation by Bar-Cohen et al. [42] for this maximal bubble pumped convection on a vertical plate, is given by

$$Nu = (1 + \lambda Z)^{1/3} Nu_{nc} \quad (53)$$

Figure 11. Theoretical performance map for a PIM.

where

$$Z = \frac{(\rho_f - \rho_g)QW}{\sqrt{gD_0\rho_f\rho_g}h_{fg}\beta(T_{sat} - T_s)V} \quad (54)$$

and Nu_{nc} is the appropriate single-phase natural convection Nusselt number. In Eq. (53), λ is an empirically determined factor that depends on the heater and condenser configuration of the module, typically ranging in value from 2 to 9.

Between the lower bound of natural convection and the upper bound of vapor-space condensation, the temperature difference between the chips and the submerged condenser surface is governed primarily by nucleate boiling on the chips and bubble pumped convection on the condenser. With sufficient condenser capacity, the performance of the PIM may be limited by the critical heat flux at the chip surfaces, which is accompanied by vapor blanketing of the surface and a large increase in surface temperature.

Kitching et al. [40] studied the thermal characteristics of a prototype, air-cooled PIM and addressed the upper-bound and bubble pumped augmentation on the finned submerged condenser surface. The experimental observations and supporting modeling studies revealed that thermal performance maps could be used to represent the behavior of finned, submerged condenser PIMs. Moreover, in this study, a two- to threefold improvement in the convective heat transfer coefficient was attained along a horizontal, submerged condenser surface, consisting of square pin fins. This augmentation was achieved with a relatively modest bubble (void) fraction of 2% to 3% in the enclosed liquid. Condensation on the exposed fin surfaces represents the upper bound for operation of a horizontal PIM.

THIN FILM RESISTORS

F. M. COLLINS
Ohmcraft, Inc.
W. A. ANDERSON
State University of New York at
Buffalo
E. M. MA
Cypress Semiconductor Inc.
(Minnesota)

1. HISTORICAL DEVELOPMENT

The earliest forms of thin film resistors were developed in Germany during World War II based on “cracked-carbon,” which was deposited onto ceramic cores during a high-temperature chemical vapor deposition (CVD) process.

The resistor was brought to value by removing material in a spiral pattern by grinding. A cap-and-lead termination was followed by polymeric encapsulation.

The performance characteristics of these carbon-film resistors were an order of magnitude improvement over prior resistors consisting of a carbon composition product. These exhibit sizable changes in value when subjected to fluctuations in temperature or humidity because of large dimensional changes in the resin matrix. By contrast, film resistors were far more stable and the inline procedure for adjusting them to value enabled production in high yield of close-tolerance (1%) components.

The next evolutionary step was adopting the low-temperature-coefficient metal alloys that were used in wire-wound resistor construction. They were deposited as films using nickel-chromium carbonyl in a CVD process. Subsequent manufacturing steps were similar to the carbon film product. These "precision" metal film resistors had a much lower temperature coefficient of resistance (TCR) and greater overall endurance than the carbon film product. TCR is defined as the unit change of resistance per unit change in temperature, expressed as parts per million per degree centigrade (ppm/°C) and discussed in Section 6.

During the 1960s, the techniques for fabricating integrated circuits were also applied to manufacturing resistive components. At that time, the only substrate material that could be made with a sufficiently uniform surface was a very low-alkali-content borosilicate glass. Nichrome alloys were evaporated in high vacuum onto flat substrates. Patterns were produced by photolithography, resulting in very fine features. The techniques used for resistance adjustment by selective removal of the film, including chemical thinning and diamond grinding, were slow and clumsy. The development of laser trimming resolved those issues, but difficulty was encountered with microcracks in the glass substrate. Soon, however, an appropriate ceramic material in wafer form was developed. This had a flaw-free surface, chemical resistance, high thermal conductivity, and sufficient strength to survive the rigors of automatic equipment handling. This material, smooth, fine-grained, high-purity alumina, represented an important step in advancing thin film technology.

The problem of maintaining compositional consistency during evaporation of multicomponent alloys, such as nickel-chromium, was eventually resolved by adopting cathodic sputtering. However, it was soon discovered that nichrome in thin film form is subject to electromigration under high humidity. This corrosion resulted in occasional catastrophic failure. For this reason, another material, tantalum nitride, which had been developed during thin film capacitor research at Bell Labs, came into use.

Resistive materials in thin film form required greater attention to the nature of the termination than had bulk materials. For instance, the deposition of gold directly onto a thin film of nichrome results in thinning of the resistor in the critical region adjacent to the termination by absorption of the nickel constituent by the gold. It was therefore necessary to interpose barrier layer materials

between the resistive film and the overlaying termination to minimize adverse metallurgical interactions.

The adaptation of integrated circuit manufacturing techniques had enormous impact on passive component manufacture. As distinct from discrete resistors, it facilitated fabricating resistor *networks* within which all the elements were uniformly matched. Good tracking was an intrinsic property of integrated multielement networks. In addition, whereas the achievement of high precision had placed strict demands on the manufacture of discrete resistors for maximum *absolute* performance, integrated network construction allowed focusing the emphasis on unprecedented *relative* performance. In addition, the small size of single chip networks allowed economic packaging in hermetic enclosures using familiar chip and wire technology. Of course, the economy of simultaneously manufacturing hundreds or even thousands of resistors per wafer significantly reduced the unit cost.

2. DESIGN CONCEPTS

In choosing a resistor technology, consideration must be given to requirements for (1) the range of resistance values, (2) their precision, and (3) the physical size in terms of power or voltage demands.

Different resistance values are obtained, in general, by selecting a material with appropriate specific resistivity, by arranging a given material in an appropriate geometrical configuration, and/or by a combination of both. For example, wire-wound resistors are composed of alloy compositions with exceptionally low TCRs. Differing values are obtained by using wires of different cross-sectional area and length. This is an exclusively geometric, mostly one-dimensional, approach.

By contrast, carbon composition resistors and thick film resistors are produced in a limited number of physical configurations in which the resistance value is varied by changing the resistivity of the material. In particular, thick film materials consist of a two-phase mixture of a conducting oxide particulate dispersed throughout a glass matrix. By varying the proportions of the two ingredients, the resistivity and, thereby, the resistance are adjusted controllably over a range of seven decades or so. The discontinuous nature of the conducting phase in composites, however, presents difficulties. It is not easy to obtain lower resistivities. Composites are also characterized by higher noise and greater voltage and temperature dependence. Nevertheless, composite materials attain resistivities far higher than those of any other technology. A comparison of thick and thin film resistor technologies is given in Table 1.

Thin film resistors are made from materials with a limited resistivity range, and different values are obtained primarily by geometric means. The most common materials, nichrome and tantalum nitride, have a resistivity of about $500 \mu\Omega \cdot \text{cm}$ (this falls in the semimetallic category, characterized by a weak dependence of resistivity on temperature). The film thickness is varied in a practical manner only from a few hundred to a few thousand angstroms.

Table 1. A Comparison of Resistor Technologies

	Thick Film	Thin Film
Manufacturing process	Screen print	Vacuum deposit and photolithography
Film thickness	10 μm	0.1 μm
Line width	30 mils	0.3 mils
Material resistivity range	6 + decades	1 decade
Typical aspect ratio	20:1	2000:1
Resistance tolerance	1%	0.01%
TCR	250 ppm/ $^{\circ}\text{C}$	25 ppm/ $^{\circ}\text{C}$
TCR tracking	50 ppm/ $^{\circ}\text{C}$	5 ppm/ $^{\circ}\text{C}$
High-voltage capability	Yes	No
Current/Voltage linearity	Poor	Excellent

Corrosion	Never	Sometimes
Custom tooling	Hard	Hard
Cost	Lower	Higher

The principal means of achieving different values is by varying the length and width of the conducting trace.

To facilitate design calculations, practitioners have rearranged the customary relationship describing the dependence of resistance R on resistivity ρ , length L , and cross-sectional area A into one that involves “sheet resistance” ρ_{sh} and “number of unit squares” n as shown in Fig. 1:

$$R = \frac{\rho L}{A} = \left(\frac{\rho}{t}\right) \left(\frac{L}{W}\right) = \rho_{\text{sh}} n \quad (1)$$

For example, a film of material with a resistivity of 500 $\mu\Omega \cdot \text{cm}$ and 50 nm thick has a sheet resistance of 100 Ω/\square . The usefulness of this concept is based on the fact that the resistance across a square area is independent of its size, unlike one- and three-dimensional geometries. The sheet resistance must be multiplied by the number of unit squares in series, which is given by the length/width ratio of the design trace, otherwise known as the aspect ratio.

The maximum resistance value attainable with a given film is determined by the highest aspect ratio that can be generated in a given area, which, in turn, is determined by the lower limit of line and space width achievable via the patterning technique employed. The optimum pattern for this is serpentine, as shown in Fig. 2. Following are the relationships among the various parameters:

$$R = \rho_s n = \rho_s \left(\frac{L_1}{\ell}\right) \left(\frac{L_2}{\ell + s}\right) = \rho_s \left(\frac{A}{\ell(\ell + s)}\right) \quad (2)$$

Figure 1. Simple rectangular resistor structure showing the basic concept.

Figure 2. Typical serpentine resistor pattern to conserve space.

For equal line/space width,

$$R = \frac{\rho_s A}{2l^2} \quad (3)$$

For example, with a film of sheet resistivity 100 Ω/\square and minimum attainable line/space width of 0.5 mil, the maximum resistance value attainable in a 50 \times 100 mil area is 1 m Ω . To achieve higher values, a film of higher sheet resistivity would be necessary, or greater substrate area, or narrower line/space width, or a combination.

Very low resistance values are not easily obtained with thin films. The lowest sheet resistivity directly obtainable is about 10 Ω/\square . Low values are therefore often designed with fractional aspect ratios. This is done with interleaving termination traces, but the performance characteristics are compromised, because of the proportionately increasing roles of the conductor itself and the resistor-conductor interface.

The potential contribution of conductor traces within networks must be minimized even with midvalue resistors, where precision tolerances or ratios are required. This is done through appropriate design by keeping the aspect ratio of the conductor as small as possible and by reducing its sheet resistance, which is commonly done by electroplating to a thickness much greater than practical with vacuum deposition. The form of the external lead must also be taken into consideration, especially with chip-and-wire assembly, where the resistance of a typical wire lead is 0.1 Ω . That amount adds significantly to the total resistance and affects the TCR, as shown in Table 2. The effect of lead resistance is minimized by using alternative packaging techniques, such as direct soldering of lead wires in a single-in-line style. Fortunately, the circuit requirements for resistance networks are more often on voltage ratio output; in which case, interconnection resistance is less important.

Table 2. Effect of 0.1 Ω Lead Resistance on Resistance Value and TCR

	Total Resistance	Temperature Coefficient ^a
10 W	1.00%	40.0
100 W	0.10%	4.0
1000 W	0.01%	0.4

^aAssuming a TCR of gold of +4000 ppm/ $^{\circ}\text{C}$.

The design of thin film resistors must also allow for adjustment to a value. Modern laser systems are capable of adjusting resistors to very close tolerances at very high speed. However, the closer the required tolerance, the more carefully the resistor must be designed for both trimming efficiency and to minimize the amount of physical damage done to the remaining active area of the resistor by the laser beam. This is done by the use of special trim geometries, which allow for sequential steps from large to small increments of resistance change. These special geometries occupy a significant amount of substrate area. An example of such a design is shown in Fig. 3.

3. WAFER-SCALE FABRICATION

The process of fabricating thin film resistors and networks is comparatively simple relative to that for active devices, but considerable variety is still possible along with much art. A typical sequence is described below.

The surface of the substrate is given some type of cleaning and/or conditioning to ensure good adhesion of the thin film. This is accomplished before deposition by chemical cleaning in ultrasonic baths followed by transport through a vaporphase solvent system. Further conditioning is accomplished by plasma treatment during the initial stage of the vacuum deposition process. This is often done within a load-lock entry chamber, a system that allows maintaining the cathode within a controlled, non-reactive atmosphere. Film deposition is accomplished by dc sputtering in a controlled atmosphere across a gap of

Figure 3. Special resistor design feature. A multitude of different designs are possible.

the order of 1 in. The substrates are often periodically cycled under the cathode. The atmosphere employed is usually 10 μm of argon containing a partial pressure of either oxygen or nitrogen. Deposition is done at rates ranging from 1 nm/min to 10 nm/min.

Most deposition systems accommodate multiple cathodes to deposit several different materials sequentially without breaking vacuum. This provides efficient operation, assures intimate contact between layers, and allows for the deposition of composite resistive films. The design and placement of physical shields, located in the cathodic dark-space region, govern the uniformity of deposition across a wafer. It is possible to attain uniformity of sheet resistance to within $\pm 10\%$ of a design value.

The general order of deposition is (1) resistive film, (2) barrier layer, and (3) conductive film. The barrier layer is included to minimize metallurgical interaction between the resistive and conductive layers, especially during subsequent high-temperature stabilization. It usually consists of nickel in the case of the nichrome/gold system and palladium in the case of the tantalum nitride/gold system.

After film deposition, the appropriate resistor and conductor patterns are formed by photolithographic techniques, often in conjunction with an electroplating operation as noted earlier. An example of such a sequence is shown in Fig. 4 in idealized form. The first photoresist layer is applied, exposed in the termination pattern, and developed. Then the wafer is electroplated, thickening the conductor traces within the openings in the photoresist layer. After stripping the photoresist, the remaining thin film conductor/barrier is etched away. Then the photolithographic patterning process is repeated with the resistive film.

It is common practice to employ a positive photoresist that stands up in electroplating solutions. The conductive layers are removed with cyanide solutions, and resistive materials are dissolved in potassium iodide or hydrogen fluoride solution.

Although there are many variants in the sequence of these steps, they always include stabilizing the resistive film by baking at high temperature in air, typically for several hours at temperatures in the 300–450°C range. This renders the material metallurgically stable and chemically inert. The precise conditions during stabilization are often adjusted slightly to bring the TCR within a required specification.

The resistors are adjusted to their required value by laser machining with automatic, specially designed high-speed operating systems. The choice of electrical probes for online measurement is critical, involving a balance between requirements for good electrical contact and optimum physical wear. Laser beam (YAG) parameters must be carefully chosen to provide clean, efficient removal of resistive film but with minimum disturbance of the remaining film and substrate. In the case of precision tolerances, a two-step trim procedure is frequently employed that includes an intermediate annealing step.

The final step in wafer-scale fabrication is dicing. This is done by laser scoring or diamond-wheel sawing. With a ceramic substrate, scoring is normally done with a CO_2

Figure 4. Typical resistor processing sequence. This is just one example of resistor fabrication.

laser system and usually in the postage-stamp mode, followed by breakage. Alternatively, high-speed diamond-sawing is done with ceramic or silicon substrates.

Chip networks are usually assembled into one of many available types of package formats, including conformably coated single-inline, hermetic dual-inline, flatpack, or several molded small-outline package styles.

4. MATERIALS

4.1. Substrates

One of the most widely used substrate materials for thin film resistors is high-alumina ceramic. This is available from many suppliers in a variety of thicknesses ranging from 10 to 40 mils. It is manufactured by a green-tape process in sizes up to 6 in. In finished form, it consists of 99.6% alumina and has a surface finish generally better than 1 microinch/inch. It provides excellent adhesion of the deposited film. Its high strength is essential for withstanding the rigors of handling by manufacturing equipment. It is reasonable in cost, and its comparatively high

thermal conductivity is important for dissipating power and reducing thermal gradients within a chip network.

High-alumina does not saw easily, but with the proper composite diamond blades and high-speed equipment, reasonable rates are achieved. Pulsed-laser scoring and subsequent breaking is done much more rapidly but with attendant risk to higher precision network tolerances.

Ceramic substrate was not always available with consistent surface characteristics, and during its evolution, the use of oxide passivated silicon wafers became, and has remained, popular for fabricating film resistance networks. This material is readily available in large sizes with consistent surface characteristics. With it, much finer circuit features can be successfully imaged. It dissipates internally generated power very adequately.

Silicon substrates are favored in applications involving highly automated assembly equipment because of the superior pattern visibility in autoalignment systems and the relative ease and speed with which they can be singulated by diamond-blade sawing. However, because of the inherent electrical conductivity of silicon and the relatively large capacitive reactance involved, it performs more poorly at higher signal frequencies than do similar networks on ceramic. On the other hand, the combination of the conductive silicon base and its overlying dielectric layer provides the basis for fabricating integrated resistor-capacitor networks.

Experience with both high-alumina and silicon substrates indicates that better stability is generally obtained on ceramic, making it the preferred choice for precision network applications. Substrates of thin sapphire wafers (single crystal alumina) were used in high reliability applications when ceramic quality was still inconsistent. It is still employed occasionally in applications for which its superior thermal conductivity is critical.

4.2. Resistive Films

The use of nickel-chromium alloys [1] for fabricating thin film resistor networks was a natural extension of their use in manufacturing wire-wound resistors. Nichrome wire was made in compositions with a very low TCR for instruments and the endurance of red heat for power applications. Compositional control of early film depositions by thermal evaporation of nichrome in high vacuum was difficult because of the different partial pressures of the constituents. This problem is resolved by high-voltage sputtering, which after an initial break-in period, delivers a film whose composition is identical to that of the cathode. Sputtering provides excellent control of the film deposition process.

The composition of nickel-chromium alloys for thin films generally falls within the range 80/20 to 40/60. The as-deposited film is uniform in composition with varying degrees of microcrystallinity, depending on the temperature at which the substrate is maintained during deposition. During thermal annealing, however, stratification occurs, with chromium migrating to the surface where it is oxidized, leaving a nickel-rich underlayer. The chromium oxide layer is etch-resistant. The deposition is also done

Figure 5. Example of nonlinear TCR. It is usually desired that TCR be linear.

using a partial pressure of oxygen, which modifies the behavior during subsequent processing.

Nichrome is made in sheet resistance ranging from 25 to 1000 Ω/■ or so, and in that range, the TCR is maintained to within ±50 ppm/°C. However, within the commonly employed narrower range of 100–200 Ω/■, the TCR is held to a very low value, less than 10 ppm/°C, by exercising careful control of critical process steps. It remains the material of choice for high-precision applications.

The TCR of the as-deposited film is generally negative and moves to a more (metallic) positive value during thermal stabilization. A near-zero TCR is attained by critical control of the process parameters. However, this is compromised by the significant nonlinearity of the resistance-temperature relationship, as shown in Fig. 5. Even with films with an incremental TCR of zero near room temperature, the slope of the curve at lower and higher temperatures may range between -5 and +5 ppm/°C.

Properly manufactured nichrome thin films on ceramic substrates are exceptionally stable. The small resistance changes that occur in circuit operation are entirely a function of substrate temperature, induced by power loading or ambient. The rate of change of resistance measured at higher temperatures can be extrapolated to lower temperatures and longer times by classic kinetic equations, as in Fig. 6 and Table 3.

Nichrome thin films are often provided with deposited gold terminations for wire-bonding. If the gold is laid directly on the nichrome, however, it absorbs chromium from the nichrome nearby, resulting in a region of high resistance and circuit vulnerability. This interaction is blocked by adding an intermediate nickel layer between the nichrome and the gold.

Figure 6. Change in TCR with time and temperature to show prediction of performance.

Unlike its bulk forms, thin film nichrome is subject to catastrophic failure by electromigration from dc voltage under high humidity, which permits a condensed water layer to form. This phenomenon resulted in dramatic field failures before it was recognized and dealt with by hermetic packaging or by applying an insulating material to the nichrome surface.

To overcome moisture difficulties associated with nichrome, thin film resistors of tantalum nitride are employed. These are deposited on ceramic substrates by dc sputtering from a tantalum cathode at a pressure of about 10 μm with a partial pressure of nitrogen, appropriate for obtaining the film in the form Ta₂N [2]. These films usually have an interdiffusional barrier layer of palladium and gold termination. They are photolithographically imaged and thermally stabilized.

Tantalum nitride is made in a range of film thickness and sheet resistance similar to that of nichrome. It is regarded as having superior reliability. The disadvantage of tantalum nitride, compared with nichrome, is that it has an intrinsic TCR of -120 ppm/°C.

Efforts to combine the best features of nichrome and tantalum nitride in a single system have been made by way of a composite, two-layer film. A film of nichrome is covered with a thin film of tantalum, which is subsequently

Table 3. Extrapolated Stability Data for Nichrome Films

Film Temp, °C Time, h	25 ΔR/R, ppm		70 ΔR/R, ppm		125 ΔR/R, ppm	
	Absolute	Ratio	Absolute	Ratio	Absolute	Ratio
1,000	—	—	50	10	500	100

^aExtrapolated data.

converted by thermal treatment to an oxynitride. The resultant composite can be made with a very low and nearly linear TCR along with greatly increased resistance to electromigration.

Still another class of vacuum-deposited thin films used in resistor products are composites of mixed chromium and silicon oxides. Historically, these are obtained as vacuum evaporated mixtures, but serious process control was almost impossible. Now such films produced by sputtering from cathodes formed of chrome-silicon in an atmosphere with oxygen. High sheet resistance is obtained with these films, to values up to 10,000–20,000 Ω/\square . The TCR of these films is more suitable for general-purpose applications, and the films exhibit higher levels of current noise and less stability than homogenous film materials. For situations requiring very high resistance and/or minimum size, these film materials fulfill a real need. A comparison of film materials is given in Table 4.

5. FINISHED FORMATS

5.1. Through-Hole Assembly

Regardless of the end product, all wafers in a given facility are processed in pretty much the same way. After singulation, however, the chips are packaged in a variety of formats. For through-hole circuit-based assembly with 100 mil pin spacing, the choice is between dual-inline and single-inline and styles. The former may be hermetic or molded plastic. Both involve chip-and-wire assembly technology, which requires that a significant amount of additional electrical resistance must be taken into account in designing and trimming precision networks. This is more critical in networks with lower value resistors.

Dual-inline construction imposes limits on chip size and thereby on the total amount of resistance that can be accommodated. However, a hermetic seal provides an added measure of reliability/stability.

An alternative format for through-hole assembly is single-inline. These are nonhermetic, usually with a conformal resin encapsulation. Single-inline format involves a much larger “chip” than does dual-inline, but this added size allows much higher total resistance values. An advantage of single-inline construction is that the external leads are connected directly to the chip, by soldering or thermocompression bonding.

The stability of thin film resistor networks is impacted by mechanical stress introduced within the chip during assembly, such as by mechanical contraction of a molding compound during curing or through the interaction of materials with a different coefficient of thermal expansion.

Where the development of such stress is unavoidable, the effects are reversed or moderated by thermal annealing. It is also possible to allow for a final “tweak” of resistance value to close tolerances by laser matching just before the final assembly step.

5.2. Surface-Mount Format

In the case of surface-mount assembly, a greater number of formats are available, beginning with individual chip resistors. These are available on ceramic in a variety of standard sizes and standard values to tolerances of 0.1%. The solderable, wraparound end termination may be a thick film or thin film.

Another form of individual chip resistor is the square silicon chip, usually either 20 or 30 mil meant primarily for hybrid circuit application, with terminal pads for wire-bond connection. A major advantage of this product is that it is usually supplied as a two-element, three-terminal version, which allows adjustment to close ratio tolerance.

Other forms of surface mount packaging for chip networks include:

1. Hermetic flatpack, with chip-and-wire internal connection and 50 mil pin spacing.
2. Leadless chip carrier, with solderable, wraparound terminals on two or four edges in 50 mil pin spacing.
3. Small-outline (50) formats, primarily of molded construction with chip-and-wire assembly, in 50 and 25 mil gull-wing lead spacing on two edges. The popular RC networks are supplied in this format.
4. Lead-frame-bonded directly to a ceramic chip in gull-wing style.

Most surface-mount networks are designed for general purpose (1% tolerance) networks to attain maximum component onboard density.

6. PERFORMANCE CHARACTERISTICS

6.1. Integrated Construction

An important aspect of integrated, thin film resistor construction is that all resistors on a given wafer close to one another are exposed to nearly identical conditions during manufacturing, which results in matching their electrical characteristics very closely. This ensures that the relative values of resistance remain virtually unchanged throughout a variety of operational conditions. During the lifetime of the circuit, the resistors within a given network are said to track one another closely.

Table 4. A Comparison of Resistive Film Materials

	NiCr	Ta ₂ N	Poly. Chrom.	Multilayer
Sheet resistivity range, Ω/\square	50–500	50–500	to 10,000	50–500
TCR ppm/ $^{\circ}$ C	10–50	– 120	< 300	5–25
Thermal stability	Excellent	Excellent	Fair	Excellent
Reliability	Marginal	Excellent	?	Excellent

The difference in TCR between a seemingly matched pair of *discrete* resistors may be as great as twice the specified absolute TCR. For example, for a TCR of $0 \pm 2.5 \text{ ppm}/^\circ\text{C}$, the tracking between a pair may be as much as $5 \text{ ppm}/^\circ\text{C}$. With integrated film networks, the tracking is independent of the absolute TCR and usually an order-of-magnitude better. For instance, even with an absolute TCR of $\pm 25 \text{ ppm}/^\circ\text{C}$, the internal tracking is generally less than $2 \text{ ppm}/^\circ\text{C}$.

An additional advantage of integrated construction is that serpentine patterns are essentially noninductive compared with discrete, spiraled resistors. Further, the interconnections between resistors in a network at the chip level are inherently more reliable than are those made with external lead connections, greatly improving the overall reliability of the network.

Thermoelectric voltages are generated if the terminations of a resistor are at different temperatures. This is a real problem with discrete precision resistors where measurable thermal gradients easily exist over the relatively large dimensions of conventional circuit boards. In thin film integrated networks, all resistors are at nearly the same temperature as a result of the small chip size, proximity, and the heat-spreading effect of the thermally conducting substrate. It is not surprising, therefore, that there are no reported thermoelectric effects in thin-film networks.

6.2. Temperature Coefficient of Resistance

The temperature coefficient of resistance is the measure of resistance change with a change in ambient temperature. It is defined as the unit change of resistance per unit change in temperature, and it is commonly expressed as parts per million per degree centigrade. It is the property by which different types of resistors are most often characterized or differentiated. In practice, the TCR is usually determined experimentally by measuring the resistance value at several temperatures and calculating the rate of change over the specific temperature interval, as indicated later. If the resistance changes linearly with temperature, the TCR is constant, regardless of the temperature interval. However, when it is not linear, the TCR varies according to the exact temperature interval over which the measurement is made. For this reason, it is critical that the interval is specified:

$$\text{TCR} = \left[\frac{R_2 - R_1}{R_1(T_2 - T_1)} \right] \times 10^6 \quad (4)$$

where TCR = temperature coefficient of resistance ($\text{ppm}/^\circ\text{C}$), R_1 = resistance at room temperature (Ω), R_2 = resistance at operating temperature (Ω), T_1 = room temperature ($^\circ\text{C}$), and T_2 = operating temperature ($^\circ\text{C}$).

By adjusting processing conditions, it is possible to tailor the resistance versus temperature curve to produce a TCR with a negative slope below 25°C and a positive slope above it, with an incremental TCR of zero in the vicinity of room temperature, as shown in Fig. 5.

A zero absolute TCR is especially advantageous in circuit operation, whereby current is switched on and off in

one resistor that is matched to a reference resistor carrying a constant current. In this case, even though the two resistors are perfectly matched, they may differ in value because of differential self-heating, depending on the absolute TCR of the pair. In these situations, the absolute TCR should be as low as possible in the operating temperature region.

6.3. TCR Tracking

TCR tracking is defined as the difference between the TCR of a pair of resistors over a given temperature interval. Close tracking is difficult to achieve among discrete components, but it is intrinsic to integrated construction. TCR tracking among neighboring resistors on the same wafer is usually no more than a few tenths of a parts per million per degree centigrade. However, an “apparent” TCR tracking is sometimes found that is higher than the “true” TCR tracking because of the contribution of terminations with a small but measurable resistance r and a large metallic TCR. The contribution of the common lead disappears when critical ratios are specified and measured according to voltage division rather than to resistance ratio.

6.4. Voltage Ratios

Frequently when resistors are employed as voltage dividers, it is more appropriate to deal with voltage ratio specifications than with resistance ratios. Ideally, the voltage drop across a pair of resistors is determined by the ratio of resistance values: $R_1/(R_1 + R_2)$ as shown in Fig. 7. When the resistance values are not equal, however, the voltage ratio differs from that calculated from the apparent (measured) resistance values by an amount governed by the resistance of the common lead. This deviation can be quite significant, especially with low-value resistors. For a $10 \text{ k}\Omega$ resistor in series with a $1 \text{ k}\Omega$ resistor with a common “tap” lead of $100 \text{ m}\Omega$ resistance, the two ratios differ by 75 ppm :

Voltage Ratio Calculated Using Apparent Resistance:

$$\frac{1000.1}{1000.1 + 10,000.1} = 0.0909165$$

$$\frac{V}{E} = \frac{R_1}{R_1 + R_2} \neq \frac{(R_1 + r)}{(R_1 + r) + (R_2 + r)}$$

Figure 7. Voltage ratio versus apparent resistance ratio.

Voltage Ratio Measured Directly:

$$\frac{1000}{1000 + 10,000} = 0.0909090$$

Voltage ratio tracking over temperature is always less (better) than TCR tracking.

6.5. Thermal Stability

The effects described in the previous sections are reversible. The changes are not permanent and disappear when the temperature reverts to its initial point. Irreversible changes, however, are brought about by holding the components at an elevated temperature for extended intervals. The advantage of integrated construction again becomes evident. All resistors in a given film network exhibit very similar absolute changes during life testing, and the changes in resistance ratio or voltage ratio are an order-of-magnitude smaller.

6.6. Power Rating

Because thin film networks are not generally used in high-power applications, methods for establishing maximum power ratings are not as formalized as for discrete resistors. However, because chip size is quite small, internally generated power *density* may reach significant levels.

Rated power is generally accepted as that power which is sustained without raising the surface temperature of a part above a specified maximum operating temperature, commonly 150°C. The designer must, therefore, consider the power density developed at the chip surface. For more precise tolerances, a limit of 25 W/in² is appropriate. More general tolerances sustain power density levels up to 200 W/in² without jeopardizing their integrity. Allowance must be made for the fact that different packaging formats vary greatly in their ability to dissipate heat and thereby lower the chip surface temperature.

6.7. Voltage Coefficient of Resistance and Current Noise

These two characteristics, which can be a serious drawback in resistors made from composite materials, such as cermets or polymers, are inconsequential in thin film networks. Voltage coefficient of resistance is the unit change in resistance per unit change in voltage expressed as parts per million per volt. It is a measure of the nonohmic behavior and, in thin films, reaches identifiable levels only in the megohm range, where it has been measured at about 0.1 ppm/V. Current noise is characterized and measured by an industry standard instrument. Typical values for thin film elements are less than -35 dB.

7. SUMMARY OF THE ADVANTAGES OF THIN FILM, INTEGRATED RESISTOR CONSTRUCTION

- Very small, high-density, multielement networks.
- Extremely close matching of all elements in a network, ensuring close tracking over temperature and throughout life.

- The small chip size enables hermetic construction in a variety of standard, contemporary formats.
- Repeatable and consistent characteristics part-to-part and lot-to-lot.
- Very low inductance.
- Outstanding reliability—fewer manmade interconnections.
- No discernible thermoelectric effects on voltage coefficient.
- Very low current noise.
- Installed costs are usually less than for discrete resistors.

8. NiCr THIN FILM RESISTORS

8.1. Background

Studies of NiCr TFRs have used resistance variation with annealing of different elemental ratios of Ni and Cr to achieve low values of the TCR [3]. Nucleation and growth of microcrystalline particles occur with annealing in air or vacuum [4,5]. Vacuum annealing may positively increase the TCR because of grain growth, whereas air annealing forms surface oxides of Cr with a negative TCR, which compensates for the effect of grain growth. Grain growth and intermetallic phases were observed [6] for SiO_x protected films, and selective oxidation of Cr on the top of unprotected films led to the development of an in-depth concentration gradient.

NiCr TFRs may be optimally developed [7] by annealing to minimize the TCR, by stability testing for various annealing conditions, and by identifying the annealing mechanism by secondary ion mass spectrometry (SIMS), electron spectroscopy for chemical analysis (ESCA), scanning electron microscopy (SEM), energy dispersive X-ray (EDAX), and transmission electron microscopy (TEM).

8.2. Fabrication Techniques

A thorough study of the NiCr TFR was conducted in a joint project by the State University of New York (SUNY) at Buffalo and Ohmtek, Inc. [8]. NiCr thin film resistors used RF sputter deposition from a 40/60 NiCr:Si target on alumina substrates to a thickness of 300–700 Å. Sheet resistivities ρ_s of 10, 100, 150, 191, 212, 280, 500, and 1000 Ω/\square were studied. The TCR was determined for both air and vacuum annealing, as in Table 5, in the range -180°C to +100°C. The TCR of 10, 500, and 1000 Ω/\square samples was not improved satisfactorily by annealing. Films within the range of 100–200 Ω/\square were successfully annealed, except for the vacuum annealing of the 191 Ω/\square case. Vacuum annealing for 100 Ω/\square samples required higher temperature to achieve the same TCR improvement as air annealing. The 150 Ω/\square sample attained the lowest TCR with less range span. For the 191 Ω/\square case, only air annealing improved the TCR. As shown in Fig. 8, air annealing flattens the TCR versus T increases, but an opposite effect was observed for vacuum annealing.

Samples were tested for stability after 1 month using repeated temperature cycling between 40 and 150°C for

Table 5. Result of TCR Measurements on NiCr TFRs

Sheet Resistivity, ohm/sq	Annealing Environment	Temperature, °C	Typical As-Deposited TCR, ppm/°C	Typical Annealed TCR, ppm/°C
10	Air	300	+70 ± 20	+90 ± 50
100	Air	337	-40 ± 20	+5 ± 5
100	Vacuum	400	-40 ± 20	+5 ± 5
150	Air	360	-45 ± 10	+3 ± 1
191	Air	350	-45 ± 8	+5 ± 4
191	Vacuum	340	-45 ± 8	-40 ± 10
500	Vacuum	300	-55 ± 10	-50 ± 8
1000	Air	200	-70 ± 27	-110 ± 20
1000	Vacuum	400	-70 ± 27	-50 ± 15
1000	Vacuum	500	-70 ± 27	-80 ± 20

8 h; elevated temperature at 150°C for 4 h; humidity >90% for 4 h and then 8 h. During a 1-month storage period, before stability tests, air annealed 100 Ω/□ samples retained the low TCR, whereas the vacuum annealed 100 Ω/□ and air annealed 191 Ω/□ samples had a TCR change from 5 to 17 ppm/°C. In 100 Ω/□ and 191 Ω/□ samples, the TCR was undisturbed by the previously described stability tests.

8.3. Mechanisms of Stabilization

SIMS analysis reveals that annealing enhances the Cr oxide to the same level as Si oxide. ESCA and TEM analyses confirm this in that an elemental Cr peak for the as-deposited film is replaced by a Cr oxide peak. The absence of Ni in the ESCA spectrum for annealed samples indicates segregation of Cr to the surface. SIMS reveals that the oxide ratio of Cr to Si in the bulk is lower for the samples with improved TCR. The lack of a Cr-Si structure in the unimproved samples, evidenced from the electron diffraction patterns, and the limited range of sheet resistivity showing a TCR improvement, suggests that the bulk Cr oxides, then coordinated with Si, are important in achieving a low TCR; that is, Si is the medium for CrO and Ni

interaction. After optimal annealing of samples consisting of enough Si-Cr structure in the 100–200 Ω/□ range, the amount of bulk oxide with a negative TCR balances the positive TCR contributed by the nucleation of segregated Ni. Thus, NiCr TFRs have a low and stable TCR after annealing because new compounds form and a balance occurs between negative and positive TCR components in the film. However, NiCr is not easily tuned to a TCR of ±5 ppm/°C and degrades in a harsh environment.

9. TANTALUM NITRIDE THIN FILM RESISTORS

9.1. Fabrication Techniques

The linear TCR and physiochemical inertness make Ta-N superior to the more popular NiCr for thin film resistors. The mass production of Ta₂N TFRs, deposited at 450°C by magnetron sputtering, with sheet resistivity of 50 to 100 Ω/sq and TCR of about -80 ppm/°C, was announced in 1982 [9]. A slow annealing process under vacuum [10] might produce a near-zero TCR.

A thorough study of Ta₂N-TFRs was jointly conducted by SUNY at Buffalo and Ohmtek, Inc. [11,12]. The Ta-N films were deposited on SiO₂/Si or alumina from a pure Ta target by either dc diode or magnetron reactive sputtering, without substrate heating, on stationary or rotating substrates for better uniformity. The end contact materials consisted of Au on an interlayer of NiCr, TiW, or Tamelex (the tradename for the Ta/NiCr), for adhesion and a diffusion barrier.

Optimal air annealing was at 425°C for 15 min followed by 375°C for 1 h. The result in Fig. 9 shows a linear TCR, better than -20 ppm/°C for the temperature range of -150 to +100°C. Air annealing effectiveness was a strong function of sheet resistance and the initial TCR. As for vacuum annealing, both high and low sheet resistivity films (25–140 Ω/sq) were effectively improved in TCR. Ten 140 Ω/sq resistors with an initial TCR = -140 ppm/°C were improved to close to zero TCR (±5 ppm/°C) by annealing at 700°C for 2 min. Figure 10 shows a linear and very low TCR resulting from vacuum annealing. Air annealing would not be successful for such high sheet resistivity films. A summary of annealing effects is listed in Table 6. The 25 Ω/sq films are extremely temperature sensitive, resulting in a wider TCR range after vacuum annealing.

Figure 8. Resistance variation versus ambient temperature for 191 Ω/□ films of NiCr. The change in resistance decreases as air annealing temperature increases from 250°C to 350°C [7]. * = 250°C in air, 1 h; ● = 330°C in air, 1 h; + = 340°C in air, 1 h; ◆ = 350°C in air, 1 h; ■ = 380°C in air, 1 h; ▲ = 340°C in air, 2 h; × = 340°C in vac, 2 h.

Figure 9. Typical TCR behavior after air annealing Ta-N TFRs, $>70\ \Omega/\square$ [12], ■ as deposited; ◆ annealed at 400°C in air, 1 h.

Figure 10. Typical TCR behavior after vacuum annealing Ta-N TFRs [12]. ▲ as deposited; × annealed at 400°C in air, 1 h. ■; annealed at 650°C in vacuum plus 250°C in air.

An aging test (or burn-in) may be conducted at 250°C and an accelerated lifetime test at 150°C. Because the Ta₂N material possesses a very high free energy of formation (−457 kcal/mol) [13], no aging would occur at a lower temperature. It is desired to maintain the change in resistance, for resistors held at 150°C, to less than 0.02% after 1000 h.

Annealing at 680–700°C in vacuum followed by 250°C in air for 100 h is effective in stabilizing TFRs with a wide range of initial values of R . Contacts of TiW or Tanelox are superior to Au/NiCr contacts. Data in Table 7 indicate results of a stability study at 150°C after air annealing at 250°C. Degradation is seen after 600 h, but this is attributed to the contacts and not to the resistor.

9.2. Mechanisms of Stabilization

TEM reveals little crystallinity in as-deposited Ta-N. Elevated temperature annealing produces Ta-N interaction and grain growth. Vacuum annealing produces Ta₂N regardless of the initial resistivity, whereas air annealing is effective for high resistivity films. Stabilized grain size is about 150 nm. Analysis by ESCA indicates a competing mechanism between oxide or nitride formation. Vacuum annealing promotes nitride formation and reduces the oxygen signal. The gradually aggregated Ta₂N crystallites follow the predicted activated tunneling conduction mechanism. As the amorphous Ta-N matrix is consumed, the exposed substrate participates in the conduction mechanism. This phenomenon happens only when the films are excessively annealed. The Ta₂N structure remains intact after overannealing, and the TCR remains around +80 ppm/°C in the vacuum annealing temperature range

from 750 to 850°C. In high-frequency applications, substrate selection is the most important factor. It has been shown that Al₂O₃ is five orders of magnitude better than the SiO₂/Si substrate.

Ta₂N thin film resistors are electrically and physically superior to NiCr. The linearity of the TCR behavior, the low TCR, high recrystallization temperature, and resistance to strong acidic medium are positive attributes. Ta-N is prepared with a TCR ranging from −150 ppm/°C to almost zero. Convenient and inexpensive air annealing is used with TCR stabilized from as low as −150 ppm/°C. For high-precision applications, a vacuum annealing process is used, with a resulting TCR within ± 5 ppm/°C. After 400 h at 150°C, the Ta₂N resistors are stable within 0.02%. Aging at 250°C is by a bulk diffusion mechanism. With confident extrapolation, the resistors would be stable at 150°C within 0.05% for 1000 h if a stable contact like TiW is used.

10. RUTHENIUM OXIDE THIN FILM RESISTORS

10.1. Background

RuO₂ TFRs represent a further improvement over presently available materials [14]. Transition-metal oxides with rutile structures, such as RuO₂, may be a very attractive metallization option in a variety of very large-scale integrated circuit applications. RuO₂ is a good diffusion barrier in silicon contact metallizations with an aluminum overlayer [15–18]. RuO₂ thick film resistors find wide application in hybrid circuits [19–22].

Table 6. Result of TCR Measurements on Ta₂N TFRs

Sheet Resistivity, Ω/\square	As-Deposited TCR, ppm/°C	Annealing Condition	After annealing TCR, ppm/°C	Comments
30–90	< −60	Air	−20	—
80	< −60	Air	−120	Not improved
25	−140	Vacuum	± 30	Extremely sensitive to condition
140	−140	Vacuum	± 5	Highly reproducible results

Table 7. Stability after Optimized Air Treatment for Ta₂N TFRs

Annealing Condition	Avg. $\Delta R/R$ Environment	Avg. TCR, ppm/°C
After vacuum annealing	—	-4.5
After air annealing (0 h)	—	-1.3
After air annealing (160 h)	0.014	0.4
After air annealing (390 h)	0.016	—
After air annealing (610 h)	0.111	—
After air annealing (1400 h)	0.363	+0.8

10.2. Fabrication Techniques

Thin RuO₂ films with thicknesses of 20–200 nm are reactively sputtered by a dc magnetron. Using a target of Ru with a purity of 99.9% and diameter 5 cm, RuO₂ thin-film resistors are deposited onto SiO₂/Si substrates, directly patterned with a shadow mask during sputtering to be 1 mm wide and 10 mm long [23]. Sputtering is done with the substrate temperature ranging from 25 to 500°C, O₂ pressure from 5×10^{-5} – 1×10^{-3} Torr, total pressure (Ar + O₂) of 10 mTorr, distance between substrate and target of 7.5 cm, and sputtering rate of approximately 50 nm min⁻¹.

The TCR is controlled by a combination of substrate temperature and oxygen pressure. Films deposited at relatively low temperature give a negative TCR. A positive TCR is obtained with films deposited at relatively high temperature. Clearly, the films undergo a change in microstructure and/or chemical composition as the TCR changes from semiconductor-like to metal-like. A critical substrate temperature T_{cs} during sputtering exists, at which the TCR changes signs from negative to positive, as shown in Fig. 11, where the O₂ pressure was 5×10^{-4} Torr. The critical temperature from a simple curve fitting of experimental data is about 85°C. A TCR as low as -30 ppm °C⁻¹ to -80 ppm °C⁻¹ may result for thin film resistors deposited at a substrate temperature of 80°C and an oxygen pressure of 5×10^{-4} Torr. The TCR is further improved to 0 ± 3 ppm °C⁻¹ by heating the sample at 150°C in air for several hours.

Figure 11. Dependence of TCR on the substrate temperature during sputtering for RuO₂ thin films with oxygen pressure of 5×10^{-4} Torr [14]. Symbols represent data points.

Figure 12. Dependence of TCR on the oxygen pressure during sputtering for RuO₂ thin films with the substrate temperature of 80°C [14]. Symbols represent data points.

Figure 12 shows that the positive or negative TCR of the film is controlled by changing the oxygen pressure during sputtering. However, the resistance becomes unstable for oxygen pressure lower than 1×10^{-4} Torr. From a practical viewpoint, the substrate temperature during sputtering rather than oxygen pressure should be used to control the TCR.

10.3. Mechanism of Stabilization

Using SEM and XRD, the films are amorphous or have a very fine grain size when deposited at lower substrate temperatures. The grain size of the film becomes much larger with increasing substrate temperature during sputtering. XRD patterns show that the films undergo a structure change when the substrate temperature changes from room temperature to 500°C during sputtering. From the viewpoint of material structure, amorphous RuO₂ gives a negative TCR, whereas polycrystalline thin films have a positive TCR [22–25].

Using in situ annealing, it is possible to routinely fabricate near-zero TCR resistors. Resistors annealed in such a way have a layer-like structure, automatically formed during the in situ annealing in oxygen. The TCR of the resistors is mainly controlled by the oxygen content in the film. The top layer, which contains more stoichiometric RuO₂, has a positive TCR, but the bottom layer, which shows oxygen deficiency, has a negative TCR. This can be clearly seen from the AES depth profiling shown in Fig. 13. The in situ technique is very controllable and reproducible.

11. DOUBLE-LAYER RuO₂/Ta₂N THIN FILM RESISTORS

A resistor design that overcomes potentially weak areas of the single-layer structure of NiCr, Ta₂N, or RuO₂ uses a layered structure of RuO₂/Ta₂N. This design combines the best characteristics of the two different materials Ta₂N and RuO₂ in one system. Thin film Ta₂N has a negative TCR, whereas RuO₂ has a positive TCR. Near-zero-TCR resistors are fabricated by layering Ta₂N and RuO₂. Because the resistance of RuO₂ decreases with time and that of Ta₂N increases with time, the layered design is expected

Figure 13. AES depth profiling of a resistor with a near-zero TCR deposited at room temperature followed by annealing in situ at 250°C in oxygen for 60 min (oxygen pressure of 0.5 m Torr during film deposition). AC = atomic concentration [23].

to be unchanged with time. The high thermal stability and acidic or environmental hardness of RuO_2 make it a perfect capping layer in this system. The use of highly conductive RuO_2 as a capping layer also provides a very easy way to form an ohmic contact in the resistor termination. More versatile techniques and materials for packaging and assembly become possible because of the unique barrier properties of RuO_2 and its resistance to acids [27–29].

12. CONCLUSION

In order of use today, TFRs are made from NiCr, Ta_2N , RuO_2 , or multilayers. Performance quality is improved in the same order. Fabrication consists of reactive sputtering, annealing in situ or ex situ, patterning, contact formation, longterm burn-in to establish R and TCR, and finally, stability testing. A near-zero TCR ($< \pm 5$ ppm/°C) is achieved with longterm stability. Each material system has a different mechanism of stabilization that includes oxidation, nitridation, grain growth, and layering. As applications become more demanding, RuO_2 or $\text{RuO}_2/\text{Ta}_2\text{N}$ TFRs may become materials of choice.

1. THIN FILM MATERIALS

Thin film ferroelectric materials and hexagonal piezoelectric materials are essential for fabrication of electronic and/or photonic devices. Historically ferroelectric materials were discovered in a form of bulk single crystals of Rochelle salt in 1920. Since then, a number of ferroelectric materials, including $\text{NH}_4\text{H}_2\text{PO}_4$ (ADP), KH_2PO_4 (KDP), LiNbO_3 (LN), LiTaO_3 (LT), BaTiO_3 (BT), PbTiO_3 (PT), and $\text{Pb}(\text{Zr},\text{Ti})\text{O}_3$ (PZT), were developed in a form of bulk single crystals or bulk ceramics. Among these ferroelectric materials, perovskite (ABO_3) with oxygen octahedral structures has become an important ferroelectric material.

Ferroelectric materials are dielectrics that have a spontaneous polarization with nonlinear hysteretic properties and show several unique properties including high dielectric permittivity, high piezoelectricity, high pyroelectricity, and high electrooptic characteristics.

Bulk ferroelectric materials were widely used to manufacture discrete electronic components including ceramics capacitors, bandpass filters, resonators, ultrasonic transducers, and positive temperature coefficient (PTC) thermistors. Novel ferroelectric materials such as optical transparent ferroelectric $(\text{Pb},\text{La})(\text{Zr},\text{Ti})\text{O}_3$ (PLZT) ceramics were developed by Haertling and Land in 1971. A high-speed electrooptical shutter was realized using hot-pressed transparent PLZT ceramics. The bulk-type ferroelectric devices, however, could not meet recent requirements of miniaturization and/or integration with Si and/or GaAs semiconductive devices.

Thin film ferroelectric materials have a high potential for miniaturization and/or integration with the semiconductive devices. Thin films are also important to the understanding of ferroelectricity. Thin films are commonly fabricated by depositing individual atoms on a substrate. The film thickness is typically less than several micrometers. The structure of thin films is essentially homogeneous on an atomic scale. Thin films exhibit the following useful aspects including thin film effects:

1. Unique material properties resulting from the atomic scale growth
2. Size effects at ultrathin films
3. Unique functional properties at layered structure including human-made superlattice and tailored ferroelectric materials

Polycrystal and/or single-crystal thin films of ferroelectric/piezoelectric materials are used for the fabri-

cation of thin film devices. The polycrystal thin films are commonly deposited on a noncrystalline substrate such as fused quartz, borosilicate glass, and passivated Si substrates. The single-crystal thin films are heteroepitaxially grown on a foreign single-crystal substrate such as sapphire, MgO , SrTiO_3 (ST), LaAlO_3 , and YSZ substrates. At the early stage, the ferroelectric thin films were considered to be a simple substitution of bulk dielectric materials by thin films, such as a fabrication of thin film discrete capacitor for an electronics system.

Since the 1970s, several kinds of thin film ferroelectric and/or piezoelectric films were developed for a fabrication of bulk acoustic wave (BAW) devices, surface acoustic wave (SAW) devices, thin film ferroelectric memory, acoustooptical (AO) devices, and electrooptical (EO) devices. Among these thin films, piezoelectric ZnO and CdS thin films of hexagonal structure were extensively studied for a fabrication of the thin film SAW devices and the thin film AO devices, although the piezoelectric hexagonal ZnO and/or CdS were not ferroelectric materials. The technology for a production of ZnO thin film SAW devices was established, and the ZnO thin film SAW devices are used in practice. Since the 1980s, much attention has been paid to the application of ferroelectric thin films such as PZT and $(\text{Pb},\text{La})\text{TiO}_3$ (PLT) to thin film optical waveguide devices, an integrated pyroelectric sensor, a memory capacitor of high dielectric permittivity at megabit dynamic random access memory (DRAM), the ferroelectric random access memory (FERAM) combined with Si and/or GaAs integrated circuits, and a thin film microactuator. Two-dimensional integrated optical devices are made by electrooptic thin films. The multilayer structures tailor SAW materials with designed acoustic velocity, electromechanical coupling, and temperature stability. The electromechanical coupling for the generation of SAW is enhanced at the layered structures. High electromechanical coupling with zero temperature coefficient of delay time (TCD) could be achieved at the layered structure of ZnO/glass substrate. The electrostrictive properties are also of interest for making a microelectromechanical system (MEMS). A MEMS provides integration of sensors, actuators, and electronic circuits in a single chip. Table 1 shows typical thin film ferroelectric materials and their devices including hexagonal piezoelectric thin films [1–3].

2. THIN FILM FABRICATION

Thin films of ferroelectric materials are fabricated by a thin film deposition process including physical vapor deposition (PVD), chemical vapor deposition (CVD), and chemical solvent deposition, as shown in Table 2.

Thin films of ferroelectric materials were first fabricated by Feldman in 1955 for BaTiO_3 by PVD using a simple vacuum evaporation. In the 1960s, others tried to deposit thin films of PbTiO_3 by cylindrical magnetron sputtering. The controlled deposition of the perovskite

ferroelectric materials of ABO₃ and A(B1,B2)O₃ structure could not be attained because of their complex chemical composition. Since the middle of the 1970s, rapid progress has been observed in the thin film deposition processes, including planar magnetron sputtering, molecular beam epitaxy (MBE), and metal organic chemical vapor deposi-

tion (MOCVD). After the discovery of high-Tc superconductors of layered perovskite in 1986, rapid progress has been seen in the development of the deposition process for complex perovskite with atomically controlled crystal structure using sputtering, MBE, laser ablation, and MOCVD.

Table 2. Thin Film Deposition Process

Classification	Deposition System	Source Materials	Film Structure
<i>Vapor phase deposition</i>			
PVD	Thermal evaporation	Individual metals Individual oxides Multisource	Uniaxial crystal by epitaxial growth (poly/single)
	Laser ablation	FE compounds Individual oxides Multitarget	Tailoring FE by layer-by-layer deposition <i>In situ</i> poling
	Sputtering	FE compounds Individual metals Individual oxides Multitarget	
CVD	Low-pressure CVD	Individual halide	Uniaxial crystal by epitaxial growth (poly/single)
	MOCVD	Metal organic gas	<i>In situ</i> poling
	Plasma-assisted MOCVD		
<i>Chemical solvent deposition</i>			
	MOD	Individual	Multiaxial (polycrystal)
	Sol-gel deposition	Metal organic gas	<i>Ex situ</i> poling (porous)

Typical configuration of deposition systems are shown in Fig. 1. A conventional thermal evaporation process provides inhomogeneous and nonstoichiometric thin films. A multisource MBE system is used for the deposition. The laser ablation is carried out by the direct evaporation of source ferroelectric materials resulting from the irradiation of high-intensity pulsed excimer laser. The mechanism of laser ablation includes photo and thermal evaporation. The pulsed evaporation by high-intensity laser improves the inhomogeneity and/or nonstoichiometry, although the laser ablation includes the thermal evaporation process. The phenomenon of sputtering consists of a nonthermal evaporation. The sputtering process essentially provides homogeneous and stoichiometric thin films of complex ferroelectric materials because the sputtering mechanism consists of removing source materials (target) on an atomic scale by an impact of energetic ions through the momentum transfer mechanism. Multitarget magnetron sputtering is used for the deposition of layered structures and/or human-made superlattices. The sputtering process has a high potential for the fabrication of complex ferroelectric thin films. In the plasma-assisted MOCVD, energetic electron in gas plasma enhances the chemical reaction. At present, these thin film processes provide the thin films of perovskite with an accuracy of 1 nm corresponding to two or three of their crystal units. The chemical solvent deposition provides a simple fabrication process. However, the deposited thin films are essentially porous because the growth process is governed by

a conventional thick film technology including dipping and/or spinning of sol-gel precursor solution followed by annealing for sintering.

The deposition, chiefly by sputtering, of transducer quality ZnO thin films has been studied since the 1970s. The technology to fabricate ZnO thin films has already been established. The *c*-axis-oriented polycrystalline thin films are deposited on a glass substrate by direct sputtering from the ZnO target. The *c*-axis orientation on the glass substrate is quite reasonable because the film growth of a hexagonal structure is governed by Bravis's empirical law for crystal growth, where the most densely packed plane (*c*-plane) will be the most preferable surface of crystal growth. Single-crystal ZnO thin films are epitaxially grown on a sapphire substrate. The *a*-axis-oriented ZnO thin films are epitaxially grown on *R*-plane sapphire.

It is particularly important to understand the structure of thin films because it can have a profound influence on the operation of the thin film devices.

Thin films of polycrystalline phase comprise a column geometry with an interfacial layer between the thin films and a substrate. Low dielectric permittivity of the interfacial layer apparently reduces the permittivity of the ferroelectric thin films and/or increases a coercive field (extrinsic thickness effect). The decrease of dielectric permittivity for ferroelectric thin films with the decrease of their film thickness is also governed by the depolarization phenomenon (intrinsic thickness effect).

Figure 1. Typical configuration of thin film deposition systems: (a) multisource MBE, (b) laser ablation, (c) multitarget sputtering, (d) plasma-assisted MOCVD.

The epitaxial ferroelectric thin films show different microstructures depending on the degree of lattice match between the thin films and substrates. It is generally believed that, under an excellent lattice match, the thin films such as PT on ST show a single domain; under a poor lattice match for both *a*- and *c*-axes, the thin films such as PT on MgO show a multi-axial crystal structure; and under a fairly good lattice match, the thin films such as PT on KTaO₃ (KTO) constitute a periodic domain structure. These microstructures are grown primarily to minimize the total energy of the heterostructure. The phenomena are understood by linear-elasticity theory and a Landau–Ginzburg–Devonshire type phenomenological theory.

The actual epitaxial thin films of ferroelectric materials commonly constitute inhomogeneous microstructures including an interfacial layer that resembles polycrystalline thin films on a glass substrate as a result of the inhomogeneous nucleation at the initial stage of film growth. A selection of substrate materials is important for the control of thin film growth. Typical structural properties of substrates are shown in Table 3 [4–6].

3. THIN FILM DEVICES

3.1. Thin Film SAW Devices

The use of thin film SAW devices is an example of a successful application using piezoelectricity of hexagonal thin films and perovskite ferroelectric thin films. In the quasistatic approximation, the acoustic fields associated with plane waves in a piezoelectric medium are obtained by solving the stiffened Christoffel equation. In the case of a half-space medium with a free boundary surface, the boundary conditions must be satisfied and the mechanical stress and electric displacement must be calculated from the piezoelectric constitutive equations. These procedures give the solution as a SAW, which acoustic vibration energy concentrates near the surface of elastic solid materials. The Rayleigh wave and Love wave are obtained as the typical solutions of SAWs. The particle displacement of the former is in the sagittal plane, which is

Figure 2. Interdigital transducer formed on the surface of the piezoelectric substrate.

perpendicular to the surface and parallel to the wave-propagation direction, and that of the latter is parallel to the surface and perpendicular to the direction of propagation. The SAW makes possible acoustoelectronic devices including the SAW filter for cellular phone/PCS/pager.

3.1.1. Generation of SAWs. The SAW modes can be generated by an interdigital transducer (IDT) formed on the surface of the piezoelectric substrate shown in Fig. 2. In the bulk SAW devices, bulk single crystals such as the LiNbO₃ and/or LiTaO₃ are adopted as the piezoelectric substrate. Whereas in the thin film SAW devices, a layered structure consisting of a piezoelectric thin film on the nonpiezoelectric medium is used as the piezoelectric substrate. Figure 3 shows the calculated result of an effective electromechanical coupling constant k^2 for four types of electrode configurations of a *c*-axis-oriented ZnO film on fused quartz. These electrode configurations for a thin film SAW transducer are also illustrated in Fig. 7. Each configuration consists of an IDT with or without a counter electrode. The value of k^2 is determined by the relation $k^2 = \Delta V_p / V_p$ where ΔV_p is the variation of SAW phase velocity V_p by the short condition of the surface electric field. The k^2 is simply evaluated by the equation $k^2 = \pi \omega_0 C_T / 4NG_a$, the inline model of Smith’s equivalent circuit model for electromechanical bulk wave, where ω_0 ,

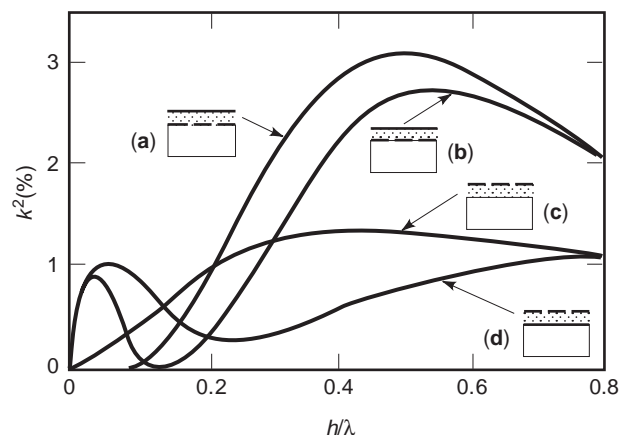

Figure 3. Calculated result of an effective electromechanical coupling constant k^2 for each configuration in the case of c -axis-oriented ZnO film on fused quartz. Four types of thin film electrode configurations are illustrated [7].

C_T , G_a , and N are the synchronous frequency, capacitance, radiation conductance, and number of finger pairs of IDT, respectively. The inline model (the major electric field component is parallel to the surface) becomes almost equal to the crossed-field model (the major electric field component is perpendicular to the surface) under the rough condition of $k^2 N > 1$. Figure 3 shows that k^2 varies with the ZnO film thickness, and the variations show a double-peaked character for the IDT structures including the counter electrodes. Note that the k^2 for thin films is higher than the bulk value at optimum film thickness.

3.1.2. Temperature Stability. SAW-layered structures have flexibility in that substrate materials can be chosen to adjust the temperature coefficient of a center frequency (TCF) and a delay time (TCD). The temperature stability of TCF or TCD is given by the equation, $(1/f)(dt/dT) = (1/t)(dt/dT) = (1/v)(dv/dT) - \beta$, where β denotes the thermal expansion coefficient of the substrate. The tendency of the phase velocity change $(1/v)(dv/dT)$ varies with the layered film thickness and elastic properties of the substrate materials. A suitable film thickness and a pertinent selection of substrate materials result in a zero TCD. Figure 4(a) shows one example of such a temperature deviation of the center frequency of the SAW IDT, which consists of the ZnO thin film, the SiO₂ or fused quartz layer, and the Si substrate. In this structure, the TCF of ZnO has a negative value of about -30 ppm/°C, and that of fused quartz has a positive value of $+60$ ppm/°C. These opposite values cancel the TCF while controlling the thickness of the SiO₂-layered film. Another example is shown in Fig. 4(b). Here the borosilicate-glass substrate can control TCF by controlling the composition ratio of the elements added to the glass.

3.1.3. SAW in Layered Media. The Rayleigh wave and Love wave are the solutions for a half-space medium with a free boundary surface. In layered structures, which

(a)

(b)

Figure 4. Temperature deviation of the center frequency of the SAW IDT constructed by the ZnO thin film: (a) the SiO₂ or fused quartz layer and the Si substrate; (b) the borosilicate-glass substrate [8].

include the thin plate rigidly bonded to the half-space (or substrate) having different material properties, the solutions for propagating waves must satisfy the appropriate wave equation in the layer and in the substrate as well as the boundary conditions imposed by the interface and the free surface. We know that fundamental and higher order modes of both Rayleigh and Love waves can propagate when the bulk shear wave velocity of the layer is lower than that of the substrate. This condition corresponds to that of the heavier and less stiff layer loads on

the substrate and will tend to confine the propagation energy to the layer. In this case, the propagating wave nodes are regarded as the modified plate modes. Sezawa discovered that a second fundamental mode may also exist in layered media. The Rayleigh modes and Sezawa modes correspond to symmetric and antisymmetric modes of a free plate modified by the contact of the surface with the substrate. In addition to these, the layer on an infinite half-space is open on one side, and there is a possibility of radiation or energy leakage out of the layer into the half-space. This condition gives the leaky wave solution for SAW.

The particle displacement of the SAW in the sagittal plane degrades with the depth from the surface. Also in the case of the layered substrate, almost the same situation exists in the half-space substrate. However, the degradation of that area in or near the top layer is different from the monotonous degradation of the zeroth Rayleigh mode. The amplitude distribution of the particle displacement is calculated for each propagating mode. Figure 5 shows the depth profiles of the particle displacement in the sagittal plane for the fundamental mode and higher four modes of the Rayleigh-type wave. More complex profiles and deeper penetration are shown for the particle displacement of higher order modes. Moreover, Fig. 5 shows that the higher order modes have a large displacement component in the substrate. So, it can be understood qualitatively that the higher order modes have a higher phase velocity because the phase velocity of the substrate is higher than that of the layer.

In Fig. 6, the solid lines and broken lines show the phase velocity V_p and the effective coupling coefficient k^2 of the Rayleigh-type and Love-type wave modes as a function of h/λ , respectively, where h is the layer thickness. These numerical results were obtained for the SAW directed to [1000] ZnO axes in the layered structure with the ZnO layer on the R -plane sapphire substrate. The first mode of the Rayleigh-type (zero Sezawa mode) shows an exceedingly large maximum value of k^2 with very high phase velocity at relatively small h/λ . These computer solutions were experimentally confirmed. For higher Rayleigh-type

Figure 6. Rayleigh-type and Love-type wave mode solutions as a function of h/λ on the [1000] direction of the single-crystal (11 $\bar{2}$ 0) ZnO thin film epitaxially grown on the (01 $\bar{1}$ 2) sapphire surface. Solid lines and broken lines show the phase velocity V_p and the effective coupling coefficient k^2 [9].

modes, responses were still observed above the mode cutoff frequency as leaky mode responses.

3.1.4. Thin Film SAW Filters. Thin film SAW devices are constructed by the thin film IDTs on nonpiezoelectric substrates, by high-frequency propagation of the higher order modes of layered SAW, the substrate selected for the temperature stability, and so on. These distinguishing characteristics can realize the high performance of bandpass filters, resonators, delay lines, convolvers, integrated devices, and acoustooptic devices. The video intermediate frequency (VIF) filters for color TV sets were the first thin film mass-production devices. The frequency range of a VIF filter of 50–60 MHz is low enough for the SAW propagation loss of polycrystalline piezoelectric thin films such as c -axis-oriented ZnO films on a borosilicate-glass substrate. The thin film SAW filter shows excellent long-term stability. The long-term drift of the center frequency is less than 100 ppm after 1000 hours of exposure to 125°C in the air. The long-term stability of the ZnO thin film SAW filter is higher than that of bulk single-crystal LiNbO₃ SAW filters because of the absence of subsurface damage inflicted during sawing and polishing, which is unavoidable for bulk SAW devices. Figure 7 shows one example of the configuration of SAW VIF filters with two normal output IDTs and one apodized input IDT.

Another example is the high-frequency filter of epitaxially grown single-crystal thin film, which has low propagation loss of higher order Rayleigh wave modes in the gigahertz range. The ZnO single-crystal film on sapphire substrate is the typical construction of devices that

Figure 7. IDT configuration of SAW VIF filters with two normal output IDTs and one apodized input IDT on the layered substrate.

provide 4.37 GHz filters with a phase velocity of 5327 m/s and an insertion loss of 16 dB by 0.27 μm thick ZnO film, 3-IDT of 50 nm thick Al electrodes, and third-order response of double electrode-type IDTs. These excellent properties of thin film SAW filters are able to provide the high performance of information communication systems [7–17].

3.2. Ferroelectric Nonvolatile Memory

The basic operation of ferroelectric nonvolatile memory is switching of polarization states in a ferroelectric ABO_3 structure. Figure 8 shows a typical configuration and

Figure 9. Schematic circuit of 256-bit FESRAM (Ramtron Corp. [18]).

schematic circuit of ferroelectric nonvolatile memories, dynamic random access memory (FEDRAM). The FEDRAM resembles a conventional dynamic random access memory (DRAM). The memory capacitor C_s of DRAM is replaced by a ferroelectric thin film capacitor. The C_s is in series with a MOS (metal-oxide-semiconductor) transistor whose source is connected to the bit line, the gate to the word line, and the drain to the pulsed 5 V common plate. In the FEDRAM, the polarization of the ferroelectric thin films switches to the opposite polarity on application of an electrical field higher than the coercive force when the MOS transistor is turned on by the appropriate voltage on

the gate. In the hysteresis loop of memory capacitor C_s , the position *A* is taken to be a bit 1 state and *B*, a bit 2 state. The switching signal is detected by the voltage change at the bit line V_b . The V_b is given by $V_b = Q_s/C_b$, where Q_s denotes change of charge at switching on the capacitor C_s and C_b denotes the storage capacitor at the bit line. The Q_s is given by $Q_s = 2P_r$, where P_r denotes remanent polarization for ideal ferroelectric thin films having a symmetric hysteresis loop. For memory capacitors, PZT thin films are widely used. The P_r is 20–30 $\mu\text{C}/\text{cm}^2$ for typical PZT thin films. The value of Q_s for each memory cell is 400–600 fC for a cell area of $1 \mu\text{m}^2$, which is enough for the switch

memory operation because the minimum detectable value of Q_s for each cell is 20–30 fC at the conventional DRAM. The switching speed is essentially governed by the switching time of polarization reversal. The switching time is 1 ns for typical ferroelectric materials. The FEDRAM has some definite advantages, including a permanent memory and radiation hard characteristics. However, there are disadvantages of switch fatigue resulting from domain switching. Historically, the ferroelectric memory was proposed in the first part of the 1970s and first developed in 1987 by Ramtron Corp., Colorado Springs, and Krysails Corp., Albuquerque. The first developed ferroelectric

memories look like the six-transistor static random access memory (SRAM) except that they include an additional pair of ferroelectric thin film capacitors, as shown in Fig. 9. Presently, the FEDRAM with a single transistor, where the ferroelectric thin films make a conventional DRAM nonvolatile, has been extensively studied to improve long-term stability. The ferroelectric thin films placed in the gate area of a MOS transistor provide another type of ferroelectric memory—the ferroelectric memory field effect transistor (FEMFET). Depending on the polarization of the gate materials, the source-to-drain current is increased or decreased significantly. The 1 or 0 state is detected by monitoring the source-to-drain current without switching the remanent polarization. This type of switch gives a nondestructive read out. This type of memory is under research because the interface control between the ferroelectric thin film and semiconductor is not completed.

Apart from the FEDRAM, the high dielectric permittivity of ferroelectric films is used for the local capacitor in highcount DRAM to reduce the area of the memory capacitor and/or eliminate the complex trenching and/or corrugation structures for the increased capacitive area. The high permittivity of the ferroelectric thin films achieves the flat structure of the memory cell. In the mega-/gigabit DRAM, the requirement for ferroelectric thin films is a permittivity of 200–2,000 at a film thickness of 100 nm

Figure 12. Cross-sectional view of thin film optical channel waveguide: (a) raised-strip type, (b) ridge type, (c) embedded type, and (d) strip-loaded type. n_1, n_2, n_3, n_4 are refractive index of waveguide, substrate, environment, and loaded strip, respectively.

without remanent polarization. The ferroelectric thin films should be used above their Curie temperature. If ferroelectric thin films are used, their operating coercive field should be large [18,19].

3.3. Thin Film Pyroelectric Infrared Detectors

Ferroelectric materials have been used for making pyroelectric infrared detectors by measuring the pyroelectric

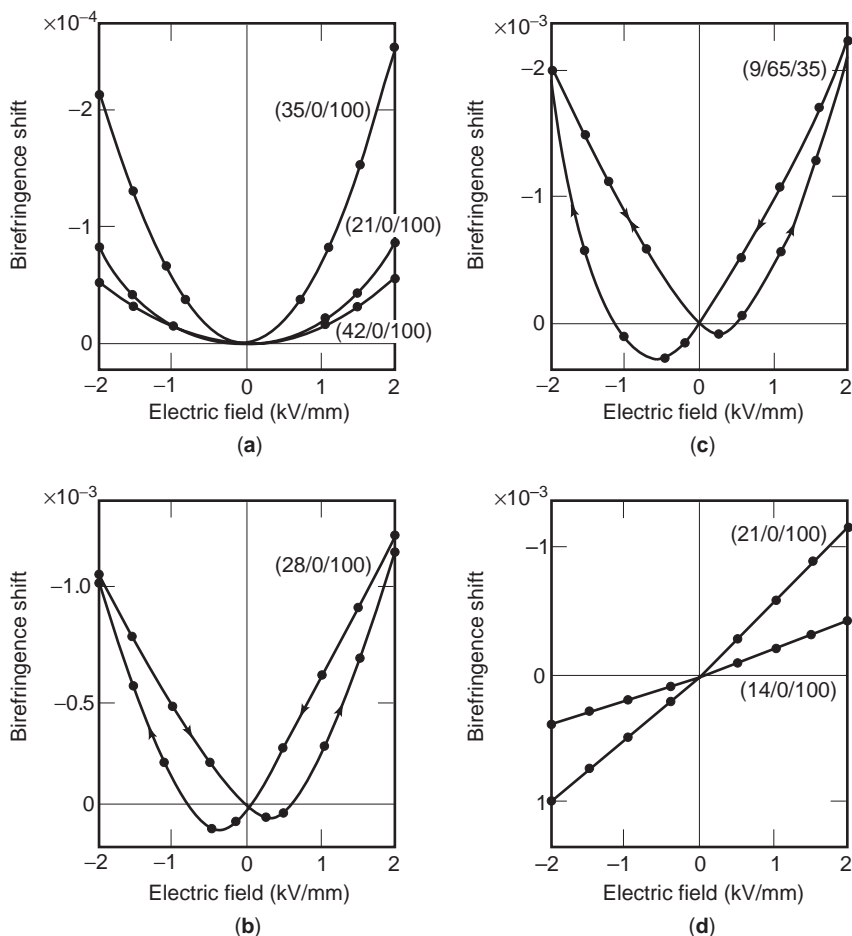

Figure 13. The effective birefringence shift as a function of transverse electric field for PLZT thin film of 0.4 mm in thickness [22].

current because they exhibit a large pyroelectric effect. The pyroelectric effect is described by the pyroelectric coefficient γ , which relates the change of polarization to the change in temperature. Pyroelectric current i_p will be detected by the temperature change of the detector materials generated by absorbed infrared radiation. The i_p is given by $i_p = \gamma(dT/dt)$. Bulk ferroelectric single crystals TGS (triglycine-sulphate) and LT, ferroelectric polymer PVDF (polyvinyl-di-fluoride), and ferroelectric ceramics PT and PbZrO_3 (PZ) are widely used for making pyroelectric infrared detectors. The pyroelectric materials are evaluated by figures of merit; $F_1 = \gamma/C_v$, $F_v = \gamma/C_v \cdot \varepsilon$, $F_M = \gamma/C_v (\varepsilon \cdot \tan \delta)^{1/2}$, where C_v denotes a volume-specific heat, ε denotes a dielectric constant, and F_1 , F_v , and F_m denote the figure-of-merit related to a current response, an output voltage response, and a detectivity, respectively. Perovskite thin films of PT and/or PLT are epitaxially grown on a Pt-metallized MgO substrate. The MgO substrate is removed after deposition of perovskite thin films. The as-deposited thin films show a highly oriented structure, which results in excellent pyroelectric properties without poling treatment after deposition. The single-domain structure with a low dielectric constant in the c -axis direction improves the figure-of-merit of conventional ceramic pyroelectric materials. Figure 10 shows the typical pyroelectric properties of bulk and thin film PLT. The integrated infrared sensor array shown in Fig. 11 was created using thin film infrared detector technology. The sensor array, manufactured by Matsushita Elec. Ind., Osaka, Japan, is used for a room air conditioner. The array detects the position and number of persons and their body temperatures to create a comfortable space [20,21].

3.4. Thin Film Optical Waveguide Devices

Thin film optical waveguide devices commonly consist of a sandwich structure of a thin film waveguide and a substrate. The refractive index of the thin film waveguide is larger than the substrate value so that a guided light beam propagates in the thin film waveguide. The direction of a propagated light beam is controlled by the channel waveguide shown in Fig. 12. The waveguide thin films comprise functional materials including EO or AO materials such as LN, PLZT, and ZnO. The PLZT thin films exhibit a linear EO effect or a quadratic EO effect depending on their composition. Typical EO properties of PLZT thin films are shown in Fig. 13. The birefringence shift $\delta\Delta n$ is several times larger than for conventional LN crystals. The linear EO coefficient r is given by the relation $\delta\Delta n = -\frac{1}{2} \times n^3 r E$ and the quadratic E/O coefficient R is given by the relation $\delta\Delta n = -\frac{1}{2} \times n^3 R E^2$, where n is the refractive index and E is the applied electric field. The value of R is $0.6 \times 10^{-16} (\text{m/V})^2$ and r is $0.81 \times 10^{-10} \text{m/V}$. The light beam is introduced using an optical coupler such as a prism, micrograting coupler, and microlens directly connected to the optical fiber. The thin film waveguide is fabricated by deposition of the functional thin films on a substrate followed by microfabrication. The surface treatment, such as doping of a foreign element on the functional crystal substrate (i.e., Ti doping on LN),

is also used for the fabrication of thin film waveguides. Typical thin film waveguide devices are shown in Figs. 14–16.

Figure 14(a) shows the Mach–Zehnder interferometric modulator. The input light signal is equally divided into two waves by the branching guide and fed through two parallel arms of guide. In each arm, the waves are electrooptically modulated by the applied field. The intensity of guided light of TE_0 mode is strongly modulated because of a large EO effect. A typical sinusoidal pattern is observed as the applied electrical field is varied as shown in Fig. 14(b). The Bragg diffraction switches comprise PLZT epitaxial thin films on sapphire for the EO switch and ZnO epitaxial thin films on sapphire for the AO switch, respectively. The guided light, chiefly TE_0 mode, is diffracted as a result of a periodic grating with refractive index by applying a periodical electrical field for the EO switch using an interdigital electrode and by applying SAW for the AO switch using an interdigital SAW transducer. The angle of diffraction is governed by the Bragg diffraction, and the diffraction angle 2θ is given by $2\theta = \lambda_0/n\lambda_s$, where θ denotes the Bragg angle, λ_0 denotes

Figure 14. (a) Configuration of a thin film Mach–Zehnder interferometer using PLZT thin film on sapphire and (b) the variation of output light intensity with applied voltage [23].

Figure 15. (a) Configuration of thin film AO Bragg deflector using ZnO thin film waveguide on sapphire and (b) a deflected light beam as a function of applied frequency at IDT driven by the first-order Sezawa mode of SAW [24].

the wavelength of light, n denotes the effective refractive index of the waveguide, and λ_s denotes the wavelength of the interdigital electrode. Figure 15 shows a typical operation of the ZnO thin film AO deflector. The Bragg deflector is driven by the first-order mode of SAW (Sezawa mode) with a phase velocity of 5700 m/s. The IDT is designed for 2 GHz operation. The TE_0 mode of a guided He–Ne laser beam is effectively deflected by the high-frequency SAW.

The total internal reflection (TIR) switch, which was first proposed by C. S. Tsai, is composed of a pair of crossed channel PLZT (20/0/100) waveguides, quadratic EO, with four terminals on sapphire as shown in Fig. 16(a). The intersecting angle of the channel waveguide θ satisfies the relation, $\theta < 90 - \theta_c$, $\theta_c = 1/\sin(1 - \frac{1}{2}n^2RE^2)$, where θ_c denotes the critical angle of total reflection, R denotes the quadratic EO coefficient, and E denotes the electrical field at the crossed area. At the crossed area, a pair of control electrodes are deposited to apply a control electrical field. Figure 16(b) shows a typical operation of the PLZT TIR switch. The TE_0 mode of the guided He–Ne laser beam directly coupled from port 1 propagates to port 3 without applying a control voltage, but the guided light is switched to port 4 as a result of the decreased refractive index at the interaction area under the application of control voltages. The switching voltage is less than 5 V because of the high EO coefficient of PLZT. The switching speed is expected to be as high as 100 GHz.

Thin film waveguide devices are flourishing. A number of promising devices are proposed for optical communication systems and integrated optical circuits, including optical computing [22–29].

 Kingdom

1. INTRODUCTION

The study of III-V compounds dates back to the dawn of semiconductor technology, when in 1952 Welker [1] suggested that gallium arsenide (GaAs) showed potential as a semiconductor material. The key aspect of this class of

materials that makes them of particular interest is their properties, which make them particularly suitable for high-frequency electronic and photonic devices. In the case of GaAs the electron velocity of bulk material, which determines the frequency limits of devices, is significantly higher than that found in silicon (Si). Furthermore, the low field mobility of electrons in many III-V materials is higher than that of Si. Diodes fabricated from III-V materials have demonstrated cutoff frequencies of several terahertz; transistors have demonstrated cutoff frequencies (f_T) higher than 300 GHz [2] and monolithic microwave integrated circuits (MMICs) operating above 200 GHz [3]. This has led to the use of GaAs and InP in a wide variety of high-frequency semiconductor devices operating in applications as diverse as low-noise amplifiers, mixers, power amplifiers, RF switches, and oscillators at frequencies up to 240 GHz. The wide operating temperature range of III-V semiconductors, typically from -200 to 300°C, coupled with superior radiation hardness compared to Si, led to GaAs and InP becoming key materials for space and defence requirements. In more recent years the photonic properties of III-V materials, arising from their direct bandgap energy band structures, have been extensively exploited for solid-state lasers, light-emitting diodes, photodetectors, and optical modulators, with the potential for fully integrated optoelectronic integrated circuits. To date these properties are unrivalled by Si, which is an indirect bandgap semiconductor.

Although many III-V materials are routinely used in microwave and optoelectronic semiconductor devices today, it wasn't until the early 1970s that the first semiconductor devices became widely available, and even then it was restricted to two terminal devices and simple transistors. The relatively slow progress in developing commercially viable technologies was partly due to the challenging problems in establishing high-quality material growth and the development of processing techniques that allow reliable devices to be fabricated. The key step to achieving volume production and widespread use of cost-effective devices is the availability of larger-diameter wafers, from which the semiconductor devices are fabricated. Early work was restricted to very small samples (parts of wafers) or small-diameter wafers of 2 in. or less. Gradually, high-quality 3- and 4-in.-diameter wafers became available and discrete devices and integrated circuits were introduced for military and commercial applications. Significant advances since the early 1980s have led to the introduction of 6-in. (150-mm) very-high-quality GaAs substrates and epitaxy suitable for high-volume production of semiconductor devices. Similarly, other materials such as InP are now well established and production is supported by 4-in.-diameter substrates.

The advent of high-quality reproducible epitaxy, provided by molecular-beam epitaxy (MBE) and organic metal vapor-phase epitaxy (OMVPE, MOCVD), led to a shift in interest from bulk III-V devices to heterostructure semiconductor devices, based on bandgap engineering, which allow higher performance to be obtained. In particular, the development of ternary and quaternary compounds, such as AlGaAs, GaInAs, and GaInAsP, were key steps forward for new transistor technologies,

Table 1. III-V Semiconductor Materials

Compound Type	III-V Material
Binary	BAs, BP, AlSb, BN, GaSb, AlAs, AlP, GaAs, InSb, GaP, InAs, InP, AlN, GaN
Ternary	AlGaAs, AlGaIn, InGaAs, InGaP, GaAsP, InAsP, GaInSb, GaInAs
Quaternary	InAlGaAs, GaInAsP, InAlGaP, InAlGaSb, AlGaAsSb

high-electron-mobility transistors (HEMTs), heterojunction bipolar transistors (HBTs), and long wavelength optoelectronic devices. The exploitation of lattice-matched (usually to InP) and strained (usually to GaAs) crystal structures using these compounds is an essential element of today's III-V technology. More recently the use of material systems such as GaN/AlGaN for high-voltage, high-power-density transistors has led to increased interest in examining the growth on nonnative layers using epitaxy to create III-V active layers on SiC, sapphire, or more recently silicon substrates. Record performance power density levels are being achieved with GaN HEMTs, reporting over 30 W/mm gate periphery, compared with less than 1 W/mm from conventional MES-FETs and HEMTs [4].

In the mid-1980s GaAs integrated circuit technology was costly and reserved only for the most demanding system requirements. Contemporary III-V semiconductor device technology is able to provide microwave monolithic integrated circuits (MMICs) at a cost of less than 20 cents per square millimeter in some very high volumes, supporting a market approaching a billion die per annum. III-V transistor technology is the foundation of high-efficiency power amplifier and low-loss RF switch MMICs in today's cellular handsets. The advent of heterostructure technologies using Si, notably SiGe, which have demonstrated the potential for very fast devices, is likely to displace III-V in some very-high-volume RF and microwave applications.

This article aims to provide a basic introduction and an overview of contemporary III-V semiconductors. Many of the topics touched on in these pages are expanded in detail elsewhere in this encyclopedia, but the reader is encouraged to explore the wealth of material available in this exciting area of semiconductor technology.

2. III-V SEMICONDUCTOR MATERIAL PROPERTIES

III-V semiconductor materials are alloys formed from elements in group III and group V of the periodic table. They are grown as single crystals and as either binary, ternary, or quaternary alloys (Table 1).

2.1. Crystal Structure

All III-V semiconductors are alloys, and unlike the elemental semiconductors silicon (Si) and germanium (Ge), which exhibit diamond cubic crystal structures, generally crystallize in more complex structures. GaAs and InP have cubic zincblende structures (sphalerite structures), with a tetrahedral arrangement of the atoms, with each group III atom bonded to four group V atoms (Fig. 1). The tetrahedral structure is characteristic of directional covalent

bonding in semiconductors, with eight valence electrons per pair of atoms (in sp^3 -hybridized orbitals). In the case of GaAs and InP, unlike diamond cubic semiconductors, there is some charge transfer between the two types of atom giving rise to the partial ionic character of the bond. Generally speaking, these partly heteropolar bonds are stronger than homopolar bonds such as those found in Si. Heteropolar bonds also tend to be associated with lower amplitude lattice vibrations and wider energy bandgaps.

The properties of crystal structures, including their electrical behavior, vary according to the plane considered. The most commonly used method of defining planes in crystals is the use of Miller indices [5], which are obtained by determining the intercepts of each plane on the three Cartesian coordinates in terms of the lattice constant and then taking their reciprocals and reducing them to the smallest three integers having the same ratio (Fig. 2). The lattice parameter is usually denoted a , for sphalerite structures. The resulting Miller indices are expressed in parentheses (hkl). For example, a plane that intercepts the x axis on the negative side of the origin is (100) . Extensions of this notation allow for planes of equivalent symmetry, defined as $\{hkl\}$; for example, $\{100\}$ for cubic symmetry. Crystal direction is defined using the notation $\langle hkl \rangle$; for example, $\langle 100 \rangle$ for the equivalent set of directions $[100], [010], [001], [100], [010], [001]$. Crystal direction is used to define the orientation of wafers for the

Figure 1. Cubic zincblende (sphalerite) crystal structure of GaAs [based on diagram from S. M. Sze, *Physics of Semiconductor Devices*, Wiley-Interscience (1981)].

Figure 2. Miller indices [based on diagram from S. M. Sze, *Physics of Semiconductor Devices*, Wiley-Interscience (1981)].

fabrication purposes, since the electrical properties and chemical etching properties differ according to orientation. Notches or “flats” are created on the edge of wafers to precisely indicate the orientation of the wafer with respect to the crystal structure.

In the case of GaAs cleaved along the (111) plane, the surface consists of either Ga atoms, which have three bonds with the crystal or As atoms that have one bond with the crystal. In fact, the bonds between the nearest Ga and As atoms are in the $\langle 111 \rangle$ directions. Gallium nitride GaN has a wurtzite crystal structure, which has two lattice parameters a and c .

2.2. Energy Band Structure

The electronic and vibrational states in crystals are usually described in reciprocal space or k space. The smallest unit cell in reciprocal space is called the *first Brillouin zone*. The first Brillouin zone in cubic semiconductors is a truncated octahedron with symmetry points and lines denoted Γ , X , L , K , U ($K=U$), W , Δ , Λ , and Σ . A very good detailed description is given in Ref. 6. The Γ point at $k=0,0,0$ in Cartesian coordinates is the point of highest symmetry in the Brillouin zone.

The energy band theory of semiconductors assumes that the lattice features perfect translational symmetry, that one electron at a time is considered, and that the influence of all electrons is represented by the average over their wavefunctions. The Schrödinger equation for the one-electron case is used to define the functional dependence of energy $E(k)$ on the wavevector k for the various bands. This model is modified to form the Sommerfeld free-electron model by introducing the idea of effective mass. The nearly free-electron approximation provides a basis for developing energy band theory, and the origin of the energy bandgap between the valence and conduction bands. It also introduces the concept of effective mass, which is defined as the reciprocal of the curvature of the E - k diagram. The band structure for a semiconductor is calculated using the well-known **k.p.** method [7]. The **k.p.** representation results from the complete set of eigen functions that are obtained from the substitution of Bloch functions [6] in the one-electron Schrödinger equation. Spin-orbit interaction is also included in the full definition of the energy-wavevector relationship, which leads to a formulation based on a series of Hamiltonians.

Valence band maxima occur at the Γ point for semiconductors with tetrahedral structure. Many semiconductors with this structure, such as GaAs and InP, also have conduction band minima at this point. In GaAs and similar semiconductors, the conduction band structure close to Γ is essentially parabolic. The lowest conduction band minimum occurs at $k=0$ with further minima in the Δ $\langle 100 \rangle$ and Λ $\langle 111 \rangle$ directions. Other important conduction and minima occur at 0.31 and 0.52 eV above the first Γ minima for X and L . The valence band structure has heavy hole and light hole bands that degenerate at $k=0$ and spin-orbit split bands at 0.34 eV below this level. The energy band structure for GaAs are shown in Fig. 3. The direct energy bandgap is the difference in energy between the conduction band minima and the valence band maxima.

The energy band structure of other III-V semiconductors such as ternary and quaternary alloys is dependent on the mole fractions x and y (e.g., $\text{Al}_x\text{Ga}_{1-x}\text{As}$ and $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$). The direct energy bandgap $E_0(x,y)$ is usually expressed as a quadratic function of the mole fraction, characterized by the coefficient of the second-order term, also known as the “bowing parameter.” The

^cIn units of free-space permittivity ϵ_0 8.85×10^{-12} F/m.

bowing parameter typically varies from 0.2 for AlGaAs to 0.88 for GaInP. Positive bowing parameters imply that the energy band bows downward. In contrast to the energy bandgap, the lattice constant of ternary alloy semiconductors generally varies linearly with composition. The lattice constant behavior for quaternary compounds is more complex with a higher-order dependence on the mole fractions. The energy bandgap, lattice constant, and other parameters of binary III-V semiconductors are shown in Table 2.

The energy bandgap is a very important parameter in device design. The temperature dependence of the bandgap E_g , which decreases with increasing temperature, is generally expressed as

$$E_g(T) = E_g(0) - \frac{\alpha T^2}{T + \beta}$$

where $E_g(0)$ is the energy bandgap at 0 K and α and β are constants; α typically lies in the range $2.5\text{--}6 \times 10^{-4}$ eV K⁻¹, β in the range 75–600. In the case of GaAs $E_g(0)$, α and β have the values 1.519, 5.405×10^{-4} eV/K, and 204.

The bandgap of ternary and quaternary III-V alloys depends on their composition and mole fraction [8]. The lattice matching criteria and compositional factors (Vegard's law) limits the range of mole fractions. In the case of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ and $\text{In}_x\text{Ga}_{1-x}\text{As}$ the bandgap dependence on mole fraction x (at 300 K) is described by simple quadratic equations:

$$\text{Al}_x\text{Ga}_{1-x}\text{As} : E_g = 1.424 + 1.429x - 0.14x^2 \text{ eV}$$

$$\text{In}_x\text{Ga}_{1-x}\text{As} : E_g = 1.425 - 1.501x + 0.436x^2 \text{ eV}$$

In the case of ternary compounds such as InAlGaAs, the energy bandgap is a function of two mole fractions x and y such that at 300 K:

$$\begin{aligned} \text{In}_{1-x-y}\text{Al}_x\text{Ga}_y\text{As} : E_g(x, y) = & 0.360 + 2.093x + 0.629y + 0.577x^2 \\ & + 0.436y^2 + 1.013xy - 2.0xy \\ & (1 - x - y)\text{eV} \end{aligned}$$

Additionally in the case of InAlGaAs, it is necessary to account for the lattice-matching condition $0.98x + y = 0.47$ and the compositional parameter z where $x = 0.48z$ and

$$E_g(z) = 0.76 + 0.49z + 0.20z^2 \text{ eV}$$

The range of mole fraction compositions in III-V ternary and quaternary semiconductors is limited by the requirement to achieve lattice matching to GaAs, InP or GaSb substrates. Figure 4 shows the variation in lattice parameter with energy bandgap for a range of III-V semiconductors [6]. The shaded regions show the range of parameters for quaternary alloys $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{Sb}_{1-y}$ and $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$.

Variation of lattice parameter with energy bandgap associated with a variety of III-V semiconductors at 300 K [Landolt-Bornstein, “Numerical Data and Functional Relationships” in *Science and Technology*, Vol. 22, *Semiconductors*, Subvol. A., O. Madelung and M. Schulz, eds., Springer, New York (1987)].

2.3. Crystal Growth

Ideally, integrated circuits require an insulating substrate to provide electrical isolation between the various circuit elements. Silicon does not have a native insulating or semiinsulating state, although the more recent silicon-on-insulator (SoI) technology facilitates a suitable substrate for silicon RF and microwave integrated circuits. On the other hand GaAs and many other III-V semiconductors can be grown as semiinsulating materials. The active (conductive) regions of the circuit are defined by combinations of epitaxy, ion implantation, and mesa etching (or isolation by ion implantation).

Active devices and integrated circuits are fabricated on semiinsulating wafers that may have epitaxial layers grown on the surface. Some devices such as diodes may use bulk doped substrates. The wafers are obtained by sawing single-crystal boules along predetermined planes. These single crystal boules may be grown using a variety of techniques, including horizontal or vertical Bridgman, Czochralski, liquid-encapsulated Czochralski (LEC), magnetic LEC, liquid-encapsulated Kryopoulos (LEK), horizontal gradient freeze, or by float-, horizontal- or vertical-zone melting [9]. Bridgman techniques are the most commonly used methods of growing semiinsulating substrates.

The horizontal Bridgman technique involves the progressive crystallization of a molten bar of material as it is passed through a carefully controlled temperature gradient. The semiconductor crystal is grown in a quartz boat using a seed crystal and the constituent materials. In the case of GaAs, the boat containing the GaAs seed crystal and Ga is placed in a sealed quartz ampoule, with an overpressure of arsenic produced from a separate charge of arsenic at the opposite end of the ampoule. A temperature difference is produced along the tube, ensuring that one end of the boat is at the melting point (1238°C for Ga) while the arsenic, at the other end of the ampoule, is maintained at 614°C. Stoichiometry is ensured by precise control of the temperature and by accurate weighing of the Ga and As. Precise temperature control is required, ensuring horizontal thermal uniformity within 0.1°C. Long crystals of up to 1 m in length have been produced using this method. Very-good-quality material is produced using the horizontal Bridgman technique, and dislocation densities approaching 10^5 m^{-3} have been achieved for low-chromium-doped GaAs. The horizontal gradient freeze technique is similar to the horizontal Bridgman method; the main difference is that the former method induces crystallization from the seed by carefully controlled cooling of a melt. Both the Bridgman and gradient freeze techniques tend to have Si as impurities in the finished GaAs crystal as a consequence of the quartz boat.

The Czochralski technique is often used to grow large-diameter boules, suitable for wafers up to 6-in. in diameter. This pulling method uses a chamber with heated walls to maintain the required arsenic pressure. The LEC method is the more common than the basic Czochralski approach since it avoids arsenic loss and atmospheric contamination. The LEC system consists of a growth chamber housing a vertical puller with a seed crystal at

the tip of a rotating tip, which, in the case of GaAs growth, is immersed in a Ga melt, which in turn is fed with arsenic vapor from a separately heated quartz ampoule of arsenic. The susceptor containing the crucible with the Ga melt is heated with an RF coil. A molten B_2O_3 encapsulating layer on the surface of a Ga melt is used to prevent arsenic loss and contamination. An inert gas, such as nitrogen, is used to pressurize the growth chamber to a level higher than the As partial pressure. The rotating seed crystal is slowly withdrawn vertically upward, and the GaAs crystal boule is grown from the melt. The magnetic LEC method is a variation on the LEC technique that reduces the thermal convection currents found in the conventional LEC approach, improving the boule's homogeneity.

2.4. Epitaxy and Implantation

Semiinsulating substrates, available as wafers usually in the region of 600 μm thickness, are usually used as the basis for fabricating devices and integrated circuits in most III-V technologies. The conductive regions required for the active devices are formed using either epitaxial layers grown on the surface of the semiinsulating substrate, or by selective ion implantation.

Ion implantation techniques, which are used widely in Si technology to define conductive regions, were used widely to form the channel regions for MESFETs, bipolar junction transistors, varactor diodes, and IMPATT diode structures, especially in earlier integrated circuit designs. This low-cost approach, which is still widely in use today, can provide devices with moderate low-field channel mobilities ($0.35 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$) associated with channel doping densities of up to the mid- 10^{23} m^{-3} range for GaAs. High doping densities of up to $2 \times 10^{25} \text{ m}^{-3}$ are achievable for ohmic contacts, but have very low mobilities ($0.03 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$) [10].

Ion implantation is achieved by bombarding the semiconductor substrate with high-energy ions of the required dopant species. These ions displace semiconductor atoms from their sites in the crystal structure. In order to avoid extreme surface damage, which would render the surface amorphous, GaAs substrates are usually heated to 150°C during implantation. Fabrication of FETs and diodes with ion-implanted active profiles usually requires several implantations with energies tailored to produce the required doping profile. Each implantation produces an almost Gaussian profile of implanted ions as a function of depth from the semiconductor surface. This allows a selective three-dimensional doping profile to be produced in planar devices with localized highly doped regions for ohmic contacts. The wafers require annealing at a temperature in the range 800–950°C (for GaAs) after implantation to reduce the damage (defects) caused by the high-energy ion bombardments and achieve activation of the donor species. The doping efficiency is a function of the type of ion, implantation dose, and annealing temperature. Annealing is performed using either annealing furnaces, infrared radiation from halogen lamps, pulsed laser beam or electron-beam, techniques. The surface of GaAs loses arsenic at temperatures above 600°C, and hence annealing is performed either under arsenic overpressure

(“capless” annealing) or encapsulated using Si_3N_4 or AlN . The implanted dopants diffuse during annealing. Implantation can be used to produce either n- or p-type materials. Materials such as S, Se, Te, Si, and Sn are used to produce n-type GaAs. Dopants for p-type GaAs include Be, Zn, Cd, Mg, and C.

Ion implantation is widely used as an alternative to etched mesa isolation in integrated circuit designs to isolate the active regions of individual devices, allowing a more planar fabrication technology. In this scenario, semiinsulating material is produced locally by ion induced damage using proton bombardment or oxygen implantation, followed by annealing at a temperature between 650 and 800°C.

The advent of heterostructure devices, including high-electron-mobility transistors (HEMTs) and heterojunction bipolar transistors (HBTs), coupled with the demand for higher mobilities, higher channel carrier densities, lower-noise-figure FETs, and higher power densities from existing devices, has led to widespread use of epitaxial layer growth techniques. Although there are four potential candidates, vapor-phase epitaxy (VPE), liquid-phase epitaxy (LPE), molecular-beam epitaxy (MBE), and metallorganic chemical vapor deposition (MOCVD, also known as OMVPE), only the latter two techniques provide the necessary abruptness of interface and quality of growth necessary for most contemporary III-V semiconductor devices. MBE allows precise thickness and dopant control and is widely used as the basis of material for HEMTs, while the thicker layers found in HBTs are normally grown using MOCVD. Both techniques have been shown to produce very-high-quality material on high-quality semiinsulating substrates, achieving high mobilities and low defect densities [11].

MBE requires an ultra-high-vacuum growth chamber in a system that has multiple ultra-high-purity sources, achieving stoichiometric growth [12]. The growth rate is relatively slow, achieving 0.1–10 $\mu\text{m}/\text{h}$, but allowing very precise control of the film thickness, material composition, and dopant density. Highly abrupt interfaces are easily achieved and pulse (or delta) doping layers are readily grown, with layer thicknesses as thin as 5 Å. Heated crucibles, known as *Knudsen cells*, containing the elements or compounds used to form the various material layers are used as the sources. Contemporary multiwafer MBE production systems are capable of simultaneously growing high-quality material, with excellent uniformity on up to seven 6-in.-diameter wafer substrates (or a larger number of smaller-diameter substrates). This has led to widespread use of MBE grown wafers in modern III-V fabrication facilities. A wide range of compound semiconductor material systems can be grown using MBE and the same system can contain a range of Knudsen cells with ultra-high-purity Ga, In, Al, As, P, and Sb, as well as smaller cells for doping such as Si. It is common practice to have the most heavily used cells, such as Ga, duplicated. Growth is carried out on a single-crystal substrate—most commonly GaAs, which is heated to a temperature in the range 540–650°C. Faster growth rates tend to occur at the higher temperatures, and require careful control of the ratio of arsenic to gallium. The upper limit on growth

temperature is generally limited by the availability of the group V element over pressure.

MBE is used to grow highly complex multilayer heterostructures such as those found in quantum-well lasers and optical guides. Indeed, it is common for over 10 layers to be grown to form the active region of HEMTs, pseudomorphic HEMTs (PHEMTs), and metamorphic HEMTs (MHEMTs). MBE is used to produce the epitaxial material for a wide range of other microwave devices, including HBTs, MESFETs and resonant tunneling diodes. Superlattices, consisting of alternating layers of wide- and narrower-bandgap materials, are often used in these structures, and MBE is ideally suited to forming these abrupt interfaces [13].

The basic configuration of an MBE system requires a stainless-steel growth chamber, analysis chamber, and a load lock for transporting wafers into and out of the system (Fig. 4). The growth chamber is maintained at an ultrahigh vacuum and requires extreme cleanliness to ensure low defect densities during crystal growth. In addition to the Knudsen cells, the growth chamber houses shutters, substrate-handling equipment (which is robotic in many production systems), cryoshrouds, and surface analysis equipment to monitor growth. The effusion cell shutters regulate the emission of material from the cells. Normally, an additional “main” shutter is placed in front of the rotating substrate. The substrate is mounted on a heated holder, which rotates at speeds of up to 150 rpm for smaller holders, although lower rates of 5 rpm are normally used. This rotation and heating assist in maintaining uniformity in doping and thickness. The cryoshroud, which requires liquid nitrogen, encloses the entire growth area and minimizes water vapor and other unwanted gases during growth. Cooling of the regions surrounding the Knudsen cells also ensures that cross-contamination is minimized. In addition, each cell is usually water-cooled. The cells themselves, which are contained in stainless-steel housings, are made of graphite or boron nitride. The flux emitted from the cells is regulated by the shutters and monitored by an ion gauge behind the wafer holder. In more recent times, many systems use additional “cracker cells” placed between the Knudsen cells and the substrate. The cracker cells operate a high temperature (850–1000°C), and as effusion beams of arsenic or phosphorus pass through the region occupied by these cells, the As_4 and P_4 tetramers form As_2 and P_2 dimers. Dimer sources have been shown to reduce the density of deep levels and have a higher “sticking” coefficient, reducing the arsenic flux required during growth. Finally, surface analysis tools are normally incorporated into the system, including a scanning electron microscope (SEM), reflective high-energy electron diffraction (RHEED), Auger electron spectroscopy, secondary-ion mass spectroscopy (SIMS), and X-ray photoelectron spectroscopy. The RHEED analysis instrument plays a crucial role in determining substrate quality, growth condition and monitoring the thickness of the layer growth.

The molecular-beam epitaxial growth process (Fig. 5) for III-V materials requires precise control of the beam fluxes from the Knudsen cells and careful control of the surface temperature on which crystal growth is required.

Figure 5. Schematic diagram of a molecular-beam epitaxy system [based on A. Y. Cho, *Molecular Beam Epitaxy and Heterostructures*, L. L. Chang and K. Ploog, eds., Kluwer, Academic Press (1985)].

Prior to initiating III-V growth, the substrate is heated to absorb the oxide layer on the surface, to ensure that the surface is atomically clean. This occurs at temperatures in the region of 590°C for GaAs and 520°C for InP. The process itself involves adsorption of the constituent atoms and molecules, surface migration and dissociation of the adsorbed molecules and incorporation of the atoms into the substrate, leading to nucleation and growth. In the case of GaAs, stoichiometric growth requires that an excess of arsenic be available at the growing surface, and that any excess that does not incorporate with gallium reevaporate. The growth of ternary (e.g., $\text{Ga}_x\text{In}_{1-x}\text{As}$) and quaternary compounds (e.g., $\text{Al}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$) is achieved with MBE using precise control of the ratios of the beam fluxes to ensure that growth occurs with the required mole fractions. A high-volume multiwafer MBE system for production purposes is shown in Fig. 6.

In contrast to the MBE, the metallorganic chemical vapor deposition growth (MOCVD) technique involves chemical reactions between gases that occur at tempera-

Figure 6. High-volume MBE production system capable of simultaneously growing epitaxial layers on seven 150-mm wafers (Veeco Applied Epitaxy GEN2000 system at Filtronic plc).

tures far below the melting point of the growing material. A typical MOCVD process involves a pyrolysis reaction between a metal alkyl vapor, such as trimethylgallium (TMGa), trimethylindium (TMIIn), or trimethylaluminum (TMAI), and a hydride such as arsine (AsH_3) or phosphine (PH_3), in proximity to a heated substrate (Fig. 7). Epitaxial growth occurs on the crystal surface of the substrate as a result of the deposition. Common substrates used for growth include semiinsulating GaAs and InP. In MOCVD, all the constituents of the process are in the vapor phase. This allows for easy control of gas flowrates and partial pressures in the vicinity of the growth surface. Also since the pyrolysis reaction is relatively insensitive to growth temperature, MOCVD achieves highly reproducible deposition of thin layers and can also produce very good abrupt interfaces between the various deposited layers.

MOCVD systems are available in a range of configurations, including high-volume 150-mm substrate growth systems. The hydrides, including arsine and phosphine are highly toxic and require special handling. The choice of source material is critical to the efficient operation of the MOCVD process. In particular, the group V sources must possess high vapor pressures, pyrolysis at temperatures above 395°C, and low temperature stability. They must also be available with very high purity and not prone to parasitic reactions with the group III sources. Group V sources used in MOCVD include the elemental, hydride, trimethyl, triethyl, and tertiarybutyl materials; As, AsH_3 , TMAs, TEAs, TBAs, P, PH_3 , TMP, TEP, IBP, and TBP. Although arsenic and phosphorus require heating to be used as sources, arsine and phosphine have high vapor pressures of 760 torr at -55 and -88°C, respectively. TMAs and TMP have vapor pressures of >250 torr at room temperature, but both these sources have the disadvantage of requiring high pyrolysis temperatures. Similarly, TEP is not an effective phosphorus source since it is stable at normal growth temperatures and TEA has a relatively low vapor pressure, despite its ability to pyrolyze at normal growth temperatures. Metallorganic sources used for MOCVD typically have the lowest molecular

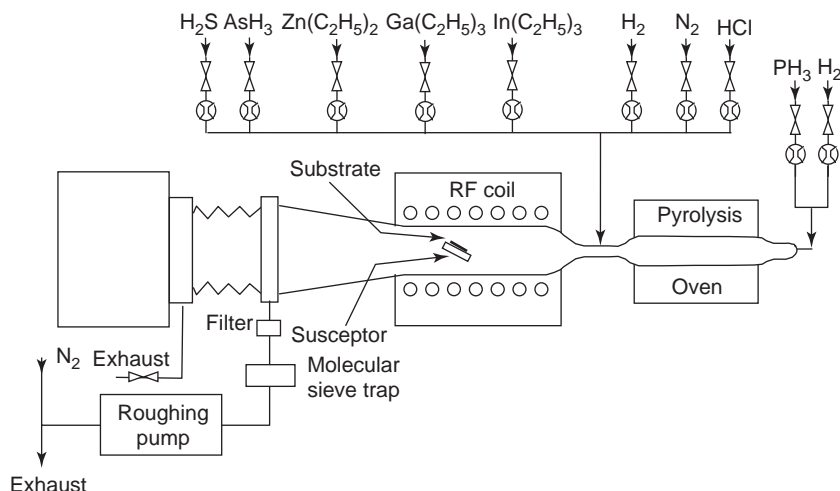

Figure 7. Schematic of a typical horizontal MOCVD system [derived from J. P. Hintz, M. Razeghi, M. Bonnet, and J. P. Duchemin, *GaInAsP Alloy Semiconductors*, T. P. Pearsall, ed., Wiley (1982)].

weights possible with vapor pressures in the region of 1–100 torr at temperatures from -25 to 25°C , and decompose thermally at the required growth temperatures of 550 – 800°C [14]. Generally, trimethyl compounds are used in preference to triethyl materials because of their higher vapor pressures promoting faster growth rates. Typical group III organometallic sources used in MOCVD include TMGa, TMAI, TMIIn, and TMSb. Group III alkyls used in MOCVD readily pyrolyze at low or atmospheric pressures.

The purity of III–V material grown using MOCVD is dependent on the quality of the substrate and the purity of the starting materials (the metal alkyls and hydrides), growth temperature, and the ratio of the constituents in the reactor. In the case of GaAs grown using TMGa and AsH_3 , the purity decreases with increasing growth temperature, probably due to the incorporation of carbon and silicon at higher temperatures. Carbon impurities usually take the form of acceptors, and Stringfellow has shown that a large increase in carbon incorporation occurs at higher growth temperatures [14]. In the case of AlGaAs growth, carbon contamination can lead to significant degradation in mobility, especially with increasing aluminum mole fraction. Doping of MOCVD grown material is usually performed using either Si, Ge, Se, S, or Te for donor impurities and Zn, Cd, Mg, and Be as acceptor impurities. Zinc (p-type) and selenium, tellurium or silicon (n-type) are the most common dopants. Hydrogen selenide H_2Se , SiH_4 , or DETe are used as sources for the donors, and dimethyl or diethyl zinc (DMZn or DEZn) as the p-type dopants.

2.5. Defects and Traps

Semiconductor crystals contain three types of defect: dislocations (or line defects), point defects, and volume defects (precipitates). Line defects occur as the melt crystallizes and shortly after solidification, and are associated with polygonization and slip interactions. The dislocation density is nonuniform and typically lies in the range 10^5 – 10^9 m^{-2} . High values of dislocation density

are detrimental to device performance and are extremely undesirable. Point defects are due to either native defects or chemical impurities. Native defects are usually associated with energy levels deep in the bandgap (known as deep levels) [15,16]. Chemical impurities often originate from the crucible or B_2O_3 encapsulant in LEC material and may include Si, C, or B. Other unwanted impurities, including Fe, Mg, Mn, S, Se, Te, and Zn, may also be found at concentrations of up to 10^{21} m^{-3} . Impurities, such as Cr, may be added to increase the resistivity of the semi-insulating material, with densities in the region of 10^{19} m^{-3} . Volume defects are often found in association with dislocations. Hexagonal precipitates of arsenic and GaAs microparticles create volume defects in some circumstances. Heat treatment of ingots reduces the effect of volume defects.

Point defects are usually characterized as either electron or hole traps. A particularly important point defect is the EL2 deep donor level, common in LEC grown GaAs. Traps play a key role in producing semi-insulating behavior in GaAs substrates [15]. Semi-insulating GaAs has intrinsic behavior in addition to high-resistivity properties, and is remarkably tolerant of small variations in impurity concentrations, retaining good uniformity throughout the ingot. It is important to appreciate that the presence of the deep donor (acceptor) and an excess of shallow acceptors (donors) are required for semi-insulating behavior. If these conditions are not satisfied, it is extremely difficult to achieve semi-insulating behavior [15]. In order to significantly reduce the concentrations of deep traps required to produce semi-insulating material, the concentrations of shallow donors and acceptors must be reduced, requiring material of very high chemical purity. In the case of bulk material, this is most easily achieved for LEC bulk material where the dominant shallow levels are acceptors, possibly due to Zn, Mg, Be, and carbon introduced in the growth process. These compensate the deep donor EL2. Bridgman material tends to be n-type, probably attributable to silicon introduced during growth. Semi-insulating material can be obtained from Bridgman by adding acceptors to compensate

the deep-level EL2 or adding chromium to introduce a deep acceptor, which, along with compensation with excess shallow donors, behaves in a manner analogous to EL2 [15].

Semiinsulating GaAs substrates (undoped and lightly Cr-doped) are often characterized using only one or two deep level traps: the EL2 midgap trap around 0.72 eV, dominant for LEC undoped substrates, and a shallower trap with an activation energy of approximately 0.39 eV. The EL2 level has been found to have an emission time constant that has a strong dependence on electric field [17]. The ionisation of the EL2 level produces an ionized EL2 center and an electron in the conduction band. Spectra associated with hole-type trap behavior have been observed bulk GaAs substrates [18].

The presence of the EL2 level, located near the middle of the bandgap, is essential to avoid nonuniformity and to ensure semiintrinsic behavior. The presence of the EL2 level and its concentration in GaAs ingots is dependent on the melt stoichiometry, and is minimized by having a slightly arsenic-rich content. The arsenic atom fraction in the melt stoichiometry during growth of the ingot determines whether the material is semiinsulating, for fractions in the range 0.475–0.535 with resistivity typically above $10^5 \Omega \cdot \text{m}$, or whether it is p-type in behavior for fractions in the range 0.43–0.47 with resistivities of the order of $10^{-2} \Omega \cdot \text{m}$. The association of semiinsulating behavior with the EL2 level suggests that the electrical properties of the material are due to the deep donor EL2 level and additional residual compensating acceptors, such as carbon.

A comprehensive survey of electron and hole traps was published in Refs. 18 and 19, in which over 33 electron and 22 hole trap levels were tabulated from various sources. It was suggested that some of these observations related to the same traps levels in differing materials. Even so, if this is the case, over 20 separate electron and 11 separate hole trap energies exist. A number of different transient spectroscopy methods have been developed to characterize traps in GaAs; the most commonly used is deep-level transient spectroscopy (DLTS) [10]. These include voltage-pulsed stimulated current and capacitive DLTS [e.g., 18,20], thermally stimulated current and capacitance techniques TSC, TSCAP [e.g., 21], and optically stimulated methods.

The presence of traps in active-device structures can have a profound effect on their transient electrical behavior. Many III–V devices suffer from adverse transient effects such as “gate and drain lag” in FETs, where the drain current responds with a transient of typically many hundreds of microseconds in response to a step excitation in the gate or drain voltages, respectively. The origin of these effects is associated with combinations of surface, bulk, and substrate traps. Surface traps, which are responsible for surface charge, play a particularly important role in determining the transient response of planar devices such as FETs. The transient behavior of these traps gives rise to dispersion phenomena in the drain current, transconductance, output resistance, and gate–drain capacitance. Surface charge can also have a profound impact on the breakdown voltage of these

transistors (which can consequently be a time-dependent phenomena). Ladbroke [22] provides a detailed insight into the impact of surface charge effects and dispersion in III–V MESFETs.

2.6. Substrates and Wafers

Although doped (and unintentionally doped) substrates were commonly grown in the past, for vertically oriented devices such as diodes, today the majority of substrates are semiinsulating. In 2003 over 13 million III–V substrates were manufactured worldwide. The rapid growth in III–V technology demand over the period 2001–2006 is expected to see a threefold increase in substrate supplies with a shift to increase wafer diameter [23].

As in all semiconductor technologies, wafer diameter plays a key role in the economics of manufacturing III–V devices. Since it is proportionately cheaper to fabricate devices on larger wafers than on smaller wafers, there has been a progression over the years from 1-in.-diameter wafers through to the current 6-in.-diameter wafers used for GaAs technologies. Up until 2000, 3- and 4-in.-diameter wafer processes dominated the industry. However, with the successful introduction of 6-in. semiinsulating substrates and associated epitaxial processes (MBE initially, followed by MOCVD), by 2004 there were over 10 large-scale 6-in. fabrication facilities worldwide, gradually displacing the less cost-effective smaller diameter fabrication facilities. This migration to larger wafer sizes can be compared with the movement from 2- through to 12-in.-diameter silicon wafers. The prospect of larger-diameter wafers for GaAs needs to be considered in the context of the level of demand and return on investment in the fabrication equipment as well as the fact that boules of GaAs have a density of more than double that of Si, presenting substantial challenges for growing boules for wafers of over 150 mm (6 in.) diameter.

Generally speaking, in applications where very low defect densities are required (e.g., laser diodes), or for more specialised materials, smaller diameter wafers are used. For example, at the time of writing high-quality GaN is usually grown on 2-in. wafers, and while GaAs is well established on 6-in. wafers, InP technology is still based on 3-in.- and more rarely 4-in.-diameter wafers. Continual improvements in epitaxy have led to dramatic improvements in defect density and epitaxial wafer quality, and this is reflected in the impressive yields, of over 95%, which can be achieved routinely on 150-mm (6-in.-) diameter GaAs wafers [24].

The quality of substrates and epitaxial layers is examined using a range of material characterization techniques, including X ray, photoluminescence, SEM/EDAX, and classical Hall mobility and sheet resistance measurements. In the case of epitaxial layers, the aim is to determine layer thicknesses, uniformity, surface morphology, chemical composition, carrier mobility, Hall factor, defect density, doping profile, and sheet carrier densities. A wide variety of techniques are used and cannot be covered in this article; the reader should consult Refs. 10 and 25. Surface and layer analysis is performed using a

range of spectrometry systems, including X-ray spectroscopy, secondary-ion mass spectrometry, Auger electron spectrometry, and X-ray photoelectron spectroscopy. Defect density and trap density and type are investigated using X-ray spectrometry systems, supported by DLTS. Sheet resistance and Hall mobility are often determined using van der Pauw measurements, based on Schottky gate patterns [26] and magnetoresistance measurements [27]. The doping density and in some cases the doping profile is determined for bulk doped materials, using tests such as C - V profiling, or evaluation from a combination of C - V and I - V data on long-gate length FETs. In the case of heterostructure layers, such as those used in HEMTs, the material is also characterized in terms of its sheet carrier concentration.

3. CARRIER TRANSPORT PROPERTIES

The carrier transport properties of materials determine a material's electrical behavior. The key properties that characterize carrier transport in semiconductor materials are the mobility and velocity of the electrons and holes, which are dependent on the scattering mechanisms in the particular material. The main scattering processes, which influence the mobility of electrons and holes, are acoustic phonon, nonpolar optical mode, polar mode, and ionized impurity scattering. Ionized impurity scattering dominates at low temperatures (< 100 K). Alloy scattering is a limiting process at room temperature in some material systems, such as in AlGaIn/GaN used in HEMTs. The bulk electrical conductivity is then expressed in terms of the mobilities and carrier densities in the bulk material. The low field mobilities of electrons and holes are a strong function of lattice temperature, carrier, and doping density. The transport properties have fundamental dependence on the electric field within the device structure, and are further modified by nonequilibrium behavior in small-scale structures, where rapid changes in the electric field can occur quickly changing the energy of the carriers leading to "hot" carrier transport phenomena.

The mobility in III-V semiconductor samples is normally determined from Hall effect measurements [5], where bulk samples of the material are characterized under the influence of a strong magnetic field. The hole mobility μ_p for p-type material in a small electric field is determined from the Hall mobility μ_H according to the relationship,

$$\mu_H = \sigma R_H = r_H \mu_p$$

where σ is the conductivity, R_H is the Hall constant, and r_H is the Hall factor, which tends to unity for strong magnetic field conditions ($B\mu_p \gg 1$). Similarly for electrons mobility μ_n for n-type material in a small electric field is determined from the Hall mobility μ_H according to the relationship

$$\mu_H = |\sigma R_H| = r_H \mu_n$$

where the Hall factor r_H is close to unity for strong magnetic fields and greater than 1 for medium or weak magnetic fields. Electron and hole mobilities are strongly temperature-dependent, showing approximately $(300/T)^{2.3}$ behavior above 100 K for GaAs. Below 70 K ionized impurity scattering reduces the mobility with decreasing temperature. Mobilities are also a function of carrier density. Typical values of hall mobility for p-type GaAs are in the region of $0.04 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ for hole densities below 10^{22} m^{-3} , falling to $0.005 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ for densities above 10^{25} m^{-3} . The Hall mobility of the electrons in GaN/AlGaIn HEMTs at 300 K has been found to be as high as $0.14 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ in high-quality material for sheet carrier concentrations of 10^{17} m^{-2} .

The electron and hole drift velocities are defined by the product of the mobility and electric field \mathbf{E} . Hence, for electrons, the drift velocity v_d is given by $\mu_n \mathbf{E}$. In the case of low doped n-type GaAs μ_n is in the region of $0.8 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 300 K for low values of electric field. At low values of electric field the velocity increases with increasing electric field. However, as the electric field increases and the electrons gain energy, the mobility decreases slightly. Increasing the electric field still further results in the most energetic electrons transferring from the central Γ valley to the first satellite valley X , which has a higher effective mass and reduced mobility. Eventually, a value of electric field is reached where the velocity attains a peak value, in the region of $2 \times 10^5 \text{ m/s}$ for GaAs. Beyond this value the drift velocity decreases with increasing electric field, asymptotically approaching the saturated value of $7 \times 10^5 \text{ m/s}$ at very high values of electric field. The steady-state electron velocity-electric field characteristics for several III-V semiconductors compared with silicon at 300 K are shown in Fig. 8 [28–32]. The region of negative-differential mobility beyond the peak velocity in each characteristic, where the velocity decreases with increasing electric field, is due to the transferred electron effect where electrons are transferring from the high-mobility central (Γ) valley to the low-mobility satellite (X) valley in the energy band structure. This phenomenon can give rise to oscillations in samples of InP and GaAs, and forms the basis of the Gunn diode (transferred electron device) [5].

The transient (nonequilibrium) carrier transport properties of semiconductors may be markedly different from their steady-state (equilibrium) characteristics [33,34]. In the case of many III-V semiconductors, the change in velocity experienced by electrons entering a high-electric-field region can lead to a phenomenon known as "velocity overshoot," where the electron is accelerated in the electric field, rapidly gaining energy, to a velocity significantly higher than the peak steady-state value, for a short interval (usually less than 0.1 ps). In the case of GaAs the transient velocity of these hot electrons may reach values in excess of $5 \times 10^5 \text{ m/s}$ over a short distance ($< 0.1 \mu\text{m}$) until scattering, energy, and momentum relaxation lead to a reduction in velocity that subsequently approaches the steady-state value over a short interval in time and distance [33,34]. Velocity overshoot in III-V devices can enhance their high-frequency performance

Figure 8. Steady-state velocity–electric field characteristics for GaAs, InP, $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$, and GaN, compared with Si at 300 K.

and is significant for short-gate (submicrometer)-length FETs.

The conductivity of semiconductors is given by

$$\sigma = \sigma_n + \sigma_p = q(n\mu_n + p\mu_p)$$

where n and p are the electron and hole densities (n_0, p_0 for intrinsic condition). In the case of GaAs doped with shallow donors or acceptors, the ratio of n/p is far from unity at 300 K, and the conduction is essentially unipolar depending on the dopant type. GaAs can be engineered to achieve a high value of resistivity, close to the intrinsic state, by the use of chromium doping, which introduces EL2 centers (see Section 2.5), creating semiinsulating GaAs. The room temperature resistivity of semiinsulating GaAs is typically in the range 10^3 – $10^7 \Omega \cdot \text{m}$, which makes an ideal substrate for integrated circuits.

4. PROCESSING AND DEVICE FABRICATION

The fabrication of semiconductor devices using either semiinsulating wafers with ion implantation of epitaxial layered wafers requires several stages of lithography, selective etching, deposition, and passivation, finishing with die separation, final test, and packaging. It is not possible to provide a detailed description of processing in this article, but an outline is a useful aid in understanding the design constraints and properties of the finished semiconductor devices. Williams provides a useful introductory text for GaAs processing [11].

4.1. Lithography

One of the most fundamental elements of device processing is the definition of the active and passive regions of the device, electrical contacts, bondpads, implantation regions, passivation areas, and interconnecting lines. This process of transferring patterns, made up of geometric shapes, to a thin layer of radiation sensitive material (*resist*) deposited on the surface of a semiconductor wafer is known as *lithography*. The resist is usually

deposited on the wafer by spinning a few drops of resist fluid into thin film at very high speeds, on to the surface of the wafer. The resist is then patterned (exposed) using photolithography, ultraviolet light lithography, electron-beam lithography, or in special cases X-ray or ion-beam lithography. The resist is then developed, selectively removing either the exposed or unexposed areas. The remaining pattern is then used to define areas for etching, deposition, or implantation. The resists are classified as either positive or negative depending on whether the exposed region is removed (positive) or whether the unexposed regions are removed (negative). An additional technique is based on image-reversal, which can provide enhanced resolution, which is particularly useful for submicrometer photolithography.

The photolithography techniques used in III–V processing include contact printing, proximity printing, projection printing, and stepping. Contact printing, which is frequently used for initial research development and for backside processing, is a straightforward process where the mask is aligned on the wafer and the resist exposed using a beam of ultraviolet light. Resolutions down to the region of one micrometer are possible as a result of the direct contact between the mask and the wafer. The two main disadvantages of this approach are (1) abrasion of the mask through direct contact, which reduces mask lifetime, and (2) *runout* due to any lack of planarity between the mask and wafer, preventing contact. Runout, due to curvature in either the mask or wafer, results in misalignment in areas of the pattern. Contact printing systems are significantly lower in cost than steppers or other precision lithography systems. Proximity printing places the mask in close proximity to the wafer, but avoids direct contact. Diffraction at edges in the pattern produces a slightly blurred image. This technique cannot achieve high resolutions and is not widely used in modern fabrication processes.

Optical steppers are the mainstay of silicon fabrication and are becoming widely used in III–V fabrication. The mask consists of the patterning for device and integrated circuit designs and is known as a *reticule*. The reticule is projected onto the wafer, which has previously been coated

in resist. A typical reticle is 20×20 mm. Many reticle patterns can be accommodated on a wafer. After the first reticle pattern is exposed, the wafer is moved very precisely and a second image is created. This process repeats across the wafer until the whole wafer is exposed. This step and repeat process is well established and is precisely indexed to allow multiple mask sets to be used, achieving precise alignment between layers. Steppers normally allow reduction of the reticle pattern on the mask by factors of 5 or 10, although in some circumstances unity reduction is used. Steppers achieve optical imaging using either lenses (refractive optics) or mirrors (reflective optics). The limitations of the optics are constrained by diffraction, where the optical surfaces must be accurate to within a quarter-wavelength. Steppers achieve a highly repeatable pattern, where any runout or misalignment is generally confined to the reticle. As a result, steppers have become established as a key element of high-yield processing, producing very-high-quality, highly repeatable lithographic patterning. Contemporary steppers for III-V lithography are available that achieve feature sizes of 0.35, 0.18, and 0.12 μm ; the cost of the system increases with increased resolution. Excimer laser (KrF) sources are used for the high-resolution steppers in the 0.18 μm range. Even higher resolutions are possible today, but the cost of the stepper is prohibitive for anything other than very-high-volume Si applications (microprocessors and memory). More recently there has been increased interest in using phase-shifting masks [35], which improve optical resolution by using interference to cancel diffraction effects. Steppers are available for 3, 4, 6, 8, and 12 in. wafer sizes.

Electron-beam (e-beam) lithography is widely used in III-V processing, as a means of both precisely patterning the masks used in photolithography and directly exposing (direct *writing*) patterns on wafers. Submicrometer gates were first written on GaAs using e-beam systems, although more recently, gate lengths above 0.35 μm are more routinely written using steppers, and it can be expected that 0.25- and 0.15- μm gates will in due course be written using steppers. At the heart of e-beam systems is the electron gun, which operates continuously, and beam-blanking plates that turn the beam on and off. The beam is moved over the surface of the wafer, within the scanned region, using deflection coils. The wafer is coated in a resist such as polymethylmethacrylate (PMMA). The wafer is positioned using a precision mechanism to move from one scanning field to the next. The pattern is generated in e-beam systems using computer controlled raster or vector scanning techniques. Electron-beam systems can achieve very high resolutions (currently below 70 nm), excellent registration, and great flexibility and do not require masks. Wafer flatness is not a problem for e-beam systems as they have a greater depth of field than do steppers. However, the throughput of e-beam systems is significantly slower than steppers at present. Also, on larger wafers e-beam systems can suffer from degradation of alignment accuracy, especially toward the edge of the wafers, away from the initial scanning fields. E-beam systems for III-V processing are available that will handle wafer sizes up to 6 in. (150 mm).

III-V processing has a number of significant differences to silicon device fabrication and in some respects is simpler — generally requiring fewer steps for monolithic microwave integrated circuits (MMICs) than for silicon ICs. A key stage in semiconductor device fabrication is the metal patterning, where, following evaporation of the required metal, the unwanted metal regions are removed. The metals used with silicon processing (typically Al) are usually fairly easy to etch, whereas the metallization schemes used in III-V processing (frequently TiPtAu, AuGeNi) are often difficult to etch. In silicon, this is achieved by depositing the metal first and then coating the metal with resist and lithographically defining the pattern. The unwanted metal, which is not protected by resist, is then removed by etching after developing the resist pattern. The resist is then removed using a solvent. In the case of III-V semiconductors a process known as “lift-off” is normally used, where the resist pattern is produced using lithography prior to evaporation of the metal. The desired metal pattern is then obtained by removing (“lifting off”) the resist (with metal evaporated on its surface) using a solvent, leaving the metal deposited on the semiconductor surface in the regions where the resist was originally removed following the development stage. The liftoff process is very sensitive to the pattern defined by the resist and an undercut in the resist profile is usually used to help define the desired metal regions.

It is convention to include a process control monitor (PCM) site in the reticle. This important element of the patterning includes a range of test devices, such as simple contact structures, transistors, and diodes and if it is a MMIC, a small range of transmission-line structures resistors, capacitors, and inductors. The purpose of these structures is to monitor the key parameters against the expected values as the wafer goes through each stage of the processing. This allows the quality of the processing to be closely monitored and assists in process control and yield optimization. The PCM sites are usually tested after each processing stage or at suitable intervals. The PCM site usually occupies only a small area of the reticle — often less than 1%.

4.2. Etching Techniques

III-V semiconductors can be etched using either wet- or dry-etch techniques or a combination of both. Prior to processing and at stages during the fabrication, it is necessary to clean the wafer surfaces. Exposure of GaAs to the atmosphere leaves an oxide layer on the exposed surface of the material, which can be 50 Å thick, which is removed using a highly diluted acid such as HCl. Highly pure deionized water is used extensively in processing to avoid contamination. Wet and dry etchings are used as a means of forming patterns and defining features in the surface of the semiconductor wafer, and for polishing (e.g., after thinning of wafers during backside processing).

Wet etching techniques have been established since the early days of fabrication and normally have the properties of providing selective and preferential etching depending on the crystallographic orientation of the wafer. In the case of Si, this allows distinctive etching that is exploited

in MEMs, and, for example, allows “V” grooves to be readily defined. Etching of III-V compounds is usually crystallographic, and key features and critical dimensions can be defined by ensuring proper alignment with the lattice planes. In the case of GaAs, (111) Ga faces etch up to 5 times slower than do (100), (110), and (111) As faces. Wet etches are categorized either as electrolytic or nonelectrolytic. Electrolytic etches require an electrical contact to the wafer and in the case of GaAs have an anodic oxidation mechanism. One advantage of electrolytic etches is that they can be used to provide accurate technical depth control. Nonelectrolytic etching rates are either diffusion or chemical-reaction-limited. Diffusion-limited etches are generally isotropic and are well suited for polishing wafers after mechanical grinding. Chemical-reaction-limited etches are often anisotropic are particularly suitable for defining patterns. Wet etches generally contain an oxidizing agent, such as Br_2 or HNO_3 , a complexing agent, such as NH_4OH , NaOH , HC , citric acid, or H_2SO_4 and water. The complexing agent ensures that the relatively insoluble oxidized layer is dissolved in the water. The etch is chosen to remove areas of the wafer that are not protected by the exposed resist pattern.

Dry etching techniques have become increasingly popular for use in III-V device fabrication in more recent years. They are widely used in III-V processing to produce recesses (e.g., single- and double-gate recesses), mesas for isolation, and via holes through the substrate that are metallized to connect the top surface to the metallized back surface of the wafer. These reactive plasma etching techniques have several important advantages over wet-etch methods, including better directional control of the etch and improved anisotropy of the etch. Specifically, the laterals etch rates in plasma etching are very low indeed, preventing undesirable undercutting of the resist pattern. Dry etching utilizes an ionized gas to achieve plasma-driven chemical reactions or use highly energetic ion beams to remove material that is not protected by the resist pattern. Dry etching can be classified as plasma etching, reactive-ion etching (RIE), ion milling, or reactive-ion-beam etching (RIBE). Inductively coupled plasma etching is also widely used in III-V device fabrication. Control of the plasma by varying the system electrode configuration, gas composition, pressure, and bias voltages allows the characteristics of the etching process to be tailored to the particular semiconductor material and the required shape of the etched region.

Plasma etching systems often use chlorine, HCL , PCl_3 as sources of chlorine ions. O_2 and Ar are often added. CH_4/H_2 systems have been used for InP and GaAs. The system itself in its basic form consists of two parallel plates with a DC and RF ionizing source (100–600 V at 13 MHz) attached to the top plate and the wafers clamped to the lower water-cooled plate. The plasma is formed between the plates and energetic ions perpendicularly impact the surface of the exposed semiconductor material. The resist prevents the ions penetrating the unexposed surface of the semiconductor. Plasma etching can give rise to radiation damage and in some circumstances leaves residues that require subsequent removal (often using a light wet etch). RIE is in many ways similar to plasma

etching, with the reactive species generated from the plasma, but with greater directionality of the ions. RIE systems typically operate at low pressures and the substrates are mounted on the powered electrode. Reactive-ion etching is usually used to etch GaN/AlGaIn because of the difficulty in finding suitable wet etches. BCl_3/Ar is found to produce surfaces smoother than those obtained with Cl_2/Ar for GaN/AlGaIn. Finally, the electrodes themselves are often asymmetric with the chamber forming the grounded electrode. In RIE the semiconductor is etched through a combination of chemical reaction and sputtering. Similar ion species can be used to plasma etching, but a smoother surface is obtained using H_2 , BCl_3 , or CCl_3F . Again O_2 is added to CCl_3F and CCl_4 to increase etch rates, and Ar to increase anisotropy.

Ion-beam milling is a high-energy (~ 1000 eV) etching process, where inert ions (Ar) are allowed to impinge on the target substrates in a uniform beam. Ion-beam milling can achieve relatively high resolutions, and can be used to define structures smaller than $0.01\ \mu\text{m}$. It is a highly anisotropic process, and the profile of the etched sidewall can be determined by positioning the relative angle of the substrate and by using shadow masking. Ion-beam milling can be used to etch metals, including Ti, Pt, and Au metallization layers and will etch materials that are challenging for plasma or wet-etch systems. The main disadvantages are damage from ion bombardment, poor sensitivity, and redeposition of materials. Focused ion-beam etching can be used to define small-scale structures. The final dry etching process, reactive-ion-beam etching (RIBE) takes advantage of both chemical reaction and ion bombardment to etch material. Unlike ion beam milling it uses a reactive gas although the etch characteristic are very similar. Redeposition of the etched material is avoided in RIBE by using a vacuum removal system.

4.3. Deposition and Metallization

It is usually necessary to provide insulating coatings on the surface of semiconductors at various stages in processing, either to planarize the surface for additional processing (e.g., metallization) or as a dielectric for capacitors in integrated circuits, or as a passivation to protect the surface of the semiconductor. The type of materials deposited can be either inorganic, such as silicon nitride or silicon dioxide, or organic, such as BCP. Plasma-enhanced chemical vapor deposition (PECVD) techniques, which use RF excited plasmas, are often used to deposit these films, as they can achieve this at relatively low temperatures (typically $250\text{--}350^\circ\text{C}$). This low temperature capability is very important for III-V processing, where higher temperatures would lead to changes or decomposition of the semiconductor material. PECVD films are amorphous, and the density and quality of the material depend strongly on growth conditions. In particular, the frequency of the RF stimulated discharge, which may lie between 50 kHz and 13 MHz, directly influences the stress in the film (the higher the frequency, the lower the compressive stress). PECVD layers are usually deposited in thickness between $1000\ \text{\AA}$ and $1\ \mu\text{m}$, with growth rates typically of the order of $300\ \text{\AA}/\text{min}$.

Plasma deposition is usually carried out in either a planar (parallel-plate) or barrel (tubular) reactor. The best uniformity is achieved in radial flow planar reactors, where the substrates are positioned on the lower electrode of the two parallel plates. Deposition is performed under a vacuum to minimize contamination, and a wide variety of highly reactive chemical species are used, including chlorine, fluorine, hydrogen, oxygen, silane (SiH_4), and ammonia. Silicon nitride, which is one of the most frequently used insulating materials, is often deposited using electron cyclotron resonance systems, which operate at 2.45 GHz.

Silicon nitride Si_3N_4 is used widely in III-V processing as a dielectric layer in capacitors, an encapsulant (to prevent diffusion) or for passivation to protect the surface of the semiconductor or die from the environment. It is normally grown using silane as a source of silicon and ammonia (or nitrogen in some cases) as the nitrogen source. The silane is mixed with an inert gas (argon). The dielectric constant of the amorphous silicon nitride is a function of film thickness and silane concentration. The film thickness dependence is due to the impact of stress and nonuniform growth of the layer. Thin films (below 1000 Å) can achieve relative dielectric constants of up to 11, whereas thicker films typically have dielectric constants in the region of 8. Silicon dioxide has a lower dielectric constant than silicon nitride and is often used as a spacer layer in metal cross-overs to minimize parasitic capacitance. Again, silane is usually used as the silicon source, and the oxygen source is selected from CO , O_2 , or N_2O .

Some III-V processes utilize aluminium nitride as an insulator or passivation layer. AlN for these purposes is grown either by sputtering, vapor phase, or MBE. Single-crystal films may be grown at temperatures in the region of 1150°C, although amorphous AlN films can be grown at lower temperatures or using plasma CVD. Other dielectric films such as silicon oxynitride are used in some circumstances.

The final element in processing is the provision of metallization on the surface of the semiconductor to act either as contacts or interconnections. Two types of metal-semiconductor contact can be fabricated in III-V devices: ohmic contacts and Schottky contacts. Ohmic contacts have the property that they possess very low resistances across the metal-semiconductor interface, while Schottky barrier contacts have a more complex rectifying contact behavior, representative of a diode, where in reverse bias the interface demonstrates very high resistance (ideally no current flow) and capacitance associated with the charge developed in the depletion region below the contact. In contrast in forward bias, the interface behaves like a diode, with the potential for significant current flow, but only supporting relatively low forward voltages across the interface. In addition to the contacts, first- and second-level metallization is used to interconnect the various elements of the active devices, and circuits, where the metal is chosen to possess high conductivity, excellent adherence, and conformal coating, coupled with compatibility with the Schottky and ohmic contacts. Additionally, via holes that connect between levels or between the top and backside metallized surfaces of the substrate.

Schottky contacts can be formed with III-V semiconductors using sputter or evaporation deposited multi-layer metal contact structures such as TiPtAu, TiW, TiWSi, Pt, Al, WSi, WAl, and TiPdAu. Metal silicides, such as tungsten silicide, widely used in silicon VLSI, can achieve low contact resistances for III-V devices when annealed at high temperatures and may be deposited using RF cosputtering. Schottky contacts on AlGaN can be achieved using Ni/Au. The barrier height of the Schottky barrier varies with the semiconductor material composition, crystal orientation, and the contact metal. In the case of GaAs and gold, for example, the barrier height varies from 0.82 eV for (100) orientation to 0.97 eV for (110) crystal orientation at the interface [36]. The range of barrier height for Schottky contacts on several III-V binary semiconductors is shown in Table 3 [5,36,37].

Ohmic contacts are formed with III-V semiconductors using n^+ or p^+ layers immediately below the contact metallization. Very high doping levels above $5 \times 10^{24} \text{ m}^{-3}$ are used with multilevel metal-alloyed contacts. In the case of GaAs, alloys based on Au or Ag are popular choices. In the case of contacts made on p-type material, zinc is usually added to the alloy, which acts as a dopant in the semiconductor. In the case of n-type contacts germanium and tin are used in the alloy. AuGeNi contacts provide among the lowest contact resistances and high reliability in III-V devices. Other GaAs metal alloy ohmic systems include Au-Zn, Au-Zn-Sb, Au-Be, and Au-Be-Ni. Ohmic contacts to InP are achieved using Au-Ge-Ni, Au-Sn, Ag-Sn-In, In-Zn, Au-Mg, and Au-Be. AlGaAs ohmic contacts are made with Al, Au-Zn, and Au-Ge-Ni; GaInAs, with Au-Zn, Au-Sn, and Au-Ge-Ni. Ohmic contacts to AlGaN/GaN devices are usually made with alloys based on Ti/Al annealed at 850–875°C. Rapid thermal annealing is usually employed for ohmic contacts. “Balling” of the metals on the contact surface can be avoided by including a thin cover layer of Ni/Au over the Ti/Al prior to annealing at 900°C. It should be noted that it is hard to form ohmic contacts to AlGaN when the mole fraction exceeds 33%.

A first-level metal used as part of the interconnection metallization has the characteristic of good adhesion to ohmic and Schottky barrier metals. Gold-based alloys are generally used for interconnection first metallization — the most common are TiPtAu and TiPdAu, using e-beam deposition systems. Copper, with its very high conductivity, which is used with silicon, diffuses in several III-V semiconductor materials and cannot be used. Aluminum

Table 3. Schottky Barrier Heights for n-Type III-V Semiconductors

Material	Barrier Heights (eV)						
	Ag	Al	Au	Ni	Pt	Ti	W
GaAs	0.88	0.80	0.90	0.79	0.85	0.82	0.79

interacts adversely with gold, with high-resistance intermetallic products. Silver is very reactive and is rarely used in III-V devices. First metallization is usually in the region of $0.5\ \mu\text{m}$ thickness. Second-level metallization is usually based on gold (Ti/Au), due to its low tendency to electromigration [38] and ability to handle very high current densities. Airbridges are also formed in the second-level metal. Metallization is achieved using sputtering, evaporation or electroplating. An evaporation system for 150-mm-diameter wafers is shown in Fig. 9. Thicker layers ($> 1\ \mu\text{m}$) are usually deposited using RF sputtering systems. Via holes may be plated using either electroplating or electroless plating (based on gold–cyanide solutions) or magnetron sputtering or by evaporation of TiAu.

4.4. Backside Processing

The final stage of the fabrication process is backside processing and die separation. After completing the frontside with the devices, metallization, contacts, and circuit elements, the reverse side of the wafer is processed. At this stage the wafer is usually thinned to its final thickness, which usually lies in the range $30\ \mu\text{m}$ (for high power) to $150\ \mu\text{m}$ (Fig. 10). A mechanical grinding process is used to remove the bulk of the material, which is then finished with a chemical etch. If there is a requirement for via holes to connect the top surface to the backside, vias will be etched, usually using dry etching techniques (Fig. 11). If a ground plane is required, the backside is metallized with gold (as in the case of vias). After completion of processing, the wafer may be attached to a film frame to facilitate temporary die retention during the on-wafer test and die separation processes. The die on the wafer are then subject to visual inspection and electrical testing. The process control monitor (PCM) sites receive their final electrical tests to complete the process data for the wafer. The die may be probed using DC and RF testing to determine whether they meet the specification (and hence determine the final yield). After on-wafer testing the final stage is to separate the die, which is achieved using either a diamond scribe (“scribe and break”) or a

Figure 9. Evaporation system for metallizing semiconductor wafers.

Figure 10. Cross section of a die, showing thinning of the GaAs to $30\ \mu\text{m}$ and gold metallization of the backside ($\sim 10\ \mu\text{m}$). The FET structure can be seen on the frontside (Filtronic plc).

diamond saw. Laser separation techniques are beginning to appear that also show promise. The die are retained on the film in preparation for packaging using robotic pick-and-place instruments.

5. RF AND MICROWAVE DEVICE TECHNOLOGY

III-V RF and microwave devices may be fabricated as unipolar or bipolar designs. The early interest in GaAs and InP centred around the properties of these materials that demonstrated negative-differential resistance as a consequence of their velocity–electric field relationships. J. B. Gunn demonstrated microwave oscillations in 1963, using a simple GaAs two-terminal structure. This phenomena forms the basis of the *transferred electron effect*

Figure 11. A via hole etched in a $125\text{-}\mu\text{m}$ substrate and plated in gold (light color) (Filtronic plc).

[5], which is characterized by the behavior of the Gunn diode. GaAs and InP Gunn diodes have found widespread application as the active devices in microwave oscillators ranging from 1–100 GHz.

The most common transistor technologies in use today are based on unipolar field-effect transistor (FET) or heterojunction bipolar transistor technologies [39,40]. GaAs and Si bipolar transistors were widely used prior to the advent of higher-frequency FETs [41]. In 1971 Turner reported a 1- μm -gate-length FET with gain of ≤ 18 GHz [42]. By 1980, GaAs metal semiconductor field-effect transistors (MESFETs) were established as the device of choice in microwave low-noise and medium-power amplifiers, achieving noise figures of less than 1 dB at 4 GHz and output powers of up to 25 W [43]. Although MESFETs were employed in oscillator designs, especially varactor tuned designs, from their introduction in the mid-1970s [44], relatively poor $1/f$ noise performance in early MESFETs led to the continued use of bipolar junction transistors in low-noise oscillators up to 6 GHz. The advent of AlGaAs/GaAs high-electron-mobility transistors (HEMTs), also known as *modulation-doped FETs* (MODFETs), in the 1980s with their improved noise performance displaced MESFETs in low-noise amplifiers and wider use in oscillators and mixers, although still with some remaining $1/f$ noise limitations. AlGaAs/GaAs heterojunction bipolar transistors (HBTs) were introduced in the early 1980s, but were not widely used until the advent of mobile communications and the widespread development of low-voltage, high-efficiency power amplifiers for cellular handsets. By 2000 pseudomorphic HEMTs (PHEMTs) had become the established high-frequency transistor, operating at frequencies up to 200 GHz and achieving noise figures below 0.2 dB at 2 GHz. HBTs based on AlGaAs/InGaAs/GaAs, and InGaP structures demonstrating maximum frequencies of oscillation f_{max} above 100 GHz, are now readily available. GaAs-based PHEMTs have demonstrated high power and high efficiency operation up to X band [45]. The state of the art is now occupied by gallium nitride transistors, with AlGaN/GaN FETs achieving power densities above 10 W/mm gate periphery and capable of over 170 W at high efficiencies [46], and power densities of over 4 W/mm at 30 GHz [47]. Similarly, GaN/AlGaN HBTs show potential for high-power high-frequency operation and demonstrate high emitter injection efficiencies.

6. APPLICATION OF TRANSISTOR TECHNOLOGIES

Up until 1985, the MESFET dominated as the preferred choice of microwave transistor, with some usage of silicon bipolar remaining for niche applications below 8 GHz (such as low-noise oscillators). By 1990, the PHEMT had begun to displace MESFETs for low noise amplifiers, and the AlGaAs/GaAs HBT had begun to emerge as a candidate for low-voltage power amplifier applications (such as in the emerging cellular handset market). Up until this time, MESFET technology had been dominated by ion-implanted designs, utilizing semiinsulating GaAs substrates. Improvements in epitaxial growth (MBE and MOCVD/OMVPE) allowed higher performance FETs to be designed, with improved gain, current, and power handling. By 2000, MESFET technology was being displaced in many applications by PHEMT and HBT, because of the superior gain and power handling of these technologies. Nevertheless, the simpler fabrication technology MESFETs remains attractive for low-cost applications where the performance is undemanding. At the present time, HBTs are the most common choice for power amplifiers in cellular handsets, while PHEMTs power FETs are being introduced in many microwave and millimeter-wave power amplifier applications and are even challenging silicon LDMOS in some specialized applications at 2 GHz. By 2006 GaAs-based HEMTs are expected to be found in over 35% of microwave applications, while HBTs provide another 30%, with MESFETs falling to around 20%.

The maximum electric field sustainable before the material breakdown determines the maximum voltage sustainable across the device, which in turn directly influences the power handling of the device. The electron and hole mobilities impact the resistivity, frequency limit, and current handling (and thus power handling) of the device. The saturation velocity determines the current handling and frequency limitations. The thermal conductivity limits the temperature of operation and thus the power-handling and frequency limits. Table 4 lists these parameters for a range of semiconductors used or potentially available for power devices. The potential for newer materials such as GaN, SiC, and diamond is still being evaluated. It should be noted that the reported data for more recent materials varies in the literature. The Johnson and Baliga figures of merit are frequently used to compare the potential of materials for power device applications [48,49]. Baliga's figure of merit is a measure of the

Table 4. Material Properties for Power Devices at 300 K

4 HSiC	455.0
Diamond	37,000.0

ON resistance of the drift region of a transistor (usually applied to vertical FETs) [50]. The Johnson figure of merit (JFM) is a measure of the ultimate high frequency capability of the material and is given by the product of critical breakdown field E_{Br} and saturated electron drift velocity v_{sat} :

$$JFM = \left(\frac{E_{Br} v_{sat}}{2\pi} \right)^2$$

The Johnson figure of merit is shown for a range of power semiconductors in Table 5. It should be noted that practical limitations encountered in fabricating power transistors limits the actual performance of devices, although the more mature technologies of Si and GaAs can approach these limits in some applications. InP has demonstrated excellent performance in applications, including MMICs, above 100 GHz, although it is still mainly applied to small-signal transistor applications and a limited range of relatively low-power millimeter-wave devices such as Gunn diodes (75 mW at 94 GHz).

7. APPLICATIONS AND MARKETS FOR MMICs AND DIGITAL ICs

Historically, the market for III-V integrated circuits grew steadily up until 2000, without the cyclical behavior often seen in the silicon digital IC market. In 2000 over \$2 billion MMICs and digital GaAs ICs were sold and despite the technology recession observed in 2001/02, the market for these products is expected to grow to over \$4 billion by 2006. Wireless communications represented over 70% of this market in 2000, but by 2006 this is expected to fall to around 60% as the use of MMICs in automotive applications increases. Interestingly, despite the intense interest in optoelectronics, the total share of the GaAs IC market in this application (for modulators, switches, driver ICs, detectors, and high-speed processing) is not expected to exceed 12% in the foreseeable future (indeed, its market share fell to 8% in 2002). Although digital GaAs was originally seen as a major growth element of the industry in the late 1990s, the collapse in the optoelectronic market in 2000 and the increase in CMOS Si and SiGe capabilities, have seen the GaAs largely displaced for digital applications below 2.5 Gbps. Analogue applications now dominate for III-V MMICs with increased usage in mobile terminal products (cellular handsets, personal digital assistants wireless LANs, etc.), principally for power amplifiers and low-loss RF switches (Fig. 12). The emer-

**Figure 12.** A microwave switch MMIC (1 × 1 mm) (Filtronic plc).

gence of automotive radar applications has led to forecasts of significant growth for chipsets at 17, 24 and 77 GHz, possibly reaching 5 million chipsets per annum by 2007.

1. COMMUNICATION SYSTEMS

The ability of electromagnetic radiation to provide almost instantaneous communication without any interconnecting wires has been a major factor in the explosive growth

of mobile communications, especially cellular and personal communications during the latter half of the twentieth century. The vacuum tube made the radio practical and affordable during the earlier half of the twentieth century. The invention of the transistor and highly complex yet cheap integrated circuits have allowed the development of ever complex digital communication systems that operate quite close to theoretical limits on channel capacity, spectrum efficiency, and so on.

The word *transceiver* is actually a combination of two words, *transmitter* and *receiver*. Figure 1 shows the block diagram of a general radio transceiver. Below each system block is a list of some of the popular techniques used. A modern digital transceiver uses most, if not all, of the system blocks in Fig. 1. Based on the direction of information transfer, radio systems are of three general types: simplex, half-duplex, and full-duplex systems. A *simplex* system transmits information in only one direction from a transmitter to a receiver. Examples of simplex systems are commercial audio and television broadcast systems organized in a *star* configuration. A *half-duplex* system is one in which transmission is bidirectional but only one transmitter at a time can transmit. A *full-duplex* or duplex system is one in which bidirectional communication can occur at any time. Although all communication systems are either some kind of simplex or duplex system, a variety of communications architectures exist dependent on the end application.

Section 2 points out the important characteristics of radio transceivers. Section 3 is devoted to the evolution of transceiver architecture. The characteristics of various different architectures are discussed in detail. Section 4 describes the implementation of important transceiver components with special emphasis on digital processing. Section 5 concludes by looking at the future.

2. TRANSCIEVER CHARACTERISTICS

2.1. Radio Transmitter Characteristics

This section details the important characteristics and performance issues for a transmitter.

2.1.1. Out-of-Band Emissions. There are stringent requirements as part of the standards for out-of-band power emissions. For example, the interim standard IS-54 for digital cellular radio specifies that power emission in adjacent and alternate channels must be 26 dB and 45 dB below the mean output power, respectively. Spectral shaping to maintain out-of-band emissions below those required by the standards is usually achieved through a combination of baseband pulse shaping, IF/RF filtering, and proper operation of the radiofrequency (RF) power amplifier.

2.1.2. Output Power, Distortion, and Efficiency of the Power Amplifier. In the early days of radio, power was amplified by vacuum tubes. With the invention of the transistor, solid state circuits have replaced vacuum tubes. The power amplifier should provide adequate output power with the least distortion and maximum possible efficiency [1]. The gain, efficiency, distortion, and power of the transistors typically used in solid-state power amplifiers depend on the choice of the bias point and the drive mechanism through the familiar designation of the operating class (Class A, B, AB, C, or E). The distortion introduced by the amplifier is specified by its AM-AM and AM-PM transfer characteristics.

The two most important parameters of the power amplifier, namely, efficiency and distortion, are incompatible with one another. Linear power amplifiers provide the least distortion but have quite large quiescent currents, resulting in poor efficiency. Nonlinear amplifiers, like

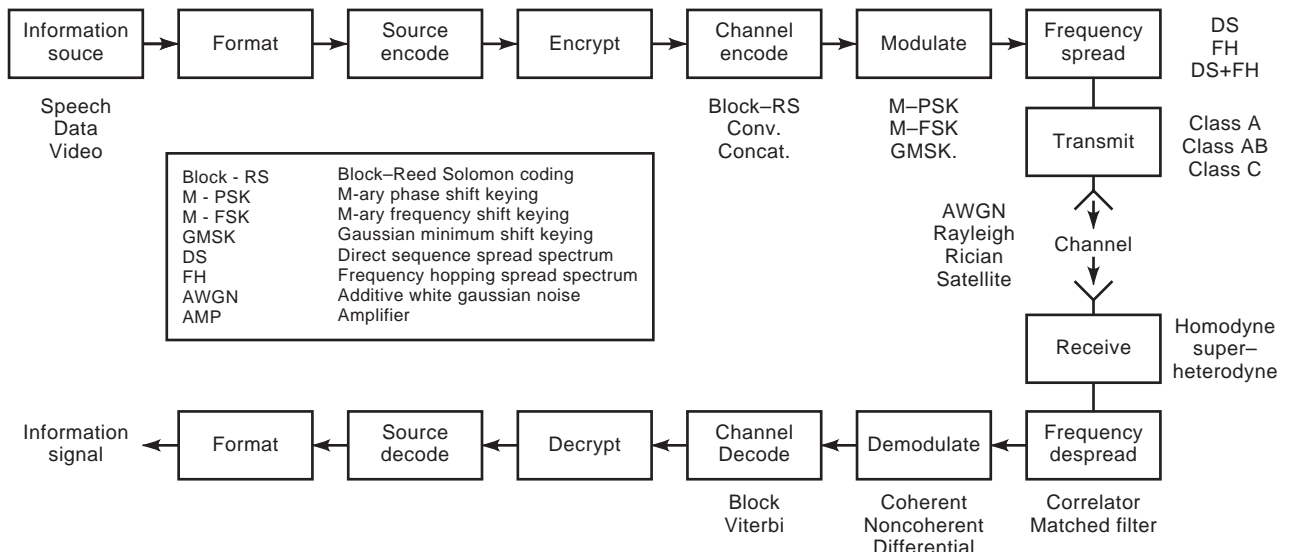

Figure 1. General block diagram of a modern transceiver. Abbreviations are listed at the end of the article.

Class C amplifiers, are highly efficient but cannot be used for linear modulation because of the distortion introduced by the amplifier. The type of power amplifier used depends on the requirements of the modulation used. Constant envelope modulation like frequency modulation (FM) can be amplified with nonlinear Class C amplifiers. However, in recent years, increasing demand for RF spectrum usage is forcing the use of spectrally efficient linear modulation techniques. These signals have a fluctuating envelope, and nonlinear amplification results in spectral spreading and intermodulation products. Therefore highly linear power amplifiers are required. One way to achieve linear amplification is to back off the amplifier from saturation and operate in the linear region of its transfer function. However, such amplifiers have poor dc-to-RF conversion efficiency. A major challenge in designing a high-power amplifier is to maintain linearity without compromising power efficiency [2].

2.2. Radio Receiver Characteristics

This section details the important characteristics and performance issues for a receiver.

2.2.1. Antenna and Input Characteristics. The main function of a radio receiver is to pick up electromagnetic radio energy at the antenna and transfer it efficiently to the processing section of the receiver. The important characteristics of an antenna are its efficiency, impedance, 3 dB beam width, bandwidth, and gain. Other characteristics are null-fill, upper sidelobe suppression, and performance versus specification. All antenna characteristics are functions of the physical antenna dimensions relative to the operating wavelength. Another important component is the coupler between the antenna and the input circuit of the receiver, which typically is a filter or an amplifier. Maximum energy is transferred if the impedance of the input circuit matches that of the antenna throughout the band of interest. Some of the antenna matching problems in a radio receiver are as follows:

1. The problem of matching the antennas at certain frequencies may be limited by component availability.
2. The impedance of antennas used in mobile applications or in locations where the environment changes with time due to foliage or traffic.

The problem of antenna matching is often solved by the system designer taking into account and compensating for a range of mismatch losses that might occur in practice. Other input characteristics that need to be taken into account are as follows:

1. The input RF circuits may be balanced, unbalanced, or both.
2. Protection from high-voltage discharges due to lightning.
3. Ability to handle high-power cochannel and adjacent channel transmissions

2.2.2. Gain and Sensitivity. Radio receivers typically process signals with a wide range of powers. The extent to which the signals can be received and processed usefully depends on the noise levels received at the antenna and those generated by the circuits within the receiver itself. The receiver is also required to produce a certain level of output power suitable for the application. Receivers are designed so that the gain is distributed among the various stages as required. Modern receivers are usually not gain-limited, and the weakest signal that can be processed is usually noise-limited. This signal level is known as the *sensitivity* of the receiver. A measure of sensitivity is the *minimum detectable signal* (MDS), which is the power of a sinusoidal signal that just equals the noise power at the intermediate frequency (IF) output of the receiver. MDS [1] can be expressed in decibels as

$$\text{MDS} = KTB_n F$$

where K is Boltzmann's constant (1.38×10^{-20} mW/°K), T is the reference temperature (typically 290°K), B_n is the noise bandwidth of the receiver, and F is the noise figure.

2.2.3. Noise Figure. The noise figure compares the total receiver noise with the noise that would be present if the receiver generated no noise. This ratio is called the *noise factor* F , and, when expressed in decibels, the noise figure (NF). It is thus a measure of the amount of noise introduced by the circuits within the receiver itself.

$$F = \frac{(S/N)_{\text{input}}}{(S/N)_{\text{output}}}$$

where (S/N) is the signal-to-noise ratio.

2.2.4. Selectivity. Selectivity is the ability of a receiver to separate a signal at one frequency from signals at other frequencies. Selectivity is defined as the bandwidth for which a signal x dB stronger than the minimum acceptable signal at a nominal frequency is reduced to the level of that minimum acceptable signal. Two important characteristics are required in establishing the selectivity of a receiver. One is that the selective components of the receiver must be sufficiently sharp to suppress unwanted interference from adjacent channel transmissions and spurious responses. The other is that the components must be sufficiently broad to pass the highest frequency of interest with acceptable gain and phase distortion.

2.2.5. Dynamic Range. Dynamic range is used to indicate the ratio between the strongest and weakest signals that a receiver can handle with acceptable noise or distortion. The weakest signal commonly considered is the minimum detectable signal. This definition is of limited value especially when the desired signal is surrounded by other signals with varying signal power. The selectivity of a receiver provides protection against many of the unwanted signals. The strong unwanted signals, however, can still cause degradation because of nonlinearities in the receiver chain. Therefore it is important to consider the

definition of the strongest signal component when determining the dynamic range of the receiver.

2.2.6. Characterization of Spurious Outputs. A modern receiver typically has a synthesizer and possibly several local oscillators, especially if superheterodyne architecture is used. It is possible for these frequencies to interact and produce spurious outputs without any inputs present. The following are other sources of spurious signals:

1. Parasitic oscillations in amplifiers because of parasitic feedback
2. Intermediate frequency subharmonics
3. Power supply harmonics

2.2.7. Frequency/Clock Generator Characteristics

2.2.7.1. Accuracy and Stability. Modern transceivers have a frequency synthesizer to which all other local oscillators are slaves. Earlier radios had free running oscillators that have largely been replaced by digital synthesizers because of the superior frequency accuracy, stability, flexibility, and cost performance of digital circuitry. Once the synthesizer has been set to operate at a specified frequency, its frequency must remain unchanged for a period sufficient for nominal operation despite temperature and environmental changes. Modern transceivers use temperature-compensated crystal oscillators as clocks for their digital circuitry. These oscillators typically are accurate to about 1 part per million. Higher accuracies are provided by oven-stabilized crystal oscillators and rubidium oscillators when sufficient power is available. In certain applications, such as mobile handsets where cost and power are at a premium, less expensive clocks with accuracies of approximately 3 to 10 parts per million are used.

2.2.7.2. Settling Time. Modern receivers typically span large frequency ranges and might be required to retune to a different frequency of operation. Because the frequency synthesizer used is typically based on a phase-locked loop, the loop goes out of lock for a short period whenever the receiver retunes. The settling time of the loop is important as any loss of lock results in degraded receiver performance.

2.2.8. Digital Receiver Characteristics. In addition to the characteristics previously mentioned, these are other important characteristics useful for systems using digital modulation.

2.2.8.1. Eye Diagram. The eye diagram [3], the traditional way of displaying digital data, is obtained by displaying the received demodulated digital data signal in successive symbol intervals on top of each other. The eye pattern provides the following wealth of information:

1. The width of the eye opening defines the time interval over which the received signal can be sampled without error from intersymbol interference.

2. The sensitivity of the system to timing error is determined by the rate of closure of the eye, as the sampling time instant is varied.
3. The height of the eye opening at any specified time defines the margin over channel noise.

2.2.8.2. Bit Error Rate (BER). The BER [1] is the primary measure of the quality of a digital communication system. The BER is defined as

$$\text{BER} = \frac{N_E}{N}$$

where N_E is the number of bit errors and N is the total number of bits transmitted.

3. RADIO ARCHITECTURES

3.1. Evolution

Radio architectures have remained relatively unchanged since the invention of the homodyne and superheterodyne receivers in the early part of the twentieth century. With the advent of integrated processors during the 1970s and 1980s, there was a migration from analog to digital processing in almost every aspect of radio systems engineering. The only radio system block that survived this migration was the RF front end, which by its function has to be analog. However, the basic radio architecture has remained the same. The word *digital* in digital radio has a double meaning. First, it refers to the fact that information is carried in digital form and second that the radio uses digital processing to recover the transmitted signal after it has been downconverted by an analog front end. The following are the advantages of using digital processing [1,4]:

1. The repeatability and temperature stability of digital processing are substantially better than analog processing.
2. Certain functions that cannot be or are difficult to implement in analog hardware, such as sharp rolloff linear phase filters, can easily be implemented with digital processing.
3. Once engineered, digitally implemented system functions do not require the tuning or tweaking typically required in analog systems.

The software radio [5] can be thought of as the next logical evolution of the digital radio, where software control of radio functions is pushed as close as possible to the antenna in the conventional digital radio architecture. Here, the entire RF band of interest is digitized right at the operating RF band by high-speed analog-to-digital converters (ADCs). The rest of the radio functions, such as downconversion, equalization, demodulation, and decoding, would be carried out by reprogrammable logic, typically digital signal processors (DSPs).

Software radio architecture has the following advantages over conventional hardwired digital radio architecture:

1. A highly flexible and reconfigurable transceiver can be implemented.
2. The transceiver can be easily adapted to any particular environment by changing the modulation, filtering, demodulation, and so on.
3. Because of open architecture, future upgrades can easily be made without reengineering the entire radio.
4. Software radio architecture benefits readily from concentration, where multiple radio channels share the same RF front end, whereas analog systems need a separate RF front end for each channel.

Applications that already use or are likely to use digital/software radio architectures include cellular and personal communications systems, satellite communications, digital television, digital audio broadcasting, navigation and position location systems, and test equipment.

3.2. Transmitter Architectures

The earliest analog radio transmitter architecture was the direct conversion transmitter. Figure 2 shows the general block diagram of an analog direct conversion architecture. Although this architecture is simple, it has the following disadvantages [6].

1. The analog implementation of precise modulators at the operating RF is difficult.
2. When used as an analog quadrature modulator, gain and phase imbalances between the mixers require compensation because unwanted sidebands are generated.
3. The filtering required to reduce out-of-band emissions to conform to government-mandated spectral masks must be carried out completely at the RF

band of interest. Designing high rolloff RF filters that introduce minimal amplitude and phase distortion across the frequency band of interest is difficult.

The superheterodyne architecture shown in Fig. 3 was intended to overcome some of the disadvantages of the direct conversion architecture. Here, modulation is carried out at a low IF. Then the desired signal band is filtered to conform to the desired spectral mask, and the filtered signal is upconverted to the desired RF band. The main disadvantage of the superheterodyne architecture is that the one or more IF stages used increase power consumption, space, and cost.

The advent of digital modulation and digital integrated circuits has resulted in the ever increasing use of digital processing in the transmitter chain. Digital processing can alleviate most of the problems associated with analog direct conversion transmitters, and as a result there is a resurgence of interest, especially for low-power mobile handsets where space and power are at a premium. Following are the advantages of digital architecture [7]:

1. Design and implementation are flexible.
2. Digital implementation overcomes the problems of gain and phase, dc offsets, and performance drifts in analog implementations.
3. Multichannel digital IFs especially at base stations eliminate the multiple analog IF chains required in analog architecture. With digital upconversion, all digital IF signals can be combined in a digital summer and then transformed into a single analog signal by a digital-to-analog converter (DAC).
4. Manufacturing is reliable.

Some of these combined analog-digital architectures are shown in Fig. 4.

The advent of software radio architecture will result in almost complete replacement of the RF system by programmable digital processing. Figure 5 shows the block diagram of an ideal software radio. In this ideal architecture, except for the final RF power amplifier and filter, the

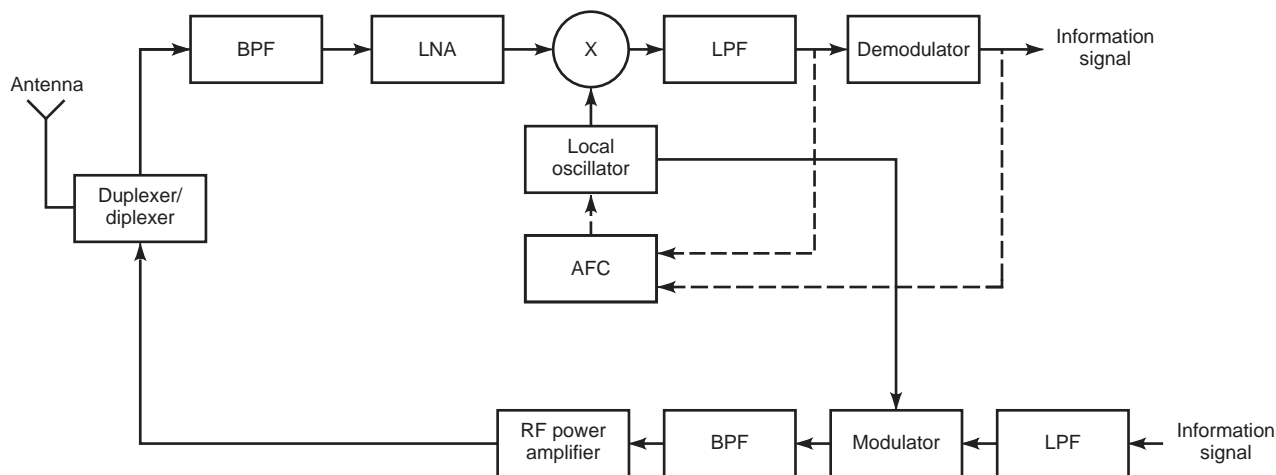

Figure 2. General block diagram of an analog homodyne transceiver.

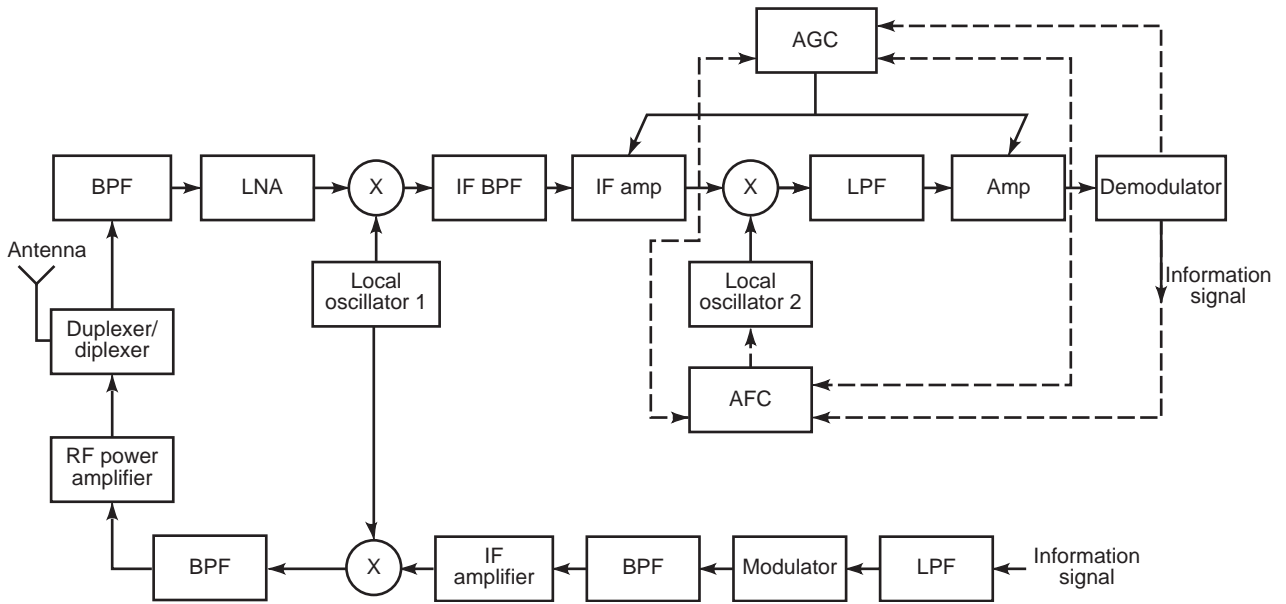

Figure 3. General block diagram of an analog superheterodyne transceiver.

analog upconversion chain has been replaced by digital IF upconversion. Limitations on the maximum sampling rate by currently available technology, however, permits replacing only the first analog IF strip.

3.3. Receiver Architectures

The earliest analog receiver architecture was the homodyne or the direct conversion architecture, as seen in Fig. 2. The receiver consists of a bandpass filter (BPF) following the antenna for noise and interference rejection

followed by a low-noise amplifier (LNA). Then the signal is downconverted to baseband by a pair of analog mixers. The in-phase and quadrature components are low-pass filtered to remove the mixer products and are demodulated. Following are the advantages of direct conversion architecture:

1. Reduced hardware complexity as there are no IF stages
2. No image frequencies

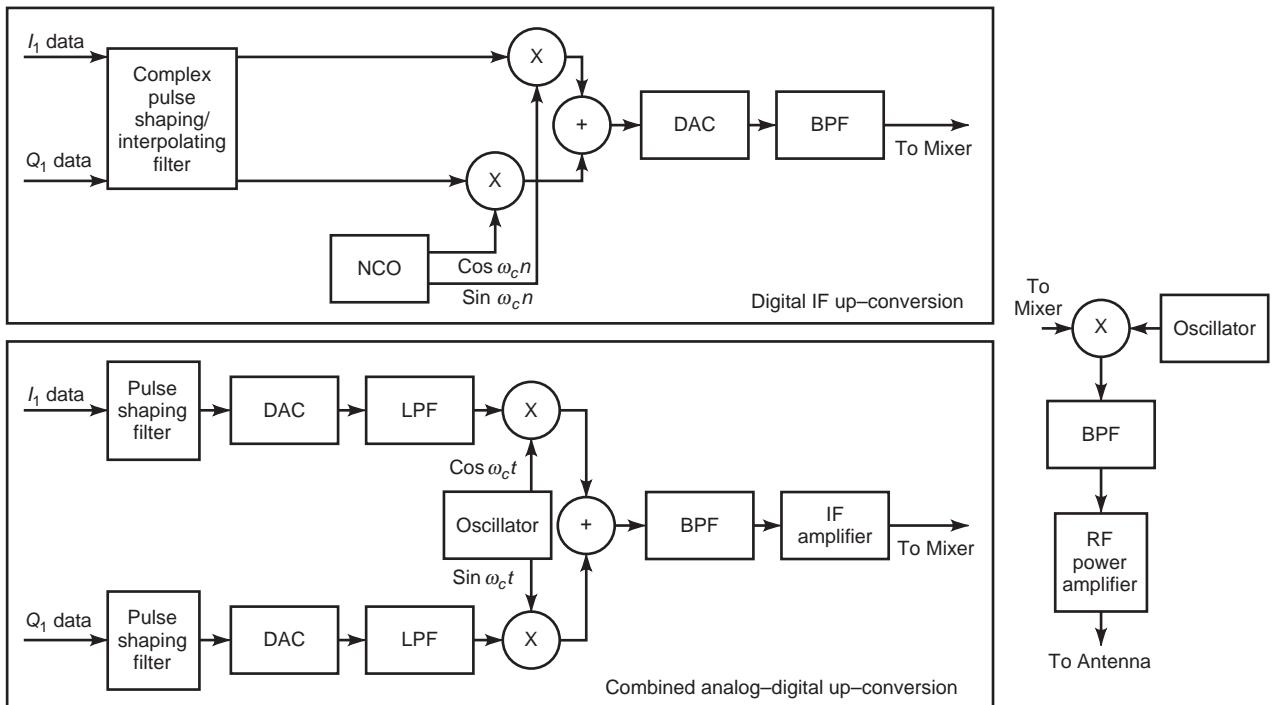

Figure 4. General block diagram of combined analog-digital upconversion architectures.

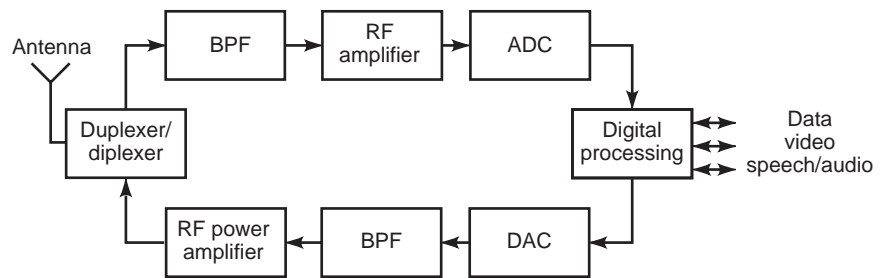

Figure 5. General block diagram of an ideal software radio architecture.

Following are the disadvantages of the direct conversion receiver, *especially* with an analog implementation:

1. Amplitude and phase mismatches between the mixers distort the signal.
2. Sharp rolloff analog low-pass filters (LPF) also distort the desired signal.
3. Carrier leakage, $1/f$ noise in the mixers, and bias in the filters all contribute to an unpredictable time-varying dc offset in the recovered signal.
4. All signal amplification has to be done at the carrier frequency. Building high-gain RF amplifiers at such high frequencies is difficult and expensive.
5. Carrier recovery for coherent reception has to be carried out at the carrier frequency. Precise control of high-frequency oscillators is difficult.

The superheterodyne receiver shown in Fig. 3 was developed to alleviate some of the disadvantages of the direct conversion receiver. In this architecture, the RF signal is downconverted to an intermediate frequency before being downconverted to baseband. This is known as the single IF stage superheterodyne receiver. Various versions of this general architecture with multiple IF stages have been developed. The most common version is the dual IF stage architecture. Following are the advantages of superheterodyne architecture compared with the direct conversion receiver:

1. Most of the signal amplification is done at relatively lower IFs, where it is easier to build high-gain amplifiers.
2. Automatic frequency control is usually carried out at the lower IFs and hence is easier to implement.

With the advent of digital modulation, high-speed ADCs, and digital integrated circuits, digital processing started to replace segments of the analog receiver architecture especially in demodulation and baseband processing. This led to the development of digital radio architecture. Both direct conversion and superheterodyne RF front-end architectures have been used in digital radios. The direct conversion digital radio requires two ADCs to digitize the in-phase and quadrature components of the downconverted signal. Superheterodyne digital radios have used both low-pass and bandpass digitization. The advantage of bandpass digitization is that it can replace the last analog downconversion stage. In addition, because the final

downconversion to center the chosen spectral image around dc is done digitally, all problems associated with quadrature analog downconversion disappear. Some of the digital receiver architectures are shown in Fig. 6.

Although the digital radio provides superior performance, its architecture is still based on the direct conversion or the superheterodyne architectures. Recently, a more fundamental change in receiver architecture occurred with the advent of software radio architecture, made possible by technological advances in ADC technology, computing technology, and software engineering. The software radio architecture looks similar to that of the digital radio with one crucial difference. In software radio architecture, programmable digital processing is pushed as close to the antenna as technology permits. The block diagram of an ideal software radio architecture is shown in Fig. 5. In this architecture, the only analog RF components are the preselection bandpass RF filter and the low-noise RF amplifier. Then the RF signal is directly digitized using bandpass subsampling, and the rest of the receiver functions are carried out in embedded software modules running on high-speed DSPs. This architecture is still a few years away from commercial implementation because high-speed ADCs that operate with sufficient resolution at the desired RF band are unavailable. Current software radio architectures use at least one IF stage.

4. TRANSCIEVER IMPLEMENTATION

4.1. Transmitter

The design and implementation of transmitters involves the following:

1. Filtering
2. Modulation and frequency upconversion
3. Power amplification

4.1.1. Filtering. In analog radios, analog filters are the only way to achieve frequency selectivity and to limit out-of-band emissions. In digital radios, digital filters in addition to analog filters are used to shape the spectrum of the transmitted signal. Analog filters are discussed in detail later. Some of the popular digital filters used for pulse shaping to achieve a compact modulated spectrum are the raised cosine and Gaussian filters [8]. The advantages of using digital filters are discussed in Section 4.2.7.2.

Figure 6. Some digital receiver architectures.

4.1.2. Modulation. Modulation [8] is the process of encoding information from a message source onto a format suitable for transmission. The process involves translating the baseband message signal, called the modulating signal, onto a bandpass signal at a much higher frequency, called the carrier. This process is called modulation. Modulation is usually carried out by varying the amplitude, frequency, phase, or any combinations of these three parameters of a carrier signal. Based on whether the message information signal is analog or digital, modulation is classified as analog or digital modulation.

4.1.2.1. Analog Modulation. In analog modulation, the modulating signal is analog and can assume an infinite number of amplitude values. Analog modulation is broadly classified into two categories, amplitude modulation and angle modulation.

In amplitude modulation (AM), the amplitude of a high-frequency carrier signal is varied in accordance with the instantaneous amplitude of the modulating information signal [3,8]. The amplitude-modulated signal is expressed as

$$S(t) = A_C[1 + m(t)] \cos 2\pi f_C t$$

where A_C is the amplitude of the carrier, f_C is its frequency, $m(t)$ is the modulating information signal, and $S(t)$ is the modulated signal. The spectrum of an AM signal contains a component at the carrier frequency and two sidebands that replicate the original information spectrum.

An AM signal is generated by a nonlinear device, such as a diode or transistor. Many variations of amplitude modulation exist based on what percentage of the sidebands is transmitted. Some of these variations are single-sideband AM (SSB-AM), pilot-tone-sideband AM, and vestigial-sideband AM (VSB-AM).

Angle modulation [3,8] varies the angle of the carrier signal according to the amplitude of the modulating signal. There are two important classes of angle modulation, FM and phase modulation (PM).

In FM, the instantaneous frequency of the carrier is varied with the information signal $m(t)$, as shown by the following equation:

$$S(t) = A_C \cos \left(2\pi f_C t + 2\pi k_f \int_{-\infty}^t m(l) dl \right)$$

where k_f is the frequency deviation constant measured in units of hertz per volt. There are two basic methods for generating an FM signal, the *direct method* and the *indirect method*. In the direct method, voltage-controlled oscillators vary the frequency of the carrier signal directly in accordance with the amplitude of the information signal. Such oscillators commonly use devices, such as varactor diodes, whose reactance can be varied in accordance with the modulating signal's voltage level. The indirect method is based on approximating a narrowband FM signal as the sum of a carrier signal and a single sideband signal where the sideband is 90° out of phase with the carrier.

PM is a form of angle modulation where the phase of the carrier is varied according to the information signal $m(t)$. A PM signal can be generated by first differentiating the information signal $m(t)$ and then outputting it to a frequency modulator.

4.1.2.2. Digital Modulation. Modern communication systems use digital modulation. In digital modulation, the modulating information signal is represented as a time sequence of symbols in which each symbol has m finite states. Each symbol represents n bits of information, where $n = \log_2 m$ bits/symbol. Digital modulation offers many advantages over analog modulation, including greater noise immunity, robustness to channel impairments, and easier multiplexing of various forms of information, such as voice, data, and video. Furthermore, digital transmissions use error-correcting codes and support complex signal conditioning and processing techniques, such as source coding/compression, encryption, and equalization to improve the performance of the communications. Advancements in very large-scale integration and digital signal processing technology have made it possible to implement digital modulators and demodulators easily. The use of embedded software to do most of the signal processing allows alterations without having to replace the hardware.

Some of the widely used digital modulation techniques are m -ary amplitude-shift keying (ASK), m -ary frequency-shift keying (FSK), m -ary phase shift keying (PSK), combined amplitude and phase modulation, combined coding and modulation, and multicarrier modulation.

In ASK, the amplitude of the carrier signal is varied in accordance with the instantaneous amplitude of the modulating information signal, which can take one of several discrete amplitudes. In FSK, the frequency of the carrier signal is varied in accordance with the instantaneous discrete amplitude of the modulating information signal. In PSK, the phase of the carrier signal is varied in accordance with the instantaneous discrete amplitude of the modulating information signal. In a general sense, ASK, FSK, and PSK can be thought of as special cases of AM, FM, and PM, respectively, where the modulating signal is discrete in amplitude. In combined amplitude and phase modulation, both the amplitude and phase of the carrier are varied according to the amplitude of the modulating signal. Ungerboeck [9] realized that error-correction coding and modulation can be combined at a fundamental level to realize performance gains greater than with the conventional method of coding and modulating separately. Combined coding and modulating is more commonly known as *trellis-coded modulation*. The basic concept of multi-carrier modulation is dividing a given RF bandwidth into many narrowband subchannels that are transmitted.

4.1.3. Frequency Upconversion. Frequency conversion is usually achieved by devices called *mixers*. A mixer is a component that acts as a frequency converter by mixing two input signals together to produce a desired signal. A mixer can be implemented by a variety of semiconductor devices, such as diodes (typically Schottky

diodes), bipolar-junction transistors, and field-effect transistors. Mixers are generally of two types, single-balanced and double-balanced. The single-balanced mixer improves port-to-port isolation and reduces the magnitude of some of the spurious signals. It consists of two single-ended mixers interconnected in a configuration that greatly reduces some spurious products. A double-balanced mixer further improves port-to-port isolation and suppresses spurious inter-modulation products even further.

4.1.4. Amplifiers. The triode vacuum tube amplifier was the mainstay for many communication systems before the transistor was invented. Because of transit time limitations, triodes were limited to VHF and UHF. For operation at higher microwave frequencies, the magnetron was invented in the early 1940s. The invention of the transistor was a boon for developing low-cost, reliable, handheld, low-power mobile communication systems. Since then, solid-state amplifiers have replaced vacuum tube amplifiers in almost all communication systems. Systems requiring extremely high power at microwave frequencies, such as deep space and radar systems, continue to use tube amplifiers.

All commercial communication systems use solid-state transistor amplifiers. Solid-state amplifiers come in four main types: discrete, hybrid, integrated (ICs), and application-specific IC (ASIC). A discrete amplifier is one built with discrete transistors and passive components. Hybrid modules, also known as microwave integrated circuits (MICs), have a substrate and discrete devices, including RF matching and bias circuitry. RF ICs, also known as microwave monolithic ICs (MMICs), have all bias and RF matching circuitry on the same substrate, whereas MICs use different materials to achieve optimum matching. The advantage of using a single substrate is that components can be closely matched in value. The difference between an IC and an ASIC is that an IC typically integrates only a few transistors together with transmission line filters and inductors, whereas ASICs, on the other hand, contain several hundred or thousands of transistors.

Several amplifier configurations are based on operating classes A, B, AB, C, D, E, or F. Silicon (Si) bipolar, heterojunction-bipolar, and field-effect transistors (FET) have been used most often to date in RF circuits. Gallium arsenide (GaAs) and complementary metal oxide semiconductor transistors have been gaining interest. GaAs amplifiers offer simple functionality with some biasing and matching components around a chain of transistors. One of the advantages of GaAs versus silicon is that GaAs is an insulator, whereas silicon is a conductor at RF frequencies. As a result, GaAs can integrate several RF components monolithically, facilitating closer components and better matching.

High-power amplification at microwave frequencies, especially those used for satellite communications, are usually handled by traveling-wave tube amplifiers (TWTAs). Other tube amplifiers are the magnetron, coupled-cavity TWT, continuous-wave TWT, helix TWT, klystron, and crossed-field amplifier (CFA).

4.2. Receiver

The main function of the receiver is to pick up the RF energy transmitted at its antenna and efficiently and effectively recover the original information signal transmitted. The design and implementation of receivers involves the following:

1. Antennas
2. Amplification
3. Filtering
4. Downconversion
5. Automatic gain control
6. Demodulation and other associated signal processing functions

Antennas, amplification, analog filtering, and downconversion are common to both analog and digital/software radios. The rest of the receiver functionality depends on its implementation, whether analog or digital. Because these implementations are quite different, they are discussed in different sections with special emphasis on digital implementation.

4.2.1. Antennas. The type of antenna used in a transceiver depends on its application. Handheld or backpacked transceivers require integral antenna structures. Vehicular transceivers must use antennas of limited size and relatively short wavelengths. Antennas that operate at frequencies substantially below their first resonance are called small antennas. Large point-to-point systems use large antennas. Some of the most popular antennas used in commercial communication systems are the vertical whip antenna, the loop antenna, and the dipole array.

4.2.1.1. Whip Antenna. For operating frequencies below the quarter-wave resonance of the antenna, the whip input impedance appears as a small capacitance in series with a resistance. The radiation resistance R_R of a short vertical whip is given by [1]

$$R_R = 40\pi^2 \left(\frac{h}{\lambda}\right)^2$$

where h is the antenna height and λ is the operating wavelength. The whip is also used as a quarter-wavelength monopole antenna for applications, such as cellular and PCS handsets. The whip antenna has an omnidirectional antenna pattern in azimuth.

4.2.1.2. Loop Antennas. Loop antennas have been used in portable broadcast receivers and radio direction finders. When the dimensions of the loop are small compared with the wavelength, the loop is said to be small and its impedance is an inductance in series with a resistance. The radiation resistance R_R for a loop with N turns is given by

$$R_R = 320\pi^4 \left(\frac{AN}{\lambda^2}\right)^2$$

where A is the area of the loop. The loop antenna responds as the cosine of the angle between its face and the arrival direction of the electromagnetic wave. This results in a figure-eight antenna pattern with the null for waves arriving perpendicularly to the loop face.

4.2.2. Amplification. The RF signal picked up by the antenna is very weak and has to be amplified before it can be processed. Typically the very first amplifier used is a specially designed, low-distortion, low-noise amplifier. The operating characteristics of the amplifier are important, as its noise performance dominates the noise figure of the receiver. Both bipolar-junction and FET amplifiers have been used. In recent years, the use of GaAs instead of Si has been gaining interest.

4.2.3. Analog Filters. The selectivity of an analog radio receiver is achieved solely by bandpass and low-pass analog filters. Even in digital and software radio architectures, the analog bandpass filter is an important component and is used both for preselection and antialiasing. Digital radios also use analog filters in their RF front end to implement some selectivity.

The most important characteristics of a filter are its amplitude and phase response. The various characteristics of a filter are interrelated because they are completely determined by the poles and zeros of the transfer function of the filter. Following are some of the common filter families:

1. Butterworth
2. Chebychev
3. Elliptic
4. Equiripple

Analog filters are implemented with a number of different resonators. Following are the available technologies:

1. Inductor–capacitor (LC) resonators
2. Mechanical resonators
3. Quartz crystal resonators

Another important filter implementation is the surface acoustic wave (SAW) filter, of interest because it can be implemented with integrated circuit techniques and can use finite impulse response designs, similar to those for digital filters.

4.2.4. Downconversion. Downconversion is the process of shifting the received RF signal to baseband. Both direct conversion and superheterodyne architectures are used. The basic components of downconversion are mixers, bandpass and low-pass filters, and oscillators.

4.2.5. Automatic Gain Control (AGC). The large dynamic range of signals that must be handled by radio receivers requires gain adjustment to prevent overload or intermodulation of the stages to adjust the demodulator input level for optimum operation. Gain control is generally distributed over several stages throughout the receiver architecture. AGC typically measures the signal level into the

demodulator and tries to keep the level in the desired range by a feedback control loop. The control should be smooth and cause a generally logarithmic variation with the input variable.

4.2.6. Other Analog Radio Receiver Functions. The remaining functionality of the analog radio receiver is demodulation. Double-sideband AM signals are usually detected by an envelope detector. An envelope detector is any rectifier circuit that produces a component at the modulating frequency that is then recovered by a low-pass filter. The rectifier is generally implemented by diodes and by bipolar and field effect transistors. Other AM transmissions, such as SSB-AM and VSB-AM, are demodulated by a coherent demodulator. The coherent demodulator uses a mixer circuit with a local oscillator signal synchronized to the AM input carrier. Carrier synchronization is achieved through a carrier recovery circuit, such as the Costas loop. Common FM demodulators are the slope detector, quadrature detector, phase-locked loop (PLL), demodulator, and zero-crossing detector. The slope detector uses linear circuits to convert the frequency variations to envelope variations that can then be detected by an envelope detector. The quadrature detector consists of a network that shifts the phase of the FM signal by an amount proportional to its instantaneous frequency and uses a phase detector to detect the phase difference between the original FM signal and the signal at the output of the phase shift network. The output of the phase detector is proportional to the instantaneous frequency of the FM signal. In this manner, a frequency-to-amplitude conversion is achieved and the FM signal is demodulated. Phase detectors are generally implemented by diode-based mixer circuits. Because a PM signal can be modeled as an FM signal where the modulating signal has first been differentiated, PM demodulation is achieved by passing the PM signal through an FM demodulator and integrating its output.

4.2.7. Other Digital/Software Radio Receiver Functions. The rest of the digital/software radio receiver can be split into two distinct segments: signal digitization and signal processing.

4.2.7.1. Signal Digitization. Signal digitization, implemented by ADCs, is a two-step process [10], signal sampling followed by quantization. The sampling process is critical in signal digitization. There are two types of sampling, uniform and nonuniform sampling. In uniform sampling, signal samples are taken at uniform intervals, whereas in nonuniform sampling, the samples are non-uniformly spaced. The ADCs in communication systems use uniform sampling, and so the rest of the discussion concentrates on uniform sampling ADCs. The sampling methods for uniform sampling are Nyquist sampling, oversampling, quadrature sampling, and bandpass sampling.

The general sampling theorem for a bandlimited analog signal with no spectral components above f_M Hz

requires that the sampling rate F_S satisfies

$$F_S \geq 2f_M$$

$F_S = 2f_M$ is known as Nyquist sampling, and at this rate, the replicas of the spectrum of the original analog signal do not overlap. Two practical problems develop when implementing Nyquist sampling. The first is defining what a truly bandlimited signal is, and the second is antialiasing filtering before the ADC. In general, an RF signal has components at all frequencies. It is desirable that the distortion of the desired signal be dominated by ADC nonlinearities, not by spectral overlap. This requires that signals higher in frequency than $F_S/2$ be lower in power than the largest spurious response of the ADC. Bandlimiting is usually carried out by the analog antialiasing filter before the ADC. Unfortunately, practical analog filters cannot provide the kind of "brickwall" filter response required. Also, as the steepness of the filter rolloff increases, the phase response of the filter becomes more nonlinear, introducing more distortion.

Sampling the signal at a rate higher than the Nyquist rate is called oversampling. The benefit of oversampling is that the spectral replicas of the original analog signal in the sampled signal spectrum become increasingly separated as the sampling rate is increased beyond the Nyquist rate. Hence, a simpler antialiasing analog filter with a more gradual transition band can be used.

In quadrature sampling, the signal to be digitized is split into two signals. One of the signals is multiplied by a sinusoid to downconvert the signal to a zero-center frequency and then filtered to form the in-phase component of the analog signal. The other signal is multiplied by a 90° phase-shifted version of the sinusoid and filtered to form the quadrature component. Because each of these two signals occupies only one half the bandwidth of the original RF signal, the sampling rate can be reduced by one half at the expense of requiring two ADCs.

Bandpass sampling is based on the bandpass sampling theorem, which states that a bandpass signal with no frequency components below f_L Hz and none above f_H Hz can be determined uniquely by sampling the signal at a rate F_S Hz, where

$$\frac{2f_H}{k} \leq F_S \leq \frac{2f_L}{k-1}$$

where k is restricted to integral values that satisfy

$$2 \leq k \leq \frac{f_H}{f_H - f_L}$$

and

$$(f_H - f_L) \leq f_L$$

Bandpass sampling provides an image of the desired signal at multiples of the sampling frequency, and the spectral replica of the original analog bandpass signal closest to dc is usually chosen for further processing.

Once sampling is over, the sampled analog signal with its infinite range of amplitudes has to be converted to a finite set of discrete amplitudes. This is known as quantization. There are two general quantization methods, uniform and nonuniform quantization. In uniform quantization, the voltage difference between each quantization level is the same. In nonuniform quantization, the quantization levels are nonlinearly spaced in voltage. The ADCs used in RF and IF digitization typically use uniform quantization. In uniform quantization, some error is introduced into the quantized signal because the analog signal cannot be represented exactly by a finite number of discrete amplitude levels. Statistically, it can be assumed that the error signal is uniformly distributed within a quantization level.

4.2.7.2. Signal Processing. Signal processing is the core of the radio receiver and is the segment where the original transmitted information signal is recovered. Many operations are carried out by this system. These operations are quite application specific and may include some or all of the following:

1. Downconversion
2. Filtering, either spatial or temporal or both
3. Equalization
4. Despreading
5. Synchronization
6. Demodulation
7. Automatic gain control
8. Carrier recovery
9. Error-correction decoding
10. Source decoding
11. Decryption
12. Timing recovery

Some of the most important signal processing functions of a receiver are examined here in further detail.

Downconversion. When bandpass subharmonic digitization is used, spectral replicas of the original analog signal are found at multiples of the sampling frequency. However, there is generally no spectral replica centered around the zero-center frequency. To generate the complex baseband signal centered around the zero-center frequency, the output of the ADC is sent to a pair of digital multipliers. The reference inputs for the digital multipliers come from a quadrature-output, numerically controlled oscillator (NCO). The multipliers shift the spectral replica to the zero-center frequency. Then the outputs of the multipliers are sent to low-pass digital filters, which are typically finite impulse response (FIR) filters, to recover the baseband signal and filter out the other mixer products.

Filtering. Digital filters [11] are widely used in communication signal processing for tasks, such as digital downconversion, equalization, interference suppression, and pulse shaping. Following are the advantages of digital filters:

1. Exact linear phase filters can be implemented easily.

2. Filters with almost any desired frequency and phase response can be designed and implemented easily.
3. Changes in filter responses due to component variations caused by aging are eliminated.
4. Changes to the filters can be carried out easily because most of the filtering is implemented in software running on programmable processors.

Digital filters are of two general types, FIR filters and infinite impulse response (IIR) filters. Finite impulse response filters are the most common digital filters in radio receivers mainly because of the following advantages:

1. Filters with exactly linear phases can be easily designed.
2. There are efficient recursive and nonrecursive realizations of FIR filters.
3. FIR filters realized nonrecursively are always stable.
4. Round-off noise inherent in finite precision arithmetic implementations are easily made small for non-recursive realizations.

Following are the disadvantages of FIR filters:

1. A large filter order is required for sharp cutoff filters.
2. The delay of linear phase FIR filters need not always be an integral number of samples.

The main advantage of IIR filters is that sharp cutoff filters can be realized in relatively small filter orders. Following are the main disadvantages:

1. IIR filters generally do not possess linear phases.
2. IIR filters are more prone to be unstable because of quantization and round-off noise.

Carrier Recovery. Coherent demodulation requires that the phase and frequency of the transmitted carrier be known. Carrier recovery is the process of estimating the phase and frequency of the carrier to establish a reference for demodulation at the receiver. Any error in estimating the phase and frequency of the carrier causes significantly degraded performance. The information signal may be modulated onto the RF carrier so that a residual component at the RF exists in the overall transmitted signal spectrum. This residual RF component can be easily tracked by a narrowband PLL and provides the desired reference signal. However, this residual component represents power unavailable to transmit the information. Techniques that conserve power are of interest especially in mobile applications where power is at a premium because batteries supply power to the radio. As such, suppressed carrier transmissions are widely used. Following are some of the popular suppressed carrier recovery techniques:

1. Squaring loop
2. Costas loop
3. Decision feedback loop

Demodulation. The ultimate function of the radio receiver is to recover the original information signal that modulated the transmitted carrier. This process is known as *demodulation*. The portion of the receiver system that implements demodulation is known as the *demodulator*.

Some of the popular FSK demodulators are the limiter-discriminator, the PLL, and noncoherent and coherent demodulators. Noncoherent demodulation is carried out by a bank of bandpass filters whose outputs are envelope-detected. The largest output is selected as the transmitted symbol. The bandpass filters used to detect the tones are implemented either as FIR or IIR filters. Coherent demodulation compares the received signal with all reference frequencies. The comparison is done by multiplying the received signal by all the reference signals and then low-pass filtering the outputs of the bank of multipliers. The largest output is selected as the demodulated symbol. The locally generated reference signals must be synchronized in phase and frequency to the transmitted signal states.

Common PSK demodulators are the coherent demodulator and the differential demodulator. PSK can also be demodulated by using a frequency demodulator, such as a limiter-discriminator or a PLL, and integrating the output before the decision stage. The block diagram of a coherent PSK demodulator is shown in Fig. 7. Differential demodulators determine the cosine and sine of the phase difference and then decide on the phase difference accordingly. Differential demodulation shown in Fig. 7 is implemented by taking the product of the signal and a delayed version of the same signal. The output of the multiplier is low-pass filtered, usually by a FIR filter, to recover the information symbol transmitted. The transmitted symbols need to be encoded differentially to use differential demodulation.

Differential demodulators are often used in highly mobile applications where fading in the channel makes it impossible to get a robust coherent estimate of the transmitted carrier.

Processing Implementation. The processing elements that implement the functions in a radio are crucial, especially in software radio architecture, as they implement virtually all of the functions of the radio transceiver except the frequency conversion and RF amplification. The main attraction of the software radio concept, namely, its flexibility and ease of adaptation, is possible because signal processing is implemented in software modules. The software requires a hardware platform to run on, and the capability of the hardware architecture of the processing platform is critical.

Typically digital signal processing functions are implemented on special digital processors called DSPs [12]. Although DSPs are also microprocessors, there are several crucial differences between general multipurpose microprocessors and DSPs. General microprocessors are typically built for a range of general functions and normally run large blocks of software. The DSP, on the other hand, is built for a small dedicated group of tasks, the most important being the multiply-accumulate arithmetic operation that forms the core of any digital filter. DSPs contain large, high-speed data busses and use direct memory access to transfer large amounts of data, thereby avoiding communication bottlenecks. In addition, DSPs contain dedicated hardware blocks, such as multipliers, to speed up the arithmetic-intensive signal processing steps.

Some of the signal processing functions are so complex that parallel and sequential partitioning of algorithms is required to get the required processing power. DSPs are getting faster but are currently incapable of implementing

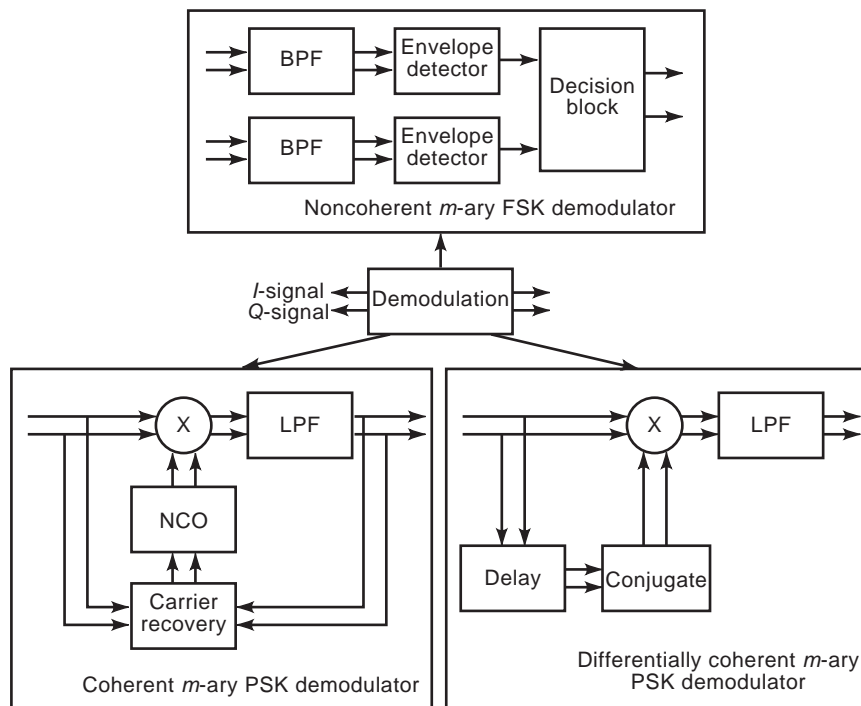

Figure 7. Some general demodulator architectures.

everything possible on a single chip. One approach has been to use multiprocessing to share the computational burden. The traditional approach to multiprocessing has been to integrate various DSPs on a board. Modern DSPs contain various hooks to simplify multiprocessing, such as simplified addressing across processors. A recent approach has been to integrate multiple processors within a single chip. This within-the-chip approach benefits from having closely coupled memory and cache, which improves communication efficiency.

To keep the flexibility of a programmable solution and the efficiency of a dedicated solution, field-programmable gate arrays (FPGAs) are increasingly becoming another viable option to implement highly complex signal processing functions. FPGAs are logic devices whose hardware architecture can be programmed before use. Techniques, such as distributed arithmetic for array multiplication, can increase the data bandwidth and throughput of an FPGA-based solution by orders of magnitude beyond those possible with general-purpose DSPs. It is projected that DSP cores will have onchip FPGA sections to provide configurable accelerators.

5. CONCLUSION

This article has presented an overview of the radio transceiver, its architecture, and the implementation of its most important system blocks. Several other specialized functions are not present in all transceivers and have not been discussed here. Some of these circuits are noise limiting and blanking, squelch, diversity reception, and adaptive antenna array processing.

Traditionally, transceivers have used analog circuits for implementation. The capabilities and advantages of digital processing have allowed replacing many of these analog functions. The movement of the digital portions of the processing closer to the antenna has resulted in the development of software radio architecture. The software radio is a powerful architectural framework that helps to deliver advanced radio services by leveraging the economics of contemporary micro-electronics and software technologies. Although much technological progress has been made in the field of digital processing, technology is not currently available to implement the ideal software radio. Following are some of the challenges and issues that face radio designers today:

1. To engineer low-cost, low-loss, and low-distortion wideband antennas
2. To engineer low-cost, low-loss, and low-distortion wideband RF front ends
3. To develop high-efficiency linear power amplifiers
4. To develop low-power integrated RF front ends
5. To develop low-cost, high-resolution (> 14 bits), and high-speed ADCs
6. To develop low-cost, high-speed reconfigurable digital processors

The development of the software radio transceiver is by no means over. Further technological advances are required,

especially in the hardware implementation of ADCs and reconfigurable processors. There will be further development toward integrating the analog RF front end into a single integrated circuit. The development of low-power RF and digital circuits is another challenge. The ultimate goal of implementing a radio on a chip, although not yet a practical reality, is not far away.

TRANSIENT ANALYSIS

ORLA FEELY
 BRIAN MULKEEN
 University College Dublin
 Dublin, Ireland

1. INTRODUCTION

Transient circuit analysis is used to find transient currents and voltages in a circuit. The word “transient” describes a quantity that is fleeting rather than permanent, and distinguishes this branch of circuit analysis from steady-state analysis, which is concerned with the long-term or settled behavior of a circuit. Transient circuit analysis asks not just “Where will my circuit end up?” but also “How will it get there?” The charging of a capacitor is one of the classic examples, but we might also consider what happens when a short pulse is applied to a transmission line (perhaps an interconnection on a high-speed digital integrated circuit), or when a burst of radiofrequency energy is applied to the antenna in a radar system. In this article, we review the basic principles of transient circuit analysis, which is a long-established branch of circuit theory with a wide range of applications. We will not consider the many techniques that are used in the simulation of transient behavior in circuits—these are an enormous topic in their own right, and are covered elsewhere.

Before proceeding, it should be noted that the circuits to be considered in this article in fact form only a subset of the universe of circuits—they are all linear and time-invariant. A linear circuit is one in which each element (except the sources that drive the circuit) is described by one or more linear equations involving its current(s) and voltage(s). For example, the resistor defined by $v = Ri$ is linear, but the diode defined by $i = I_s(e^{v/V_T} - 1)$ is nonlinear, and any circuit containing the diode is therefore nonlinear. Nonlinear circuits can exhibit highly complex behavior

and cannot be handled by the techniques described in this article. A time-invariant circuit is one in which the equations defining the elements (except the independent sources) do not change with time.

The equations describing a circuit arise from two sources: (1) Kirchhoff’s laws tell us how the elements in the circuit are interconnected, and then (2) each element in the circuit has an individual equation (or equations) describing its behavior. If all of the circuit elements are described by algebraic equations (i.e., ones in which no derivatives appear) involving their currents and voltages, these equations can be combined with Kirchhoff’s equations to give a set of algebraic equations that completely describe the circuit. These equations are linear equations in terms of the currents and/or voltages in the circuit, and can be solved by any of the techniques of linear algebra. The power of linear algebra means that these circuits, known as *resistive circuits*, are (relatively) easy to analyze. The behavior of these circuits is quite simple; if a linear resistive circuit is driven by a 1-V battery, then changing to a 2-V battery will cause all voltages and currents in the circuit to double. There is no time delay in this response—the doubling of voltages and currents occurs at the precise instant when the 2-V battery is inserted into the circuit. If the battery is replaced by a more complicated voltage source that varies with time, each voltage and current in the circuit will also vary with time as a scaled replica of the new voltage source.

Although easy to analyze, the limited behavior of a linear resistive circuit means that such circuits are not hugely useful. Instead of producing a scaled replica of the signal that drives them, most circuits are required to convert a signal into a more useful form. For example, the ignition circuit in a car is “driven” by a battery with almost constant voltage, but its output is a short, sharp spark; the circuits in a radio receiver are “driven” by a jumble of signals from many different sources, but must select the signal of interest and extract some information from it. These effects rely on the use of capacitors and/or inductors. These circuit elements are defined by equations involving not only their currents and voltages but also the rate of change (or derivative) of these quantities with time. Specifically, the current through a capacitor is proportional to the derivative of the capacitor’s voltage with respect to time, and the voltage across an inductor is proportional to the derivative of the inductor’s current with respect to time. Capacitors and inductors are known as *dynamic circuit elements*, conveying the importance to them of time variation, or energy storage elements, since they are capable of storing energy for later release.

Dynamic elements can be placed deliberately in a circuit, or they can be unwanted parasitic elements, modeling, for example, the capacitance between wires in the circuit. If a circuit contains even a single dynamic element, it is in general described no longer by a set of algebraic equations, but by one or more differential equations, in which the variables are not only the voltages and currents but also the derivatives of certain of these quantities with respect to time. A dynamic circuit is one that contains at least one dynamic element.

At higher frequencies, there is an additional complexity to consider in our circuit analysis, namely, the appearance of distributed circuit effects. Distributed circuits, unlike lumped circuits, have voltages and currents that vary not only with time but also with position within the circuit. The basic distributed circuit element is the transmission line, an incremental length of which is commonly modeled by a series resistance and inductance and a shunt capacitance and conductance. The inductance and capacitance in the model give rise to time derivatives in the equations that describe the line, while the distributed nature of the element gives rise to derivatives with respect to position along the line. Thus circuits of this nature are described by differential equations containing derivatives with respect to position as well as derivatives with respect to time. This gives rise to new forms of transient behavior in a circuit.

The goal of transient circuit analysis is to solve the differential equations that describe a dynamic circuit and thus to come up with expressions predicting the way in which the voltages and currents in the circuit will vary with time. It is often concerned in particular with the response of the circuit to changes, such as when a source is inserted, removed, or suddenly changed in some way, or a switch is closed and the makeup of the circuit thereby changed.

Dynamic circuits can exhibit more interesting behavior than resistive circuits, but they are also more difficult to analyze. One of the simplest dynamic circuits contains a single capacitor in series with a resistor and a constant voltage source that is switched on at some specified time. This circuit is described by an equation involving the capacitor voltage v_C and its derivative with respect to time dv_C/dt . The absence of any higher derivatives gives this equation the description “first order.” A circuit containing just a single dynamic element is described by a first-order differential equation and is called a *first-order circuit*.

The solution of a first-order differential equation will contain an unknown constant. To find this constant, it is necessary to apply some additional information about the value of the solution at a specified time instant. Since we are in general concerned with finding the response of the circuit to changes that occur at a certain time instant, we often know the state of the circuit just before the change occurs and can apply this information in order to find the unknown constant. The value of the capacitor voltage (or inductor current, if the circuit contains an inductor rather than a capacitor) just before the change occurs, is known as the *initial condition*.

Solving the first-order circuit just described yields the result shown in Fig. 1. The capacitor voltage plotted as a function of time is of exponential form, moving from its initial value toward the value of the constant voltage source and eventually settling there. (Certain assumptions have been made here, and are discussed in the next section.) This is intuitively plausible—once the voltage source has been inserted, the resistor voltage and capacitor voltage must sum to equal the voltage of the source. If the capacitor voltage does not initially equal that of the source, the voltage difference must be developed across the resistor by a current flowing through it. This current

Figure 1. Capacitor voltage in a first-order circuit increasing exponentially from its initial value to its final value.

charges the capacitor, bringing its voltage closer to that of the source, and the net effect is to cause the capacitor voltage to approach that of the voltage source.

Already in this simple circuit we can see how dynamic circuits behave in ways that would be impossible for a resistive circuit. If the circuit described above had been resistive, all voltages and currents would have been scaled versions of the source. In this circuit, however, the capacitor voltage takes on a form quite unlike that of the source—it varies exponentially with time, whereas the source is constant. The action of the resistor and capacitor has processed the source signal, with the capacitor voltage resisting the sudden change when the source was inserted, but retaining the steady behavior of the source. The resistor voltage, on the other hand, captures the change in the source very well, but eventually dies away to include nothing of the steady behavior of the input. This behavior is an example of the filtering behavior of this simple resistor–capacitor combination, which is useful in a variety of communications applications.

The exponential nature of the voltage observed in this simple circuit is not unusual—in fact, as we shall see, exponential functions appear in various guises in the solution to linear differential equations. Possibly the most widely known example of an exponential function appears in the analysis of radioactive decay, where the rate of decay of a substance is proportional to the amount of the substance present, and so the amount remaining decays exponentially to zero at a rate depending on the half-life of the substance.

A circuit that contains two dynamic elements in general gives rise to a second-order differential equation (containing the second derivative of the variable with respect to time) and is termed a *second-order circuit*. If all sources in the circuit are DC (constant) sources, this equation can be solved by application of standard theory of linear differential equations, with the aid of two initial conditions, one for each dynamic element. Instead of the single exponential transient of the first-order circuit, this circuit contains two exponential transients that are added to give the overall transient. The relationship (via complex numbers) between the exponential and sinusoidal functions can give rise to new types of behavior arising from these transients, as shown in Fig. 2. If the arguments of these exponentials are complex, as may turn out to be the case, then they can

Figure 2. Two possible responses of a second-order circuit, made up of the sum of two exponentials.

be added to give a transient that oscillates sinusoidally. In most circuits the magnitude of this oscillation decays exponentially with time. A common example of such a decaying oscillation is produced when a tuning fork is struck or a child's swing given a single push. If there are no losses in the circuit (not a practical requirement), the oscillation could persist indefinitely without decaying, and if the circuit is unstable, it is possible that the oscillation can actually grow.

In a radiofrequency system, a circuit would normally be “driven” by a more complicated signal, but the same basic principles apply. We can consider a simple example, where a short burst of a sinusoidal signal is applied to a second-order system. Such a signal might arise in a radar system or in a digital communication system. The resulting transient, shown in Fig. 3, is essentially sinusoidal in form, but its amplitude changes with time in a way that is similar to the transients shown earlier, first increasing in response to the start of the burst of sinusoidal signal, eventually settling to a steady amplitude, and then decaying exponentially following the end of the burst.

While it is possible to analyze simple first- and second-order dynamic circuits by applying standard theory of differential equations, such solution becomes rapidly more difficult when the order of the circuit increases or when the sources become more complicated. When faced with

Figure 3. Example transient response of a second-order circuit in response to a short burst of a sinusoidal signal.

such a problem, one might look enviously back at the much simpler process of solving a resistive circuit. In fact, it is possible to apply techniques of resistive circuit analysis to dynamic circuits with the aid of a variety of transforms. A *transform* is a method of changing a problem into a different form, solving it in the new form (where the solution is easier to obtain) and then changing the solution back to the original form. For example, a student unfamiliar with binary arithmetic, when asked to add two binary numbers, might convert the numbers to decimal form (presumably with the aid of a table), add the decimal numbers, and then convert back to binary. The transforms to be applied in this context change a system of differential equations to a system of algebraic equations that are significantly easier to solve.

The most important and most widely used of these transforms in circuit analysis is the Laplace transform. A second transform, the Fourier transform, is particularly useful in analyzing circuits designed for applications in communication systems. These transforms convert a set of differential equations involving the time variable into a set of algebraic equations involving a new variable called the *frequency* (in the case of the Fourier transform) or the *complex frequency* (in the case of the Laplace transform). Application of these transforms allows us to analyze a circuit by transforming it into an equivalent form in the frequency domain, where its equations are purely algebraic, analyzing the circuit in this frequency domain using the techniques of linear algebra, and then applying the transform in reverse to convert the result of this analysis into a function of time. We will see how the Laplace transform can be applied to distributed circuits as well as lumped circuits.

Once again, Laplace transform analysis shows up the special role of the exponential function (and its complex cousin, the sinusoid) in the behavior of circuits. Every dynamic circuit favors certain exponential (including sinusoidal) modes of behavior whose rate of decay (and frequency of oscillation, if applicable) is governed by the so-called natural frequencies of the circuit. These natural frequencies tell us whether the currents and voltages in a circuit will, of their own accord, tend to exhibit exponential or oscillatory decay, constant behavior or steady oscillation, exponential or oscillatory growth, or some

combination thereof. When an input signal is applied to the circuit, the currents and voltages may contain components controlled by the natural frequencies as well as a component controlled by the input. In many practical circuits it is desirable for the output to depend on the input, and the prospect of a growing oscillation in the circuit is a designer's nightmare. (This effect is similar to that demonstrated by sound systems when a microphone is placed in the path of a loudspeaker and an unwanted tone appears and swamps the desired signal.) In other cases, a sustained oscillation is the objective, and the designer's aim is to fix the frequency and amplitude of this oscillation. The issue here is one of *stability*. An asymptotically stable system is one in which all exponential transients die away, leaving only the effect of the input signal. Laplace transform techniques allow us to analyze a system to determine whether it is asymptotically stable, or whether a sustained oscillation is possible.

The effects of transients are seen in a huge range of electronic and electrical engineering applications, from the transmission of tiny pulses between parts of a communication system to the behavior of an electrical power system struck by lightning. The techniques described in this article provide the reader with the ability to understand and analyze transient behavior in a wide variety of circuits.

2. TIME-DOMAIN ANALYSIS

2.1. Natural Response and Step Response of a First-Order Circuit

Consider the circuit shown in Fig. 4a. Until the time $t = 0$, the switch S is in position 1, and the resistor R and capacitor C are connected in a loop. At time $t = 0$ the switch is moved to position 2, connecting the DC voltage source E in series with R and C . We assume that the switch closes instantaneously and that it presents a short circuit between the terminals that it connects. Mathematically, we say that the voltage applied to the RC series combination is $EU(t)$, where $U(t)$ is the unit step function given by

$$U(t) = \begin{cases} 0 & \text{for } t < 0 \\ 1 & \text{for } t \geq 0 \end{cases} \quad (1)$$

The circuit of Fig. 4a can, therefore, also be drawn in the form shown in Fig. 4b.

The analysis of the circuit for $t \geq 0$ in Fig. 4 will require knowledge of the initial voltage across the capacitor just after the switch is thrown, $v_C(0^+)$, where $0^+ = \lim_{\epsilon \rightarrow 0} \epsilon$.

Figure 4. (a) The switch S moves from position 1 to position 2 at time $t = 0$, so the voltage applied to the RC series combination is 0 for $t < 0$ and E thereafter. The switch/voltage source combination is represented in (b) by the single voltage source $EU(t)$.

We generally know, or can find from analysis of a previous regime, $v_C(0^-)$, the voltage at the instant just before the switch is thrown: ($0^- = \lim_{\epsilon \rightarrow 0} -\epsilon$). If the capacitor current is finite, $v_C(0^+)$ must equal $v_C(0^-)$, and we can refer to both as $v_C(0)$. Similarly, if the voltage across an inductor is finite, its current waveform must be continuous. We will assume these continuity conditions throughout this analysis. The alternative case, where the capacitor current or inductor voltage can be infinite, is not practical but turns out to be mathematically interesting and useful in analysis. It can be handled by an extension of our analysis in this section (see Ref. 1 for details), but we will postpone consideration of this possibility until Section 3, where it can be handled more conveniently.

For $t \geq 0$, Kirchhoff's voltage law gives the equation

$$v_C(t) + i(t)R = E$$

or, applying the constitutive relation $i(t) = C \frac{dv_C(t)}{dt}$ for the capacitor

$$RC \frac{dv_C(t)}{dt} + v_C(t) = E \quad (2)$$

This is a first-order differential equation in the capacitor voltage v_C , and so this circuit is referred to as a *first-order circuit*. It can be solved by a number of methods to give an expression for v_C as a function of time. One such method is to recast the equation in the form

$$\frac{d(v_C(t) - E)}{dt} = -\frac{1}{RC}(v_C(t) - E)$$

This equation is of the familiar form

$$\frac{dx(t)}{dt} = ax(t)$$

which has the solution [2]

$$x(t) = x(0)e^{at}$$

where $x(0)$ is the value of x at time $t = 0$. This initial condition must be known if the equation is to be solved for $x(t)$. Thus Eq. (2) has the solution

$$v_C(t) - E = (v_C(0) - E)e^{-t/RC} \quad (3a)$$

or

$$v_C(t) = v_C(0)e^{-t/RC} + E(1 - e^{-t/RC}) \quad (3b)$$

The response of the series RC circuit with zero initial capacitor voltage to the application of a voltage source given

by the unit step function is known as the *step response* of the series RC circuit. (Note that we will use the word “response” to signify any current or voltage in the circuit, or any set thereof, including, for example, the set of all currents and voltages. Throughout this article the variables that constitute the response in any given instance will be clear from the context in which the term is used.)

It is clear from Eq. (3a) that the difference between v_C and E varies exponentially with time, and when the product RC is positive (a condition that will be assumed to hold unless otherwise stated), this difference tends to zero as t tends to infinity. v_C is plotted as a function of time in Fig. 5, where, as expected, v_C is seen to converge exponentially to E . The rate of this convergence is governed by the value of RC , which is termed the time constant of the waveform and denoted by the symbol τ . The smaller the time constant, the faster the rate of convergence. After one time constant has elapsed (i.e., at $t = \tau$), $v_C(t) - E$ has decreased to $e^{-1} = 36.8\%$ of its value at $t = 0$, and at time $t = 5\tau$ this difference has decreased to $e^{-5} = 0.7\%$ of its initial value. Although v_C does not reach E within any finite time (unless, of course, it started out at E), after five time constants have elapsed, the difference between v_C and E has been reduced to less than 1% of its initial value. The time constant is a useful measure of the response speed of a first-order circuit. For more general circuits, the risetime is used as a measure of response time. This is defined as the time taken for the step response to rise from 10% to 90% of the steady-state value. For the first-order circuit analysed in this section, the risetime can be found to be $\tau \ln 9 \approx 2.2\tau$.

The value E to which the capacitor voltage converges is termed the *steady-state value* of this voltage. It is the only value of capacitor voltage at which the circuit can settle, or in other words it is only when $v_C = E$ that all currents and voltages in the circuit cease to vary with time. Clearly, when a quantity ceases to vary with time, its derivative with respect to time is zero, and so the steady-state value of v_C can be found directly from the differential equation (2) by setting the term dv_C/dt to zero (or, in circuit terms, replacing the capacitor by an open circuit), yielding the

Figure 5. The capacitor voltage in the circuit of Figure 1 varies exponentially from its starting value $v_C(0)$ to its steady-state value E , with time constant $\tau = RC$.

equation $v_C = E$, as expected. The overall waveform $v_C(t)$ is the sum of this steady-state component and a second component that dies away with time. This second component is known as the transient component (or just the transient). The exponential form of the transient in this circuit is, as we will see later, particularly common in linear circuits and other linear systems.

Note, however, that the procedure just outlined yields the value of v_C at which the circuit variables (currents and voltages) can remain constant, but it does not guarantee that the circuit will actually converge to this state. For example, if $RC < 0$, Eq. (3a) implies that v_C will diverge exponentially away from E and the circuit has no steady-state response. [The only exception to this divergence is when $v_C(0) = E$, in which case it will theoretically remain fixed at E for all time. The word “theoretically” is important—in practice, any noise in the circuit that causes v_C to differ even infinitesimally from E will result in its diverging exponentially from E .] This distinction relates to the issue of the stability of equilibria of differential equations [2].

Another useful view of the solution waveform (3b) for $v_C(t)$ is that it is composed of two components: one caused by the initial condition $v_C(0)$, and the other caused by the voltage source E . If $E = 0$, the response (3) reduces to $v_C(t) = v_C(0)e^{-t/RC}$, which is termed the “natural” or “unforced” response of the circuit. This is a viewpoint to which we will return later.

Any circuit consisting of a single capacitor in an otherwise resistive circuit containing only DC sources is generally analyzed by transforming it to single-loop form by means of a Thévenin transformation [3], as shown in Fig. 6. The analysis described above is then applicable, where E is the Thévenin equivalent voltage source, and R the Thévenin equivalent resistance. (The small number of circuits that do not have a Thévenin equivalent can be handled separately.)

Before leaving the single-loop first-order circuit of Fig. 4, we note that the analysis of this section can be used to find the response of a first-order circuit to a voltage source that is piecewise-constant, that is, constant over certain time intervals with discontinuous jumps between these constant levels. One important such waveform is the pulse

$$p(t) = \begin{cases} 0 & \text{for } t < 0 \\ E & \text{for } 0 \leq t < t_0 \\ 0 & \text{for } t \geq t_0 \end{cases}$$

Figure 6. A circuit consisting of a single capacitor in an otherwise resistive circuit is simplified by replacing the resistive one-port seen by the capacitor by its Thévenin equivalent.

The response of the first-order RC circuit to this source waveform is found by an extension of the analysis just performed. For $0 \leq t < t_0$, the analysis proceeds as before and $v_C(t)$ is given by Eq. (3b):

$$v_C(t) = v_C(0)e^{-t/RC} + E(1 - e^{-t/RC}) \text{ for } 0 \leq t < t_0 \quad (3c)$$

For $t \geq t_0$, the response is just the natural response found previously; the only difference is that since this phase of the analysis commences at $t = t_0$ instead of $t = 0$, the initial condition is $v_C(t_0)$ instead of $v_C(0)$. Applying this initial condition in the usual way, we find that

$$v_C(t) = v_C(t_0)e^{-(t-t_0)/RC} \text{ for } t \geq t_0 \quad (4)$$

$v_C(t_0)$ is, by our assumption of bounded currents, equal to $v_C(t_0^-)$, the capacitor voltage just before the source waveform drops to zero. Since Eq. (3c) gives $v_C(t)$ for all times in the range $0 \leq t < t_0$, it can be used to find that

$$v_C(t_0^-) = v_C(0)e^{-t_0/RC} + E(1 - e^{-t_0/RC})$$

Substituting this value for $v_C(t_0)$ in (4) completes the analysis of the response of the series RC circuit to the voltage pulse. This response is plotted in Fig. 7 for two different values of the time constant. The response of a circuit to a pulse is particularly important in communication systems where such pulses are used to carry information and must be clearly identifiable at the receiver. An RC combination of the type studied here often occurs in such transmission systems, formed by the output resistance of the part of the system where the signal originates and the input capacitance of the part of the system into which the signal is fed, and thus exponential distortion will inevitably ensue. Clearly the “smearing” of the pulse evident in Fig. 7 when the time constant is large limits the rate at which pulses can be transmitted if they are to be separated at the receiver.

The response of the series RC circuit to any piecewise-constant source waveform is found by an extension of the

Figure 7. The response of a first-order RC circuit to a voltage pulse of amplitude E and duration t_0 . The solid line shows the response if $\tau = t_0/50$; the dashed line, the response if $\tau = t_0/5$.

analysis performed above. The circuit is analysed using the standard method over each of the time intervals in which the source is constant, starting with the first time interval. The initial condition for the n th time interval, commencing at time $t = t_n$, is found by evaluating the response from the previous time interval at time $t = t_n^-$.

The second type of first-order circuit is one in which the single energy storage element in the circuit is an inductor rather than a capacitor, and by application of a Norton transformation (where possible) is of the form shown in Fig. 8, where the constant current source I is connected in parallel with conductance G and inductance L for $t \geq 0$. Kirchhoff’s current law applied to this circuit gives the following differential equation in the inductor current i_L for $t \geq 0$

$$GL \frac{di_L(t)}{dt} + i_L(t) = I$$

which can be solved as before to find

$$i_L(t) - I = (i_L(0) - I)e^{-t/GL}$$

or

$$i_L(t) = i_L(0)e^{-t/GL} + I(1 - e^{-t/GL})$$

Thus the inductor current waveform for the circuit of Fig. 8 takes the same form as the capacitor voltage waveform for the circuit of Fig. 4b, with time constant GL and steady-state value I . This is a consequence of the fact that the circuit of Fig. 8 is the dual of that of Fig. 4b. The response to a piecewise-constant source waveform can be found by applying the method previously described for the series RC circuit.

2.2. Natural Response of Second-Order Circuits

The circuit in Fig. 9 consists of a resistor and two energy storage elements—a capacitor and an inductor. Kirchhoff’s voltage law gives the equation

$$v_C(t) + L \frac{di_L(t)}{dt} + Ri_L(t) = 0$$

which on application of the relation $i_L(t) = C[dv_C(t)/dt]$ becomes

$$LC \frac{d^2v_C(t)}{dt^2} + RC \frac{dv_C(t)}{dt} + v_C(t) = 0 \quad (5)$$

Figure 8. First-order circuit consisting of the parallel combination of current source $IU(t)$, conductance G , and inductor L .

Figure 9. Second-order circuit consisting of resistor R , capacitor C and inductor L .

This is a second-order differential equation, and so the circuit is termed a *second-order circuit*. The exponential waveform

$$v_C(t) = Ae^{st}$$

is a solution to Eq. (5) provided

$$LCs^2 + RCs + 1 = 0$$

which yields

$$s = \frac{-R}{2L} \pm \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}}$$

If these two values, s_1 and s_2 , are distinct (i.e. $s_1 \neq s_2$), then the general solution of Eq. (5) is of the form

$$v_C(t) = A_1 e^{s_1 t} + A_2 e^{s_2 t} \quad (6)$$

Since there are no sources in the circuit, this is the natural or unforced response of the series RLC circuit. The constants A_1 and A_2 will be determined by applying the initial conditions $v_C(0)$ and $i_L(0)$ and solving the resulting simultaneous equations:

$$v_C(0) = A_1 + A_2$$

$$i_L(0) = C \left. \frac{dv_C}{dt} \right|_{t=0} = CA_1 s_1 + CA_2 s_2$$

We will now consider the nature of the natural or unforced voltage waveform represented by Eq. (6). We will use the following shorthand form for s_1 and s_2

$$s_1 = -\alpha + \sqrt{\alpha^2 - \omega_0^2} \quad \text{and} \quad s_2 = -\alpha - \sqrt{\alpha^2 - \omega_0^2}$$

where

$$\alpha = \frac{R}{2L} \quad \text{and} \quad \omega_0 = \frac{1}{\sqrt{LC}}$$

We will assume for now that $\alpha \geq 0$.

The first case to be considered is the case where $\omega_0^2 < \alpha^2$ and s_1 and s_2 are real and distinct. In this case the circuit is said to be overdamped and the response $v_C(t)$ is the sum of two exponentials with time constants $1/|s_1|$ and $1/|s_2|$.

An example of an overdamped response is plotted in Fig. 10a.

The second case occurs when $\omega_0^2 > \alpha^2$ and s_1 and s_2 are complex conjugates of the form $-\alpha \pm j\omega_d$, where $\omega_d = \sqrt{\omega_0^2 - \alpha^2}$. In this case the circuit is said to be underdamped. Equation (6) remains valid but can be expressed more clearly in the form

$$v_C(t) = e^{-\alpha t} [(A_1 + A_2) \cos \omega_d t + j(A_1 - A_2) \sin \omega_d t]$$

where A_1 and A_2 are complex conjugates, and so the coefficients $B_1 = (A_1 + A_2)$ and $B_2 = j(A_1 - A_2)$ are real and can once again be found from the initial conditions. The underdamped response takes the form of an oscillation of frequency ω_d multiplied by an exponential envelope $e^{-\alpha t}$. If $\alpha > 0$, the amplitude of the oscillation decreases exponentially with time, with the rate of this decrease, known as “damping”, controlled by α . If $\alpha = 0$, the response is an oscillation of constant amplitude and frequency $\omega_d = \omega_0 = 1/\sqrt{LC}$. This is the case of the well-known LC oscillator, which arises when $R = 0$ and there is no dissipation in the circuit. The underdamped response is plotted in Figs. 10b and 10c for the two cases $\alpha > 0$ and $\alpha = 0$. Note that the underdamped response is always characterized by oscillation, sometimes termed “ringing”.

If $\omega_0^2 = \alpha^2$, then $s_1 = s_2 = -\alpha = -R/2L$. In this case the general solution of Eq. (5) is no longer given by Eq. (6) but instead by [2]

$$v_C(t) = (D_1 + D_2 t) e^{-\alpha t}$$

and is said to be “critically damped”. The constants D_1 and D_2 are once again found by application of the initial conditions. An example of a critically damped response is plotted in Figure 10d.

2.3. Step Response of Second-Order Circuit

The circuit in Fig. 11 is identical to that of Fig. 9 but for the addition of the voltage source E at $t = 0$. Applying Kirchhoff’s voltage law for $t \geq 0$ gives the equation

$$v_C(t) + L \frac{di_L(t)}{dt} + Ri_L(t) = E$$

which on application of the relation $i_L(t) = C[dv_C(t)/dt]$ becomes

$$LC \frac{d^2 v_C(t)}{dt^2} + RC \frac{dv_C(t)}{dt} + v_C(t) = E \quad (7)$$

To solve this equation, we apply the fact that the general solution to a differential equation is the sum of two components, which are known in mathematics as the “homogeneous solution” and a “particular solution” [2]. The homogeneous solution is the solution to the differential equation obtained when all input terms (i.e., all terms not involving the variable or its derivatives) are set to zero. In circuit terms, this is just the response obtained when all independent voltage and current sources are removed, namely, the natural or unforced response. A particular

Figure 10. Examples of the natural response of the series *RLC* circuit: (a) overdamped; (b) underdamped; (c) underdamped and lossless; (d) critically damped.

solution is any solution to the differential equation. This decomposition may seem to be of no particular benefit, since it states that to solve the differential equation, one must obtain a solution to the differential equation. The benefit lies in the ability to choose a particularly simple form for the particular solution, which can then be extended to yield the general solution by the addition of the homogeneous solution. The simplest particular solution is the constant solution, which is obtained by setting all derivatives to zero.

The particular solution to Eq. (7) obtained by setting all derivatives to zero is $v_C(t) = E$. Adding this solution to the homogeneous solution that has already been found in Eq. (6) yields the general solution, which is of the form

$$v_C(t) = A_1 e^{s_1 t} + A_2 e^{s_2 t} + E \text{ if } \omega_0^2 < \alpha^2 \text{ (overdamped)} \quad (8a)$$

$$v_C(t) = e^{-\alpha t} [B_1 \cos \omega_d t + B_2 \sin \omega_d t] + E \text{ if } \omega_0^2 > \alpha^2 \quad (8b)$$

(underdamped)

$$v_C(t) = (D_1 + D_2 t) e^{-\alpha t} + E \text{ if } \omega_0^2 = \alpha^2 \text{ (critically damped)} \quad (8c)$$

The appropriate constants A_1 and A_2 , B_1 and B_2 , or D_1 and D_2 are found by applying the initial conditions. If the initial conditions are zero, Eqs. (8) represent the step response of the series *RLC* circuit, and are plotted in Fig. 12.

Depending on the system in which a circuit is to be used, different demands may be made of its step response. In some applications, for example, there may be a requirement that the voltage reach its steady-state value as soon as possible, while in others it may be necessary that the

Figure 11. Second-order circuit consisting of resistor *R*, capacitor *C*, inductor *L*, and voltage source $EU(t)$.

Figure 12. Examples of the step response of the series RLC circuit: (a) overdamped; (b) underdamped; (c) critically damped.

voltage never exceed its steady-state value by more than some specified percentage, to avoid driving circuit elements into saturation. A number of figures of merit have been defined to characterize the step response of a circuit in order to test its suitability for a given application [1]. The risetime has already been defined. The *settling time* is the time beyond which the step response does not differ from its steady-state value by more than 2%. The *delay time* is the time taken for the step response to reach 50% of its steady-state value. The *overshoot* is defined as the difference between the peak value and the steady-state value of the step response, expressed as a percentage of the steady state value.

3. LAPLACE TRANSFORM CIRCUIT ANALYSIS

The analyses described above have found the circuit variables as a function of time by directly solving the differential equations that describe the circuit. While such a procedure is reasonably straightforward for first- and second-order circuits with simple source waveforms, it becomes significantly more difficult as the order of the circuit increases and as the source waveforms become more complex. It is desirable, therefore, to have a more powerful method of finding a solution. In the special case where all sources in the circuit are sinusoidal of the same frequency, the transformation of circuit variables into phasor or complex number form [3–5] allows the circuit to be handled using purely algebraic equations instead of differential equations. Although extremely useful in certain circumstances, this is not a general circuit analysis method: it can handle only sinusoidal sources, it is applicable only if the circuit is stable, it finds only the steady-state component of the waveform and does not allow consideration of initial capacitor voltages and inductor currents.

3.1. The Laplace Transform

A more general transform than the phasor transform is the Laplace transform, named after the French mathematician Pierre-Simon Laplace (1749–1827) [3–6]. This transform method retains the fundamental advantage of the phasor transform, which is the ability to transform a system of differential equations into a system of algebraic equations, but has the additional advantages of being able to handle a much broader class of source waveforms

(including all that are of any practical interest), accommodating initial conditions, and yielding solutions that incorporate both transient and steady-state components without requiring that the circuit be stable.

The Laplace transform is discussed in the article on linear systems, and we will merely summarize its properties here. Given a function of time $f(t)$, its Laplace transform is

$$F(s) = \mathbf{L}\{f(t)\} = \int_{0^-}^{\infty} f(t)e^{-st} dt \quad (9)$$

where the variable s is complex and is termed the (*complex*) *frequency*. Thus the Laplace transform converts a function $f(t)$ from the time domain into a function $F(s)$ in the frequency domain. There exist functions that do not have a Laplace transform, since the integral in (9) fails to converge, but all functions of interest in circuit theory have a Laplace transform. Since the interval of integration is from 0^- to ∞ , the transform defined by Eq. (9) is sometimes called the “one-sided Laplace transform”, to distinguish it from another version in which the integration is from $-\infty$ to ∞ , but we will not need to draw this distinction here and will refer to it simply as the *Laplace transform*. The lower limit of integration of 0^- is chosen in order to accommodate functions with infinite spikes at $t=0$. Such functions will prove extremely useful in our analysis.

Some of the properties of the Laplace transform that make it so useful in circuit analysis are the following [3,6], where $F(s)$ denotes the Laplace transform of $f(t)$, $F_1(s)$ the Laplace transform of $f_1(t)$ and $F_2(s)$ the Laplace transform of $f_2(t)$:

Uniqueness: $f_1(t) = f_2(t)$ for all $t \geq 0 \Leftrightarrow F_1(s) = F_2(s)$ (More precisely, if $F_1(s) = F_2(s)$ then $\int_{0^-}^{\infty} |f_1(t) - f_2(t)| dt = 0$, but for our purposes it will suffice to assume that $F_1(s) = F_2(s) \Rightarrow f_1(t) = f_2(t)$ for all $t \geq 0$)

Linearity: $\mathbf{L}\{k_1 f_1(t) + k_2 f_2(t)\} = k_1 F_1(s) + k_2 F_2(s)$, where k_1 and k_2 are scalars.

Differentiation: $\mathbf{L}\{(d/dt)f(t)\} = sF(s) - f(0^-)$.

Integration: $\mathbf{L}\left\{\int_{0^-}^t f(\tau) d\tau\right\} = (1/s)F(s)$.

Time shift: $\mathbf{L}\{f(t - \tau)U(t - \tau)\} = e^{-s\tau}F(s)$, where $\tau > 0$ and $U(t)$ is the unit step function given by Eq. (1).

Frequency shift: $\mathbf{L}\{e^{-\alpha t}f(t)\} = F(s + \alpha)$.

The first three of these properties are particularly important. The uniqueness property guarantees that if a system of differential equations is solved by transforming to the frequency domain, solving in the frequency domain and transforming back to the time domain, the solution obtained will be the same as would have been obtained if the solution had been carried out entirely in the time domain. The linearity property guarantees that a system of linear equations in the time domain will remain linear in the frequency domain, allowing powerful linear analysis techniques to be applied in both domains. The differentiation property allows differentiation in the time domain to be replaced by multiplication in the frequency domain, together with the addition of a term related to the initial condition. It is this property that allows a system of differential equations in the time domain to be replaced by a system of algebraic equations in the frequency domain, which can be solved by a variety of powerful and elegant techniques. The Laplace transforms of some important functions are given in Table 1, in which $\delta(t)$ is the delta function defined by

$$\begin{aligned} \delta(t) &= 0 \text{ for } t \neq 0 \\ \int_{-\infty}^{\infty} \delta(t) dt &= 1 \end{aligned} \tag{10}$$

Three steps are to be taken in solving a set of differential equations using Laplace transform analysis: (1) the system of differential equations in the time domain is transformed to a set of algebraic equations in the frequency domain; (2) this set of algebraic equations is solved in the frequency domain, using standard linear techniques; and (3) the solution is transformed from the frequency domain back to the time domain. Step (1) involves application of the definition of the Laplace transform (9) together with certain of its properties (notably the differentiation property). Step (2) involves standard techniques from linear algebra. The third step involves the application of the inverse Laplace transform, which converts a function $F(s)$ in the frequency domain to a function of time $f(t) = \mathbf{L}^{-1}(F(s))$ in such a way that $\mathbf{L}(f(t)) = F(s)$. Note that the function $f(t)$ is unique only for $t \geq 0$, since two functions of time that

differ for $t < 0$ but are identical for $t \geq 0$ will have the same Laplace transform.

3.2. The Inverse Laplace Transform

There is a closed-form equation for the inverse Laplace transform (see Ref. 6 for details), but it is rather difficult to apply (involving contour integration) and is rarely used in circuit analysis applications. Instead, the inverse Laplace transform of a function is generally found by writing the function as the sum of simpler functions, each of whose inverse Laplace transform is known. A technique that is particularly useful here is the partial fraction expansion [2,6]. This is a technique that allows the decomposition of a function $F(s)$ that is the ratio of two real polynomials in s into the sum of simpler terms. It is assumed that the degree of the numerator of $F(s)$ is less than that of the denominator—if this is not the case, then $F(s)$ can be expressed in the form $F(s) = r(s) + \hat{n}(s)/\hat{d}(s)$, where $r(s)$ is a polynomial in s and the degree of $\hat{n}(s)$ is less than that of $\hat{d}(s)$. The inverse Laplace transform of $R(s)$ can be found from Table 1, leaving only the component $\hat{n}(s)/\hat{d}(s)$ to be handled by the partial fraction expansion. Thus, without loss of generality, we can assume that the degree of the numerator of $F(s)$ is less than that of the denominator. The first step in the partial fraction expansion is the factorization of the denominator polynomial:

$$F(s) = \frac{n(s)}{d(s)} = \frac{n(s)}{(s - p_1)^{\alpha_1} (s - p_2)^{\alpha_2} \cdots (s - p_m)^{\alpha_m}}$$

The quantities p_i , the zeros of the denominator $d(s)$ of $F(s)$, are known as the *poles* of $F(s)$, and the multiplicity of the pole p_i is the number of times α_i that it appears as a zero of $d(s)$. A pole of multiplicity 1 is called a *simple* pole. If all poles are simple, then

$$\begin{aligned} F(s) &= \frac{n(s)}{(s - p_1)(s - p_2) \cdots (s - p_m)} \\ &= \frac{k_1}{s - p_1} + \frac{k_2}{s - p_2} + \cdots + \frac{k_m}{s - p_m} \end{aligned}$$

where $k_i = [(s - p_i)F(s)]_{s=p_i}$.

The term k_i is the *residue* of $F(s)$ at the pole p_i . If $F(s)$ has a pole of multiplicity α_j at p_j , the partial fraction expansion takes the form

$$\begin{aligned} F(s) &= \frac{n(s)}{(s - p_j)^{\alpha_j} \hat{d}(s)} = \frac{k_{j1}}{s - p_j} \\ &+ \frac{k_{j2}}{(s - p_j)^2} + \cdots + \frac{k_{j\alpha_j}}{(s - p_j)^{\alpha_j}} + \frac{\hat{n}(s)}{\hat{d}(s)} \end{aligned}$$

where

$$k_{ji} = \left\{ \frac{1}{(\alpha_j - i)!} \frac{d^{\alpha_j - i}}{ds^{\alpha_j - i}} [(s - p_j)^{\alpha_j} F(s)] \right\} \Big|_{s=p_j}$$

Since the numerator and denominator of $F(s)$ are real polynomials in s , poles appear in complex conjugate pairs,

Table 1. Some Important Laplace Transforms

$f(t)$	$F(s) = \mathbf{L}(f(t))$
$\delta(t)$	1
$U(t)$	$\frac{1}{s}$
t^n	$n! \frac{1}{s^{n+1}} \quad n = 1, 2, \dots$
e^{-at}	$\frac{1}{s+a}$
$\sin \omega t$	$\frac{\omega}{s^2 + \omega^2}$
$\cos \omega t$	$\frac{s}{s^2 + \omega^2}$

Figure 13. Transformation of a capacitor with initial voltage $v_C(0^-)$ into the frequency domain.

as do their residues. This allows the combination of any complex term in the expansion with its conjugate to give a real term.

The inverse Laplace transform of each of the terms in the partial fraction expansion is known:

$$\mathbf{L}^{-1}\left\{\frac{k_{j\alpha_j}}{(s-p_j)^{\alpha_j}}\right\} = k_{j\alpha_j} \frac{t^{\alpha_j-1}}{(\alpha_j-1)!} e^{p_j t}$$

In this way it is possible to find the inverse Laplace transform of any function consisting of the ratio of two polynomials in s by decomposing the function via the partial fraction expansion and taking the inverse Laplace transform of each of the constituent functions. This method relies fundamentally on the uniqueness and linearity properties of the Laplace transform. Clearly the method applies only to a restricted range of functions, those which can be expressed as the ratio of two polynomials in s . As will be seen, however, functions of this type are particularly important in circuit analysis, and so this is not a significant limitation.

3.3. Circuit Analysis

The first step in the Laplace transform analysis of a circuit is the transformation of the circuit from the time domain to the frequency domain. All branch voltages $v(t)$ and currents $i(t)$ that appear as variables in the differential equations describing the circuit will appear in the transformed equations as variables $V(s) = \mathbf{L}\{v(t)\}$ and $I(s) = \mathbf{L}\{i(t)\}$. Independent voltage and current sources are transformed from known functions of time $v_s(t)$ and $i_s(t)$ to known functions of frequency $V_s(s) = \mathbf{L}\{v_s(t)\}$ and $I_s(s) = \mathbf{L}\{i_s(t)\}$. A resistor is described in the time domain by the linear equation $v(t) = Ri(t)$ and so is defined in the transformed circuit by the relation $V(s) = RI(s)$. Similarly the linear equations describing all resistive two-ports (including ideal transformers, gyrators and controlled sources), and indeed resistive n -ports, are unchanged in the transformation from time domain to frequency domain. The

capacitor is defined in the time domain by the equation

$$i_C(t) = C \frac{dv_C(t)}{dt}$$

Applying the differentiation property of the Laplace transform yields the frequency-domain equation for the capacitor:

$$I_C(s) = sCV_C(s) - Cv_C(0^-)$$

Thus the capacitor C with initial voltage $v_C(0^-)$ appears in the transformed circuit as the parallel combination of the independent current source $Cv_C(0^-)$ and the linear element defined by the relation $V(s) = (1/sC)I(s)$. This second element can be regarded as a generalized resistance (known as an *impedance*) $1/sC$ and throughout the analysis in the frequency domain can be handled as if it were a resistance. Figure 13 shows the transformation of a capacitor from the time domain into the parallel combination of an impedance and an independent current source in the frequency domain or, by Thévenin's theorem, into the series combination of an impedance and an independent voltage source. In a similar manner, the inductor defined in the time domain by the relation

$$v_L(t) = L \frac{di_L(t)}{dt}$$

is defined in the frequency domain by the relation

$$V_L(s) = sLI_L(s) - Li_L(0^-)$$

Thus, as shown in Fig. 14, the inductor appears in the transformed circuit as the series combination of an impedance sL and voltage source $Li_L(0^-)$ or the parallel combination of the same impedance and current source $[i_L(0^-)]/s$. Note that once again this circuit transformation could have been obtained from Fig. 13 by application of the

Figure 14. Transformation of an inductor with initial current $i_L(0^-)$ into the frequency domain.

principle of duality. Coupled inductors can be transformed in a similar manner.

When all the elements in the circuit have been transformed into the frequency domain, the first step of the analysis process is complete. The second step is to analyze the circuit in the frequency domain, employing any of a wide variety of techniques such as loop current analysis, node voltage analysis, modified nodal analysis, and sparse tableau analysis. The analysis of a circuit in the frequency domain is described in the article on frequency-domain circuit analysis, and also in most circuit theory textbooks, such as Refs. 3–5. The third step is then to transform the results of the analysis back to the time domain via the inverse Laplace transform.

Example 1. The circuit of Fig. 4 can be transformed into the Laplace transform domain, yielding the circuit of Fig. 15. Analysis in the frequency domain, followed by partial fraction expansion, yields the result that

$$V_C(s) = \frac{v_C(0^-)}{s + \frac{1}{RC}} + \frac{E}{s} \frac{1}{\left(s + \frac{1}{RC}\right)} = \frac{v_C(0^-)}{s + \frac{1}{RC}} + \frac{E}{s} - \frac{E}{s + \frac{1}{RC}}$$

The inverse Laplace transform is then applied to find

$$v_C(t) = v_C(0^-)e^{-t/RC} + E(1 - e^{-t/RC}) \text{ for } t \geq 0$$

which agrees with the time domain analysis performed earlier.

3.4. Laplace Transform Analysis of Distributed Circuits

Laplace transform techniques can also be applied to the analysis of distributed circuits. Consider the example of a transmission line modeled as in Fig. 16 by incremental series inductance L and resistance R and shunt capacitance C and conductance G , all per unit length. Applying Kirchhoff's laws and taking the limit of vanishing line length gives the telegrapher's equations

$$\begin{aligned} \frac{\partial i(x, t)}{\partial x} &= -Gv(x, t) - C \frac{\partial v(x, t)}{\partial t} \\ \frac{\partial v(x, t)}{\partial x} &= -Ri(x, t) - L \frac{\partial i(x, t)}{\partial t} \end{aligned}$$

Figure 15. Laplace transform of the circuit of Figure 4.

Figure 16. Basic model of a length Δx of transmission line.

The current and voltage now vary not only with time t but also with distance x along the line. The appearance of distance in this fashion, and also of the derivative with respect to distance, does not occur in lumped circuits.

The new parameter x can be shown explicitly in the definition of the Laplace transform:

$$\mathbf{L}[f(x, t)] = \int_0^\infty f(x, t)e^{-st} dt = F(x, s)$$

There is now a second differentiation property:

$$\mathbf{L} \left[\frac{\partial f(x, t)}{\partial x} \right] = \frac{\partial F(x, s)}{\partial x}$$

Then taking

$$I(x, s) = \mathbf{L}[i(x, t)]$$

$$V(x, s) = \mathbf{L}[v(x, t)]$$

the telegrapher's equations become

$$\begin{aligned} \frac{\partial I(x, s)}{\partial x} &= -GV(x, s) - sCV(x, s) + Cv(x, 0^-) \\ \frac{\partial V(x, s)}{\partial x} &= -RI(x, s) - sLI(x, s) + Li(x, 0^-) \end{aligned}$$

If, for simplicity, we assume zero initial voltage and current along the line, these equations can be solved for $V(x, s)$ and $I(x, s)$:

$$\begin{aligned} V(x, s) &= V^+(s)e^{-\gamma x} + V^-(s)e^{\gamma x} \\ \Rightarrow I(x, s) &= \frac{1}{Z_0} [V^+(s)e^{-\gamma x} - V^-(s)e^{\gamma x}] \end{aligned}$$

where $Z_0 = \sqrt{(R + sL)/(G + sC)}$, $\gamma = \sqrt{(R + sL)(G + sC)}$ and V^+ and V^- are as yet unknown constants of integration. Z_0 is called the characteristic impedance of the line, and γ is the propagation constant. If the line is lossless, $R = G = 0$, and so $Z_0 = \sqrt{L/C}$, which is purely real (generally denoted R_0) and $\gamma = s\sqrt{LC}$. We define $u = 1/\sqrt{LC}$, and so $\gamma = s/u$. (We shall shortly see the physical significance of this variable.)

Inserting typical terminations for a line of length L , consisting of the series combination of voltage source $V_0(s)$

and generator impedance Z_g at $x = 0$, and load impedance Z_L at $x = L$, we can solve these equations for V^+ and V^- to find

$$\frac{V^-}{V^+} e^{2\gamma L} = \frac{Z_L - Z_0}{Z_L + Z_0} = \Gamma_R$$

where Γ_R is the receiving end reflection coefficient, and in a similar manner we define the generating end reflection coefficient

$$\Gamma_g = \frac{Z_g - Z_0}{Z_g + Z_0}$$

We can substitute for V^+ and V^- to find the expressions for the voltage and current along the line in the frequency domain:

$$V(x, s) = \frac{Z_0 V_0}{Z_0 + Z_g} \left[\frac{e^{-\gamma x} + \Gamma_R e^{-\gamma(2L-x)}}{1 - \Gamma_R \Gamma_g e^{-2\gamma L}} \right]$$

$$I(x, s) = \frac{V_0}{Z_0 + Z_g} \left[\frac{e^{-\gamma x} - \Gamma_R e^{-\gamma(2L-x)}}{1 - \Gamma_R \Gamma_g e^{-2\gamma L}} \right]$$

In the important case of a lossless line, these equations can be rewritten as

$$V(x, s) = \frac{V_0 R_0}{R_0 + Z_g} \left[\frac{e^{-(sx/u)} + \Gamma_R e^{-s(2\tau - (x/u))}}{1 - \Gamma_R \Gamma_g e^{-2s\tau}} \right] \tag{11}$$

$$I(x, s) = \frac{V_0}{R_0 + Z_g} \left[\frac{e^{-(sx/u)} - \Gamma_R e^{-s(2\tau - (x/u))}}{1 - \Gamma_R \Gamma_g e^{-2s\tau}} \right]$$

where $\tau = L/u$ is the delay of the line. (Once again, we shall shortly see the physical significance of this variable).

We will now consider the solution of these equations in three cases of increasing complexity. It suffices to consider the voltage equation (11), since the current follows easily.

3.4.1. Matched Lossless Line. If the load impedance Z_L equals the characteristic impedance R_0 of the line, then $\Gamma_R = 0$ and Eq. (11) becomes

$$V(x, s) = \frac{V_0 R_0}{R_0 + Z_g} e^{-(sx/u)}$$

In the time domain, applying the time-shift property of the Laplace transform, we get

$$v(x, t) = \mathbf{L}^{-1}[V(x, s)] = f\left(t - \frac{x}{u}\right) U\left(t - \frac{x}{u}\right)$$

where $U(t)$ is the unit step function given by (1) and

$$f(t) = \mathbf{L}^{-1}\left[\frac{V_0 R_0}{R_0 + Z_g}\right]$$

The voltage at the generator end of the line, that is, at $x = 0$, is

$$\frac{V_0 R_0}{R_0 + Z_g}$$

which agrees with the result expected by voltage division. The voltage at any point x along the line is an undistorted

replica of the voltage at $x = 0$ delayed by the time interval x/u , where u is the velocity at which the waveform propagates along the line.

3.4.2. Lossless Line with Matched Source and Unmatched Load. If the lossless line is matched at the source end but unmatched at the load end (i.e., $\Gamma_g = 0$ and $\Gamma_R \neq 0$), the voltage in the frequency domain is given by

$$V(x, s) = \frac{V_0}{2} \left[e^{-(sx/u)} + \Gamma_R e^{-s(2\tau - (x/u))} \right]$$

The inverse Laplace transform gives the voltage in the time domain:

$$v(x, t) = f_1\left(t - \frac{x}{u}\right) U\left(t - \frac{x}{u}\right) + f_2\left(t - 2\tau + \frac{x}{u}\right) U\left(t - 2\tau + \frac{x}{u}\right) \tag{12}$$

where

$$\mathbf{L}^{-1}\left[\frac{V_0}{2}\right] = f_1(t) U(t)$$

and

$$\mathbf{L}^{-1}\left[\Gamma_R \frac{V_0}{2}\right] = f_2(t) U(t)$$

The voltage given by Eq. (12) is the sum of two terms. The first of these is a waveform that starts from the generator end of the line ($x = 0$) at $t = 0$ and travels along the line toward the load with velocity u . This waveform reached the load at time $L/u = \tau$. The second, or reflected, term originates at the load end of the line ($x = L$) at time $t = \tau$, and travels to the left with velocity u .

3.4.3. Lossless Line with Unmatched Source and Unmatched Load. The voltage equation (11) can be expanded to the form

$$V(x, s) = F(s) \sum_{n=0}^{\infty} \Gamma_R^n \Gamma_g^n e^{-s(2n\tau + (x/u))} + F(s) \sum_{n=0}^{\infty} \Gamma_R^{n+1} \Gamma_g^n e^{-s(2(n+1)\tau - (x/u))}$$

where

$$F(s) = \frac{V_0 R_0}{R_0 + Z_g}$$

Defining

$$F_1^{(n)}(s) = F(s) \Gamma_R^n \Gamma_g^n = \mathbf{L}\left[f_1^{(n)}(t) U(t)\right]$$

and

$$F_2^{(n)}(s) = F(s) \Gamma_R^{n+1} \Gamma_g^n = \mathbf{L}\left[f_2^{(n)}(t) U(t)\right]$$

we get

$$V(x, s) = \sum_{n=0}^{\infty} F_1^{(n)}(s) e^{-s(2n\tau + (x/u))} + \sum_{n=0}^{\infty} F_2^{(n)}(s) e^{-s(2(n+1)\tau + (x/u))}$$

Taking the inverse Laplace transform, we get the time-domain voltage

$$v(x, t) = \sum_{n=0}^{\infty} f_1^{(n)}\left(t - 2n\tau - \frac{x}{u}\right) U\left(t - 2n\tau - \frac{x}{u}\right) + \sum_{n=0}^{\infty} f_2^{(n)}\left(t - 2(n+1)\tau + \frac{x}{u}\right) U\left(t - 2(n+1)\tau + \frac{x}{u}\right)$$

Hence the voltage waveform consists of a sum of two types of terms. The first type has the form

$$f_1^{(n)}\left(t - 2n\tau - \frac{x}{u}\right) U\left(t - 2n\tau - \frac{x}{u}\right) \quad (13)$$

which represents a waveform traveling toward the load with velocity u . This expression is zero for $t < 2n\tau + (x/u)$. Since $0 \leq x \leq L$, $0 \leq x/u \leq \tau$, and so the term (13) is zero everywhere on the line if $t < 2n\tau$. Thus this term represents a waveform that starts at the generator end of the line at time $t = 2n\tau$ and travels to the load, reaching it at time $t = (2n+1)\tau$.

The second type has the form

$$f_2^{(n)}\left(t - 2(n+1)\tau + \frac{x}{u}\right) U\left(t - 2(n+1)\tau + \frac{x}{u}\right)$$

which represents a waveform traveling to the left with velocity u . This expression is zero for $t < 2(n+1)\tau - (x/u)$, and is zero everywhere on the line if $t < 2(n+1)\tau - x/u$. Thus this term represents a waveform that starts at the load at time $t = (2n+1)\tau$ and travels toward the generator end of the line, reaching it at time $t = (2n+2)\tau$.

4. NATURAL RESPONSE AND ZERO-STATE RESPONSE

When converted into the frequency domain, a (lumped or distributed) circuit contains independent sources of two types. The first are the transformed versions of the independent sources from the time domain. These sources drive the circuit in the time domain, and are often termed the “inputs” to the circuit, borrowing a viewpoint from system theory. The second group of independent sources in the frequency-domain circuit are those that are introduced during the transformation of energy storage elements and account for the initial conditions in the circuit, specifically, the capacitor voltages and inductor currents at time $t = 0^-$. We will call these sources the “initial” condition generators, to distinguish them from those sources that represent the independent sources from the time domain. By superposition, the response of the circuit to these sources (by which we mean any current or voltage in the circuit, or any collection thereof) is the sum of two components: one due to the independent sources acting alone, with the initial condition generators removed, and the

other due to the initial condition generators acting alone, with the independent sources removed. Since these two components of the response arise from different mechanisms, it is often useful to treat them separately. The component of the response due to the independent sources, with the initial conditions set to zero, is called the *zero-state response*, and the component due to the initial conditions, with the independent sources set to zero, is the *natural or unforced response* (also called the *zero-input response*).

4.1. Natural Response and Natural Frequencies

We will consider first the natural response of a circuit. Application of any of the standard frequency-domain analysis techniques will yield a matrix equation of the form [3]

$$\mathbf{M}(s)\mathbf{X}(s) = \mathbf{U}(s)$$

where $\mathbf{M}(s)$ is a matrix each element of which is a polynomial in s ; $\mathbf{X}(s)$ is a vector containing some subset of the unknown branch voltages, branch currents, node voltages, and loop currents; and $\mathbf{U}(s)$ is a vector, each nonzero element of which is a linear combination of the initial condition generators. If the circuit has a unique solution, that solution is given by [2]

$$\mathbf{X}(s) = \mathbf{M}^{-1}(s)\mathbf{U}(s) = \frac{1}{\det(\mathbf{M}(s))} \text{Adj}(\mathbf{M}(s)) \cdot \mathbf{U}(s)$$

where the existence of a unique solution guarantees that the determinant $\det(\mathbf{M}(s))$ is not identically zero. We assume, unless otherwise stated, that all zeros p_1, p_2, \dots, p_m of $\det(\mathbf{M}(s))$ are simple. Each component $X_i(s)$ of the vector $\mathbf{X}(s)$ is the ratio of two polynomials in s , and so the partial fraction expansion can be applied to yield the expression

$$X_i(s) = \frac{k_1}{s - p_1} + \frac{k_2}{s - p_2} + \dots + \frac{k_m}{s - p_m}$$

The time-domain response $x_i(t)$ is therefore

$$x_i(t) = k_1 e^{p_1 t} + k_2 e^{p_2 t} + \dots + k_m e^{p_m t}$$

for $t \geq 0$. [If some of the zeros of $\det(\mathbf{M}(s))$ have multiplicity greater than one, the time response will contain terms of the form $t^2 e^{p_i t}$.]

Clearly the zeros p_i of $\det(\mathbf{M}(s))$ play a crucial role in determining the natural response of the circuit. These quantities are known as the *natural frequencies* of the circuit. The number of natural frequencies in a circuit is less than or equal to the number of energy storage elements in the circuit. The contribution of each natural frequency to the natural response depends on its location in the complex plane. A natural frequency at zero contributes a constant term to the natural response. A real and positive natural frequency p_i contributes a term $k_i e^{p_i t}$ that grows exponentially with time. A real and negative natural frequency p_i contributes a term $k_i e^{p_i t}$ that decays exponentially with time. Complex natural frequencies occur in conjugate pairs, and their contributions add to make a

real contribution to the response waveform. If the natural frequencies in question lie on the imaginary axis at $\pm j\omega$, their composite contribution to the time response is of the form $k_i e^{j\omega t} + \bar{k}_i e^{-j\omega t} = 2|k_i| \cos(\omega t + \angle k_i)$, an oscillation of constant amplitude. If the complex natural frequencies lie in the right half-plane at $\alpha \pm j\omega$, their composite contribution is of the form $k_i e^{(\alpha + j\omega)t} + \bar{k}_i e^{(\alpha - j\omega)t} = 2|k_i| e^{\alpha t} \cos(\omega t + \angle k_i)$, an oscillation whose amplitude grows exponentially with time. Finally, if the complex natural frequencies lie in the left half-plane at $\alpha \pm j\omega$, their composite contribution is of the form $k_i e^{(\alpha + j\omega)t} + \bar{k}_i e^{(\alpha - j\omega)t} = 2|k_i| e^{\alpha t} \cos(\omega t + \angle k_i)$, an oscillation whose amplitude decays exponentially with time. (If some of the natural frequencies have multiplicity greater than one, their contribution to the time response will be more complicated, with polynomials times exponentials in place of exponentials, but can be handled by an extension of the preceding analysis.)

The preceding discussion leads to the important conclusion that if all natural frequencies of a circuit lie in the open left half-plane (i.e., if their real parts are less than 0), then for any set of initial conditions the natural or zero-input response of the circuit decays to zero as $t \rightarrow \infty$. This decay may be oscillatory, depending on the presence of complex natural frequencies. A circuit is said to be asymptotically stable or exponentially stable if all of its natural frequencies lie in the open left half-plane. If any natural frequency lies in the open right half-plane, then the initial conditions can cause certain currents and voltages to grow exponentially with time, which is clearly undesirable. Obviously in a real circuit this growth cannot continue indefinitely as the circuit elements will eventually cease to function, possibly in dramatic fashion. Also obvious is the fact that this behavior cannot occur in a circuit made up entirely of passive elements, since the exponential growth requires that energy be supplied to the circuit by an active element such as a controlled source or negative resistance.

While the natural frequencies determine the possible natural modes of behavior of a circuit, the actual response that will be observed in a circuit with zero input depends on the values of the initial conditions. Certain sets of initial conditions will excite one mode only, which means that all circuit variables will exhibit the same exponential or oscillatory behavior, but for most sets the response will be the combination of various modes. Also, not all modes can be observed in any given circuit variable—it may be that certain variables are not susceptible to the influence of one or more natural frequencies.

Example 2. To find the natural frequencies of the circuit of Fig. 17, the voltage source can be set to zero and the resulting circuit analyzed by any of the usual methods. In this case node voltage analysis is possible, yielding the matrix equation

$$\begin{pmatrix} \frac{1}{R_1} + sC_1 & 0 \\ -g_m & \frac{1}{R_2} + sC_2 \end{pmatrix} \begin{pmatrix} V_1(s) \\ V_2(s) \end{pmatrix} = \begin{pmatrix} C_1 v_1(0^-) \\ C_2 v_2(0^-) \end{pmatrix}$$

Figure 17. Circuit to be analyzed in Examples 2 and 3.

The natural frequencies are the values of s for which the determinant of the matrix in this equation is zero, and therefore equal $(-1)/R_1 C_1$ and $(-1)/R_2 C_2$. Solving explicitly for $V_1(s)$ and $V_2(s)$, we find that

$$V_1(s) = \frac{V_1(0^-)}{s + \frac{1}{R_1 C_1}} \quad \text{and} \quad V_2(s) = \frac{\frac{g_m}{C_2} V_1(0^-) + \frac{1}{C_1} V_2(0^-)}{\left(s + \frac{1}{R_1 C_1}\right) \left(s + \frac{1}{R_2 C_2}\right)}$$

Thus the voltage v_1 (natural or zero-input component) exhibits only the behavior controlled by the natural frequency at $(-1)/R_1 C_1$ and is unaffected by the natural frequency at $(-1)/R_2 C_2$.

4.2. The Zero-State Response and Transfer Functions

The zero-state response of a circuit is its response to one or more independent sources (inputs) with all initial capacitor voltages and inductor currents set to zero. It suffices to consider the response to a single input, since superposition can then be applied to calculate the response due to multiple inputs. Application of any of the standard frequency-domain analysis techniques to a single-input zero-state circuit will yield a matrix equation of the form

$$\mathbf{M}(s)\mathbf{X}(s) = \mathbf{U}(s)$$

where $\mathbf{M}(s)$ is a matrix, each element of which is a polynomial in s ; $\mathbf{X}(s)$ is a vector containing some subset of the unknown branch voltages, branch currents, node voltages, and loop currents; and $\mathbf{U}(s)$ is a vector, each nonzero element of which is a term involving the independent source, say, $V_s(s)$ (although the theory applies equally to the case where the input is a current source). It follows from linear algebra [2,3] that

$$X_i(s) = \frac{n(s)}{\det(\mathbf{M}(s))} V_s(s) = H(s) V_s(s) \quad (14)$$

where $n(s)$ is a polynomial in s and $\det(\mathbf{M}(s))$ is nonzero, by our standing assumption of unique solvability. Thus the zero-state response to a source $v_s(t)$ is obtained by multiplying its Laplace transform $V_s(s)$ by the appropriate function $H(s) = n(s)/\det(\mathbf{M}(s))$ and taking the inverse Laplace transform to return to the time domain. This function is known as a transfer function or network function. Note that the poles of a transfer function are zeros of $\det(\mathbf{M}(s))$ and are therefore natural frequencies of the circuit.

However, not all natural frequencies need show up as poles of a given transfer function, due to cancellations with numerator terms.

Once again we see that the natural frequencies play a crucial role in determining the response of the circuit—even, as in this case, when the initial conditions are zero. From (14) the poles of $X_i(s)$ will be some subset (determined by numerator cancellations) of the poles of $V_s(s)$ and the natural frequencies. Therefore, $x_i(t)$ will in general, contain terms related to the input together with exponential, constant, or oscillatory terms governed once again by the natural frequencies. If the circuit is asymptotically stable, the contributions governed by the natural frequencies will die away, leaving only the component governed by the input.

The simplest application of Eq. (14) occurs when $V_s(s) = 1$, that is, when the independent source $v_s(t)$ is the delta function or impulse function defined by (10). Although this function is physically unrealizable, it proves extremely useful in circuit and system analysis. When $v_s(t) = \delta(t)$, then $X_i(s) = H(s)\mathbf{L}\{\delta(t)\} = H(s)$, and so the zero-state response is $x_i(t) = h(t) = \mathbf{L}^{-1}\{H(s)\}$. The zero-state response to an impulse function is known as the *impulse response*, and so we have found that the Laplace transform of the impulse response equals the transfer function. The expression

$$X_i(s) = H(s)\mathbf{L}\{v_s(t)\}$$

giving the frequency-domain response of the system with transfer function $H(s)$ to an input $v_s(t)$ can be expressed in the time domain as

$$x_i(t) = h(t) * v_s(t) = \int_{0^-}^{t^+} h(t - \tau)v_s(\tau)d\tau$$

where $h(t) = \mathbf{L}^{-1}\{H(s)\}$ is the impulse response and the asterisk $*$ is the convolution operator [3,6].

If the input is the unit step function $U(t)$, which has Laplace transform $1/s$, that is, $X_i(s) = H(s) \cdot \mathbf{L}\{u(t)\} = H(s)/s$, and so the step response is $x_i(t) = \mathbf{L}^{-1}\{H(s)/s\}$. It is easy to see that the impulse response is the derivative of the step response.

Example 3. The transfer function $V_2(s)/V_s(s)$ of the circuit of Fig. 17 is

$$\begin{aligned} H(s) &= \frac{\frac{g_m s}{C_2}}{\left(s + \frac{1}{R_1 C_1}\right)\left(s + \frac{1}{R_2 C_2}\right)} \\ &= \frac{\frac{g_m}{C_2}}{R_2 C_2 - R_1 C_1} \left[\frac{R_2 C_2}{\left(s + \frac{1}{R_1 C_1}\right)} - \frac{R_1 C_1}{\left(s + \frac{1}{R_2 C_2}\right)} \right] \end{aligned}$$

and so the impulse response is

$$\begin{aligned} h(t) &= \frac{g_m R_2}{R_2 C_2 - R_1 C_1} e^{-t/R_1 C_1} \\ &\quad - \frac{g_m R_1 C_1 / C_2}{R_2 C_2 - R_1 C_1} e^{-t/R_2 C_2} \text{ for } t \geq 0 \end{aligned}$$

The step response is

$$\begin{aligned} &\mathbf{L}^{-1} \left\{ \frac{\frac{g_m}{C_2}}{\left(s + \frac{1}{R_1 C_1}\right)\left(s + \frac{1}{R_2 C_2}\right)} \right\} \\ &= \frac{g_m R_1 C_1 R_2}{R_2 C_2 - R_1 C_1} \left[-e^{-t/R_1 C_1} + e^{-t/R_2 C_2} \right] \text{ for } t \geq 0 \end{aligned}$$

Note the exponential modes corresponding to the natural frequencies in both the step response and the impulse response. Note also that the impulse response is the derivative of the step response.

5. FOURIER TRANSFORM CIRCUIT ANALYSIS

The power of the Laplace transform in finding the transient and steady-state response of a circuit, the variety of source waveforms that it can handle and its ability to accommodate initial conditions make it the method of choice in transient circuit analysis. Despite these advantages, another transform, closely related to the Laplace transform, is preferred in certain situations. This is the Fourier transform [4–6], named after the French mathematician Jean Baptiste Joseph Fourier (1768–1830). The close relationship between the Fourier transform of a signal and the frequency content of that signal make it particularly useful in applications such as communications and signal processing where this frequency content is of paramount importance. However, the Fourier transform is defined for a smaller class of source waveforms than the Laplace transform, and it cannot handle initial conditions. The latter condition in particular makes it poorly suited to transient circuit analysis and so we will merely give a brief discussion of its properties here, with the intention of (1) explaining why it is unsuited to transient circuit analysis and (2) providing a link to other forms of transient circuit analysis for circuits such as filters that are more usually handled using Fourier analysis.

The Fourier transform is closely related to the Fourier series [4–6], in which a periodic function with period T is decomposed into the weighted sum of sinusoids whose angular frequencies are integer multiples of $2\pi/T$. By superposition, the response of a circuit to a periodic function could be obtained by decomposing the function into the sum of sinusoids, finding the response to each of these sinusoids via phasor analysis, and summing these responses to find the overall response. The main disadvantage to this Fourier series method of analysis is that many source waveforms of interest are not periodic, and since the

method is based on phasor analysis, it finds only the steady-state component of the response. The fundamental idea underlying this method, however, namely, the idea of a sum of input sinusoids being processed (i.e., altered in magnitude and phase) in different ways by a circuit and then added to form the response, is a very useful one and underlies the more general Fourier transform analysis.

The Fourier transform is a generalization of the Fourier series to accommodate nonperiodic functions. A nonperiodic function can be viewed as the limit of a periodic function as the period T tends to infinity. The Fourier series of this periodic function consists of weighted sinusoids spaced in frequency at integer multiples of $2\pi/T$. As T tends to infinity, the separation of these sinusoidal frequency components tends to zero, and in the limit we have the nonperiodic function represented by a continuum or spectrum of sinusoidal components. This spectrum of sinusoidal components constitutes the Fourier transform of the function. The Fourier transform of a signal $f(t)$ is found, as in the preceding discussion, by taking the limit of the expression for the Fourier series of a periodic function as the period tends to infinity, which turns out to be

$$F(j\omega) = \mathbf{F}\{f(t)\} = \int_{-\infty}^{\infty} f(t)e^{-j\omega t} dt \tag{15}$$

and exists if the integral in (15) converges. Once again we say that the Fourier transform converts a function from the time domain into the frequency domain, with $F(j\omega)$ indicating the frequency content of the signal at frequency ω . If $f(t) = 0$ for $t < 0$ and the integral shown above converges, the Fourier transform of f is just the Laplace transform with $j\omega$ substituted for s . Given $F(j\omega)$, the function $f(t)$ such that $F(j\omega) = \mathbf{F}\{f(t)\}$ is found by application of the inverse Fourier transform

$$f(t) = \mathbf{F}^{-1}\{F(j\omega)\} = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(j\omega)e^{j\omega t} d\omega$$

One important feature of the Fourier transform is the differentiation property, which states that differentiation in the time domain is equivalent to multiplication by $j\omega$ in the frequency domain. Thus the Fourier transform can, like the Laplace transform, be used to transform a system of differential equations in the time domain to a system of algebraic equations in the frequency domain.

In Fourier transform analysis a circuit is transformed into the frequency domain by replacing all independent sources by their Fourier transforms, replacing each inductor L by an impedance $j\omega L$ (and replacing any time-domain coupling M between inductors by the frequency-domain coupling $j\omega M$), replacing each capacitor C by an impedance $1/j\omega C$ and leaving resistive components unchanged. Note the lack of any initial condition generators—this is a consequence of the fact that the lower limit of integration in the definition of the Fourier transform is $-\infty$ rather than 0^- . Analysis in the frequency domain proceeds as described in the article on frequency-domain analysis or in Refs. 4 and 5, using the standard tools, and

the frequency-domain response is converted back to the time domain by application of the inverse Fourier transform. Once again there is a transfer function—in this case a function of frequency $H(j\omega)$ —relating input and output in the frequency domain. Note that the response obtained through Fourier transform analysis is the zero-state response only, since the method contains no provision for handling initial conditions.

Given a circuit with input $\sin(\omega_0 t)$ and transfer function $H(j\omega)$ [which is in general complex and, for the circuits in which we are interested, has the property that $H(-j\omega)$ is the complex conjugate of $H(j\omega)$], the output is obtained by taking the inverse Fourier transform of $H(j\omega) \cdot \mathbf{F}\{\sin(\omega_0 t)\}$, which turns out to be $|H(j\omega_0)| \sin(\omega_0 t + \angle H(j\omega_0))$. In other words, the sinusoidal input appears at the output as a sinusoid of the same frequency, with amplitude multiplied by the magnitude of the transfer function at that frequency and phase incremented by the phase of the transfer function at that frequency. If the input to the circuit is more general, it can be viewed as the finite or infinite sum of sinusoids, which will be altered in magnitude and phase by the action of the circuit and then recombined to form the output of the circuit. The magnitude and phase of the transfer function will generally vary with frequency, and when plotted against frequency are called the *amplitude* (or *magnitude*) *response* and *phase response* plots.

Frequency-selective circuits that pass certain ranges of frequencies from input to output while blocking other ranges are known as *filters* [7]. For example, an ideal low-pass filter would pass to the output all frequency components of its input up to a certain cutoff frequency, and pass no higher frequency components. This ideal lowpass filter cannot be realized and is therefore approximated by a variety of functions such as the Butterworth and Chebyshev approximations. Figure 18 plots the amplitude response of the ideal lowpass filter with cutoff frequency at 1 rad/s, together with the amplitude responses of the normalized Butterworth filters of orders 2,3,4,5. The amplitude response of each of these Butterworth filters is 0.7071 or -3 dB at $\omega = 1$ rad/s, which is to say that their 3 dB bandwidth is 1 rad/s.

In a communication system designed to transmit pulses, the step response of a filter is crucial. Too slow a risetime leads to neighboring pulses in a pulsetrain being smeared over one another, rendering them indistinguishable at the output. Too high an overshoot can drive circuit elements into saturation. The step response of a filter can be found by Fourier transform methods, by taking the inverse Fourier transform of the function $H(j\omega)\mathbf{F}\{u(t)\}$, but there is in general no reason to prefer the Fourier transform over the Laplace transform in this situation, and it is usual to take instead the inverse Laplace transform of the function $H(s)\mathbf{L}\{u(t)\}$. For example, the normalised third order Butterworth lowpass filter has transfer function $H(s) = 1/(s^3 + 2s^2 + 2s + 1)$, and so its step response is $\mathbf{L}^{-1}\{1/[s(s^3 + 2s^2 + 2s + 1)]\}$, which can be found by the partial fraction decomposition to be

$$1 - e^{-t} - \frac{2}{\sqrt{3}}e^{-t/2} \sin \frac{\sqrt{3}}{2}t \quad \text{for } t > 0$$

Figure 18. Amplitude response of the ideal lowpass filter with cutoff frequency at 1 rad/s, together with the amplitude responses of the normalized Butterworth filters of orders $n=2, 3, 4, 5$. Note that the approximation more closely matches the ideal as the order of the filter increases.

Figure 19 plots the step response of the normalised Butterworth filters of orders 2,3,4,5, as obtained by application of the Laplace transform. It can be seen that as the order increases (and the amplitude response more closely approximates the ideal) the overshoot, settling time and delay time of the filters all increase, but the risetime is approximately constant.

The procedure outlined above can be used to find the exact step response of a filter, allowing a designer to compare the suitability of various filters in pulse transmission applications. Designers should also have an intuitive understanding of the relationship between amplitude response and transient response of a filter. A lowpass filter allows low frequencies to pass to the output, but blocks high frequencies. Thus when the input is a step

function, the output will preserve the steady-state constant behavior of the input, but will act to block the high frequencies involved in the transition from 0 to 1. This can be seen in Fig. 19, where the high-order filters that are most effective at blocking high frequencies are least effective in capturing the discontinuity in the input. We now recognize the RC circuit of Fig. 4, with the output voltage taken across the capacitor, as a lowpass filter. If the output voltage were taken across the resistor, we would have a highpass filter whose step response captures the initial discontinuity in the step but then falls away to zero due to its inability to pass DC. Readers interested in a more detailed discussion of the relationship between frequency response and transient response of filters are referred to Refs. 1 and 7.

Figure 19. Step response of the normalized Butterworth filters of orders $n=2, 3, 4, 5$.

TRANSMISSION LINE MATRIX (TLM) METHOD

CHRISTOS CHRISTOPOULOS
 Director, George Green Institute
 for Electromagnetics Research
 University of Nottingham,
 Nottingham, United Kingdom

1. HISTORICAL BACKGROUND

The transmission-line modeling or matrix method, commonly referred by the acronym TLM, belongs to the class of differential equation methods and it is best known in its implementation in the time domain (TD-TLM). Implementations in the frequency domain are also available, but the method is known primarily as a time-domain method. It models electromagnetic field phenomena by analogy to pulse propagation in networks of transmission lines—hence its name. The idea of using circuits to model fields is not a new one. The foundation work in this area was done some time ago [1–3], but the difficulty at the time of solving such large networks precluded any useful implementation. This had to wait the advent of modern digital computers and the work of John and Beurle in 1971 [4], which set the scene for the rapid development of TLM into a versatile and general tool for EM simulation. The first developments were for models in two dimensions where an intuitive derivation of suitable network topologies is straightforward. The first three-dimensional structure appeared in 1975 [5]. There followed a period of development to obtain a circuit structure with good accuracy, efficiency, and versatility as described by Hofer [6]. The circuit structure (TLM node), which is the workhorse of TLM today, is described as the symmetric condensed node (SCN) and was developed in 1985 [7]. This marks the year when TLM entered its period of maturity. Many developments followed thereafter both improving the basic SCN and introducing complementary techniques that enhanced the power

of TLM. These are described in more detail in the following sections. More details of the TLM technique may be found in a large number of journal papers and in a number of texts that may be consulted for a fuller explanation of TLM and its applications [8–10]. The next section introduces the basics of TLM in a manner that should be accessible to all before more complex issues are addressed.

2. BASIC CONCEPTS

A basic introduction to the idea of TLM can proceed from an example of propagation in a transmission line and of one-dimensional field propagation. For a typical transmission line, as shown by two segments in Fig. 1, the differential equation describing the evolution of the current in space and in time is

$$\frac{\partial^2 i}{\partial x^2} = \frac{LC}{(\Delta x)^2} \frac{\partial^2 i}{\partial t^2} + \frac{GL}{(\Delta x)^2} \frac{\partial i}{\partial t} \quad (1)$$

where L and C are the inductance and capacitance, respectively, for a segment of the line of length Δx and G represents line losses.

In a similar way one can derive an equation for the current density j in one-dimensional field propagation

$$\frac{\partial^2 j}{\partial x^2} = \mu\epsilon \frac{\partial^2 j}{\partial t^2} + \mu\sigma \frac{\partial j}{\partial t} \quad (2)$$

where μ , ϵ , and σ respectively are the magnetic permeability, electric permittivity, and electrical conductivity of the medium.

One can see that Eq. (1) for the circuit and (2) for the field have the same structure. This isomorphism between the two equations means that field behavior may be understood by reference to circuit behavior. All that needs to be done is to establish appropriate circuit topologies in two and three dimensions and a formal equivalence between field and circuit quantities. This is possible to do. For the case of the one-dimensional example shown here, the equivalence is shown in Table 1.

Inspection of Eq. (2) shows that the two terms on the right-hand side represent wavelike behavior and diffusionlike behavior, respectively. By minimizing the wave term relative to the diffusion term, the models described

Table 1. Equivalence between Circuit and Field Quantities

Circuit	EM Field
I	j
$L/\Delta x$	μ
$C/\Delta x$	ϵ
$1/R \Delta x$	σ

thus may be used to study diffusion phenomena such as thermal conduction [9].

The lumped circuit shown in Fig. 1 can be replaced by transmission-line (TL) segments. Hence, in essence, in TLM models the field problem is reduced to lumped circuit models (space discretization), which in turn are reduced to TL models (time discretization). The art in TLM modeling is to devise TL interconnect topologies, in what are referred to as “nodes,” with each node describing a small block of space of dimensions $\Delta x \Delta y \Delta z$, such as there is an exact equivalence between the voltages and currents in each node and electric and magnetic fields. The TLM node is the equivalent of the computational element or molecule in other methods much like the Yee cell in FDTD.

A schematic arrangement in two dimensions is shown in Fig. 2a. Here, a mesh of transmission lines is shown, each line in the diagram representing a TL, namely, a line and its return conductor (not shown). One node is shown highlighted by a broken line. If a voltage pulse

Figure 2. Schematic of a 2D TLM mesh: (a) 2D mesh with one node marked out; (b) impulse excitation at one port; (c) output after the first scattering event.

of magnitude 1 V is incident as shown in Fig. 2b, then this pulse will scatter at the node. If the TL characteristic impedance is Z , then at the node the pulse encounters three TLs in parallel (characteristic impedance $Z/3$) and scatters at this discontinuity with a reflection coefficient -0.5 and a transmission coefficient 0.5 . The scattered pulses are as shown in Fig. 2c. The reflected pulse of -0.5 V combines with the incident pulse of 1 V so that in total the pulse on this TL has a magnitude of 0.5 V. As a result of the scattering, a secondary isotropic wavefront is formed at the node in accordance with Huygens’ principle [11]. TLM can thus be viewed as a discrete implementation of the Huygens principle [12]. After the initial scattering, pulses propagate to adjacent nodes and the process repeats. The TLM algorithm consists of the process of “scattering” at each node; “connection,” that is, the exchange of pulses between nearest neighbors; followed by another “scattering”; and so on. Figure 3 illustrates the results of scattering and connection at the first two timesteps following the isotropic excitation of one node.

For TM modes the basic TLM node in two dimensions (2D) is described as a “shunt” node and is shown in Fig. 4. The dual of this node for TE modes is described as a “series” node. As an illustration, the scattering process in a shunt node is described below:

In order to proceed for the node shown in Fig. 4, we assume that four incident pulses travel toward the node at timestep k . These are labeled as

$${}_k V_j^i \quad j = 1, 2, 3, 4$$

where the superscript “i” stands for incident pulse (traveling toward the center of the node). We also assume that the characteristic impedance of each line segment is Z_{TL} . For each of the four line segments, a Thevenin equivalent circuit is derived and therefore each node is now represented as in Fig. 5. The total voltage at the center of the node can then be obtained directly:

$${}_k V_z = 0.5({}_k V_1^i + {}_k V_2^i + {}_k V_3^i + {}_k V_4^i) \quad (3)$$

The electric field component E_z and magnetic field components H_x, H_y are then directly obtained:

$${}_k E_z = -0.5 \frac{({}_k V_1^i + {}_k V_2^i + {}_k V_3^i + {}_k V_4^i)}{\Delta z} \quad (4)$$

$${}_k H_x = \frac{{}_k V_3^i - {}_k V_1^i}{Z_{TL} \Delta x}, \quad {}_k H_y = \frac{{}_k V_2^i - {}_k V_4^i}{Z_{TL} \Delta x} \quad (5)$$

Scattering is directly implemented as follows

$${}_k V_1^r = {}_k V_z - {}_k V_1^i = 0.5(-{}_k V_1^i + {}_k V_2^i + {}_k V_3^i + {}_k V_4^i) \quad (6)$$

and similarly for the other reflected components. These expressions can be put into a matrix form

$${}_k \mathbf{V}^r = S_k \mathbf{V}^i \quad (7)$$

Figure 3. Scattering in a 2D TLM mesh: (a) symmetric excitation at one node; (b) output after the first timestep; (c) output after the second timestep.

where S is the scattering matrix, which for the case of the shunt node shown here is given by

$$S = 0.5 \begin{bmatrix} -1 & 1 & 1 & 1 \\ 1 & -1 & 1 & 1 \\ 1 & 1 & -1 & 1 \\ 1 & 1 & 1 & -1 \end{bmatrix} \quad (8)$$

Equations (7) and (8) show the process of scattering at each node. Scattered pulses are passed on to the adjacent ports of neighboring nodes to form the new incident voltages at timestep $k + 1$ in a process described as “connection.” This is expressed schematically as

$${}_{k+1}V^i = C_k V^r \quad (9)$$

where C is described as the “connection” matrix. The TLM algorithm consists of the repetition at each timestep of the processes of scattering and connection at each node with appropriate modifications to account for initial and boundary conditions. The same procedure applies to all TLM schemes, including those in three dimensions, but the form of the scattering matrix in (8) is different. It will be seen from this basic description of TLM that it is a

Figure 4. The shunt 2D TLM node for TM modes.

Figure 5. The Thevenin equivalent circuit of the shunt node.

scattering algorithm—energy goes in at each node (incident pulses) and comes out (reflected pulses). The scattering process is lossless (S is unitary). Because we have an exact solution of a passive network, unconditional stability is ensured. Accuracy is good as long as at least 10 segments per wavelength are used.

Several modifications can be made to this basic scheme to extend the applicability of the model in Fig. 4. Foremost among them is the inclusion of stubs to allow for the modeling of inhomogeneous lossy materials. A suitable node is shown in Fig. 6, where two stubs are included: an infinitely long stub (conductance G_s) and an open-circuit stub (admittance Y_s). This node can model TM propagation in a medium of relative dielectric constant ϵ_r and electrical conductivity σ . The choice of parameters is as follows:

$$u_{\text{TL}} = \frac{\Delta x}{\Delta t} = \sqrt{2} \frac{1}{\sqrt{\mu_0 \epsilon_0}}, \quad Z_{\text{TL}} = \sqrt{2} \sqrt{\frac{\mu_0}{\epsilon_0}} \quad (10)$$

$$Y_s = 4 \frac{(\epsilon_r - 1)}{Z_{\text{TL}}}, \quad G_s = \sigma \Delta x \quad (11)$$

In this case the scattering matrix is given by

$$S = \frac{1}{\hat{Y}} \begin{bmatrix} 2 - \hat{Y} & 2 & 2 & 2 & 2\hat{Y}_s \\ 2 & 2 - \hat{Y} & 2 & 2 & 2\hat{Y}_s \\ 2 & 2 & 2 - \hat{Y} & 2 & 2\hat{Y}_s \\ 2 & 2 & 2 & 2 - \hat{Y} & 2\hat{Y}_s \\ 2 & 2 & 2 & 2 & 2\hat{Y}_s - \hat{Y} \end{bmatrix} \quad (12)$$

where

$$\hat{Y} = 4 + \hat{Y}_s + \hat{G}_s, \quad \hat{Y}_s = Y_s Z_{\text{TL}}, \quad \hat{G}_s = G_s Z_{\text{TL}} \quad (13)$$

Figure 6. The shunt node with capacitive and lossy stubs added.

The inclusion of stubs permits the development of a model where all linklines have the same (free-space) parameters, hence ensuring the same timestep (synchronism) in the entire mesh. Stubs add capacitance to account for the presence of dielectric materials other than free space. Similar procedures apply to the dual node (series node). More detailed information may be found in the references already cited.

3. TLM IN THREE DIMENSIONS

In the previous section the rudiments of TLM were presented with reference to simple two-dimensional structures so that the basic modeling philosophy could be explained in simple physical terms. In this section the model is extended to three dimensions (3Ds) by presenting the *symmetric condensed node* (SCN), which is extensively used in 3D TLM models.

The structure best suited to general 3D models is the SCN described by Johns [7] and shown in Fig. 7. In this figure the traditional labeling of each port is shown (numbers 1–12) alongside an alternative labeling scheme introduced latter. This node describes the properties of EM propagation in a cuboidal block of space $\Delta x \Delta y \Delta z$. In a regular SCN, $\Delta x = \Delta y = \Delta z$. But with the addition of stubs, this restriction can be removed to form a more flexible structure for general modeling. For simplicity, the regular SCN is discussed first, which results in a uniform mesh.

At each of the six faces of the cube there are two ports polarized at 90° to each other to account for all possible wave polarizations. In total, therefore, there are 12 ports and the scattering matrix is a 12×12 . It is a sparse matrix, and its elements, which are nonzero, can be identified by physical intuition or by formal methods. The value of each element can be readily obtained by enforcing circuitual laws, charge, and energy conservation

Figure 7. The three-dimensional symmetric condensed node (SCN).

(the scattering matrix must be unitary). A detailed discussion may be found in Refs. 7 and 9. For the stubless SCN, S is given by

$$S = 0.5 \begin{bmatrix} 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & -1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 & 1 & 0 & -1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 1 & 0 & -1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & -1 & 0 & 1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & -1 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & -1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 \end{bmatrix} \quad (14)$$

It will be seen from (this matrix) that the scattering process is particularly simple, amounting to a simple averaging of four incident voltage pulses to obtain each scattered (reflected) pulse. There is no need for matrix inversion or matrix manipulation of any kind. The 3D TLM algorithm is then an implementation of the scheme described for 2D format in connection with Eqs. (7) and (9), where the scattering matrix is as given by (14). The connection matrix C is again very simple, codifying information for each node and its nearest ports in each coordinate direction. The correspondence between field and circuit quantities is again, as in the case of the 2D node, straightforward.

Fields may be calculated at the center of the node or at the boundaries between nodes. As an illustration the electric field component E_x at the center of the node is associated with port generating voltages in the x direction and is obtained as follows:

$$E_x = -\frac{V_x}{tax} = -\frac{V_1^i + V_2^i + V_9^i + V_{12}^i}{2tax} \quad (15)$$

Similarly, for the magnetic field component in the same direction, we obtain

$$H_x = \frac{I_x}{tax} = \frac{V_4^i + V_7^i - V_5^i - V_8^i}{2Ztax} \quad (16)$$

Fields at the boundary between nodes are also easily obtained as shown below for two field components at the boundary between nodes (x,y,z) and $(x+1,y,z)$:

$$E_y = -\frac{V_{11}^i(x,y,z) + V_3^i(x+1,y,z)}{tay} \quad (17)$$

$$H_z = \frac{V_3^i(x+1,y,z) - V_{11}^i(x,y,z)}{Ztaz}$$

Current and charge density may be obtained directly from the fields using Ampere and Gauss laws or with reference to the analogies between field and circuit quantities.

Excitation of the mesh is achieved by launching appropriate voltage pulses on the TL of particular nodes. As an illustration, to launch an electric field component $E_x = E_0$ at a particular node, the following voltage pulses must be applied:

$$V_1^i = V_2^i = V_9^i = V_{12}^i = -\frac{E_0 tax}{2} \quad (18)$$

Perfectly conducting boundaries are easily imposed on the mesh at the connection stage, at the boundaries between nodes, by specifying that the reflection coefficient there is equal to -1 . More complex boundaries (e.g., with frequency-dependent properties) can also be specified as explained in the following sections.

A variable mesh ($\Delta x \neq \Delta y \neq \Delta z$), or a mesh describing an inhomogeneous material, is established by adding stubs to the standard SCN described above, to maintain synchronism and account for values of permittivity and permeability larger than one. In the most general case, open-circuit, short-circuit, and infinitely long stubs are used to account for ϵ, μ, σ of the medium [7,9]. The structure thus obtained is referred to as the *stubbed SCN*. However, this is not the most efficient structure, and in most practical implementations of TLM the *hybrid SCN* is employed. In this node, synchronism is maintained, but the condition that all link lines have the same characteristic impedance is relaxed. This allows all the required inductance (μ in field terms) to be modeled by the linklines, and stubs are needed only to account for ϵ [13]. This results in a reduction of the storage required and in operating the mesh at a larger timestep compared with a stubbed SCN. Alternatively, all the required capacitance may be described by the linklines, and stubs then account for extra inductance. A general discussion of the properties of the hybrid SCN may be found in a paper by Trenkic et al. [14]. For problems with

cylindrical symmetry, non-Cartesian nodes are available to facilitate modeling [15].

Developments to increase the efficiency of TLM computation are described in the literature. A particular technique to speed up scattering is described in another paper by Trenkic et al. [16]. For each coordinate direction, total voltage and current are first calculated and the reflected voltages are then obtained from

$$V_{y\text{mx}}^r = V_x - ZI_z - V_{y\text{px}}^i \quad (19)$$

Similar equations apply for the y and z directions. The notation used to designate voltage pulses in (19) is as follows: superscripts “i” or “r” indicate incident or reflected voltages, the first subscript indicates direction of propagation (x , y , or z), the second subscript (“ n ” or “ p ”) indicates line segment along the negative or positive axis, and the third subscript indicates the polarization direction of the pulse (x , y , or z).

4. THEORETICAL FOUNDATIONS OF TLM

In this section some of the general concepts that underpin the foundation of TLM are discussed together with important features of the method such as dispersion and accuracy.

4.1. The General SCN TLM Node

A number of TLM nodes are available, many of them derivatives of the basic SCN, which appeared in the literature over the years. These may be unified under a general formulation described in Ref. 17. It accounts for a general anisotropic materials represented by ϵ_{ri} , μ_{ri} , $i = 1, 2, 3$ where the indices 1, 2, 3 refer to the coordinate directions x, y, z . In this node, for the i -directed, j -polarized link line, the capacitances and inductances per unit length are C_{ij}, L_{ij} . The i -directed stubs represent capacitance and inductance:

$$C_0^i, L_s^i$$

The TLM constitutive equations are (Δi is the node size in i direction)

$$\begin{aligned} C_{kitak} + C_{jitaj} + C_0^i &= \epsilon_{r0} \epsilon_{ri} \frac{t_j t_k t a k}{t a i} \\ L_{jktaj} + L_{kjtak} + L_s^i &= \mu_0 \mu_{ri} \frac{t_j t_k t a k}{t a i} \end{aligned} \quad (20)$$

Synchronism requires that the same timestep prevail throughout; therefore

$$t a t = t a i \sqrt{C_{ij} L_{ij}} \quad (21)$$

Using all possible permutations of $i, j, k \in \{x, y, z\}$, we obtain six equations from (20) and another six from (21). There

are 18 unknown parameters

$$C_{ij}, L_{ij}, C_0^i, L_s^i$$

and therefore there remain 6 degrees of freedom. By imposing additional restrictions on the linkline and stub parameters, several TLM nodes may be derived. According to Trenkic et al. [17], a classification of 3D TLM condensed nodes in the time domain is as follows:

- *Stub-loaded nodes*, which have the same characteristic impedance for all linklines (constant L/C ratio for all six lines giving the additional constraints).
- *Hybrid nodes*, which have either open- or short-circuit stubs (thus supplying three additional conditions), the other three conditions obtained by demanding that all the line impedances modeling the same magnetic or electric field components are the same.
- *Supercondensed nodes*, which have no stubs at all; therefore six conditions are imposed by demanding that all stub capacitances and inductances be equal to zero. The supercondensed node is described in Ref. 18.
- *General nodes*, which have a combination of linklines and stubs.
