PREFACE

There has been rapid development in RF and microwave technologies during the past decade. RF and microwave wireless applications have been and continue to be among the hottest growth areas. Some of the expanding activities in these fields include wireless communications (mobile, cellular, and satellite), wireless sensors, local area networks, remote control and identification, global positioning systems (GPS), and intelligent highway and vehicle systems (IHVS). In view of these growing applications, it is timely to publish this *Encyclopedia of RF and Microwave Engineering*.

The Encyclopedia is intended to serve as a compendium of theory, design methods, applications, overview, and future trends of technologies. Each article is a self-contained unit and is written for both non-specialists and specialists. Some overlap among articles is allowed for easy study. It is hoped that this Encyclopedia will provide useful information for technicians, students, professors, engineers, managers, and researchers in today's rapidly changing high-frequency technologies.

The Encyclopedia consists of six volumes. The articles include an overview of each subject, followed by in-depth descriptions of important theory, technology developments, and applications. Each article includes a list of references for further study. Some articles are adapted from the *Encyclopedia of Electrical and Electronics Engineering*. Most of these articles have been revised and updated. Among the major topics are the following:

- Electromagnetics
- Numerical Methods
- Wave Propagation
- Transmission Lines
- Transmission Line Discontinuities
- RF Circuits
- RF Components and Devices
- RF Technology
- RF Integrated Circuits
- RF CMOS Technology
- RF Antennas

- RF Transmitters
- RF Receivers
- RF Systems
- Microwave Passive Components and Devices
- Microwave Active Components and Devices
- Microwave Semiconductor Devices and Processing
- Microwave Hybrid and Monolithic Integrated Circuits
- Microwave Antennas
- Microwave Transmitters
- Microwave Receivers
- Microwave Superconductors
- Microwave Systems
- Millimeter-wave and Submillimeter-wave Technologies
- RF and Microwave Measurements
- RF and Microwave Propagation
- RF and Microwave Photonics
- CAD Techniques and Modeling
- Modulation and Demodulation Techniques
- Packaging and Interconnects
- Frequency Synthesizers
- Signal and Baseband Processing
- Solid-state Devices
- Semiconductor Materials
- High Power Tubes
- Noise
- Low Power Electronics
- Radar Systems
- Communication Systems
- Navigation Systems
- Radio Technologies
- Remote Sensing
- Broadcasting

The Editor would like to thank Cassie Craig of Wiley for managing this project, and George Telecki of Wiley for his constant encouragement and support. The Editor would also like to thank all of the members of the Editorial Board for their suggestions and advice.

Kai Chang
College Station, Texas

1. INTRODUCTION

Data conversion is a broad area of activity that involves both theory and implementation. Our goal in this article is to provide a focused treatment of key fundamentals and an in-depth study of the latest approaches available for data converter design in communication systems. The coverage provided here should allow the reader to plan the design of a data converter integrated circuit or begin an independent investigation of the field.

Since the early 1990s, the transceiver core shown in Fig. 1 has provided a technological backdrop for the analog integrated circuit (IC) engineer. All popular communication devices, including mobile phones, wired modems, and network interface cards, are based on some variant of this system. Although simple in form, the core embodies a wide range of expertise, and usually requires a team of engineers to develop.

This article is concerned with the data conversion subsystem that interfaces the front-end and back-end portions of the transceiver core. A data converter translates signals between analog and digital representations.¹ Our emphasis is on data converters for mobile communication systems in which cost and power savings are a priority. Therefore, although much of our discussion is of a general nature, our presentation is geared toward CMOS integrated circuit implementation and applications with low to moderate bandwidths (e.g., communications with WCDMA, IEEE 802.11a/b, or Bluetooth protocols). The emerging trend in communications of higher data rates and greater mobility necessitates the use of economical IC technologies such as deep-submicrometer CMOS that facilitate full system integration.

The design of data converters can be challenging, particularly if a concurrence of speed, accuracy, and power efficiency are required [1]. Quite often, as one attempts to improve accuracy, the area and power dissipation of a data converter design increase substantially. The tradeoff between speed and converter accuracy is most evident with oversampled converters, in which the suppression of

quantization noise is closely related to the sampling rate. Broadband networking protocols such as WCDMA and IEEE 802.11b can require between 80 and 100 dB of dynamic range and signal bandwidths in the multi-megahertz range. Until 1997, such performance had not been achieved using standard CMOS fabrication [2–4].

The current state of the art (as of the end of 2003) for CMOS Nyquist-rate D/A technology provides 10-bit dynamic range at signal bandwidths up to 500 MHz [5], while CMOS Nyquist-rate A/D converters are achieving between 8 and 10 bits of dynamic range with signal bandwidths from 40 to 100 MHz [6–9]. Higher dynamic ranges (around 14 bits) at moderate speeds (up to 10 MHz) have been reported for CMOS architectures employing pipeline techniques. In Section 4, we provide a detailed discussion of the latest flash and pipeline techniques for the design of higher-speed converters.

Oversampled converters exhibit greater tolerance to component nonidealities than do their Nyquist-rate counterparts, so that 15-bit dynamic range can be readily achieved. Using feedback, the effective resolution of a coarse quantizer can be substantially increased (at the expense of reduced conversion speed). However, because of the higher sampling rates required (and limitations imposed by stability requirements on the degree of quantization noise shaping), the signal bandwidths of CMOS oversampled converter ICs are typically on the order of 1 MHz. Section 7 provides an introduction to oversampling techniques and an overview of proven architectures that achieve high resolution for narrowband applications.

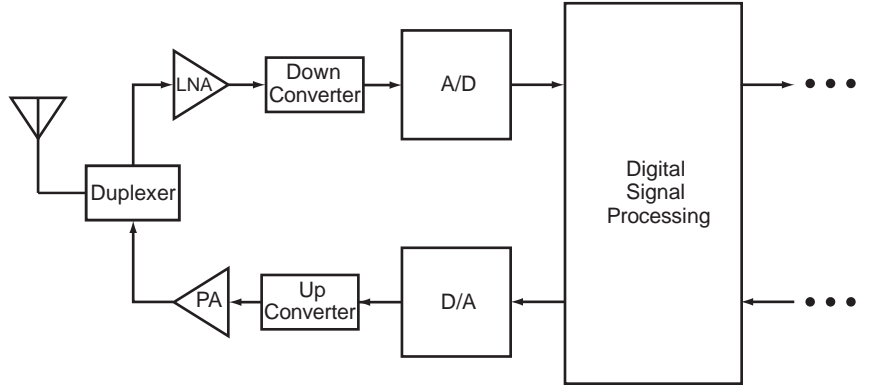

1.1. Overview of Data Conversion

Data converters are categorized as either *Nyquist-rate* or *oversampled* architectures. The former class of converter includes architectures that are typically open-loop and that operate at sampling rates that (usually) do not exceed 10 times the Nyquist rate. The Nyquist-rate D/A converter is the basis of many architectures and is formed by a series of passive or active elements, switches, and an output buffer, as shown in Fig. 2 (in binary-weighted form). Oversampled converters are feedback systems that operate with relatively high clock rates, up to 100 times the Nyquist rate or more. The kernel of the oversampled converter is the delta-sigma modulator, described in Section 7, which embeds a quantizer and filter within a feedback loop. The flash or parallel converter, described in Section 4, is perhaps the most straightforward type of Nyquist-rate A/D. A thermometer-coded binary number is generated through approximately 2^N parallel comparisons; conversion to conventional binary code (in addition to error correction) is performed by digital logic. The main advantage of this approach is speed. In Section 4, we present methods to “contain” the high complexity of the flash architecture by invoking pipeline techniques.

Nonidealities, particularly element-size mismatch, can reduce the dynamic range of data converters. Without mismatch compensation techniques (described below), the dynamic range of the converter is limited by the

¹We define *analog signals* as those with amplitudes that vary over a continuum, for example, signals such as voltage fluctuations induced by electromagnetic or acoustic waves impinging on transducers. Note that analog signals may be either discrete (i.e., sampled) or continuous in time. Digital signals are discrete in both amplitude and time. A system in which both analog and digital signals are used is called a *mixed-signal* system.

Figure 1. A generic wireless transceiver core for digital communication. The RF front end includes a low-noise amplifier (LNA) for the receiver and a power amplifier (PA) for the transmitter. The data conversion subsystem consists of an analog-to-digital (A/D) converter and a digital-to-analog (D/A) converter.

capabilities of the manufacturing technology, to—in the case of standard CMOS fabrication—approximately 10–12 bits. To see this, note that a D/A converter with N bits of accuracy, by definition, must satisfy

$$\text{Maximum error due to nonidealities} \leq \frac{V_{\text{LSB}}}{V_{\text{ref}}} = \frac{1}{2^N} \quad (1)$$

where the error associated with the converter must be less than the smallest possible change in the output voltage of the converter, defined as V_{LSB} (normalized by the reference voltage). If the D/A has a component mismatch error, which we assume to be the dominant source of error, of 0.1% (the minimum matching precision in standard CMOS [10]), we may write

$$\begin{aligned} 0.001 &\leq 2^{-N} \\ \Rightarrow \log_2(0.001) &\leq -N \log_2(2) \\ \Rightarrow N &\leq -\log_2(0.001) \approx 10. \end{aligned}$$

Therefore, the converter accuracy is limited to approximately 10 bits or 60 dB.

2. DATA CONVERTER FUNDAMENTALS

Data conversion can be viewed as a two-stage process of sampling followed by amplitude quantization, as shown in

Fig. 3. In many instances, the sampling operation is implicit in the functioning of the converter. However, it is often helpful to consider sampling as distinct from amplitude quantization, since certain performance degradations can be traced to sampling nonidealities.

In the case of D/A conversion, the sampling operation is simply a resampling and filtering of the digital input signal, which can be realized with digital circuits or software. In the A/D case, sampling is performed by an analog sample-and-hold (sometimes referred to as a “track-and-hold”) circuit, as shown in Fig. 4. The design of a suitable sample-and-hold can be challenging. Operating at the sampling rate of the converter, the sample-and-hold circuit must transition from “track” to “hold” mode with a minimum of error and provide an accurate measurement of the analog input with a minimum of signal feedthrough. The reader interested in a more in-depth discussion of sample-and-hold circuits is referred to the book by Johns and Martin [11, Chap. 8]; the remainder of our discussion will focus on the process of amplitude quantization.

The signal band of the data converter is the range of frequencies of width f_b from a minimum frequency (often DC) to a specified maximum frequency. For simplicity we assume throughout this article that the signal band begins at DC, where signals are restricted to the frequency range $[0, f_b]$. Sampling rates for bandlimited analog signals must exceed the Nyquist rate, denoted by $2f_b$, as shown in Fig. 5.

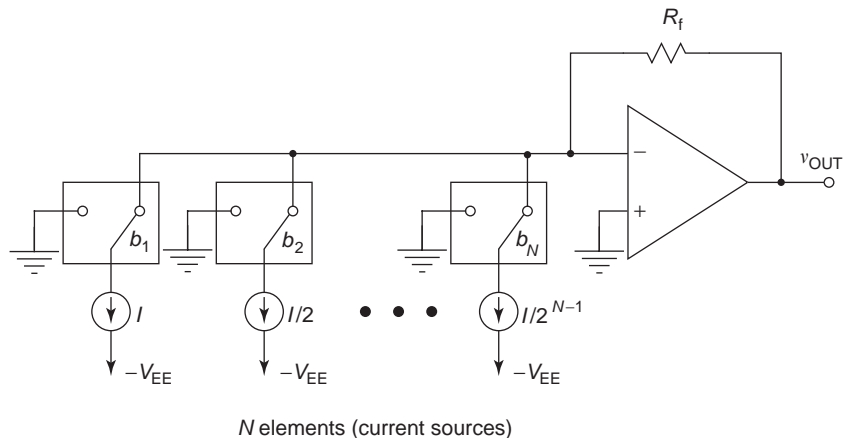

Figure 2. A binary-weighted N -bit Nyquist-rate D/A. Switching elements control current flow through the buffer based on bit values. The analog output voltage is expressed as $v_{\text{out}} = V_{\text{ref}} \sum_{i=1}^N 2^{-i} b_i$, where $V_{\text{ref}} = 2IR_f$.

Figure 3. A conceptual view of the data conversion process.

For D/A converters, amplitude quantization can be expressed as a scaling of a digital input by an analog reference quantity. Formally, the amplitude quantization of an N -bit D/A converter (shown in general form in Fig. 6) is expressed as

$$v_{\text{out}} = V_{\text{ref}} \sum_{i=1}^N 2^{-i} b_i \quad (2)$$

where b_i are the bits of the input word, $\{b_1, b_2, \dots, b_N\}$, which may be in either signed or unsigned digital form; b_1 denotes the most significant bit (MSB); and b_N , the least significant bit (LSB). We assume that V_{ref} and v_{out} represent voltages, although other physical quantities (such as current) may be used. In the case of a thermometer code representation, $\{b_1, b_2, \dots, b_{2^N-1}\}$, of the digital input, we have

$$v_{\text{out}} = \frac{V_{\text{ref}}}{2^N} \sum_{i=1}^{2^N-1} b_i \quad (3)$$

We may provide a similar description for a generalized N -bit A/D converter, shown in Fig. 7. The relationship between analog input v_{in} and output bits is expressed as

$$v_{\text{in}} = V_{\text{ref}} \sum_{i=1}^N 2^{-i} b_i + v_Q \quad (4)$$

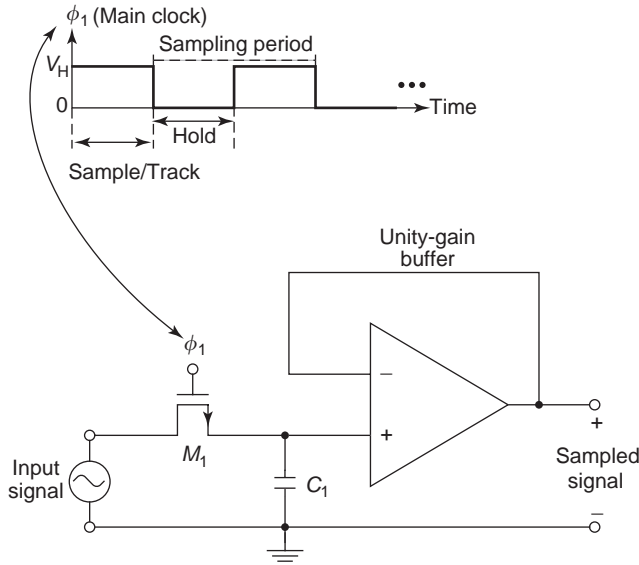

Figure 4. A conceptual sample-and-hold circuit. The sampling rate is set by the frequency of the main clock. During the sample phase, the switch M_1 is on and the capacitor voltage tracks the input signal voltage. During the hold phase, the switch opens and the voltage across C_1 can be read through a unity-gain buffer.

for binary-weighted encoding, or

$$v_{\text{in}} = \frac{V_{\text{ref}}}{2^N} \sum_{i=1}^{2^N-1} b_i + v_Q \quad (5)$$

for thermometer code converters. The variable v_Q denotes the quantization error, which we describe in detail below. These equations help us define the “staircase” characteristic that is often seen in A/D converter descriptions (please see Fig. 8). In addition to these equations, the ideal A/D has specific *transition* values for the analog input; Thus the transition points should occur $\frac{1}{2} V_{\text{LSB}}$ away from the midpoints of the staircase characteristic, as shown in Fig. 8. Assuming that v_{in} is within the designated limits of the converter, given by

$$-\frac{V_{\text{ref}}}{2^{N+1}} \leq v_{\text{in}} \leq \frac{2^{N+1} - 1}{2^{N+1}} V_{\text{ref}} \quad (6)$$

[note that the upperbound on v_{in} can be expressed as $V_{\text{ref}} - (V_{\text{LSB}}/2)$], the quantization error should satisfy

$$-\frac{V_{\text{ref}}}{2^{N+1}} \leq v_Q \leq \frac{V_{\text{ref}}}{2^{N+1}} \quad (7)$$

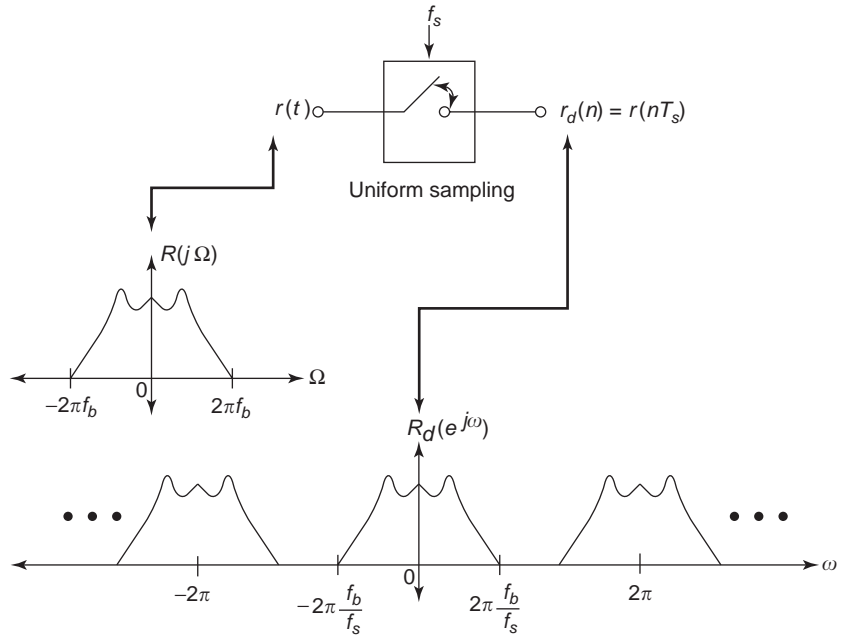

For dynamic measurements of converter performance, quantization error is often modeled as a uniformly distributed (zero-mean) uncorrelated random variable. Based on (7), the variance (i.e., power) of the quantization error is $V_{\text{LSB}}^2/12$. We can now derive the relationship between signal-to-quantization-noise ratio (SQNR) and N , the number of bits associated with an A/D converter. We assume that v_{in} is a sinusoidal input (commonly used for testing purposes) with amplitude that varies between 0 and V_{ref} [approximately within the bounds indicated by (6)]. We obtain the peak SQNR in units of dB as follows:

$$\begin{aligned} \text{SQNR} &= 10 \log_{10} \left(\frac{\text{power of sinusoidal input}}{\text{power of quantization error}} \right) \\ &= 10 \log_{10} \left(\frac{V_{\text{ref}}^2}{\frac{8}{V_{\text{LSB}}^2} \cdot \frac{1}{12}} \right) \\ &= 10 \log_{10} \left(\left(\frac{3}{2} \right) 2^{2N} \right) \\ &\approx 6.02N + 1.76 \end{aligned}$$

Thus we find that the resolution or peak SQNR of an N -bit converter is approximately $6N$ dB; therefore, we often say that 1 bit is equivalent to 6 dB.

The *signal-to-noise-and-distortion ratio* (SNDR) of a data converter is defined as the ratio of the signal power to the signal-band noise and distortion power measured at

Figure 5. An illustration of Shannon’s sampling theorem. The bandlimited analog input signal r is sampled uniformly in time at a sampling rate f_s [note that the sampling interval is given by $T_s = (1/f_s)$]. In the figure, the quantity Ω refers to frequency f in radians per second (i.e., $\Omega = 2\pi f$); the quantity ω is normalized frequency [i.e., $\omega = 2\pi(f/f_s)$] in radians per second. The sampled spectrum $R_d(e^{j\omega})$ consists of copies of the original spectrum $R(j\Omega)$ centered at integer multiples of the sampling frequency. To avoid aliasing (i.e., overlap and superposition of the copies), it is sufficient for f_s to exceed $2f_b$. Note that a generalized sampling theorem exists for bandpass signals that can reduce sampling rate requirements in many applications [12].

the output of the converter. *Noise* includes quantization error, modeled as a random process, and uncorrelated noise arising from circuit components. *Distortion* refers to signals that correlate with the input signal that are often harmonically related to frequency components of the input. The *signal-to-noise ratio* (SNR) is similar to the SNDR, but distortion frequency components are ignored in the calculation.

The DR of a data converter, obtained as illustrated in Fig. 9, is the ratio of the power level of the largest allowable input signal to the power level of the input signal corresponding to an SNDR of unity. The “largest allowable input signal” is the input signal that yields a specified drop in SNDR (sometimes 3 dB [13]) beyond the maximum SNDR. Dynamic range, SNDR, and SNR/SQNR are often expressed in units of bits (where, as mentioned above, 1 bit is equivalent to 6 dB). The *effective number of bits* (ENoB) is usually obtained by dividing the DR (in dB) by 6 dB/bit

and provides a measure of the true accuracy of the converter. For example, a 16-bit converter with a dynamic range of 72 dB is accurate to only 12 bits, and, therefore, has an ENOB of 12.

2.1. Nonidealities

Practical data converters typically fall short of ideal performance (specified, e.g., in terms of SNDR or DR). As mentioned, performance flaws can often be traced to mismatches between constituent elements. For example, in the binary-weighted D/A of Fig. 2, each current source must be exactly one-half the size of the next-larger current source in order to achieve an ideal characteristic. Any error in sizing results in a corresponding deviation of the converter characteristic from ideal. The precision with which these elements can be sized depends on the manufacturing technology.

Figure 6. A generalized D/A converter. The binary input word $\{b_1, b_2, \dots, b_K\}$ describes a conventional (signed or unsigned) code ($K=N$) or a thermometer code ($K=2^N - 1$).

Figure 7. A generalized A/D converter. The analog input signal v_{in} is “within a least significant bit” of the binary output word, $\{b_1, b_2, \dots, b_K\}$. For conventional (signed or unsigned) codes, $K=N$, and for thermometer codes, $K=2^N - 1$.

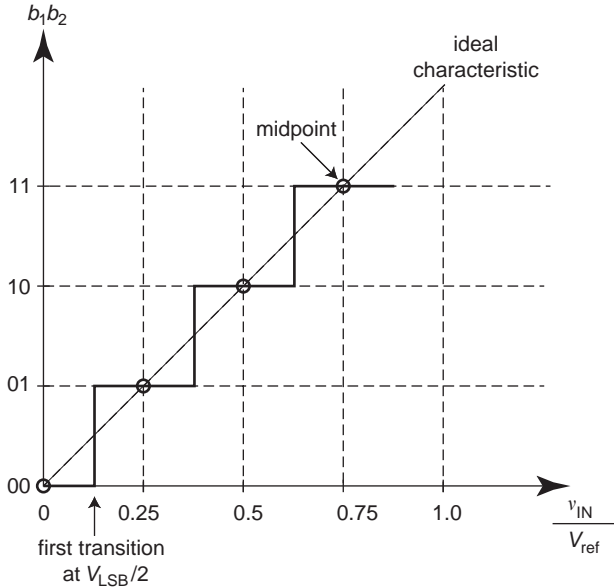

Figure 8. Ideal A/D staircase characteristic (shown here for a 2-bit converter), shown for positive values of v_{in} only. The midpoints of each output are indicated; transitions occur at analog input amplitudes $V_{LSB}/2$ away from the midpoints.

In Fig. 10, we superimpose the ideal and actual (D/A) characteristics to illustrate the various nonidealities that can be observed. For D/A converters, *offset error* is measured as the output corresponding to a zero input (i.e., the input defined by setting all bits to zero), often normalized

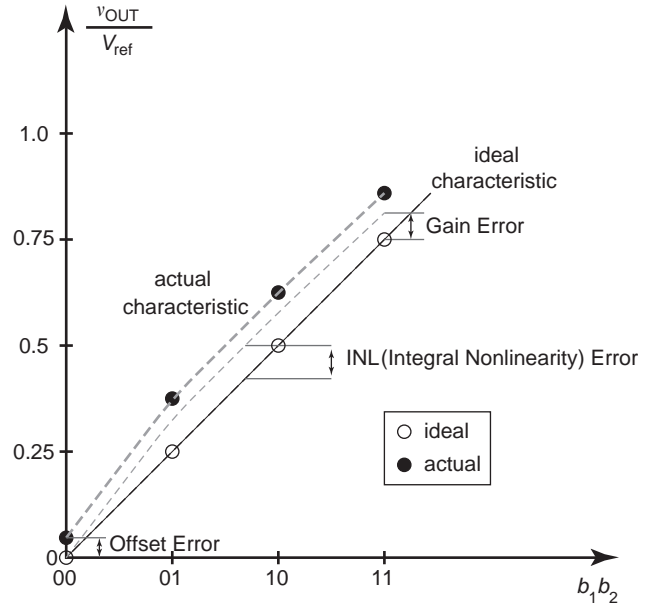

Figure 10. Plot of a 2-bit D/A converter characteristic. Deviations of the actual characteristic from ideal behavior are characterized using a variety of static metrics including offset, gain, and integral nonlinearity errors. Note that the offset error is typically removed before gain and nonlinearity errors are measured.

by V_{LSB} . To find the offset error for A/Ds, we measure the deviation of the lowest transition voltage of the input away from $V_{LSB}/2$. The notion of *gain error* is the endpoint difference between two straight lines (with offset error removed), as illustrated in Fig. 10; one line is defined by the ideal characteristic (for either A/D or D/A converters), and the second line has a slope computed using the extremes of zero and “full-scale” inputs.

Nonlinearity is characterized as either *differential* or *integral*, and is computed after offset error is removed. For D/A converters, differential nonlinearity (often abbreviated as DNL) is given by the difference between the largest step (between two adjacent binary input codes) and V_{LSB} ; integral nonlinearity (often abbreviated as INL) is the largest deviation of the actual characteristic from a straight line drawn between the endpoints of the characteristic [1]. Differential and integral non-linearities are calculated in much the same way for A/D converters. Differential nonlinearity is the difference between the largest increase in the analog input needed to generate a transition between consecutive digital output codes and V_{LSB} . Integral nonlinearity is largest difference between the actual A/D characteristic and the straight line formed by joining the endpoints of the actual characteristic.

SNDR vs. Input Signal Magnitude for a Hypothetical Data Converter

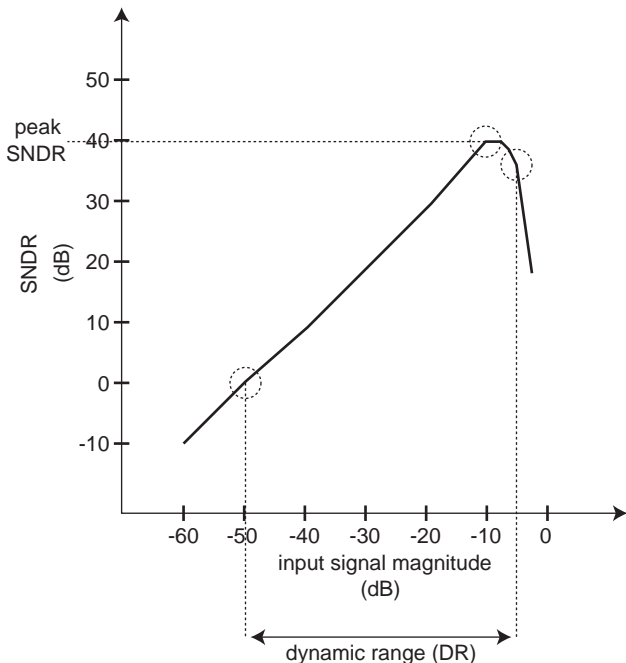

Figure 9. Illustration of SNDR variation with input signal magnitude for a hypothetical data converter. The peak SNDR and DR are indicated on the plot.

3. OVERVIEW OF D/A CONVERTER ARCHITECTURES

The digital-to-analog (D/A) converter is one of the basic building blocks of most analog/digital interface systems. For example, in audio-CD players and music synthesizers, D/A converters with accuracy as high as 16–24 bits are desired for speeds in the range of few kilohertz.

Telecommunication applications like radio transmitters require D/A converters (DACs) operating at hundreds of MHz for resolutions in the range of 10–15 bits.

There are several architectures for D/A converters depending on the speed, resolution, complexity, and area requirement [14]. In this section, we will focus on one particular type of D/A converter commonly known as a *current steering array*, which offers high-speed D/A conversion using current as a *unit* element for analog computation of digital input. Other formats such as switched-capacitor architectures or resistor ladder architectures are also used for D/A conversion. In switched-capacitor D/A converters, charge across unit capacitors is used as the *unit* for analog computation instead of current. Such architectures are popular in the design of a coarse D/A converters, also called *multiplying D/A converters* (MDACs) in pipelined A/D converters. Such architectures are introduced in another section on pipelined converters. A resistor ladder architecture uses voltage drop across the *unit* resistors as a basic *unit* for analog computation. More information about resistor ladder DACs and switched capacitor DACs can be found in the literature [1,11,14].

For most applications, the main performance measure for a D/A converter is its spurious-free dynamic range (SFDR). The SFDR measures the ability of the D/A converter to suppress the spurious harmonic tones generated as a result of circuit and system nonidealities. In case of current-steering D/A converters, the SFDR is limited by the matching of the unit current sources. Higher dynamic range is usually achieved through the use of dynamic element matching techniques discussed in brief toward the end of this section. There are three types of current steering D/A converters: binary-coded current steering DACs, thermometer-coded current steering DACs, and segmented current steering DACs. A conceptual binary-coded current steering DACs is shown in Fig. 2.

The binary DACs are not popular for high-resolution applications. This is because of the nonmonotonicity introduced due to current mismatch and momentary glitches during code transitions. Nonmonotonicity occurs because the amount of mismatch introduced by switching in of a new set of current sources for one LSB increase in

the input is greater than one LSB with an opposite sign. This causes the output to be nonmonotonic for increasing input. Glitches are another source of dynamic errors and are usually dominant during the worst-case code transition when input changes from 011...1 to 100...0. Because of finite delay in the ON time of the switches and mismatch therein, the MSB switch may turn on before (MSB goes from 0 to 1) the LSB switches (LSBs go from 1 to 0), causing a momentary output of all 1s. This glitch is equal to half the full scale and lasts as long as the delay mismatch between the MSB and the LSB switches. Such glitches are unacceptable for high-performance D/A converters since they affect the SFDR of the D/A converter.

The thermometer-coded D/A converter does not have the limitations described above. In a thermometer code D/A converter, all the current sources are of unit value, and are controlled by a monotonic thermometer code. A binary to thermometer digital logic is used to generate a thermometer code. Since an LSB increase in the digital input corresponds to a simple addition of another unit current source to the output, the monotonicity is guaranteed. Moreover, the glitch is completely eliminated as just one current source is switched on or off for one LSB change in the input. However, the main problem in a thermometer-decoded D/A converter is the complexity in the layout that is needed in generating a thermometer code for high-resolution binary input. Moreover the number of unit current sources to be individually controlled by the thermometer code increases exponentially. In most implementations, a combination of binary-coded D/A converters and a thermometer-coded D/A converter is used. An example for a $(M+K)$ -bit D/A converter is shown in the Fig. 11. Such converters are called segmented current steering DACs. A careful RAM-like physical layout usually achieves compact implementation of the thermometer-coded array. A segmented array offers a compromise between the complexity of layout for a thermometer-coded array and the amount of manageable glitch area from a binary-coded array.

In all the current steering D/A converters, the mismatch in the current sources introduces a systematic error wherein, for the same input, the error introduced is

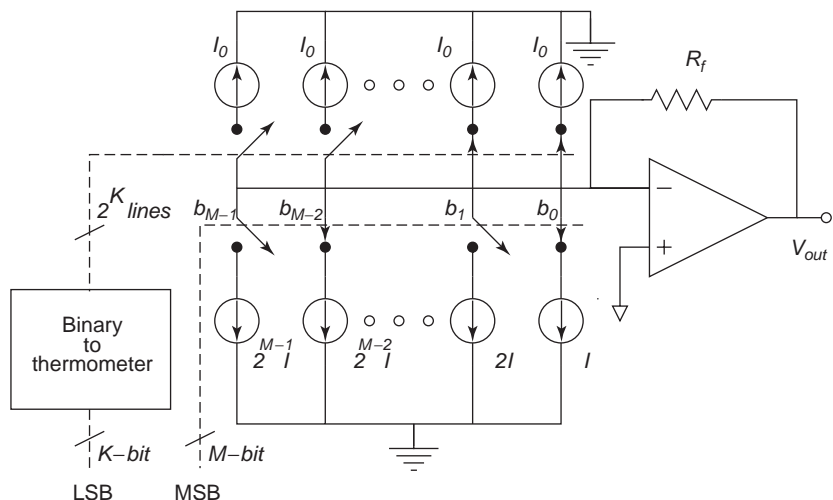

Figure 11. A popular segmented current steering D/A converter for $(N=M+K)$ -bit resolution. I is the unit current source, and currents are thermometer coded for the K most significant bits. The remaining M bits are implemented through a binary-weighted current steering D/A converter. The value of the unit current source in the binary-coded array is $I = 2^K I_0$, where I_0 is the unit current source for a thermometer array.

Figure 12. Data-weighted averaging illustrated for a 3-bit converter having eight unit current sources. The shaded squares correspond to the current sources chosen to generate the analog current-domain output. At time index 0, an input of 5 generates an output with a total mismatch error of $e_1 + e_2 + e_3 + e_4 + e_5$. At time index 1, the next four current sources (modulus 8) are chosen to generate an output with total mismatch error of $e_6 + e_7 + e_8 + e_1$. The next occurrence of 5 generates an output with total error of $e_2 + e_3 + e_4 + e_5 + e_6$, which is different from the previous occurrence of 5. A simple rotation scheme like this provides dynamic element matching through first-order shaping of the mismatch induced noise.

always the same because the same current sources are used in generating the output. Such systematic error introduces pattern noise in the form of spurious tones that appear as harmonics of the input signal frequency. Since harmonics are most undesirable in telecommunications and audio applications, techniques are needed to alleviate this problem. A dynamic element matching (DEM) techniques provide one such solution. Various DEM algorithms have been proposed in the literature offering different flavors, but their end goal is the same [14–17]. The main purpose of the DEM algorithm is to provide either random scrambling or permutation of the current sources such that the amount of error introduced by the D/A converter is not the same for the same input applied at two different time instants. This removes the systematic nature of the error signal and thus alleviate the problem of harmonics. However, depending on the schemes used, the harmonics either move at higher frequency or cause an increase in the noise floor (which can be tolerated in audio and telecommunication applications). A data-weighted averaging (DWA) technique proposed by Redman-White [14] is shown in Fig. 12. The technique provides first-order shaping of mismatch induced noise. However this technique still carries harmonics at higher frequency. Many variants of this technique have been suggested in the literature to avoid such tones [14,17].

4. OVERVIEW OF HIGH-SPEED A/D CONVERTER ARCHITECTURES

This section reviews the existing data converter architectures suitable for high-speed applications, with more emphasis on the analog-to-digital (A/D) converter design. A brief overview of digital-to-analog (D/A) converters is also provided for completeness. The architectures for the A/D converter discussed below are “flash,” “two-step,”

“interpolation,” “folding,” and “multistage” A/D converters. All the architectures discussed in this section pertain to single-channel ADC implementation. Time interleaved ADC perform parallel A/D conversion with a number of single-channel ADCs connected in parallel, offering high speed for a given resolution. However this is achieved at the cost of higher power consumption and increased area. Design issues related to time-interleaved A/D converters is discussed in detail in the literature [18], and is not discussed here. For communication applications, a behavioral survey and analysis of the A/D converters can also be found [19].

4.1. Flash Converters

Flash A/D converters are potentially the fastest ADCs and relatively easy to design compared to other architectures. Figure 13 shows the block diagram of a simple flash ADC. For an N -bit resolution, flash ADC consists of a resistor ladder that subdivides the main reference voltage into 2^N equally spaced voltage levels, and the $2^N - 1$ comparators to compare the input signal against these voltage levels. The output of a flash ADC is a thermometer code that is then passed on to the encoder to generate the binary output. Comparators usually consists of a moderate-gain preamplifiers followed by a regenerative-type latch to achieve high speeds. A sample comparator circuit is shown in Fig. 14. Transistors M_1 and M_2 along with the diode connected load form the input preamplifier. The preamplifier amplifies the difference between the input V_{in} and the

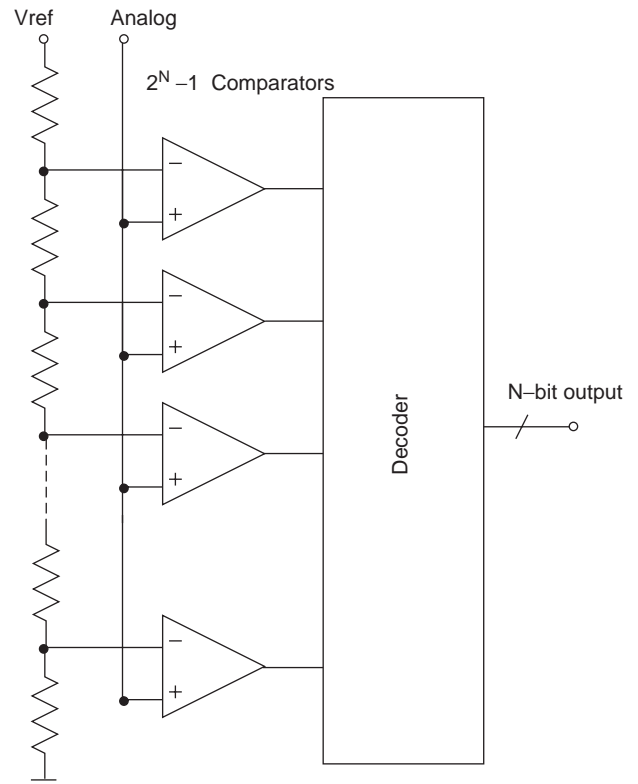

Figure 13. Conceptual flash A/D converter for an N -bit resolution.

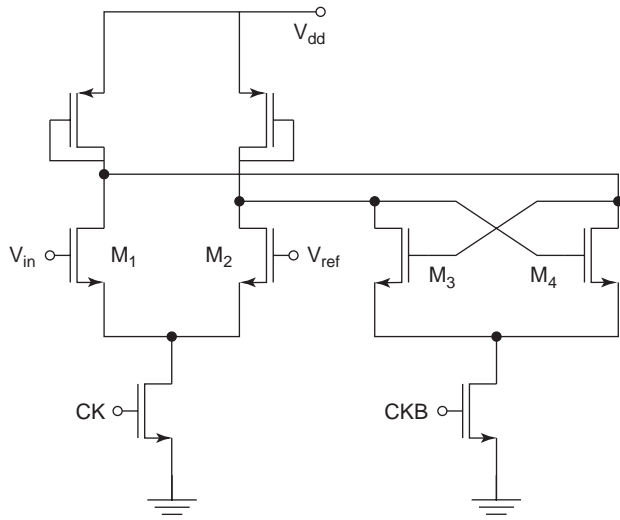

Figure 14. A simple comparator schematic: M_1 – M_2 form the input differential pair for preamplification. Transistors M_3 – M_4 form a positive-feedback latch for regeneration. CKB is opposite in phase to CK .

reference V_{ref} during clock phase CLK . This amplified difference is regenerated by the positive-feedback latch formed by transistors M_3 and M_4 , during clock phase $CLKB$. More comparator architectures can be found in the literature [1,11,18,20]. Flash ADC essentially performs distributed, parallel processing of the input signal, with no potential need for an explicit front-end sample-and-hold amplifier (SHA), resulting in the highest speeds among the data converter architectures. However, the number of components (e.g., resistors and comparators) increase exponentially with the overall resolution N of the converter. Also, higher resolutions are difficult to achieve from flash ADC because of various static and dynamic nonlinearities.

The main source of static nonlinearity in flash ADC appears from the offsets in the comparators and the resistor mismatch in the reference ladder. Input device transistors having large area is therefore needed to reduce the amount of offset, at the cost of increased nonlinear input capacitance. Large input capacitance at the input of the flash ADC also increases the load on the buffer driving the ADC, increasing its power consumption. Apart from large die-size and increased power consumption, flash ADCs also suffer from various issues such as metastability, kickback noise, slew-dependent sampling point, and clock jitter [1]. Metastability arises when the input to the flash A/D converter is very close to one of the comparator thresholds, which results in long settling times to regenerate the outputs to logic levels. This causes indeterminate latch outputs that are decoded incorrectly to give erroneous digital outputs. Metastability can be removed through gray coding as an intermediate step between the thermometer and binary codes [1]. Sparkles are also a source of static nonlinearity that arise directly from resistor mismatch and comparator offsets. Sparkles are caused when the comparator gives an *out-of-sequence* zero instead of a one due to these offsets. It is also caused by mismatch in

the sampling instants of the preamplifiers in the comparator array. Such sparkles can also be caused by slew-dependent sampling points. This occurs for rapidly varying input signals due to finite time between the tracking and the latching phase for certain implementations of the comparator. The rapidly varying input signal at the preamplifier input can cause the comparator to change its decision erroneously during the finite time between the latch phase and track phase. Such sparkles are removed through *bubble correction* in the thermometer to binary encoder. However, *bubble correction* can detect and correct for only a limited number of occurrences of sparkles. Gray-coding provides a soft degradation in performance for increasing number sparkles in the thermometer code and is therefore used in most flash A/D converter implementations. The slew-dependent sampling point and clock jitter can be minimized through the use of a dedicated sample and hold in front of the flash ADC at the expense of more power and area.

Two-step converter architectures trade speed for lower power consumption, small real estate, and lower input capacitance. Alternate architectures such as interpolation and folding maintain the one-step distributed nature of flash A/D conversion, and reduce the power consumption and real estate requirement of the pure flash ADC by reducing the number of preamplifiers and the latches needed in the implementation. Interpolation and averaging have also been shown to improve the differential nonlinearity performance (DNL) of the ADC [1,18].

4.2. Two-Step Converters

Figure 15 shows a two-step ADC architecture that has relatively small die size and low power consumption compared to flash ADCs. In a two-step ADC, the coarse flash A/D converter produces the most significant bit (MSB) decisions and the fine-flash ADC produces the least significant bit (LSB) decisions. The coarse D/A converter generates the coarse analog estimate of the input that has been resolved by the coarse A/D converter. This estimate is then subtracted from the input to generate the residue to be processed by the fine-flash ADC. The residue of the first stage is same as the quantization noise of the first stage, which indicates the portion of the input that is not resolved by the coarse A/D converter. The digital output of the coarse and fine ADC can be added appropriately to give the final ADC output.

Comparing the number of comparators needed in the two-step architecture versus the flash architecture, we can see that significant area savings can be achieved. An 8-bit flash ADC will require 256 comparators, whereas a two-step ADC, with a 4-bit MSB stage and a 4-bit LSB stage, will need only 32 comparators, which is a significant savings in the area. However, the speed of the two-step converter is less than that of a pure flash A/D converter, due to additional delays introduced by the D/A converter and the subtractor. The throughput of the two-step can be made comparable to the flash A/D converter, by adding a sample and hold between the two stages for pipelining. Pipelining can be extended to more than two stages and is covered in detail in a section on multi-stage converters.

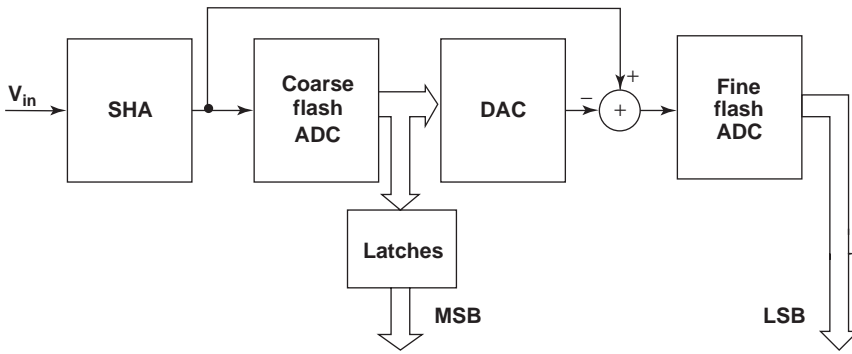

Figure 15. Conceptual schematic of a two-step A/D converter.

A main problem with the two step converter shown in Fig. 15 is that the residue generated for the fine-flash ADC is much smaller in magnitude, requiring that the coarse D/A converter and the subtracter be accurate to the overall resolution of the converter. To solve this problem, the residue output can be first passed through an inter-stage gain amplifier with a value of 2^M , where M is the resolution of the MSB stage, so as to make the signal swings same for both the coarse and fine ADCs. This also relaxes the offset requirement for the comparator of the fine-flash ADC. As in pipelined converter, if digital error correction is used, the accuracy requirements of the coarse A/D converter is greatly relaxed too. Some implementations of the two-step architecture can be found in the literature [21–23].

4.3. Interpolation-Based Flash Architectures

To reduce the input capacitance, power dissipation, and large area required from flash A/D converters, interpolation

can be used. The main idea behind interpolation is to use the linear region of the adjacent preamplifiers to generate additional thresholds for comparison, and hence reduce the number of preamplifiers needed for a given resolution [1,11,18,20].

In flash converters, the linearity of the preamplifier in the comparator is a nonissue, since only the sign of the amplifier outputs is needed for making a decision. However, in case of interpolating flash A/D converters, the linearity of the preamplifiers is needed at least over a small range of the input signal. The overall one-step nature of the flash conversion is still maintained in the interpolating flash A/D converters. Figure 16 shows the basic architecture for interpolation in flash A/D converters for a case of interpolation by 2. For this example, an additional output is generated as an average of the two adjacent preamplifier outputs using a resistor or capacitive dividers as shown in the figure. Since, the additional output resembles a preamplifier output for the threshold at the midpoint of the adjacent comparator thresholds, the number

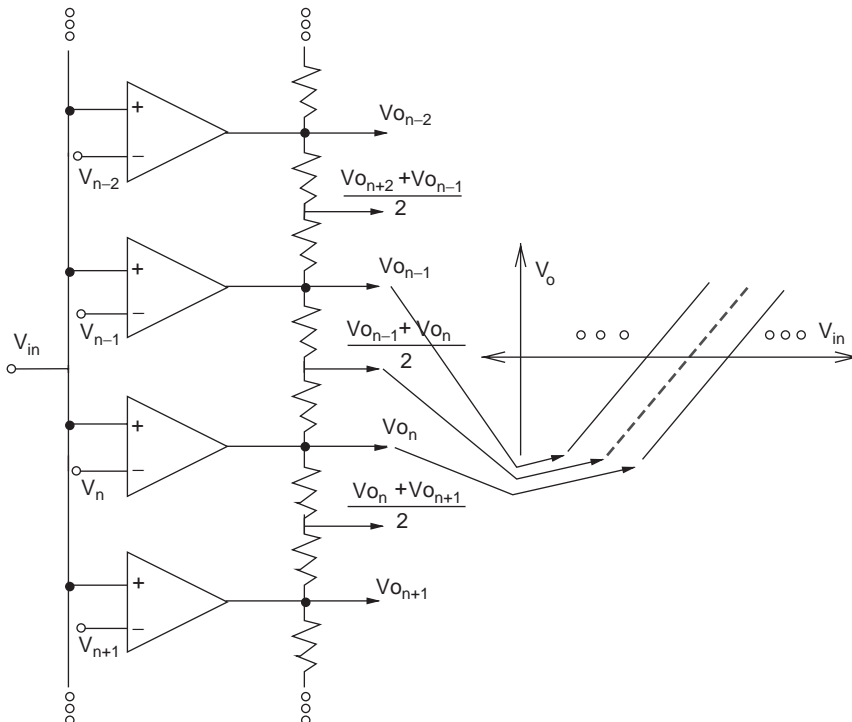

Figure 16. Conceptual schematic of an interpolating A/D converter using resistors. The interpolation is by 2. The dotted line indicates the interpolated waveform generated from the adjacent preamplifier outputs. The outputs V_o feed the latch to regenerate to logic levels (latch not shown).

of preamplifiers has been reduced by 2 for this flash A/D converter for the given resolution. Thus a reduction in the number of preamplifiers is achieved for a given resolution by interpolation. But the overall number of latches required is still the same as in a pure flash A/D converter. To further reduce component count and power consumption, interpolation is generally used alongside *folding* to enable further area and power savings [24]. Folding will be discussed in detail in the next section. Interpolation can also be pipelined to offset the lower speed and bandwidth attributed to resistive loads, to increase throughput [25].

Interpolation indicates that effective resolution of the flash A/D converter can be increased by interpolating between the outputs of the adjacent preamplifiers. An interesting property of the interpolation is that it improves the differential nonlinearity of the original flash converter. This is evident in Fig. 16, which shows that the effective interpolated reference threshold (level) generated lies between the thresholds of the adjacent preamplifiers, which guarantees that the differential nonlinearity for the interpolated threshold is bounded and is less than that of its pure flash counterpart. The reduction in DNL increases with the factor of interpolation. Since the accuracy of the interpolation depends on the linearity of the preamplifiers, a wider range between the preamplifiers would be required for a higher interpolation factor. Any nonlinearity when interpolating between preamplifiers not in the linear region, can cause deviation of the interpolated threshold from its ideal value or even a deadband around the interpolated threshold. The main problems of interpolation are the added time constants introduced by the interpolation resistors and capacitances from the following latches, sacrificing speed of conversion. The reduction in bandwidth scales approximately with the square of the interpolation factor, thereby making interpolation not feasible for factor exceeding 4. A conceptual schematic of a folding ADC is illustrated in Fig. 17.

4.4. Folding A/D Converters

In folding A/D converter (shown in Fig. 17), the speed trade-off of the two-step converter is mitigated by generating

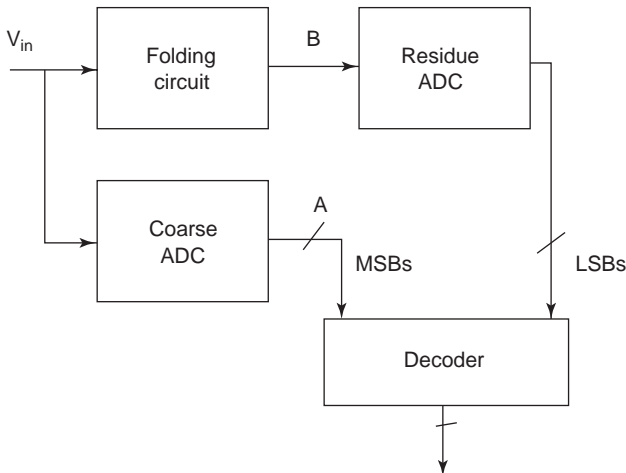

Figure 17. Conceptual schematic of a folding A/D converter.

the residue for the fine flash ADC of Fig. 15 in parallel using a separate analog preprocessor and is generated independent of the coarse MSB flash stage [1,11,26]. This eliminates the need for the D/A converter and a subtractor, resulting in power savings and reduced delay. The analog pre-processor uses a technique called “folding” to generate the residue independent of the MSB decisions. A simple voltage mode differential folding circuit for a folding factor of 4 is shown in Fig. 18. A folding factor is defined as the number of times the output changes sign (or direction) as the input V_{in} varies over its input range. The input-output characteristic of the folding circuit is also shown in Fig. 18. The ideal expected folder waveform is shown by the triangular dotted line. This is related to the sawtoothlike residue output of the first stage in the two-step ADC through simple reversal of signs and level shift operations. Hence, the folder output waveform can be used by the fine-flash stage instead of the sawtoothlike ideal residue output to generate LSBs. The operation of the circuit in Fig. 18 is given below. When the input is below V_{r1} , transistors $M_1, M_3, M_5,$ and M_7 are off and $M_2, M_4, M_6,$ and M_8 are on. A total of $2I_b$ flows through R_1 and $3I_b$ flows through R_2 , pulling down voltage at node $OUT -$ by $I_b R$ below the voltage at node $OUT +$. When input is equal to V_{r1} , equal currents $I_b/2$ flow through transistors M_1 and M_2 . However, transistors $M_3, M_5,$ and M_7 are still off and $M_4, M_6,$ and M_8 are still on. This, in essence, steers current $I_b/2$ from resistor R_2 to R_1 , causing equal currents of $2.5I_b$ to flow through both resistors and voltages at the node $OUT +$ and $OUT -$ are equal. As input is increased from V_{r1} , but maintained less V_{r2} , M_1 turns on and M_2 turns off. A total of $3I_b$ current now flows through R_1 and $2I_b$ flows through R_2 . This causes node $OUT +$ to be $I_b R$ lower than the node $OUT -$. As input approaches V_{r2} , M_3 begins to turn on and M_4 begins to turn off, causing the current to steer from R_1 to R_2 , and the output at node $OUT +$ and $OUT -$ changes direction. The circuit behaves in a similar manner as V_{in} is increased further. The number of times the output slope changes sign is equivalent to the number of times, the excess current steers between R_1 and R_2 . This number is also equal to the folding factor of the ADC.

It is to be noted for best performance, the folding circuit should have exactly one differential pair switch for any given input voltage, which mandates that the reference levels should be spaced far apart. However, this will cause saturation of the outputs for inputs closer to the midpoint of the two reference levels and none of the differential pairs would switch, resulting in deadband and inaccurate folder output around this input region. The main advantage of folding is that it maintains the one-step operation of flash, and does not need a subtractor and interstage D/A converter as in two-step converter, potentially achieving high speeds. Even though the sample-and-hold amplifier is not ideally needed for the folding A/D converter, it is used nevertheless to avoid input dependent errors resulting from clock skew and jitter. In spite of speed improvements, folding suffers from a few drawbacks. One of them is the increased frequency specifications for the design of the folding circuit. If a ramp input varying from 0 to full scale is applied to the folder with folding factor n , the output of the folder will change from V_{min} to V_{max} , n times.

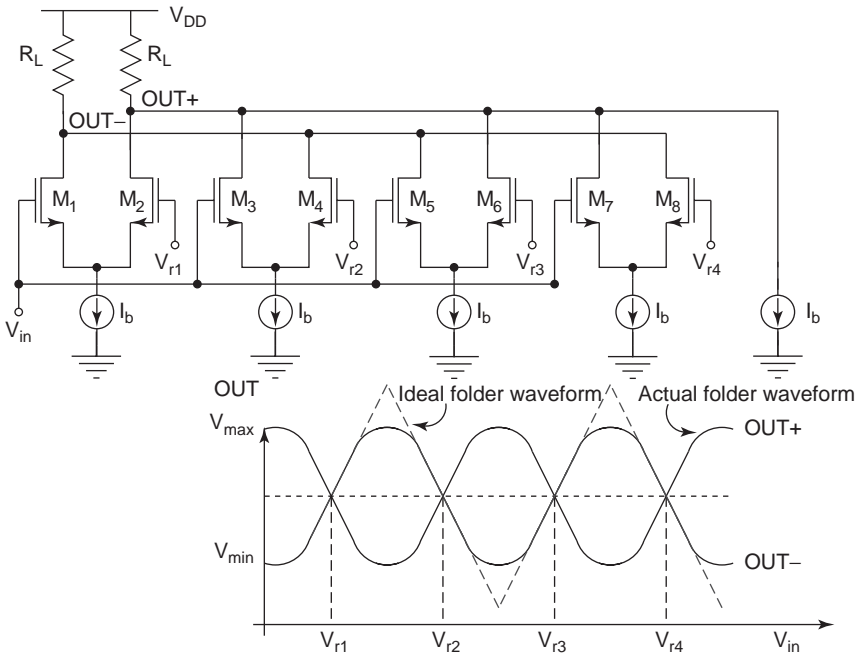

Figure 18. Differential folding circuit that has a folding factor of 4. The folder output feeds the latches that regenerate its output to logic levels. In case of folding and interpolating ADC, the outputs of the folder may be averaged by a resistor network.

This effect results in frequency multiplication by n . Hence the bandwidth and slewing requirements for the folder is n times the maximum allowable input frequency. Therefore, folding with a high folding factor is not effective at high operating frequencies. Another drawback of the folding is substantial nonlinearity in the folder waveform. Comparing the ideal dotted waveform and the actual waveform in Fig. 18, it can be seen that the output of the folder is grossly inaccurate toward the peaks V_{\max} and V_{\min} . The effect is similar to residue errors in a two-step converter or a pipelined converter which cause integral nonlinearity or differential nonlinearity. To alleviate this problem, double folding can be used, where the folding waveform is replicated with an additional shift of half the distance between the two reference levels. This ensures that in the region where one of the folders exhibit nonlinearity due to rounding effect, the other folder exhibits high linearity. Then depending on the input level an appropriate folder can be chosen.

The other main drawback of the folding architecture is the need for synchronization in absence of sample-and-holds between the MSB output and the output of the fine stage following the folder. Furthermore, any offset in the MSB stage may result in gross overall error with the magnitude as high as half of the full scale. Folding is usually used along with interpolation to further alleviate the linearity requirement of the folder and for obvious area savings due to reduced number of preamplifiers [1,24]. When interpolation is used between folder outputs for additional comparison thresholds, the nonlinearity of the folder output waveform does not directly affect the overall linearity and resolution of the converter, since the A/D converter extracts all its information from the location of the comparison thresholds (or zero crossings) and not from the amplitude of the folding waveform. However, this does not imply that the folder waveform can be nonlinear, since the accuracy of the comparison thresholds generated after

interpolation depends on the linearity of the individual folder waveforms over a large input range. The folding operation can also be pipelined to increase throughput and relax design requirements on the individual folders [6,27].

4.5. Multistage Converters

A multistage converter is a natural extension of the two-step converter discussed in Section 4.2, where more than two stages are used for digitization [1,11,18,28,29]. The second stage in the two-step ADC will also now consist of a sub-D/A converter and subtractor to generate a residue output that can be further digitized by the following stages that may appear identical to the first two stages. Use of an interstage gain amplifier relaxes the resolution requirement of the D/A converter and subtractor and also enables the use of the same flash ADC for all its stages. The bandwidth and the gain of the amplifier used in the MDAC is limited by the op-amp (operational amplifier) settling time, which depends on the speed and resolution specifications of the overall ADC. For an A/D converter without calibration, the finite op-amp gain needed is usually of the order of 2^{M+1} , where M is the number of remaining bits resolved by the following stages in the ADC. The overall speed of the multistage ADC reduces the conversion rate by the number of stages in the ADC, for the same reasons as in a two-step converter. This also puts stringent requirement on the timing skew for the subtractors for each stage. To alleviate this problem, a sample-and-hold amplifier is added at every stage to hold the amplified residue before passing on to the next stage [1,30]. This also increases the overall throughput of the system; the speed is limited by the delay of only one stage. Such an ADC is also called “pipelined” ADC because of the inherent concurrency of the operations. The pipelined converter is discussed in greater detail in the following section.

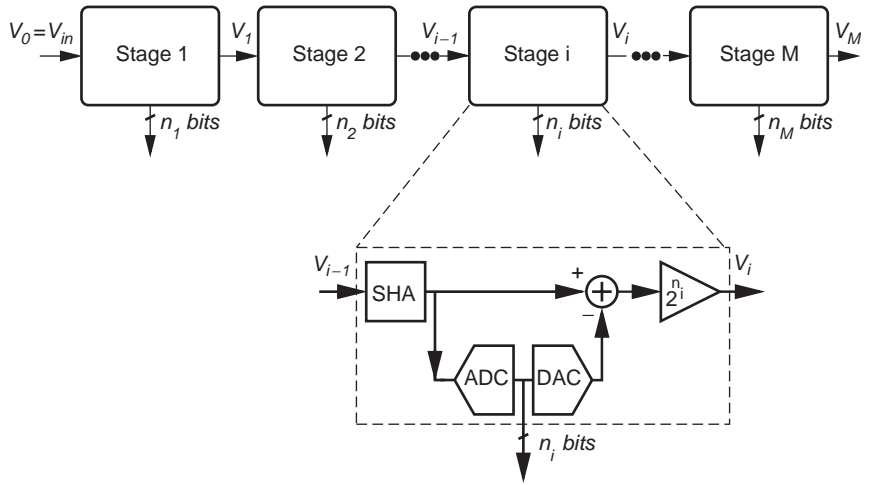

Figure 19. A generic block diagram of a pipelined ADC.

4.6. Pipelined Analog-to-Digital Converters

Pipelined A/D converters (ADCs) are multistage converters that use interstage sample-and-hold amplifiers to enable pipelining and concurrent processing of the input signal [1,18,31–33]. The residue output of one stage is kept on hold and the pipeline stage is not tied up for the fine LSB decisions to be carried out by the following stages. On the contrary, it can sample the next input data for conversion, while the previously held residue signal in the subsequent stage is digitized to make the LSB decisions. Thus pipelined A/D converters behave in concurrent manner and the overall data rate becomes independent of the number of stages. The overall speed is limited only by the speed of one pipeline stage, and therefore a pipelined converter can achieve close to the speeds achieved by flash ADC. Also, the complexity of the pipelined converter ideally scales linearly with the resolution desired, compared to flash which is exponentially related to the desired resolution. This is really beneficial for ADCs with resolutions greater than 8 bits at higher speeds.

5. BASIC PRINCIPLES OF PIPELINED A/D CONVERSION

A simplified block diagram of a multibit per stage pipelined ADC is shown in the Fig. 19. Each stage i resolves its input (or in other words, quantizes its input) into n_i bits of digital output using a coarse ADC (typically a flash-type converter) and then uses a coarse DAC, a subtractor, and an interstage gain amplifier of gain 2^{n_i} to amplify the unresolved input which we had defined as the residue. The operation of D/A conversion, subtraction, and amplification is designated as a MDAC (multiplying D/A conversion) operation. In switched-capacitor implementation, each stage has two nonoverlapping phases of operation: The sampling phase and the MDAC phase. During sampling phase, the residue output of the previous stage (or input if the stage in the first stage in the pipeline) is sampled and held later for subtraction. During this phase, a coarse decision is also made. During the MDAC phase, the MDAC operation is carried out. This is the time when the sampler of the following stage will be

active. The waveform for consecutive pipeline stages is shown in Fig. 20.

When stage 1 is sampling input sample for time index n , stage 2 is performing MDAC operation over the residue output of stage 1 corresponding to sample $n - 1$, and stage 3 is sampling this residue output corresponding to sample $n - 1$, and so on. A pipelined converter therefore exhibits a concurrent nature of processing of input, enabling high-speed operation. As mentioned earlier, the complexity of the pipeline, measured in the number of stages, scales linearly with the desired resolution and therefore pipelined A/D converters show substantial power and area savings for high-resolution applications at high speed.

In the pipeline architecture, as in all multistage ADC, the most significant bits are resolved by the stages earlier in the pipeline and the least significant bits are resolved later in the pipeline. A simple example for a pipeline would be a 1-bit per stage architecture ($n_i = 1$). Each stage of such a pipeline will consist of a simple 1-bit comparator as a coarse ADC, a multiply-by-2 DAC (MDAC) that performs coarse D/A conversion, subtraction, and interstage amplification by 2. A conventional switched-capacitor implementation of a one-bit pipeline stage is shown in Fig. 21. A single ended circuit is shown for simplicity. V_{ref} is the value of the reference voltage, where the complete resolvable input range is $\{-V_{ref}, +V_{ref}\}$ [18,34,35].

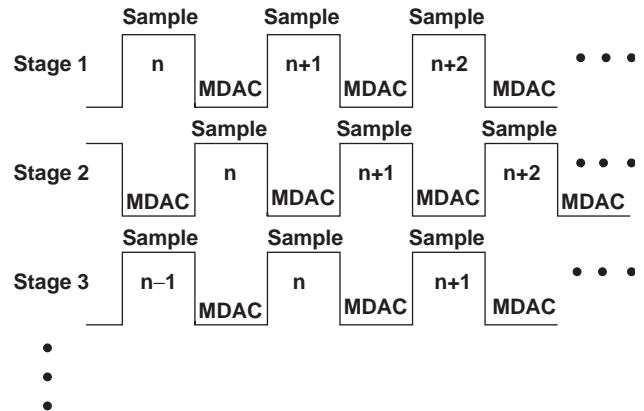

Figure 20. Timing diagram of a pipelined ADC.

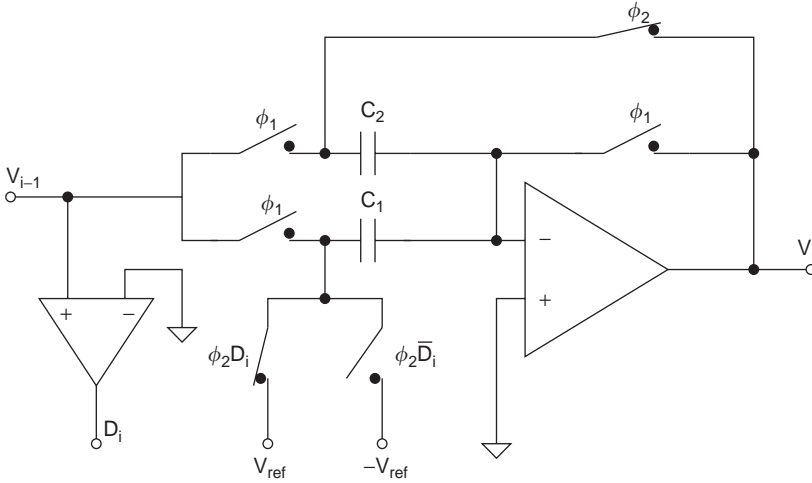

Figure 21. Switched-capacitor (SC) 1-bit pipeline stage (ϕ_1 -sampling phase, ϕ_2 -multiply-by-2/subtract phase).

Each stage consists of two nominally equal capacitors C_1 and C_2 , an operational amplifier (op-amp), and a comparator. During the sampling phase ϕ_1 , the comparator produces a digital output D_i by comparing its input V_{i-1} with comparator threshold V_{th}

$$D_i = \begin{cases} 1 & \text{if } V_{i-1} \geq V_{th} \\ -1 & \text{if } V_{i-1} < V_{th} \end{cases} \quad (8)$$

where $V_{th}(=0)$ is the threshold voltage of the comparator. The bipolar representation $\{-1, +1\}$ for the digital bit D_i is chosen instead of $\{0,1\}$ to facilitate analysis of the pipelined ADC for differential inputs. During the multiply-by-2/subtract (ϕ_2) phase, known as the MDAC phase, the circuit generates a residue voltage output V_i given by

$$V_i = K \left[\left(1 + \frac{C_1}{C_2} \right) V_{i-1} - \frac{C_1}{C_2} D_i V_{ref} \right] \quad (9)$$

$$K = \frac{A_0}{1 + \frac{C_1}{C_2} + A_0}$$

where the parameter K is an op-amp gain error coefficient (ideally unity) and A_0 is the finite op-amp gain. V_{i-1} is the residue output of the previous stage (for the first stage, the input is $V_0 = V_{in}$). The output residue voltage of the stage i is then passed to the next stage $i+1$, and the same operation continues. Ideally, we expect the residue output voltage to be

$$V_i = 2V_{i-1} - D_i V_{ref} \quad (10)$$

The ideal residue output of a one-bit pipeline stage is shown in Fig. 22, assuming $\{-V_{ref}, +V_{ref}\}$ as the resolvable input range. We see that as input is increased from $-V_{ref}$ to $+V_{ref}$, the output spans the full scale twice, once for the output $D_i = -1$ and for the output $D_i = +1$.

For a multibit per stage pipeline, consider a simple conceptual switched-capacitor implementation in Fig. 23, which indicates a n_i bit per stage output realization. When no error correction is used (see following section), a n_i bit per stage pipeline stage consists of a total of n_i capacitors $C_1, C_2, \dots, C_{2n_i}$. During the sampling phase the sub-ADC

compares the input with a set of reference voltages possibly a reference ladder to generate the raw bit decisions. At this time the input is also sampled across the 2^{n_i} capacitors. During the MDAC phase, one of the capacitors is connected across the operational amplifier, and the thermometer code corresponding to the raw bit decisions made is applied to the remaining capacitors. This produces an amplified residue output of this stage that will be processed by subsequent sections. The ideal expression for the residue output is given by

$$V_i = 2^{n_i} V_{i-1} - \sum_{k=1}^{k=n_i} 2^{(n_i-k)} D_{Sn_{i-1}+k} V_{ref} \quad (11)$$

The digital output of stage i is $\{D_i : i = Sn_{i-1} + 1, Sn_{i-1} + 2 \dots Sn_i\}$, where $D_{Sn_{i-1}+1}$ is the stage i MSB and D_{Sn_i} is the stage i LSB. Here the variable Sn_i indicates an index to conveniently tag the digital output of the stage i

Figure 22. Ideal residue output of a 1-bit pipeline stage.

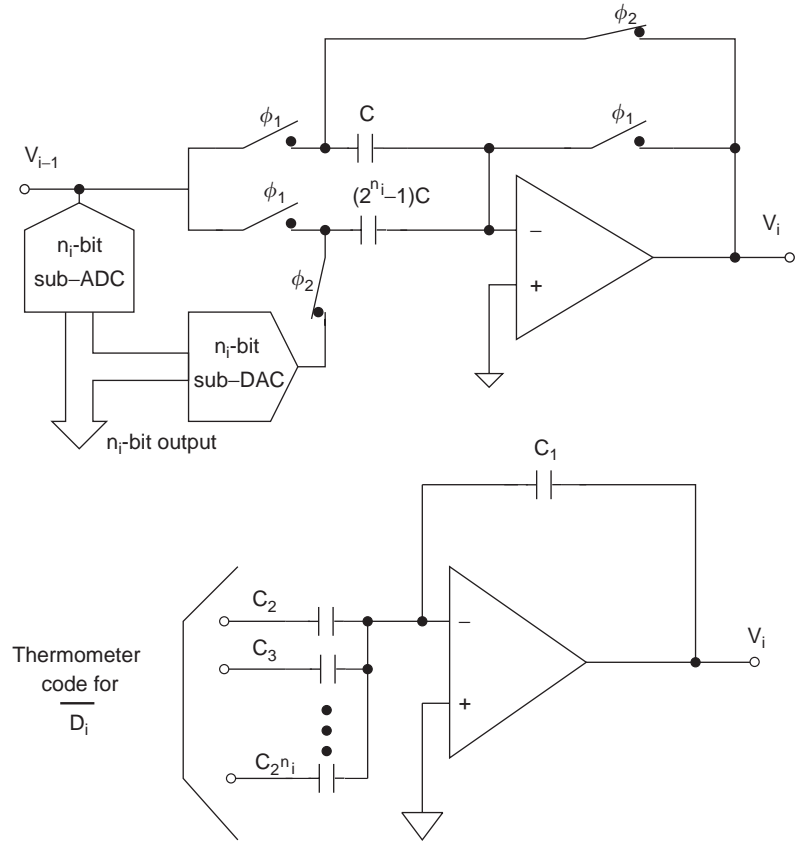

Figure 23. Example of a switched-capacitor (SC) implementation of a multibit pipeline stage.

and is given by

$$S n_i = \sum_{k=1}^{k=n_i} n_k \tag{12}$$

$$S n_0 = 0$$

The ideal residue output for a multibit pipeline stage looks similar to the one-bit case and is shown for a 2-bit pipeline stage in Fig. 24. The bipolar digital outputs for each region are also highlighted in the figure. The main points to note from the residue output plots for an ideal pipeline stage, is that the output spans the complete range of $\{-V_{ref}, +V_{ref}\}$, so that each stage input has the same dynamic range. This guarantees linearity for the complete pipelined converter. As is evident from the Eqs. (9) and (10) for a singlebit pipeline, the accuracy of a pipeline stage and hence of the overall converter depends on the accuracy of the residue output generated by the pipeline stage. We see that gain errors are introduced in the overall transfer characteristic because of the term K attributed to the finite amplifier gain and the term C_1/C_2 , which deviates from the ideal value of 1 because of poor capacitor matching. The same case is also valid for any multibit pipeline stage. For comparator offsets, the output of the pipeline stage will exceed the allowable input range of the following stage. This results in the *missing decision levels* in the overall ADC transfer characteristic. This is undesirable, since the information about the input is completely lost and cannot be recovered further. Other sources of errors due to capacitor ratio mismatch and finite amplifier gain

error result in *missing codes* in the overall transfer characteristics if the overall gain is less than nominal. Although this is undesirable, it is preferred over the case with missing decision levels, since the information about the input is not lost and can be recovered through calibration. Finally, it can also be seen that any nonlinearity in the operational amplifier will affect the linear output curve of the residue and contribute to the overall

Figure 24. Ideal residue output of a 2-bit pipeline stage.

INL of the ADC. These nonidealities along with errors due to finite amplifier settling and charge injection errors usually limit the overall resolution of the ADC to 8–10 bits without calibration in today's CMOS processes. Charge injection errors can be minimized using bottom-plate sampling techniques [11], and the effect due to comparator offsets can be mitigated through the use of error correction or redundancy [31]. This concept is discussed in the next section.

6. DIGITAL ERROR CORRECTION THROUGH REDUNDANCY

Nonlinearity due to comparator offsets can be mitigated through the use of redundancy [18,31]. For example, with one-bit error correction in a n_i bit per stage pipeline, the interstage gain is chosen as $2^{(n_i-1)}$ instead of 2^{n_i} allowing redundancy so that inputs closer to comparator thresholds that would possibly result in swings beyond the allowable input range can now be resolved by the following pipeline stages.

Consider the modified switched capacitor implementation that incorporates one-bit redundancy (Fig. 25). The stage now consists of two comparators with thresholds on either side of $V_{th} = 0$, one at $V_{ref}/4$ and the other at $-V_{ref}/4$. Also, three different D/A converter outputs are used during the MDAC phase. The main idea behind redundancy is to let prevent the overrange of the residue output when the input is between the two thresholds. This prevents any missing decision levels and improved DNL performance. The expression for the residue output of this 1.5-bit pipeline stage is

$$V_i = 2V_{i-1} - D_i V_{ref} \quad (13)$$

where D_i is just a conceptual term that can have one of three values $\{-1, 0, 1\}$ instead of the previous bipolar representation $\{-1, 1\}$.

Table 1 suggests the relationship between D_i and D_{i1} and D_{i2} . The residue output of a 1.5-bit pipeline stage is shown in Fig. 26. The transfer characteristic of a 1.5-bit pipeline stage suggests that comparator offsets of up-to

Table 1. Relationship between D_i , D_{i1} , and D_{i2}

D_i	D_{i1}	D_{i2}
-1	-1	-1
0	+1	-1
+1	+1	+1

$|V_{ref}/4|$ can be tolerated without the residue exceeding the following stages resolvable input range.

The digital outputs of individual pipeline stages are now combined by overlapping the adjacent bits as shown in the Fig. 27. A unipolar representation is used for this illustration where the digital output is 00 when input is less than $-V_{ref}/4$, and 01 when the input is between $-V_{ref}/4$ and $+V_{ref}/4$ and 11 when input is greater than $+V_{ref}/4$.

However, to correct for errors due to capacitor ratio mismatch and finite amplifier gain, calibration schemes (also called error correction schemes in the literature) have to be used. Redundancy will not suffice enough to guarantee a good linearity from the converter, since the shape of the curve still depends on the capacitor ratio mismatch and the finite amplifier gain. Calibration has become an essential building block in today's pipelined data converters designed in deep-sub-micrometer CMOS due to poor technology parameters for realization of analog components such as capacitors, amplifiers, and reference circuits. Without calibration, the resolution of the data converters is limited to 8–10 bits for speeds under 100 MHz in CMOS.

6.1. Linearity Improvement Techniques

Data converters designed in digital CMOS technology for low-cost implementations and to facilitate higher integration do not offer high resolution because of poor component matching, low amplifier gains attributed to lowering supply voltages, charge injection errors, and offset errors. For example, in case of a current steering D/A converter, it is necessary that all the unit current sources be matched to each other. Otherwise, the D/A converter will exhibit nonuniform output transitions, giving rise to static

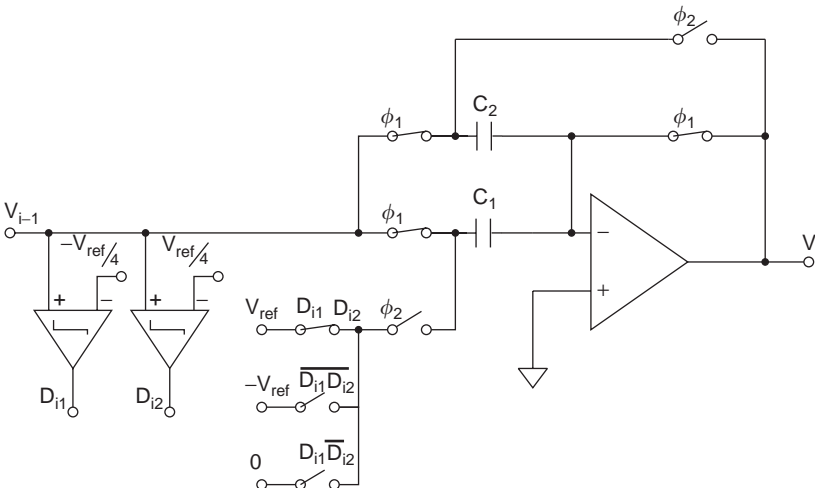

Figure 25. A 1.5-bit pipeline stage that exhibits one-bit redundancy.

Figure 26. A 1.5-bit pipeline stage that exhibits one-bit redundancy.

nonlinearities that are measured as differential nonlinearity (DNL) and integral nonlinearity (INL) errors. These errors result in poor spectral performance measured by the spurious-free dynamic range (SFDR). When such nonideal D/A converters are used in oversampling A/D converters, the mismatch error adds directly at the input and in most implementations, and is not noise-shaped, resulting in spurious tones in baseband. The nonideal D/A converter used in multibit per stage pipelined A/D converter architectures also gives rise to spurious tones and therefore degrades the dynamic range of the overall A/D converter. Similar issues due to mismatch, offsets, charge injections, and finite amplifier gain errors arise in all architectures for data converters. Therefore, precision techniques need to be developed at both circuit and system levels to improve the resolution performance of the A/D converters.

Dithering and dynamic element matching are two popular techniques that have been widely used to improve the accuracy and the linearity of the converter. *Dithering* involves addition of a pseudorandom dither signal at the input that is either subtracted digitally from the output (a subtractive dither scheme) or not subtracted from the output (an additive dither scheme). The overall result in

both cases is an average linearization of the overall converter transfer characteristic, especially around sharp discontinuities [36]. The linearity improvement depends on the magnitude of the dither and that of the discontinuity. A subtractive dither scheme enables high linearity improvement, compared to the additive dither scheme. However, both cases suffer from reduced input dynamic range. *Dynamic element matching* (DEM) techniques, on other hand, perform permutation of the unit elements to convert the systematic error into an error spectrum that is either shaped out of the band of interest or contributes only to increased noise floor. Any spurious tones due to systematic error is removed through DEM schemes. Various DEM schemes have been proposed in the literature depending on the application [2,11,18,36–39].

Self-calibration is another way to push the resolution performance of the data converters. Many self-calibration schemes have been proposed in the literature for pipelined and multistage ADC [34,35,40–47]. Some of these schemes are implemented in analog domain (e.g., capacitor error-averaging [48], capacitor trimming [46]), and some of them are implemented in digital domain [40–42]. Capacitor error averaging involves mitigating the effect of the capacitor mismatch through averaging of the pipeline output over all permutations of the capacitors. This yields better overall accuracy at the cost of lower speed and increased complexity. Self-trimming of the elements that exhibit mismatch also improve the overall accuracy, but the techniques are usually expensive and can be calibrated only once.

Digital self-calibration schemes have proved to be more robust compared to analog self-calibration schemes [35,40,42] because of their ease of implementation in today’s CMOS technology and lower cost. Most of the digital schemes employ techniques to correct for errors by measuring code error transitions in the ADC transfer characteristics. This is achieved by providing appropriate input stimuli [41,42] to the ADC during the calibration phase. The scheme proposed in Ref. 34 performs calibration of both capacitor ratio mismatch and finite amplifier gain in the analog domain for a pipelined A/D converter. It performs continuous calibration by using an extra pipeline stage that is constantly being calibrated in the background while the ADC is in use. Once the extra stage is calibrated, it replaces an active pipeline stage that will be taken out for calibration. Such techniques involving redundant computation show promise for future calibration schemes in emerging CMOS technologies. A few promising digital calibration schemes based on adaptive signal processing techniques have been proposed to correct for errors introduced by finite amplifier gain and capacitor ratio mismatch in a pipeline stage [7,35,44]. One of these schemes needs a separate calibration signal to be added to the input for background calibration, through an adaptive technique for measurement of the gain error introduced for the calibration signal. This technique, proposed in Refs. 35 and 44, adaptively corrects for the residue errors in the pipeline with the use of a slow high-resolution ADC (typically a $\Sigma - \Delta$ ADC) for calibration. This is achieved at the cost of slight increase in hardware and power consumption.

Figure 27. A 1.5-bit pipeline stage that exhibits one-bit redundancy.

Figure 28. An oversampled analog-to-digital converter. The noise-shaping stage operates at the oversampled clock rate, producing the digital output y that is decimated (filtered and downsampled) to a lower clock rate.

7. OVERSAMPLED CONVERSION

Like Nyquist-rate converters, oversampled converters assume the general form of Fig. 3² in which amplitude quantization is also referred to as *noise shaping*. In this section, we cover the basic topologies and methods for achieving noise shaping of analog and digital signals.

An oversampled A/D takes the form shown Fig. 28. Here, the noise-shaping stage is implemented using mainly analog circuitry. Configured as a D/A, the oversampled converter appears as shown in Fig. 29. The noise-shaping stage is completely digital in this system, and therefore any deviation from ideal performance can usually be attributed to imperfections in the Nyquist-rate D/A [17].

All oversampled converters in popular use are derived from the delta-sigma (or sigma-delta) modulator (Fig. 30). It is no wonder, then, that the terms “oversampled” and “delta-sigma” have become interchangeable. A readable and general overview of discrete-time delta-sigma modulation can be found in Ref. 49. Although oversampled converters are often based on a single delta-sigma modulator, it is also possible to interconnect multiple delta-sigma modulators to form a *cascaded* design [2,17]. Well-known variants of the cascaded form include the MASH and Leslie-Singh architectures [50,51]. It is possible to achieve greater SNR performance at lower oversampling ratios with cascading; a more detailed discussion of this approach is provided below.

We note that for oversampled A/D conversion, the delta-sigma modulator is implemented in mixed-signal form, as depicted in Fig. 31. The quantizer block is comprised of a simple Nyquist-rate A/D (generating the output y) and a complementary Nyquist-rate D/A (providing a suitable feedback signal) in cascade. Often, the D/A block is implemented as a thermometer-coded current steering design with dynamic element matching. The use of element matching techniques is necessary to avoid SNR degradation from nonlinearities in the D/A characteristic. For oversampled D/A conversion, the delta-sigma modulator is implemented in purely digital form. Thus the modulator loop itself can be expected to perform ideally. However, the problem of mismatch is now relegated to the cascaded Nyquist-rate D/A, which must be sufficiently linear to allow the oversampled converter to achieve maximum resolution.

Oversampled converters can be developed using a wide range of architectures and technologies. A survey of state-of-the-art oversampled high-speed analog-to-digital converters is provided in Table 2. The results are sorted by

²The exception is the case of continuous-time delta-sigma modulation (in which H is realized with continuous-time analog circuitry) in which the sampling operation and amplitude discretization occur simultaneously.

signal bandwidth in descending order. With the exception of the technique employed by Paul et al. [52], each design employs a conventional delta-sigma modulator architecture. We see that CMOS oversampled A/Ds now process megahertz-range bandwidths, attaining resolutions of up to 15 bits. Specifically, SNDRs greater than 80 dB are achieved using the basic formula of discrete-time loop filtering and multibit quantization in a cascade (MASH) configuration.

7.1. Design of the Delta-Sigma Modulator

In delta-sigma D/A conversion, the noise shaping stage is implemented digitally, and the system is described in discrete time. In A/D conversion, the delta-sigma modulator is a mixed-signal system, and either continuous-time or discrete-time design descriptions for the loop filter are used.³ We shall present much of our discussion in a manner that is applicable to either discrete- or continuous-time by employing operator notation; for instance, the symbol H denotes a linear filter that may be considered to be either $H(z)$ or $H(s)$, depending on the context.

The design of the delta-sigma modulator typically proceeds in the frequency domain. Using the pseudolinear model of Fig. 32, the operation of the delta-sigma modulator can be described mathematically as follows:

$$y = G_s r + G_n e_Q \quad (14)$$

where G_s and G_n denote the signal and noise transfer functions, respectively. Both transfer functions are shown conceptually in Fig. 33, where it is seen that, within the designated signal band of the modulator, the magnitude of G_s is roughly unity, while the magnitude of G_n approximates 0 (and describes the noise shaping characteristic of the loop).

The design of the delta-sigma modulator begins with the selection of an appropriate noise transfer function. The loop filter H is in general a two-input system as shown in Fig. 30. Using the expressions for loop filter output

$$\sigma = H_1 r + H_2 y \quad (15)$$

(where H_1 and H_2 describe the responses of H to its first and second inputs, respectively) and overall output according to the pseudolinear model

$$y = e_Q + \sigma \quad (16)$$

³Note, however, that although the modulator loop filter may be described in continuous time, the delta-sigma modulator is itself a sampled-data system. Therefore, the overall system must be converted to discrete time as described in Ref. 56 to obtain a correct description of modulator operation.

Figure 29. An oversampled digital-to-analog converter. The digital input signal is first upsampled to the oversampled data rate before being encoded by the purely digital noise-shaping stage.

we obtain the closed-loop expression for y as follows:

$$y = H_1(1 - H_2)^{-1}r + (1 - H_2)^{-1}e_Q \quad (17)$$

Therefore, the signal and noise transfer functions are given by $G_s = H_1(1 - H_2)^{-1}$ and $G_n = (1 - H_2)^{-1}$. Special attention is paid to the selection of G_n since the level of noise attenuation dictates overall performance and modulator stability [57]. A G_n that exhibits an aggressive profile can drive the system into instability. As a rule of thumb, the peak gain of G_n should be less than 1.5 for single-bit quantization to reduce the likelihood of instability. If finer quantization is employed, the noise transfer function can be more aggressive. Although a sufficient condition exists to ensure stability in the multibit case [58], it is thought to be too conservative, and most designers rely on simulation to assess modulator robustness. Nevertheless, it is important that simulation not be misconstrued as proof of stability, and the designer should anticipate the onset of instability, however infrequent.

A design recipe for achieving any desired SQNR (signal-to-quantization-noise ratio) has been provided [57]. A toolbox developed by Schreier [59] based on Matlab provides an outstanding array of scripts to assist the designer from noise transfer function design to full block-level realization, and is highly recommended. Using this toolbox, we generated the plots of Figs. 34 and 35. These graphs indicate the performance achievable with single- and multibit designs, respectively, in terms of peak SQNR versus (normalized) signal bandwidth. Various orders are shown and optimum noise transfer function zero placement has been used.

The realization of the loop filter H can proceed in several ways; a popular continuous-time structure is shown in Fig. 36. In the continuous-time case where there is significant parametric uncertainty (brought on by mismatch between active and passive circuit elements), loop filter sensitivity is an important issue, particularly for higher-order designs. Filter tuning may be necessary to mitigate

Figure 30. The basic delta-sigma modulator. The output y is a noise-shaped version of the input r . The *quantizer* element is a clocked device, and the *loop filter* is a linear time-invariant (LTI) system. The clock rate of the system is often many times higher than the specified signal bandwidth. For D/A conversion, the modulator is implemented entirely in digital form; for A/D converters, the modulator is a mixed-signal loop.

the effects of sensitivity [60]. The main advantage of using more sensitive realizations is that some savings in hardware complexity can be achieved. A thorough treatment of discrete-time loop filter realizations is provided in the documentation accompanying the toolbox by Schreier [59].

Cascaded architectures use multiple delta-sigma modulators to achieve greater attenuation of quantization noise without the need to increase oversampling ratio. Figure 37 shows the general form of a cascaded noise-shaper. The main challenge in the design of oversampled A/Ds is that the transfer functions $G_i(z)$ must match quantities that are realized with analog hardware (as shown below). For oversampled D/As, mismatch is not an issue since all blocks (including the modulators) are realized digitally and perfect matching is possible. The analysis in the case of a cascade of modulators proceeds as follows. The outputs of the first, second, and third modulators can be written as:

$$y_1 = H_{11}(1 - H_{12})^{-1}r + (1 - H_{12})^{-1}e_{Q1} \quad (18)$$

$$y_2 = H_{21}(1 - H_{22})^{-1}e_{Q1} + (1 - H_{22})^{-1}e_{Q2} \quad (19)$$

and

$$y_3 = H_{31}(1 - H_{32})^{-1}e_{Q2} + (1 - H_{32})^{-1}e_{Q3} \quad (20)$$

where H_{ij} denotes the j th loop filter transfer function associated with modulator $i \in \{1,2,3\}, j \in \{1,2\}$. The overall noise-shaped output can be written as

$$y = y_1 - G_1y_2 - G_2y_3 \quad (21)$$

$$\begin{aligned} &= H_{11}(1 - H_{12})^{-1}r + [(1 - H_{12})^{-1} - G_1H_{21}(1 - H_{22})^{-1}]e_{Q1} \\ &\quad - [G_1(1 - H_{22})^{-1} + G_2H_{31}(1 - H_{32})^{-1}]e_{Q2} \\ &\quad - G_2(1 - H_{32})^{-1}e_{Q3} \end{aligned} \quad (22)$$

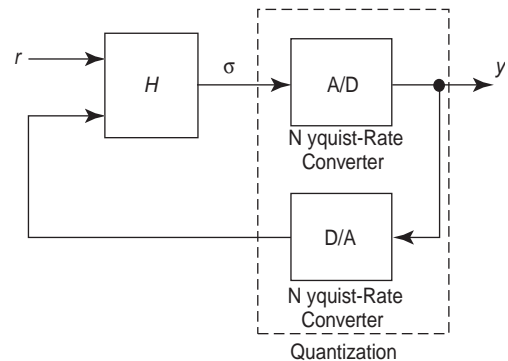

Figure 31. A mixed-signal delta-sigma modulator used in oversampled A/D conversion.

Table 2. Reported High-Speed Oversampled Architectures for A/D Conversion^a

Peak SNDR (dB)	Signal BW, OSR	Technology	Architecture, Quantization Supply, Power Consumption	Ref.
43	990 MHz, 9	InAlAs/InGaAs, bipolar	CT ^b 2nd-order lowpass, single-bit, 8 V, 1.5 W	[53]
55	50 MHz, 32	InP, bipolar	CT 2nd-order lowpass, single-bit, ± 5 V, 1 W	[54]
71	9 MHz, 1	1.2- μ m-Si CCD-CMOS	Oversampled pipelined lowpass, multibit, 5/4/3.3 V, 324 mW	[52]
87	2 MHz, 16	0.5- μ m-Si CMOS	SC ^c cascaded (2-2-1) lowpass, multibit, 2.5 V, 150 mW	[2]
90	1.25 MHz, 8	0.5- μ m-Si CMOS	SC cascaded (2-1-1) lowpass, multibit, 5 V, 270 mW	[3]

^aThe results indicate the typical performance possible with conventional delta-sigma modulation techniques.

^bContinuous time.

^cSwitched-capacitor.

from which we see that if the matching conditions

$$G_1 = (1 - H_{12})^{-1}[H_{21}^{-1}(1 - H_{22})] \quad (23)$$

and

$$G_2 = -G_1(1 - H_{32})^{-1}[H_{31}^{-1}(1 - H_{32})] \quad (24)$$

are met, then y becomes

$$y = H_{11}(1 - H_{12})^{-1}r - G_2(1 - H_{32})^{-1}e_{Q3} \quad (25)$$

where e_{Q3} is a residual error that is, in general, strongly attenuated relative to the original single-stage quantization error, e_{Q1} .

Note that the conditions (23) and (24) can imply that the digitally realized transfer functions G_1 and G_2 match responses of filters made from analog components. Thus, in the case of cascaded oversampled A/Ds, careful analog circuit design or the use of adaptive filtering may be necessary to ensure that (23) and (24) approximately hold. In spite of this potential shortcoming, cascaded architectures have achieved the highest performance levels in practice (as shown in the literature). Another distinct advantage of using cascaded noise shaping is that stability may be guaranteed if delta-sigma modulators of order ≤ 2 are employed throughout the design.

7.2. Architectural Choices

We may consider various options in the design of delta-sigma modulators, including the choice of quantizer

Figure 32. The pseudolinearized model of the delta-sigma modulator. By using a uniformly distributed random variable e_Q , it is possible to approximate the behavior of the actual delta-sigma modulator.

size, higher-order loop filtering, and continuous-time techniques.

7.2.1. Single-Bit or Multibit Quantization? In general, the in-band noise power for multibit mixed-signal delta-sigma modulators is dominated by component nonidealities, and not by quantization noise. The mismatch amongst elements comprising the quantizer D/A is a dominant noise source (even if mitigated by the use of dynamic element matching). Therefore, multibit modulators are used for higher-speed applications in which lower oversampling ratios mean that the ideal SQNR (signal-to-quantization-noise ratio) of the architecture is moderate (generally less than 90 dB). On the other hand, with the perfect linearity of a single-bit quantizer, single-bit delta-sigma modulators can come much closer to ideal SQNR performance at high oversampling ratios. Thus they are used for narrowband applications (particularly digital audio) in which high resolution is a priority.

Both single-bit and multibit delta-sigma modulators are susceptible to spurious tones, albeit for different reasons. In the single-bit case, dithering as described by

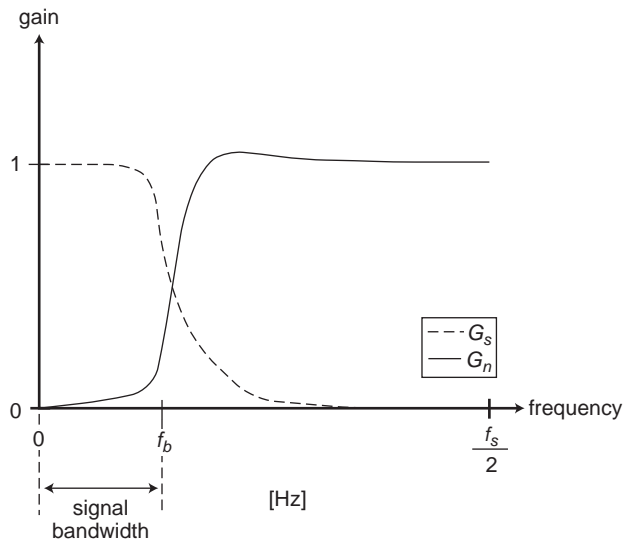

Figure 33. Depictions of modulator noise transfer function (G_n) and signal transfer function (G_s).

Figure 34. Resolution of single-bit delta-sigma modulators of various orders versus sample-rate-normalized signal bandwidth. The noise-transfer function out-of-band gain is set to 1.5 for all designs.

Norsworthy [61] can be applied to diffuse tones with only a slight impact on dynamic range. Multibit modulators can exploit various techniques for randomizing the selection of D/A elements. This helps to minimize tones generated by any periodicities in the dynamic element matching strategy.

In the case of oversampled D/A conversion, the delta-sigma modulator is implemented digitally; therefore, there are no linearity issues associated with a multibit quantizer. However, a single-bit architecture can be advantageous because the digital circuitry is simplified.

Multiplication of a multibit filter coefficient by a single-bit quantity is trivial. An additional complication with multibit delta-sigma D/A converters is that the noise-shaping loop is typically followed by a Nyquist-rate D/A. Therefore, because the Nyquist-rate D/A appears “open loop” in cascade with a digital delta-sigma modulator, it must be highly linear.

7.2.2. Higher-Order/Coarser Quantizer or Lower-Order/Finer Quantizer? A current trend in broadband CMOS delta-sigma A/D converters is the use of low (typically less

Figure 35. Resolution of 3-bit delta-sigma modulators of various orders versus sample-rate-normalized signal bandwidth. The noise transfer function out-of-band gain is set to 6.0 for all designs.

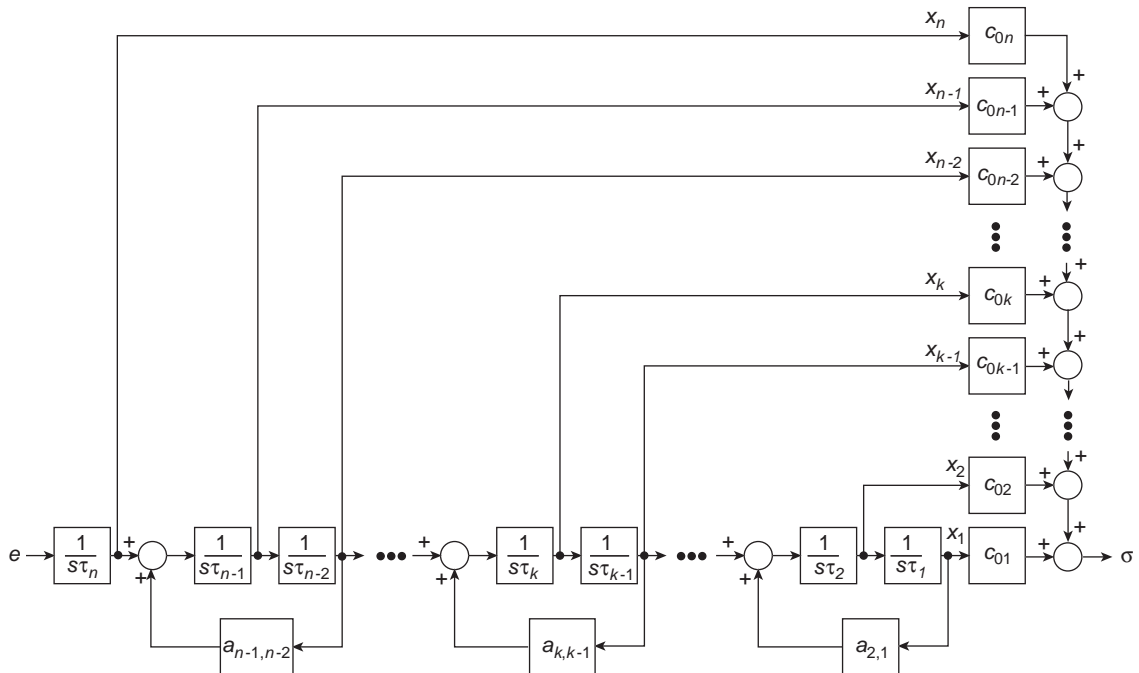

Figure 36. A common loop filter realization for continuous-time delta-sigma modulators (odd order case). If n is even, the leftmost integrator is omitted.

than fourth) order loop filters with finer quantization (up to 5 bits). Such a combination often makes sense because stability is more manageable at lower orders, and greater signal bandwidths can be used because of the SNR “boost” provided by a larger quantizer. A given peak SQNR specification may be achieved either by using a loop filter with sufficiently high order (given a quantizer of fixed size), or by employing a quantizer with sufficiently many bits (given a fixed order for H). The choice is dictated by such considerations as power consumption, chip area, or the designer’s own expertise. While higher-order loop filters may result in more analog power consumption, the use of a coarse quantizer helps to conserve digital power consumption at higher sampling rates. Area usage can increase exponentially with the number of quantizer bits; in spite of this, a number of designers have managed to produce compact multibit designs.

7.2.3. Continuous-Time or Discrete-Time H ? The use of continuous-time loop filtering provides two primary advantages: (1) the maximum clock rate (and hence the oversampling ratio) of the system can be much higher than with discrete-time loop filtering and (2) a sample-and-hold circuit preceding the noise shaping stage of the converter is unnecessary. With discrete-time designs based on switched-capacitor technology, the unity-gain bandwidths of the integrator opamps are required to be between 3 and 5 times the sampling rate of the system [11]. This can place a restrictive upper bound on the maximum rate with which the modulator can be clocked. In contrast, the maximum sampling rate of continuous-time modulators is determined by

considerations of excess loop delay (for which compensation is possible) and quantizer metastability [62,63], which are, in general, less severe constraints on the maximum sampling frequency. The sampling operation of a continuous-time modulator occurs at the quantization stage, therefore, a sample-and-hold circuit preceding the modulator is not needed. However, because the signaling scheme of the modulator is in continuous time, any quantizer sampling imperfections (sampling jitter or quantizer metastability), can severely degrade SNR performance. Quantizer metastability is usually the more significant noise source, and strategies exist to counter it (at the expense of greater loop delay).

8. CONCLUSION

This article provides an overview of modern A/D and D/A converter design for integrated circuits. Nyquist-rate and oversampled techniques are covered with an emphasis on fundamental concepts and key strategies for high-performance design.

Nyquist-rate architectures are most suitable for higher bandwidth applications with modest resolution requirements. Flash, folding, and pipelined techniques for converter design offer varying tradeoffs between hardware complexity and conversion speed. Oversampled converters based on delta-sigma modulation are appropriate for narrowband wide-dynamic-range applications. System requirements dictate the selection of noise shaping architecture, modulator loop filter realization, and quantizer characteristics.

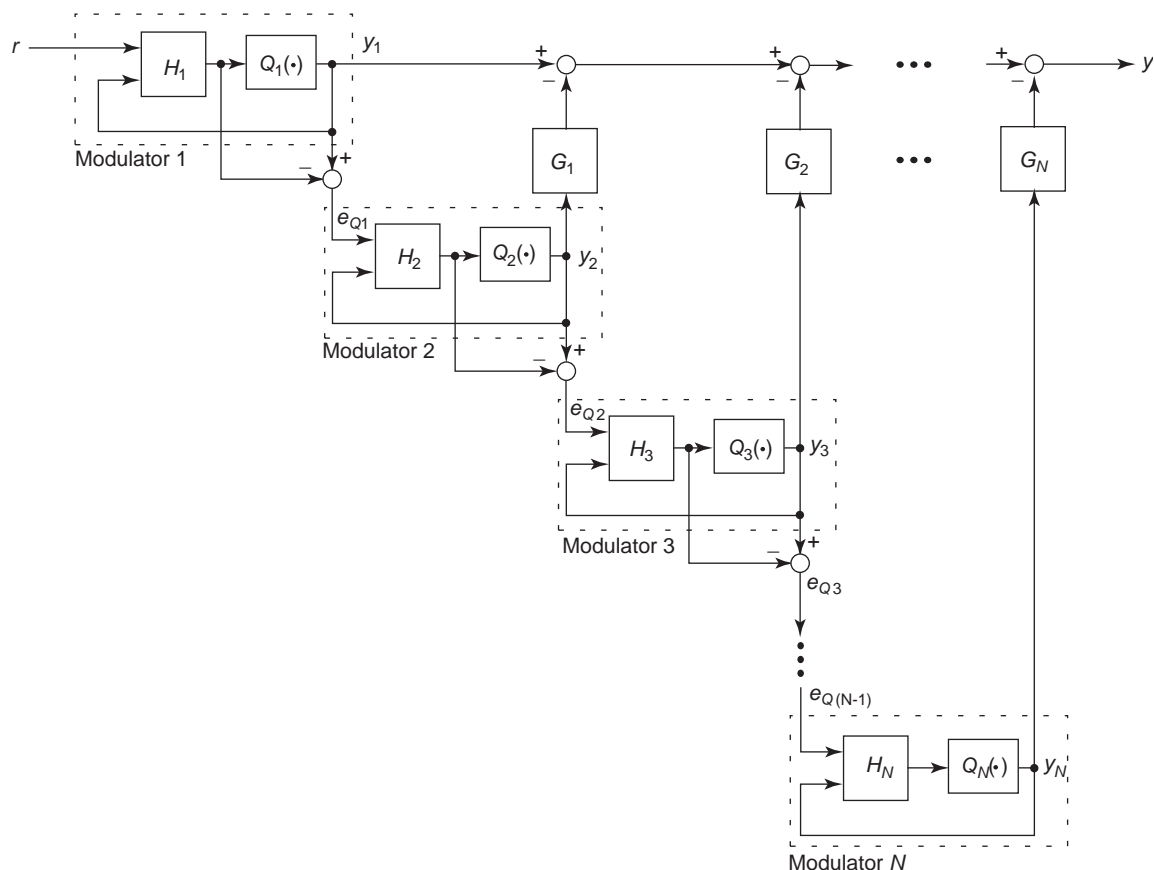

Figure 37. The general form of a cascaded noise-shaping architecture. The delta-sigma modulators are either digital or mixed-signal blocks (depending on the application), and the filter G_i are digital filters.

ACOUSTIC MICROWAVE DEVICES

PETER M. SMITH
 McMaster University
 Hamilton, Canada

1. INTRODUCTION

Since the first experiments on piezoelectricity by the Curie brothers in 1880, many devices have employed mechanical waves to process electrical signals. While their frequency of operation is usually well beyond the audible range, these waves are referred to as *acoustic waves* because of their mechanical nature. From an electrical standpoint, their principal benefits stem from the relatively low velocities of acoustic waves, which are in the order of 10^5 times lower than the velocity of electromagnetic waves. This leads to very small devices that can be made to meet very stringent specifications.

In virtually all radiofrequency (RF) and microwave applications, the acoustic waves are generated and detected in crystals through piezoelectricity, which couples electric fields to mechanical deformations. There are two broad types of devices:

- *Bulk acoustic wave* (BAW) resonators employ surface electrodes to generate mechanical waves that travel through the interior ("bulk") of the crystal. They have proved to be compact and reliable, and have become ubiquitous in high-precision oscillators having a

fundamental frequency of up to 20 MHz. Their resonant frequency depends on the exterior dimensions of the crystal. At high frequencies, standalone bulk crystal resonators become too thin and fragile for most applications.

- *Surface acoustic wave* (SAW) devices employ transducers to generate waves that propagate along the surface of a crystal [1]. They overcome the frequency limitations of the bulk acoustic wave resonators because the frequency of operation becomes independent of the crystal thickness. They also make the acoustic waves accessible along their entire propagation path, thus permitting sampling of the waves at arbitrary points.

2. BAW DEVICE STRUCTURES

At microwave frequencies, the most practical structure for employing bulk acoustic waves is known as the *thin-film bulk acoustic wave* (FBAW) resonator. It consists of a thin-film piezoelectric layer grown between two metal electrodes. The film is normally in the order of $1\ \mu\text{m}$ thick, and the structure is often built on an airbridge in order to isolate it mechanically from the substrate. This is illustrated in Fig. 1.

In general, the FBAW offers less flexibility than does its SAW counterpart. Its main advantage is the ability to integrate multiple FBAWs with electronic circuitry, where they can be used as high- Q circuit elements in filters having passband frequencies of up to ~ 10 GHz.

3. SAW DEVICE STRUCTURES

3.1. SAW Delay Line

A SAW delay line, illustrated in Fig. 2, is the simplest device of its type. It consists of two thin-film metallic transducers placed on the surface of a piezoelectric substrate. Common substrates are listed in Table 1. The transducers are usually created using a single-step photolithographic process and are made of a light metal such as aluminum to minimize the effect of their mass on the substrate. The

Figure 1. FBAW resonator structure.

Figure 2. SAW delay line.

photolithographic resolution in the fabrication process limits the frequency of operation of SAW delay lines, where an achievable linewidth of $0.5\ \mu\text{m}$ limits the frequency of operation to $\sim 2\ \text{GHz}$.

The principal benefit of employing SAW devices as delay lines is the large group delays that are possible. For example, a device having a distance (center to center) between transducers of $0.5\ \text{cm}$ would produce a delay in the order of $1.5\ \mu\text{s}$. In addition, because the wave velocity is frequency-independent, this delay would apply to all frequency components that the device supports.

The structure of the transducers varies, but the most common type by far is the *interdigital transducer* (IDT), which consists of an array of parallel strips (“fingers”) of alternating polarity. When a RF signal is applied to the input IDT, the electric fields between the metal strips induce mechanical deformations that propagate as waves in the crystal. These waves in turn generate an electric potential between the strips in the output IDT, which produces a current in the load.

The frequency response of the device can be estimated by recognizing that a modulated pulse can approximate the impulse response of each IDT. The frequency response for a device having two identical transducers is thus

$$|H(f)| \approx A \left| \frac{\sin \left[\frac{N\pi(f - f_0)}{f_0} \right]}{\frac{N\pi(f - f_0)}{f_0}} \right|^2 \quad (1)$$

where A is a constant and N is the number of finger pairs in each transducer. f_0 is the device’s center frequency given by

$$f_0 = \frac{v}{p} \quad (2)$$

Here, v is the acoustic wave phase velocity in the transducer region and p is the finger periodicity, shown in Fig. 2.

The insertion loss of a SAW delay line is often high. Since both IDTs are bidirectional three-port (one electrical, two acoustic) devices, each IDT will contribute an inherent 3 dB loss (6 dB in total) when the two electrical ports are matched to the source and load, respectively. This matched condition unfortunately also results in the maximum level of acoustic wave regeneration by each IDT, and leads to severe multipath interference known as *triple-transit interference* (TTI). Consequently, most SAW delay lines are intentionally mismatched at the electrical ports so that acoustic regeneration is reduced. An insertion loss of between 20 and 30 dB is common.

The frequency response of SAW delay lines usually exhibits several other distortions attributed to second-order effects. The dominant effects are direct electromagnetic coupling (“feedthrough”) between input to output transducers, reflections from finger edges, acoustic beam diffraction, and bulk wave interference.

3.2. SAW Transversal Filter

The SAW transversal filter is a generalization of the delay line in which the relative efficiency of individual IDT fingers is varied so that the frequency response of the transducer can be tailored. The control is commonly achieved either by *apodization*, which consists of varying the individual finger lengths, or by *withdrawal weighting*, which involves selectively removing fingers. These techniques are illustrated in the device shown in Fig. 3.

In a first-order design process, each finger in an IDT is represented by a delta function whose magnitude is proportional to the length. The impulse response of the IDT is then a sequence of weighted delta functions separated by $\tau = p/2v$ seconds. This representation corresponds directly to the one commonly used for the design of finite-impulse-response (FIR) digital filters, for which there are extensive design tools. One of the most common of these tools is the Remez exchange algorithm, for which computer programs are readily available [2], but other optimization algorithms can also be used. Once the equivalent digital FIR filter has been designed, the SAW filter is obtained by making the finger lengths proportional to the tap weights of the digital filter. If the transducer has an impulse response that is symmetric, then its frequency response will exhibit a linear phase. This property is important in communications applications.

Care must be exercised when designing a SAW filter having two apodized transducers. Since in this case the acoustic beam generated by the first apodized transducer will not be uniform across acoustic aperture, the signal detected by each finger in the second transducer will seldom be proportional to its length. Because of the

Table 1. Common Substrates Used in Surface Acoustic Wave Devices

Substrate	Cut	Velocity v (m/s)	k^2 (%)	Temperature Coefficient (ppm/K)
Quartz	ST-X	3158	0.116	0
Lithium niobate	Y-Z	3488	4.82	+ 94
Lithium niobate	128° -X	3992	5.44	+ 75
Lithium tantalate	Y-Z	3230	0.66	+ 35

Source: Morgan [17].

Figure 3. SAW device employing an apodized transducer and a withdrawal-weighted transducer.

difficulties that this behavior introduces in the design process, the second transducer is rarely apodized. In this case, withdrawal weighting is an attractive option.

3.3. Dispersive SAW delay line

Both the SAW delay line and transversal filter are usually designed to have a linear phase response. There are situations, however, where a nonlinear phase response is desirable. For example, a frequency-modulated (“chirp”) impulse response is often used to improve the range and resolution of radar systems.

A dispersive SAW delay line can be made by varying the finger positions of a delay line. Alternatively, grooves of varying periodicity can be etched into the substrate, as shown in Fig. 4, to create a *reflective array compressor* (RAC) [3]. The various frequency components in the acoustic beam will be reflected efficiently in the region where the grooves have a periodicity equal to half the acoustic wavelength. The frequency components will thus travel different distances and will reach the output transducer with differing delays. The phase response of the filter is obtained by integrating the radial frequency with respect to time, so a nonconstant delay can produce a desired nonlinear phase response.

3.4. Single-Mode SAW Resonator

An array of metal strips or grooves on the surface of the substrate can reflect SAW energy. If we place such arrays on the far sides of a one- or two-transducer device as shown in Fig. 5, we can create an acoustic resonant cavity. Resonance will occur, and the acoustic energy will be trapped in the cavity when the acoustic wave has a

Figure 4. Reflective array compressor (RAC).

Figure 5. SAW resonator.

wavelength that is approximately equal to an even multiple of the reflector strip periodicity.

When properly designed, a SAW resonator can achieve a quality factor, measured as the inverse of the fractional bandwidth, equal to about 10,000. In addition, the SAW resonator usually has a low insertion loss because the acoustic energy is trapped in the cavity. An insertion loss of less than 2 dB is easily achievable.

3.5. Multimode SAW Resonator

If we allow the acoustic energy in two identical resonant cavities to couple, the resonant frequency of the combined structure will split into two resonant frequencies. This property is often used to produce resonators that exhibit a higher fractional bandwidth than do single-cavity resonators, while still maintaining their low insertion loss.

The resonators can be longitudinally coupled, in which case two acoustic cavities are placed in line and the reflector array that they share is shortened to allow the acoustic energy to “leak” into the adjacent cavity. This approach allows the designer to precisely control the coupling between the cavities. Alternatively, the cavity length can be increased sufficiently to permit two or more modes to exist within the single cavity. However, at frequencies not reflected by the reflector arrays, the SAW waves will be able to freely propagate between transducers in these inline structures. This leads to poor out-of-band rejection.

The resonators may also be transversely coupled. In this case the acoustic cavities are placed in parallel, with a very narrow gap (usually a grounded metal strip) between them. Acoustic energy is coupled between the cavities through the evanescent “tail ends” of the transverse energy distribution of each cavity. This approach gives limited control over the coupling between cavities, but leads to excellent out-of-band rejection, in the order of 60 dB.

3.6. Low-Loss Structures

The previous paragraphs have described many “first generation” SAW devices, which can be divided into high-loss filters with outstanding frequency response

characteristics, and low-loss narrowband resonant devices with responses over which the designer has limited control. A “second generation” type of device has emerged that can provide both low loss and control over the shape of the frequency response.

Designing transducers that launch acoustic energy primarily at one port can reduce the insertion loss. This is done by introducing wave reflections within each IDT that add in phase with waves propagating in the desired direction, but that add out of phase with waves propagating in the opposite direction. Since the standard IDT is symmetric, it cannot generate unsymmetric output unless the substrate is unsymmetrical. We must employ instead transducers that have multiple electrodes, often of varying width, per period. Several examples of structures, known as *single-phase unidirectional transducers* (SPUDTs), are given in Ref. 4. These devices require higher photolithographic resolution, and their fabrication presents difficulties at frequencies above 1 GHz.

A second approach to reducing the insertion loss is to employ multiple bidirectional transducers that are alternately connected to the input and output ports. Since each input transducer (unless located at the ends) has a receiving transducer at both acoustic ports, and since each output transducer (unless located at the ends) has a transmitting transducer at each port, very little acoustic energy is lost. These devices, known as *interdigitated interdigital transducers* (IIDTs), are not subject to the same fabrication limitations at high frequencies as the devices described in the previous paragraph, but they often exhibit severe ripples in the frequency response.

3.7. SAW Ladder Networks

One-port SAW resonators have been increasingly used as circuit elements in ladder networks [5]. These filters, known as *impedance element filters*, offer low insertion loss and high power-handling capability. They are therefore often used in the output stage of wireless transceivers.

The basic configuration for an impedance element filter is given in Fig. 6, which also shows the typical frequency response of the circuit elements. The resonant frequencies of the shunt and series elements are offset so that the antiresonant frequency of the shunt elements matches the resonant frequency of the series elements. The result is a filter with a wider bandwidth than achievable with individual resonators, with sharp transition bands and good close-in stopband suppression.

4. SUBSTRATES

4.1. SAW Substrates

At low frequencies, most BAW devices employ a cylindrical quartz crystal that is polished on the two faces, on which are placed metal electrodes. Since the fundamental resonant frequency is inversely proportional to the distance between the two faces, the crystal becomes extremely thin at high frequencies, and impractical at microwave frequencies.

In the case of the FBAW, the thin-film piezoelectric substrate must be easily deposited and processed. The

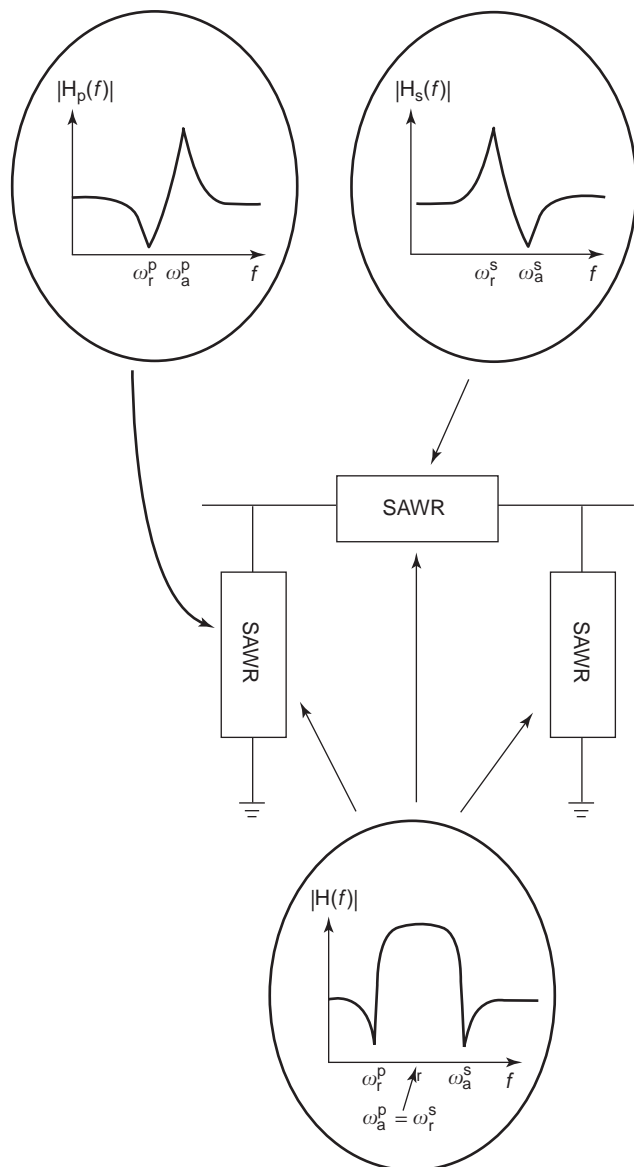

Figure 6. Configuration of impedance element filter employing SAW resonators.

most commonly used materials are aluminum nitride (AlN) and zinc oxide (ZnO).

4.2. SAW Substrates

There are currently many substrates in use for SAW devices. The most common are lithium niobate (LiNbO_3), quartz (SiO_2), and lithium tantalate (LiTaO_3), which are cut at various angles to the crystalline axes. Table 1 summarizes the most important properties of some of the more common crystal cuts.

The phase velocity v of the wave, combined with the photolithographic resolution of device fabrication process, determine the maximum sampling frequency of the transducers. Clearly, since IDT electrodes must be at most half a wavelength apart, a high velocity is desirable at microwave frequencies.

The coupling coefficient k^2 provides an indication of the electromechanical coupling efficiency. It is computed by evaluating the fractional velocity difference between waves propagating under metallized and free surfaces. Filters built on substrates with a higher k^2 can achieve lower insertion loss and wider bandwidths.

The temperature coefficient determines the effect of temperature changes on the acoustic phase velocity. This parameter is particularly important in oscillator applications where the cost of controlling the substrate temperature is excessive.

In general, LiNbO₃ crystals are used for wideband devices such as transversal filters, where the device may be placed in a temperature-controlled environment, or where small passband shifts due to temperature variations are of minor concern.

Quartz is usually preferred for narrowband applications, such as for resonators to be used in oscillators, where minor frequency shifts due to temperature variations are of major concern. The ST-X cut of quartz, with its zero first-order temperature coefficient at room temperature, is ideal for this type of application.

LiTaO₃ is often selected as a compromise between the two other substrates. Its temperature coefficient is lower than that of LiNbO₃, but its coupling coefficient is higher than for quartz.

There has been considerable interest in the use of multilayer substrates. A substrate that shows great promise is diamond because of its hardness, which leads to a high acoustic velocity. Since it is not piezoelectric, the diamond substrate must be layered with a piezoelectric thin film such as zinc oxide (ZnO). Nakahata reported that a silicon substrate coated with diamond and ZnO films can support a SAW having a velocity of 10,500 m/s and an electromechanical coupling coefficient k^2 of 1.5% [6]. Commercial diamond-based SAW devices operating well above 2 GHz are now available.

5. APPLICATIONS

5.1. Nyquist Filter

Consider a communication system designed to transmit digital bits (assume that each bit is transmitted as a delta function for now) every T seconds. The frequency response of the transmitted information must be restricted to the available channel bandwidth, which makes the impulse response of the channel infinite in length. Unless special steps are taken, successive bits will produce intersymbol interference (ISI). The solution is usually to employ a Nyquist filter in the transmitter.

To minimize this interference, it is important that the channel's impulse response be zero at all sampling instances $t = T_0 + nT$, $n \neq 0$, where T_0 is the delay through the channel. A channel with an ideal rectangular frequency response and a bandwidth of $1/2T$ Hz would have a sinc impulse response

$$\text{sinc}\left(\frac{t}{T}\right) = \frac{\sin(\pi t/T)}{\pi t/T} \quad (3)$$

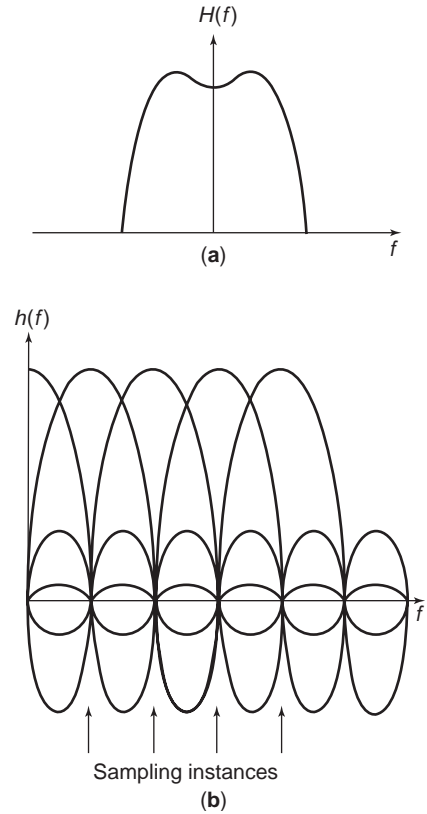

Figure 7. (a) Raised-cosine Nyquist filter frequency response; (b) impulse response of Nyquist filter.

which has the desired property. Other functions, such as the *raised-cosine function* [7], have the same property and are easier to realize. Any deviation from these precise frequency responses by the channel filter will quickly degrade the performance of the system.

The frequency response of the channel filter must be modified to account for the frequency response of the transmitted bit, which in practice cannot be a true delta function. If we assume a rectangular bit (with its sinc-shaped frequency response), a corresponding $1/\text{sinc}$ response must be superimposed on the frequency response of the channel filter. The resulting frequency response and its time-domain properties are illustrated in Fig. 7.

Because of their performance, reproducibility, and their ability to operate at intermediate frequencies (so that a single filter can operate on the combined in-phase and quadrature signals instead of requiring a baseband filter for each of these signals), SAW filters are often used in these applications [8].

5.2. Satellite Subchannelizers

Satellites usually have several transponders, and these are often leased to users. For example, the standard bandwidth of a C-band (6/4-GHz) satellite channel is 40 MHz, of which 36 MHz is usable because of the required guard bands between channels. In a conventional system, the user must lease the entire channel, regardless of whether the bandwidth is needed. The high cost of leasing the entire channel can be a major deterrent.

Figure 8. Filters in a SAW filter-bank seamlessly combine to dynamically vary channel bandwidth.

The high selectivity of SAW filters makes it possible to divide the satellite channel into three or more subchannels, possibly of varying bandwidth. Furthermore, if the magnitude and phase of these filters are carefully controlled, it is possible to combine two or more of these subchannels to form a contiguous channel of higher bandwidth, up to the full bandwidth of the transponder. Such a system is illustrated in Fig. 8. The Inmarsat-3 satellite uses this type of system to service its mobile users [9].

5.3. Wireless Handsets

Wireless communications systems require inexpensive, rugged, and compact components that consume very little power. Low-loss SAW devices excel in all four attributes, and have been widely adopted by all major manufacturers [10]. Cellular telephones are currently the largest market for SAW devices, at over 1 billion units per year.

SAW longitudinally coupled resonator filters are often used in the front end to remove out-of-band signal interference. A waveguide-coupled resonator filter is then used to select the desired channel. Figure 9 illustrates the possible uses of SAW components in a wireless handset.

5.4. SAW Oscillators

Stable oscillators require a narrowband device in their feedback path whose passband frequency can be precisely established. The frequency response of the device should also present a low insertion loss and be highly stable. Finally, for volume applications, the response must be easily reproducible.

SAW resonators meet all of these requirements, and are lightweight and rugged. When compared to other technologies, they can be manufactured at a low cost. For these

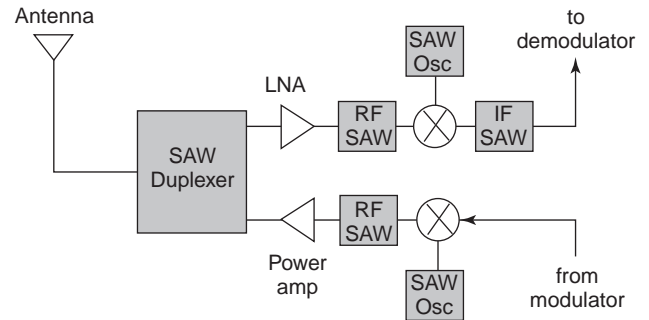

Figure 9. Block diagram of a wireless transceiver. Shaded blocks routinely use SAW devices.

reasons, SAW oscillators are widely used whenever signals in the range from 50 MHz to 2 GHz are required.

Oscillator stability is usually categorized as either short- or long-term. *Short-term stability* refers to output frequency variations lasting less than 1 s and caused by random thermal vibrations and the discrete nature of electric charge. *Long-term stability* encompasses effects due to temperature variations and component aging.

Short-term stability can be improved by selecting a high- Q feedback filter, an amplifier with low flicker noise and noise factor, and a clean power supply. In the case of SAW oscillators, it is also important to isolate the SAW device from mechanical vibrations, since the piezoelectric substrate can convert the vibrations to electrical signals. Short-term stability is usually measured in terms of single-sideband phase noise, which describes the oscillator output power density, normalized to the power of the carrier, at specific offset frequencies. A 500-MHz SAW oscillator, for example, is typically able to achieve phase noise levels of -130 dBc/Hz at 1 kHz offset from the carrier (dBc refers to decibels with respect to the carrier). The phase noise then typically drops to about -175 dBc/Hz at 100 kHz offset, and levels off [11].

Long-term stability can be improved by placing the oscillator in a temperature-controlled environment. Placing the SAW device in a package with thermal characteristics that are similar to those of the substrate also helps reduce mechanical stresses. Because component aging occurs predominantly early in its life, it is also important to “burn in” all oscillator components by subjecting them to high signal levels and high temperatures for an extended period of time. SAW oscillator long-term stability is usually measured in parts per million (ppm), and a good design can achieve 1 ppm per year at a fixed temperature or about 20 ppm over a temperature variation of 50 K.

5.5. SAW Chirp Fourier Transformer

The SAW chirp Fourier transformer is an analog circuit that is able to perform a finite-bandwidth windowed Fourier transform. The circuit is based on a simple algebraic manipulation of the formula for the Fourier transform $S(\omega)$ of a time signal $s(t)$:

$$S(\omega) = \int_{-\infty}^{\infty} s(t)e^{-j\omega t} dt \quad (4)$$

Figure 10. A multiply-convolve-multiply SAW Fourier transformer.

Substituting $-2\omega t = (t - \omega)^2 - t^2 - \omega^2$ and $\omega = \mu t$, we obtain

$$S(\omega) = S(\mu t) = e^{-j(\mu/2)t^2} \int_{-\infty}^{\infty} (s(\tau) e^{-j(\mu/2)\tau^2}) e^{j(\mu/2)(t-\tau)^2} d\tau \quad (5)$$

This expression can clearly be represented by the circuit shown in Fig. 10, which involves a multiplication by a linear frequency-modulated (FM) signal, followed by a convolution with another FM signal having a frequency variation opposite that of the first. The output of the convolver is then multiplied by a third FM signal having the same frequency variation as that of the first signal. A similar transformation can show that the dual circuit, consisting of a convolve–multiply–convolve system, produces the same result.

In a practical system, the convolutions can be performed by feeding the signal into a SAW chirp filter having a linear group delay. The multiplying signals can be provided by impulsing SAW chirp filters, but are usually generated digitally because this approach makes it easier to compensate for imperfections in the convolving SAW chirp filters.

While the SAW chirp Fourier transformer has not been widely used in commercial applications, studies have shown that it could be very competitive in some communications satellite applications [12].

6. ACOUSTIC WAVE PROPAGATION

A solution to the acoustic wave propagation in a piezoelectric substrate requires that both Maxwell's and Newton's equations be solved simultaneously in a nonisotropic medium. These two sets of equations are linked through the piezoelectric relationships. The equations that rule the behavior are

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} = -\boldsymbol{\mu} \frac{\partial \mathbf{H}}{\partial t} \quad (6)$$

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} = \frac{\partial}{\partial t} (\boldsymbol{\epsilon}^T \mathbf{E} + \mathbf{d} \mathbf{T}) \quad (7)$$

$$\nabla_s \mathbf{v} = \frac{\partial \mathbf{S}}{\partial t} = \frac{\partial}{\partial t} (\mathbf{d}' E + \mathbf{s}^E \mathbf{T}) \quad (8)$$

$$\nabla \cdot \mathbf{T} = \boldsymbol{\rho} \frac{\partial \mathbf{v}}{\partial t} \quad (9)$$

where

- \mathbf{B} = magnetic flux density vector
- \mathbf{d} = (3×6) piezoelectric strain coefficient matrix
- \mathbf{D} = electric flux density vector
- \mathbf{E} = electric field vector
- $\boldsymbol{\epsilon}^T$ = (3×3) electric permittivity matrix
- \mathbf{H} = magnetic field vector
- $\boldsymbol{\mu}$ = (3×3) magnetic permeability matrix
- \mathbf{s}^E = (6×6) compliance coefficient matrix
- \mathbf{S} = strain vector
- \mathbf{T} = stress vector
- $\boldsymbol{\rho}$ = diagonal (3×3) material density matrix
- \mathbf{v} = particle velocity vector = $\partial \mathbf{u} / \partial t$
- \mathbf{u} = particle displacement vector

Here, $\nabla \times$ represents the curl and the prime refers to the transpose of a matrix. Assuming the standard abbreviated subscript notation described in Ref. 13, we have

$$\nabla \cdot = \begin{bmatrix} \frac{\partial}{\partial x} & 0 & 0 & 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial y} \\ 0 & \frac{\partial}{\partial y} & 0 & \frac{\partial}{\partial z} & 0 & \frac{\partial}{\partial x} \\ 0 & 0 & \frac{\partial}{\partial z} & \frac{\partial}{\partial y} & \frac{\partial}{\partial x} & 0 \end{bmatrix} = (\nabla_s)' \quad (10)$$

$$\nabla \times = \begin{bmatrix} 0 & -\frac{\partial}{\partial z} & \frac{\partial}{\partial y} \\ \frac{\partial}{\partial z} & 0 & -\frac{\partial}{\partial x} \\ -\frac{\partial}{\partial y} & \frac{\partial}{\partial x} & 0 \end{bmatrix} \quad (11)$$

The wave solutions obtained by solving these equations, subject to boundary conditions, can be classified by their propagation properties. The most common types are bulk waves, Rayleigh waves, Bluestein–Gulyaev waves, and leaky waves.

6.1. Bulk Waves

Bulk acoustic waves are waves that propagate in the interior of the substrate, so that they are subject to the substrate boundary conditions only when they strike the boundaries. A bulk wave will in general have a particle motion that is composed of a superposition of three fundamental modes. These are known as the *fast longitudinal wave*, whose particle motion is in the same direction as the wave, and two *slower transverse waves*, whose particle motions are perpendicular to the wave. The latter are usually termed *fast-shear* and *slow-shear* waves, owing to their different phase velocities (in some crystal directions, these two waves could have the same velocity). Since these components travel independently, their relative magnitudes and phases will be determined by the launching conditions. In a piezoelectric substrate, each of these wave components will have a phase velocity that depends on its propagation direction.

6.2. Rayleigh Waves

Rayleigh waves satisfy the Maxwell and Newton equations in a piezoelectric half-space. Their motion is retrograde elliptical in the sagittal plane (defined by axes x_1, x_3 in Fig. 2), and their velocity is lower than that of all other waves. This slow velocity leads to very low propagation loss because the acoustic power is confined to within about 1 wavelength of the surface and does not leak into the substrate.

6.3. Bluestein–Gulyaev Waves

Bluestein–Gulyaev waves, also called *surface transverse waves* (STWs), contain particle motion only in the x_2 direction and can be generated with the traditional IDT structure. In general, the energy will propagate at a non-zero angle to the surface, which makes the wave lossy. However, if the surface is subjected to a periodic stress, the STW can be guided parallel to the surface so that it behaves very much like a surface wave; it is then called a *surface-skimming bulk wave* (SSBW). IDTs or reflector arrays built with a heavier or thicker metal film are usually used to guide the wave.

For particular substrate cuts, STW or SSBW can be the dominant acoustic modes. They have a higher velocity than do Rayleigh waves, so they are sometimes used instead of their Rayleigh counterparts in high-frequency devices.

6.4. Leaky Waves

For some substrates, it is possible to satisfy the surface boundary conditions with waves that travel at a velocity that is higher than that of the slow shear wave. Such waves are referred to as “leaky waves” because they are not confined to the surface and their acoustic energy leaks into the substrate. However, in some cases their electromechanical coupling coefficient is higher than that for Rayleigh waves and their propagation loss is small enough to make them practical. In addition, many of these substrates offer very small temperature coefficients. For these reasons, leaky waves are being increasingly used, particularly at high frequencies.

7. DEVICE MODELS

7.1. Introduction

Attempts to accurately model surface wave devices have met with varying success. The electromechanical interactions that are central to their operation require that both Maxwell’s and Newton’s equations be solved for the given boundary conditions. Until recently (as of 2003), the computational requirements to fully model even the simplest devices have been excessive. As a result, varying levels of simplification have been adopted in order to generate useful design tools. Effects that have not been predictable with these simplified models have been classified as “second-order effects,” with several techniques used to minimize their effect on the desired behavior of the device [14].

7.2. Impulse Response Model

The impulse response model was first derived by Hartmann et al. [15] as an alternative to more complicated

equivalent circuit approaches. It provides more information on a SAW device’s performance than does the delta function model described by Eq. (1) because it includes information on electrical impedances and can cater to transducers with nonuniform electrode spacing.

The process of modeling a SAW device with the impulse response model involves three steps:

1. Each electrode is replaced with a half-cycle of a sine wave whose magnitude is proportional to the length of the electrode.
2. If electrode spacing is not uniform, then the magnitude of each i th half-cycle is further scaled by $f_i^{3/2}$, where f_i is the instantaneous frequency at that point in the transducer.
3. The frequency response is obtained by taking the Fourier transform of the resulting impulse response. This technique is illustrated in Fig. 11.

The input impedance of a transducer can be computed from the impulse response model through energy conservation arguments. The equivalent circuit consists of a radiation conductance, representing acoustic energy generation, in parallel with a radiation susceptance, corresponding to energy absorption and regeneration in the transducer, and with a static capacitance. The radiation conductance of an IDT with uniformly spaced electrodes is found to be

$$G_a(f) = 8k^2 C_s f_0 N^2 \left| \frac{\sin \left[\frac{N\pi(f - f_0)}{f_0} \right]}{\frac{N\pi(f - f_0)}{f_0}} \right|^2 \quad (12)$$

while the radiation susceptance is the Hilbert transform of $G_a(f)$ and is given by

$$B_a(f) = 8k^2 C_s f_0 N^2 \frac{\sin \left[\frac{2N\pi(f - f_0)}{f_0} \right] - \frac{2N\pi(f - f_0)}{f_0}}{2 \left[\frac{N\pi(f - f_0)}{f_0} \right]^2} \quad (13)$$

Figure 11. Impulse response model of a transducer.

The static capacitance for the transducer is

$$C_t = NC_s \quad (14)$$

In Eqs. (12) through (14), k^2 is the electromechanical coupling constant, C_s is the capacitance per finger pair, and N is the number of finger pairs in the transducer. The equivalent circuit values for transducers with nonuniformly spaced electrodes can be found in Ref. 15.

7.3. Coupling-of-Modes Model

The *coupling-of-modes* (COM) model is a phenomenological description of the behavior of propagating waves that are subjected to a periodic disturbance in their propagation medium. The technique is ideally suited to the computation of the behavior of SAW structures that contain a large number of equally spaced transducer fingers or reflector strips. The COM approach is very numerically efficient, but is only accurate over fractional bandwidths of about 10%. It also must be slightly modified to model devices that employ leaky waves.

Consider two sinusoidal waves having complex amplitudes $w^+(x)$ and $w^-(x)$ propagating in a transducer region in the $+x_1$ and $-x_1$ directions shown in Fig. 2, respectively. Because of reflections and acoustic generation at the electrodes, these waves will be coupled to each other so that

$$\begin{aligned} \frac{\partial w^+(x)}{\partial x} &= -j\delta w^+(x) + j\kappa w^-(x) + j\alpha V \\ \frac{\partial w^-(x)}{\partial x} &= j\delta w^-(x) - j\kappa^* w^+(x) - j\alpha^* V \\ \frac{\partial I(x)}{\partial x} &= -2j\alpha^* w^+(x) - 2j\alpha w^-(x) + j\omega C_0 V \end{aligned} \quad (15)$$

where κ is the distributed reflection coefficient, α is the distributed transduction coefficient, V is the applied voltage, ω is the radian frequency, C_0 is the static capacitance per unit length of the transducer, and δ is a measure of frequency deviation from the Bragg frequency given by

$$\delta = \beta - \frac{\pi}{a} \quad (16)$$

where β is the propagation constant and a is the electrode separation. The terms containing V and the equation for the incremental current $I(x)$ can be disregarded when dealing with reflector arrays.

If we write Eq. (15) in matrix form, we obtain

$$\begin{aligned} \frac{\partial \mathbf{w}(x)}{\partial x} &= \mathbf{C}\mathbf{w}(x) + \mathbf{f}V \\ \frac{\partial I(x)}{\partial x} &= \mathbf{N}\mathbf{w}(x) + j\omega C_0 V \end{aligned} \quad (17)$$

where

$$\mathbf{w}(x) = \begin{bmatrix} w^+(x) \\ w^-(x) \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} -j\delta & j\kappa \\ -j\kappa^* & j\delta \end{bmatrix}, \quad \mathbf{f} = \begin{bmatrix} j\alpha \\ -j\alpha^* \end{bmatrix}$$

and $\mathbf{N} = [-2j\alpha^* \quad -2j\alpha]$, the general solution for the waves is

$$\mathbf{w}(x) = \mathbf{V}_e \mathbf{E}(x) \mathbf{V}_e^{-1} \mathbf{w}(0) + (\mathbf{V}_e \mathbf{E}(x) \mathbf{V}_e^{-1} - \mathbf{I}) \mathbf{C}^{-1} \mathbf{f} V \quad (18)$$

where \mathbf{V}_e is the 2×2 matrix containing the eigenvectors of \mathbf{C} in its columns, \mathbf{I} is the 2×2 unit matrix, and

$$\mathbf{E}(x) = \begin{bmatrix} e^{\lambda_1 x} & 0 \\ 0 & e^{\lambda_2 x} \end{bmatrix} \quad (19)$$

for which λ_1 and λ_2 are the eigenvalues of \mathbf{C} [16]. In the case of transducers, the solution requires an expression for the current, which is obtained by integrating the incremental current over the length of the transducer. For a transducer of length L_T , we get

$$\begin{aligned} I &= \mathbf{N} \mathbf{V}_e \Lambda^{-1} (\mathbf{E}(L_T) - \mathbf{I}) \mathbf{V}_e^{-1} \mathbf{w}(0) + \{ \mathbf{N} [\mathbf{V}_e \Lambda^{-1} (\mathbf{E}(L_T) - \mathbf{I}) \mathbf{V}_e^{-1} \\ &\quad + L_T \mathbf{I}] \mathbf{C}^{-1} \mathbf{f} + j\omega C_t \} V \end{aligned} \quad (20)$$

where $C_t = xC_0$ is the total static capacitance of the transducer and

$$\Lambda = \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} \quad (21)$$

The admittance parameters for the device can be computed as

$$y_{ij} = \left. \frac{I_i}{V_j} \right|_{V_k=0, k \neq j} \quad (22)$$

where the subscripts identify the transducers in the device. Scattering parameters are then obtained from the admittance parameters by using standard transformations.

7.4. Green's Function Model

The Green's function models for SAW devices were first developed in the 1970s, with many simplifications applied to make the numerical computations tractable with the resources available at that time. The most common assumption at that time was that the substrate interface was stress-free [17]. The technique has attracted considerable attention more recently because of its ability to model essentially all aspects of a SAW device's performance and to take into account all acoustic propagation modes.

A Green's function describes the behavior of a structure due to a point source. This source can be an electrical charge on the surface of the substrate, or a mechanical stress due to, for example, the mass of a surface electrode. In the k domain (corresponding to the Fourier transform of these terms), these relationships can be summarized as

$$\begin{bmatrix} \bar{u}_1(k_1) \\ \bar{u}_2(k_1) \\ \bar{u}_3(k_1) \\ \bar{\phi}(k_1) \end{bmatrix} = \begin{bmatrix} \bar{G}_{11}(k_1) & \bar{G}_{12}(k_1) & \bar{G}_{13}(k_1) & \bar{G}_{14}(k_1) \\ \bar{G}_{21}(k_1) & \bar{G}_{22}(k_1) & \bar{G}_{23}(k_1) & \bar{G}_{24}(k_1) \\ \bar{G}_{31}(k_1) & \bar{G}_{32}(k_1) & \bar{G}_{33}(k_1) & \bar{G}_{34}(k_1) \\ \bar{G}_{41}(k_1) & \bar{G}_{42}(k_1) & \bar{G}_{43}(k_1) & \bar{G}_{44}(k_1) \end{bmatrix} \quad (23)$$

$$\times \begin{bmatrix} \bar{T}_5(k_1) \\ \bar{T}_4(k_1) \\ \bar{T}_3(k_1) \\ \bar{D}_3(k_1) \end{bmatrix}$$

where the overbar indicates a Fourier transform. G_{ij} are Green's functions, ϕ is the electric potential, and u_i, T_i, D_3 are elements of the displacement, stress, and electric flux density vectors, respectively.

A convenient method to evaluate all the Green's functions was proposed by Peach [18]. For an assumed x_1 component of the acoustic wavenumber given by k_1 , the possible x_3 components can be evaluated by solving Eqs. (6)–(9). The solution can be written as an eighth-order eigenvalue problem, where the k_3 terms are the eigenvalues, and the eigenvectors are the partial waves that make up the solution. The boundary conditions determine the relative contributions of these partial waves. The $\tilde{G}_{ij}(k_1)$ terms are then readily obtained.

The singular terms in the $\tilde{G}_{ij}(k_1)$ functions must be quantified so that the spatial domain Green's functions $G_{ij}(x_1, \omega)$ can be obtained. This step is often the most time consuming, but it is necessary because these singular points determine the long-range effect of the sources. The spatial domain Green's functions are then convolved over all sources and the overall device behavior is obtained.

Recently, a periodic Green's function methodology was introduced that is well suited to the analysis of long periodic structures [19]. This approach limits the analysis to that of a single period, which greatly reduces the computation requirements.

7.5. Finite-Difference Time-Domain Model

The finite-difference time-domain (FDTD) method was first introduced by Yee for the simulation of electromagnetic wave propagation [20]. It involves the discretization of the wave equations in both time and space, which then leads to a numerical solution of the wave propagation problem. The technique's main benefits are that it permits the description of wave propagation in nonuniform and nonlinear media, and it can easily include a wide range of boundary conditions. The technique is particularly well suited to broadband analyses, because the spectral response can be computed from the structure's time response to a narrow Gaussian impulse excitation.

There has been some early work on the extension of the method to the propagation of ultrasonic waves through piezoelectric media [21]. Stability considerations require that a quasistatic approximation be imposed on Eqs. (6)–(9), so that they can be reduced to

$$\nabla_s \mathbf{v} = \hat{\mathbf{s}}^E \frac{\partial \mathbf{T}}{\partial t} \quad (24)$$

$$\nabla \cdot \mathbf{T} = \rho \frac{\partial \mathbf{v}}{\partial t} \quad (25)$$

where the stiffened compliance matrix is defined as

$$\hat{\mathbf{s}}^E = \mathbf{s}^E - \mathbf{d}'(\boldsymbol{\epsilon}^T)^{-1} \mathbf{d} = (\hat{\boldsymbol{\epsilon}}^E)^{-1} \quad (26)$$

In the saggital plane, the resulting time-stepping equations become

$$-\mathbf{V}_{i+(1/2),j+(1/2)}^{n+(1/2)} = \mathbf{V}_{i+(1/2),j+(1/2)}^{n-(1/2)} + \frac{\Delta t}{2\rho\Delta x} \hat{\mathbf{T}}_{i+(1/2),j+(1/2)}^n \quad (27)$$

$$\mathbf{T}_{i,j}^{n+1} = \mathbf{T}_{i,j}^n + \frac{\Delta t}{2\Delta x} \hat{\boldsymbol{\epsilon}}^E \hat{\mathbf{v}}_{i,j}^{n+(1/2)} \quad (28)$$

where the superscripts refer to the time instant and the subscripts indicate the gridpoint index. In Eqs. (27) and (28), we have

$$\hat{\mathbf{T}}_{i+(1/2),j+(1/2)}^n = \begin{bmatrix} T_1|_{i+1,j+1}^n - T_1|_{i,j+1}^n + T_1|_{i+1,j}^n - T_1|_{i,j}^n \\ + \cdots + T_5|_{i+1,j+1}^n - T_5|_{i+1,j}^n + T_5|_{i,j+1}^n - T_5|_{i,j}^n \\ T_6|_{i+1,j+1}^n - T_6|_{i,j+1}^n + T_6|_{i+1,j}^n - T_6|_{i,j}^n \\ + \cdots + T_4|_{i+1,j+1}^n - T_4|_{i+1,j}^n + T_4|_{i,j+1}^n - T_4|_{i,j}^n \\ T_5|_{i+1,j+1}^n - T_5|_{i,j+1}^n + T_5|_{i+1,j}^n - T_5|_{i,j}^n \\ + \cdots + T_3|_{i+1,j+1}^n - T_3|_{i+1,j}^n + T_3|_{i,j+1}^n - T_3|_{i,j}^n \end{bmatrix} \quad (29)$$

$$\hat{\mathbf{v}}_{i,j}^{n+(1/2)} = \begin{bmatrix} v_1|_{i+(1/2),j+(1/2)}^{n+(1/2)} - v_1|_{i-(1/2),j+(1/2)}^{n+(1/2)} + v_1|_{i+(1/2),j-(1/2)}^{n+(1/2)} - v_1|_{i-(1/2),j-(1/2)}^{n+(1/2)} \\ 0 \\ v_3|_{i+(1/2),j+(1/2)}^{n+(1/2)} - v_3|_{i+(1/2),j-(1/2)}^{n+(1/2)} + v_3|_{i-(1/2),j+(1/2)}^{n+(1/2)} - v_3|_{i-(1/2),j-(1/2)}^{n+(1/2)} \\ v_2|_{i+(1/2),j+(1/2)}^{n+(1/2)} - v_2|_{i+(1/2),j-(1/2)}^{n+(1/2)} + v_2|_{i-(1/2),j+(1/2)}^{n+(1/2)} - v_2|_{i-(1/2),j-(1/2)}^{n+(1/2)} \\ v_3|_{i+(1/2),j+(1/2)}^{n+(1/2)} - v_3|_{i-(1/2),j+(1/2)}^{n+(1/2)} + v_3|_{i+(1/2),j-(1/2)}^{n+(1/2)} - v_3|_{i-(1/2),j-(1/2)}^{n+(1/2)} \\ + \cdots + v_1|_{i+(1/2),j+(1/2)}^{n+(1/2)} - v_1|_{i+(1/2),j-(1/2)}^{n+(1/2)} + v_1|_{i-(1/2),j+(1/2)}^{n+(1/2)} - v_1|_{i-(1/2),j-(1/2)}^{n+(1/2)} \\ v_2|_{i+(1/2),j+(1/2)}^{n+(1/2)} - v_2|_{i-(1/2),j+(1/2)}^{n+(1/2)} + v_2|_{i+(1/2),j-(1/2)}^{n+(1/2)} - v_2|_{i-(1/2),j-(1/2)}^{n+(1/2)} \end{bmatrix} \quad (30)$$

Further development of the FDTD method for piezoelectric substrates is expected in the future.

7.6. Diffraction and Beamsteering

Surface acoustic waves are generated by sources of finite aperture and are therefore subject to diffraction effects. As is done in optics, the effects are classified as near-field (Fresnel) effects and far-field (Fraunhofer) effects. In SAW devices, the Fraunhofer region is of most interest.

Many of the techniques developed for optics can be applied to SAW, with the small modification that the velocity, and therefore the wavenumber, of the waves depend on the direction of propagation. The wave velocity in a specified direction is computed by solving the stiffened Christoffel equation, as outlined in Ref. 13.

A commonly used method of computing the effect of diffraction is known as the *angular spectrum of waves* (ASoW) technique. If we ignore any wave dependence in the x_3 direction, the amplitude of the surface wave ψ at a point (x, y) on the surface of the substrates can be written [22]

$$\psi(x, y) = \int_{-\infty}^{\infty} \Psi(k_y) e^{-j(k_x x + k_y y)} dk_y \quad (31)$$

where $\Psi(k_y)$ is the Fourier transform of the wave amplitude at a reference point $x = 0$, while k_x and k_y are x_1 and x_2 components of the wavenumber for a wave propagating at an angle ϕ to the x_1 axis shown in Fig. 2. The signal detected at the receiving transducer is calculated by integrating $\psi(x, y)$ over all receiving electrodes.

Because of the anisotropy of SAW substrates, the acoustic wavefront does not always propagate in the direction that is normal to the electrodes. This effect, known as *beamsteering*, must be considered when positioning the receiving transducer.

ACTIVE ANTENNAS

ALAN MICKELSON
University of Colorado
Boulder, Colorado

1. INTRODUCTION TO ACTIVE ANTENNAS

A good place to start a discussion of active antennas might well be to define what we mean by an *active antenna* as is

done in two review articles on active integrated antennas [2,3]. An antenna is a structure that converts electromagnetic energy propagating in free space into voltage and current¹ in an electrical circuit and vice versa. In a transceiver system, the antenna is used to both receive and transmit free-space waves. At minimum, a transceiver then must consist of a signal source that serves to drive the antenna as well as a receiver circuit that reads out the signal from the antenna. Until relatively recently, practically all antenna systems operating in the microwave frequency regime (operation frequencies greater than 1 billion cycles per second, or 1 GHz) went to great lengths to isolate the antenna from the circuits—that is, to find ways to make system operation independent of the antenna's electrical characteristics. In contradistinction, an active antenna is one in which the antenna actually serves as a circuit element of either the driver or readout circuit. To really understand why this is different from conventional antenna driving or readout will require us to take a bit of a historical trip through the last century or so.

Actually, the first antenna of all time was an active one. Heinrich Hertz back in 1884 [4] was the first person to demonstrate that one could generate radiowaves and that they would propagate from a transmitter to a receiver at the speed of light. The apparatus used is schematically depicted in Fig. 1. The idea of the transmitter is that, by discharging an induction coil (a wire looped about a magnetic core such that the composite device can store significant amounts of magnetic energy) into a sparkgap, one can generate a current in the 5-mm-diameter wire. The voltage in the sparkgap induces a current in the wire, which in turn induces a voltage in the wires, and this voltage in turn induces current such that the voltage and current propagate along the two pieces of the wire to either side of the sparkgap as waves, appearing much like a one-dimensional slice through a water wave propagating away from the point where a pebble has struck the water's surface (the sparkgap). A wave will propagate rectilinearly until it encounters an obstruction, at which point it can suffer reflection and transmission from the barrier that the obstruction presents. There will then be reflections off the metal spheres on the ends of the wire. The spark will generate a broad spectrum of frequencies—that is, different lengths of waves. The reflections off the two ends, though, will tend to cancel each other except at certain special frequencies. The effect at these wrong frequencies is much like the effect of throwing a handful of pebbles into the pond and noting that, in between the points where the pebble struck, the waves are much less

Figure 1. Hertz apparatus for (a) transmitting and (b) receiving radiowaves, where the transmitting antenna serves to choose a specific frequency of the sparkgap voltage to transmit to the receiving antenna, which also serves to pick out this special frequency from the free-space waveform and turn this electromagnetic disturbance into a voltage across the receiver antenna gap.

distinct than they are far from where the handful struck the surface. The special frequencies are ones that just fit into the region between the spheres. The current needs to be zero at the two ends in order to fit, whereas the voltage needs to be maximum at the ends. The current and voltage waves at the right frequency may appear as depicted in Fig. 2. The Hertz transmitter is the archetypical active antenna. The source is the sparkgap, which is actually placed in the antenna. The antenna then acts as a filter to pick the right frequency out of a large number of frequencies that could be launched from the sparkgap. The receiver is picked to be of a length to also select this primary frequency.

Hertz-style sparkgap transmitters, after further development and popularization by Marconi, were the primary ones in use for some 50 years after Hertz until they were banned for by the Federal Communications Commission (FCC). Indeed, sparkgap transmitters do exhibit some rather severe drawbacks. The main problem is that the simple resonant dipole antenna (i.e., a straight-wave antenna with a gap used to feed in current) is a pretty lousy frequency filter; that is, if one increases the frequency by 50%, there is 75% as much power transmitted at this frequency as at the first resonance, which is called the *fundamental*. There is a second resonance at twice the frequency of the first resonance and others at each integer multiple of the fundamental. Therefore, with increasing frequency the transmitted power decreases a little and then flattens out around the second resonance, decreases a little, flattens out at the third resonance, and so on, as is illustrated in Fig. 3. If the spark discharge is really broadband (i.e., if it really generates a large number of frequencies

¹A recurring theme in this article will be that voltage and current can be independently measured only at low frequency. Active antennas are useful in the frequency regime where we cannot really operationally have independent voltage and current, but only a combination of the two that forms a wave. It would really be better to define an antenna as a structure that converts waves propagating in free space to waves propagating in a guiding structure and vice versa. Such wording is a bit overpowering and requires a bit too much qualification for the second sentence of an introduction.

Figure 2. Current and voltage waveforms for the lowest-order (least number of zeros) waveform for the Hertz transmitter of Fig. 1a. The current must go to zero at the points where the wire ends, whereas the potential will be highest there.

Figure 3. A sketch of what the transmission as a function of frequency might look like for the Hertzian dipole antenna of Figs. 1 and 2.

where the highest frequency may be many times the lowest), then what is transmitted by the antenna will also be broadband, albeit with somewhat higher transmission at the fundamental frequency and its harmonics than in between. In the very early days of radio, this was somewhat acceptable, although I would imagine that any information that one tried to impress on such a broadband carrier would be rather severely degraded on reception. However, the demise of the sparkgap transmitter was really instigated by the early success of radio, which caused the available frequency bands to begin to fill up rapidly. This band filling was a motivation for the formation of the FCC in 1934, which was then charged with allocation of frequency bands. That as allocation was necessary was in and of itself a justification for a (1934) ban on sparkgap transmitters, which were needlessly wasting bandwidth.

In a later experiment, Hertz noticed that the waves he was generating would tend to have a component that hugged the ground and could therefore travel over the horizon and, in fact, across the Atlantic Ocean, skimming along the surface of the water. Other researchers noticed that the effect became more pronounced at wavelengths longer than the roughly 2 m wavelength that Hertz originally used. (For the relation between frequency and wavelength for some important frequency bands, see Table 1.) In order for wave transmission to be useful, however, the transmitted signal needs to carry information. To impress information on the wave is said to be *modulating* the carrier. One can modulate either the heights (amplitudes) of the wave or the frequency of the wavetrain. The discovery of a technique to *amplitude-modulate* the waves coming off an antenna (in 1906) then led to the inception of AM radio in bands with wavelengths greater than 300 m, which corresponds to roughly 1 MHz. AM radio became commercial in 1920. By the 1930s, other researchers noted that waves with frequencies around 10 MHz, corresponding to a wavelength around 30 m, could be quite efficiently propagated over the horizon by bouncing the wave off the ionosphere. This led to the radio bands known as *shortwave*. In 1939, a researcher realized a technique to modulate the frequency of the wave. This realization led in the 1950s to FM radio, which was allocated the band around 100 MHz with a corresponding wavelength around 3 m. However, the FM technique was used first during World War II as a radar modulation technique. Radars today, as will be

Table 1. A Listing of the Allocated Microwave and Millimeter-Wave Bands as Defined by the Frequency and Wavelength Range within Each Band

Band Designation	Frequency (GHz)	Wavelength
L	1–2	15–30 cm
S	2–4	7.5–15 cm
C	4–8	3.75–7.5 cm
X	8–12	2.5–3.75 cm
Ku	12–18	1.67–2.5 cm
K	18–26	1.15–1.67 cm
Ka	26–40	0.75–1.15 cm
Q	33–50	6–9 mm
U	40–60	5–7.5 mm
V	50–75	4–6 mm
E	60–80	3.75–5 mm
W	75–110	2.7–4 mm
D	110–170	1.8–2.7 mm
G	140–220	1.4–2.1 mm
Y	220–325	0.9–1.4 mm

brought up in a subsequent paragraph, are at frequencies above roughly 1 GHz or wavelengths below 30 cm.

There is a fundamental difference between circuits that operate at frequencies whose corresponding wavelengths are less than the maximum circuit dimension and those circuits that are large compared to the carrier wavelength. The effect is closely related to the concept of impedance. As was mentioned above, in the wire antenna, the voltage and current feed each other and thereby travel on the antenna as waves. The same effect takes place in a circuit. At any point along the path (line) in a circuit, one defines the ratio of voltage at one frequency to the current at the same frequency as the impedance at that frequency. If the impedance tends to preserve the phase relation (where the wave peaks lie, relatively), then we would say that the impedance is *resistive*. If the impedance tends to drive the voltage peaks forward with respect to the current peaks, we say that the impedance is *capacitive*; in the converse case we say that the impedance is *inductive*. In a small circuit, one generally tries to carefully craft passive components—resistors, capacitors, and inductors—such that they exhibit large local impedance; that is, large impedance within their physical dimension. The lines (wires) between them have little or no effect on the electromagnetic disturbance passing through the circuit, then, as the impedances in the wires are small and reasonably constant with length. When the circuit is large (compared to the highest frequency into which any signal handled by the circuit can be decomposed), the lines themselves become circuit elements, and they themselves must be carefully crafted in order to exhibit the proper impedances. To illustrate, consider the parallel-plate capacitor of Fig. 4. The capacitance is maximized by maximizing the permittivity ϵ (a material parameter that denotes the ratio of electrical displacement to applied electric field) and area A while minimizing the plate spacing d . However, that the capacitance depends on the plate spacing d is the important point here. Consider the circuit of Fig. 5. The only ground in the figure is the one on the battery, but the wires connecting the circuit elements together in essence form

Figure 4. Schematic depiction of a parallel-plate capacitor in which the flow of a current will tend to change the upper plate, causing a voltage difference between upper and lower plates. The *capacitance* is defined as the ratio of the amount of change of the upper plate to the magnitude of the voltage this change induces between the plates.

at each point a capacitor, with a point on the wire that is carrying charge as the upper plate and the ground as the lower. This capacitance value changes as a function of position along the wire. For a small enough circuit (relative to the wavelength of the highest frequency carried by the circuit), the effect is not too important, as the wire-ground pair is not optimized for capacitance value and the position-varying effect is small. For a large circuit, the effect is disastrous, as we'll consider below.

Consider the circuit of Fig. 6. The idea is to discuss what happens when impedances aren't carefully controlled. Let's first say that the circuit is short (compared to wavelength). If the load resistor R_L is not matched to (i.e., isn't equal to) the resistance of the source R_S , some amount of reflection will occur at R_L , propagate back to R_S , be reflected with a minus sign times the reflection at R_L , propagate back to R_L , and so on. The reflections add up perfectly out of phase (i.e., simply subtract from one another) at the source and load, and the amount of power supplied to the load is less than optimal. In this limit of a small-circuit case, it is as if the load will not allow the source to supply as much power as it is capable of. Let's now say that the line is "nice" but long compared to a wavelength. Then the same argument applies to the reflections, but in this case the source doesn't know that the load is there until several wave periods have passed (several maxima and minima of the waveform have left the source), so the source supplies all the power it can. The power, though, is not allowed to be fully absorbed by the load, and some amount of the power will rattle around the line until it is radiated or absorbed. As we mentioned above, in a long enough circuit the wire itself becomes a distributed element—that is, one with an impedance of its own. If the distance to the nearest ground is not kept fixed

Figure 5. A circuit with lumped elements connected by wire segments.

Figure 6. A circuit in which one is trying to supply power from a source with internal resistance R_S to a load with resistance R_L . The power transfer is maximized only when R_S and R_L are equal, in which case half the power supplied by the source is supplied to the load, the other half being dissipated in the source and causing it to heat.

along the line, this impedance becomes dependent on the position. In this case, we would have distributed reflections all along the line and the circuit would probably not work at all. This spatially variable impedance line is flexible, though, as illustrated by the drawing of a coaxial cable in Fig. 7. The idea is that, if the line brings along its own ground plane in the form of a grounded outer conductor, the impedance of the line can be kept constant with distance. The problem becomes the connection of the line to the source and load. A byproduct of this problem is a measurement reality. That reality is that a sufficiently high frequency one can no longer accurately sample voltage or current individually. Voltage sampling requires a measurement circuit that exhibits a high resistive impedance parallel to the impedance, which separates the sampling points of this composite voltage probe, whereas a current probe requires a small parallel impedance. Such probes are not impedance matched and disrupt the normal operation of the circuit under test. High-frequency circuit probes must use carefully impedance-matched termination, and thereby can only sample the power of waves propagating on the circuit's lines.

Before going on to discuss the "conventional" solution versus the "new" active-antenna solution, perhaps we should summarize a bit. In AM, shortwave, and FM applications, the wavelengths are greater than meters. If one considers typical receivers, the whole circuit will generally

Figure 7. A coaxial cable in which signals are carried on an inner conductor and in which the grounded outer conductor serves to carry the ground plane along with the signal in order to give a constant impedance along the line.

be small compared to the carrier wavelength. This is also to say that in all of these cases, the antennas will be active in the sense that the antenna presents an impedance to the circuit. One needs pieces of line comparable to a wavelength to really match or isolate a component. However, from here on we won't be interested in the low-frequency case but rather in the well-above-1-GHz case. During World War II, radar was the application that drove the frequencies above 1 GHz (wavelength less than 30 cm). In a radar, one sends out a pulse and, from the return scattered wave, tries to infer as much as possible about the target. Target resolution is proportional to wavelength. There has been a constant drive to shorten wavelength. Therefore, as is indicated by Table 1, one notes that bands have been allocated out to 100s of GHz. Presently, however, there are a plethora of nonmilitary drivers for pushing to higher frequencies. These relate to compactness and lower power dissipation. But as we'll see, the conventional solution, which was developed for radars, is really not conducive to compactness nor to the pressures of cost minimization of the commercial market.

A typical conventional transmitter may appear as that schematically depicted in Fig. 8. A main concept here is that the transmission lines and matching networks are being used to isolate the oscillator from the amplifier and the amplifier from the antenna, in contrast to the situation in an active antenna. There were a number of reasons why the conventional solution took on the form that it did. Among them was the urgency of World War II. Radar was developed rapidly in both Great Britain and the United States in the 1930s and 1940s. Rapid development required numerous researchers working in parallel. When operating frequencies exceeded 1 GHz (corresponding to 30 cm wavelengths), matching networks, whose main requirement is that they must consist of lines of lengths comparable to a wavelength, became convenient to construct (in terms of size) for ground-based radar. In this case, then, the oscillators could be optimized independently of the amplifiers, which in turn could be optimized independently of the antennas and the receiver elements. The impedances of the individual pieces didn't matter, as the matching networks could be used to effectively transform the effective impedances looking into an element into something completely different for purposes of matching pieces of the network to each other. There are costs associated with such a solution, though, such as total system size as well as the tolerances that components must satisfy. However, once the technique was in place, the industry standardized on the conventional solution and perfected it to the point where it was

Figure 8. Schematic of a conventional RF microwave transmitter in which each individual element of the transmitter is matched to each other element.

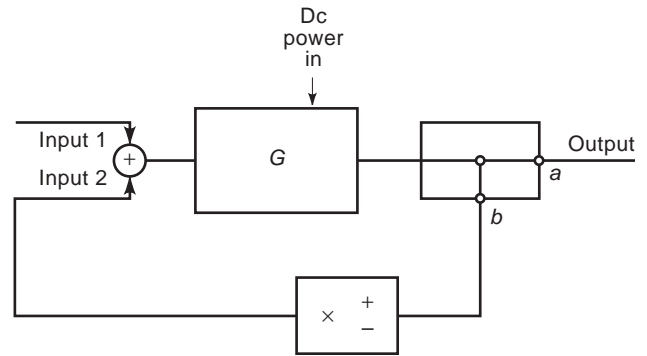

Figure 9. Schematic depiction of a feedback system that can operate as an oscillator when G is greater than 1, the feedback is positive, and there is a delay in feeding back the output to the input.

hard to challenge. The reemergence of the active solution really owes itself to two independent technologies, the emergence of high-frequency solid-state devices and the development of planar circuit and planar antenna technology.

A single frequency of electromagnetic energy must be generated in an *oscillator*—that is, a circuit that converts DC electrical power to AC electromagnetic power at the proper frequency. The basic operation of an oscillator can be described with respect to Fig. 9. What is shown here schematically is an amplifier in which a portion b (< 1) of the output is fed back to the input with either a plus or a minus sign. When the feedback is off ($b = 0$), then the signal out will be just G times the input. When the feedback is negative, the output will be less than G times the input. However, in the negative feedback mode, the stability to noise increases since fluctuations will be damped; that is, if the output fluctuates up, this lowers the effective input, whereas if the output fluctuates down, the output is driven up. The opposite is true in the positive-feedback case. In the positive-feedback case, if there were no fluctuation, any input would cause the output to increase until all the DC power in as well as all of the input signal would show up at the output. (This is all of the power that can show up at the output. This behavior is typical of unstable operation.) This would not be such an interesting case. However, there are always fluctuations of the input, and the positive feedback will cause these to grow. If there is a delay from output to input, then fluctuations with a period corresponding to this delay will be favored, as a rise in the input would show up as a rise in the output one period later, and rapidly all the DC power in would be converted to power out at this magic frequency. A real

circuit would operate a bit more interestingly than our ideal one. In a real circuit, as the fluctuations build up, the gain would be affected and some elements would absorb power, but the oscillations still would take place, although perhaps with a different frequency and amplitude from what one would have predicted from nondynamic measurements.

The transistor was first demonstrated in 1947, with publication in 1948 [5], with the diode not far behind [6]. Although the field-effect transistor (FET) was proposed in 1952 [7], it was not until the mid-1960s that the technology had come far enough that it could be demonstrated [8]. The high-electron-mobility transistor (HEMT) is a modification of the FET which allows for higher-frequency (and lower-noise) operation than the FET. The heterojunction bipolar transistor (HBT) is a more complex three-dimensional structured yet still integrated circuit (IC)-compatible semiconductor device that is now replacing the FET/HEMT in certain high-frequency applications. Two-terminal transferred electron devices (TEDs) were used before the FET for microwave applications and are still in use but tend to have a much lower wallplug efficiency, especially as the amplifying device of an oscillator. Radar systems, however, were already in use in the late 1930s. Essentially all of the microwave sources in radars up until the 1970s operated on principles that required that the source have physical dimensions larger than a wavelength, and perhaps many wavelengths. This fact almost required the use of conventional solution. Transistors, though, can have active areas with dimensions of micrometers; even packaged hybrid devices can have complete packages of dimensions smaller than a millimeter. The transistor can, therefore, act as an amplifier with dimensions much smaller than a wavelength and does not, therefore, need to be placed in a conventional solution design.

The last piece of our story of the new active-antenna era involves the development of printed-circuit technology, along with slot and patch antennas. The two most common planar “open waveguide” designs are microstrip line and coplanar waveguide (CPW). Depictions of these waveguide lines are given in Fig. 10. The idea behind the microstrip line is to propagate electromagnetic energy along the line by confining the electric field between the upper signal line and a lower ground plane. As the upper line carries current, a magnetic field encircles the upper line. As power flow takes place in a direction perpendicular to the electric and magnetic fields, the power flow is beneath the signal line in the dielectric. As we discussed before, on a low-frequency wire, the voltage and current waveforms couple to generate a wave. The coupling of the electric and magnetic fields in the microstrip is analogous to the coupling of voltage and current on the Hertz antenna wire, except that the microstrip line can be electrically long in the sense that the distance from the signal line to the ground plane is kept constant so that the impedance can be kept constant, as with the earlier-discussed coaxial cable. Lines that carry along their ground planes are generally referred to as *transmission lines*. Components (i.e., capacitors and inductors) can be built into the line by doing such things as changing the width or cutting gaps

Figure 10. Views of (a) a microstrip and (b) a coplanar waveguide line. In the microstrip, the ground plane is the lower electrode, whereas in the coplanar waveguide the ground plane is placed on the surface of the dielectric substrate.

into the upper line or putting slits in the ground plane. In this sense, we can still describe transmission-line circuits by conventional circuit theory if we use a special circuit model for the line itself. The CPW line is quite similar to the microstrip line except that there the ground planes are on top of the dielectric slab. Either of these line types is reasonably easy to fabricate, as one needs only to buy a metal-coated dielectric plate and then pattern the needed shapes by photographically defining the patterns using a technique known as *photolithography*, a process common to all present-day circuit fabrication. These planar structures are quite compatible with transistor technology, as is indicated by the simple transistor oscillator circuit depicted in Fig. 11. The gap in the line on the drain side is there in order to provide the proper feedback for oscillation. In this case, the total oscillator linear dimension can be less than a wavelength.

In order to have an active antenna, one needs to have a radiating element—that is, a passive-antenna element in the active antenna. Certain antenna technologies are compatible with microstrip and CPW technologies, and these antenna types are illustrated in Fig. 12. The idea behind either of these antenna types is that the patch or slit is designed to have one of its dimensions in the plane match the operating wavelength such that the structure resonates (such as we had discussed in conjunction with the Hertz dipole antenna). In the case of fundamental mode operation of the patch antenna, the resonating direction is

Figure 11. A simple transistor oscillator implemented in CPW technology.

Figure 12. A depiction of (a) a patch antenna in a microstrip line and (b) a slot antenna in a CPW line.

the direction of the patch that lies along the direction of the feedline and extends from the end of the feedline to the end of the patch. The other dimension must be chosen such that it does not resonate, which requires that its dimension not correspond too closely to a resonance along that direction. A possible choice is to make this dimension smaller than the other so that its length is too short to resonate. However, square patches are also possible as the feedline will favor the resonance along the feed direction. Now, in a microstrip configuration, the electric field points primarily from the upper conductor to the ground plane. For the patch antenna, this configuration is illustrated in Fig. 13. The downward-pointing electric field component along the edges of the patch that are directed along the same direction as the input feedline (resonating direction) will then have a field pattern as sketched in Fig. 13a, and this downward component of the electric field along the edges perpendicular to the feedline direction (where it has been assumed that there is no resonance along this direction) will have a field pattern as sketched in Fig. 13b, with

Figure 13. Illustration of the electric field directions along (a) the nonradiating edge and (b) the radiating edge, and (c) a schematic depiction of the edge fields around the patch.

a composite sketch given in Fig. 13c. The important part of the sketches, however, is really the so-called fringing fields in Fig. 13a—that is, the fields that point neither up nor down but rather point across. Along the input *radiating edge*, that is, the edge that is perpendicular and connects to the input line, electric field lines point along the direction of the feedline extending from some distance out in the dielectric to the edge. Along the other *radiating edge*, the other edge that is perpendicular to the input feedline but at the other side of the patch, there is a field pointing out (i.e., in phase with the electric field of the input radiating edge) from the edge into the dielectric. These two stripes of field, in phase and a resonating distance apart, then combine together to create an upwardly radiating wave field. The non radiating edges, those that are along the direction of the input feedlines, do not give rise to fringe field contributions as well, but these fringe field contributions are out of phase with each other and thereby cancel and do not contribute to the radiation from the patch. The operation of a slot antenna can be explained by a similar argument if one notes that the radiating edges must be those edges that lie along the direction of the feedline that is the downward-pointing magnetic field (the dominant component of the magnetic field that rings the currents) that takes the part of the electric field in the slot antenna’s operation.

We have now introduced all the pieces necessary to describe the new resurgence in active-antenna research. A possible active-antenna design could appear as in Fig. 14 [9], where the transistor is actually mounted right into the patch antenna element, and therefore the design can be quite compact; that is, the source plus oscillator plus antenna can all be fit into less than a wavelength area. The design of Fig. 14, which comes from R. Compton’s group at Cornell, will be discussed further in the next section.

There are a number of advantages to the use of active antenna ideas. One is that an active antenna can be made compact. Compactness in itself is advantageous,

Figure 14. Depiction of the upper surface metallization of a microstrip active patch antenna discussed in Ref. 7. The short circuit on the gate together with the slit between gate and drain provides the proper feedback delay to cause oscillation.

as throughout the history of microelectronics, miniaturization has led to lowered costs. There are really two more advantages, though, that relate to compactness. One is that the power-handling capabilities of a device go down with increasing frequency. We would therefore like to find ways to combine the power from several devices. One can try to add together outputs from various oscillators in the circuit before feeding them to the elements, but this goes back to the conventional solution. A more advantageous design is to make an array of antennas, with proper spacing relative to the wavelength and antenna sizes, and add the power of the “locked” oscillators in the array quasioptically in free space.² The locking requires that the oscillators “talk” to each other such that the phases of all the array elements stay in a given relation. As will be discussed in more detail in the next section, however, an important problem at present in the active-antenna field relates to keeping elements locked yet still being able to modulate the output as well as steer the beam in order to be able to electronically determine on output direction. These issues will be discussed in Section 2 and in more detail in Section 3.

2. SOME QUANTITATIVE DISCUSSION OF ASPECTS OF ACTIVE ANTENNAS

Antennas are structures that convert free-space radiation to guided radiation and vice versa. In order to carry out this operation efficiently, antennas must have some dimension that is significant compared to a wavelength. Antenna design then must require a full treatment of the electromagnetic field, including its geometric structure to sub-wavelength accuracy and its polarization. Such analysis requires the full apparatus of Maxwell’s field equations. An early motivation for the use of the active-antenna concept was that of using the field generating devices in proximity to the antenna such that the physical length of an electromagnetically small antenna could be augmented by the characteristics of the generating mechanism. Presently, attention has turned to higher frequencies, but the active-antenna concept that an antenna and a circuit be coupled such that the circuit can be used to alter the antennas characteristics is the same. An interesting point is that although the operating frequency of active antennas is usually high, that is, higher than the frequency regime at which integrated electronic circuits operate, the driving circuit tends to be small in total extent relative to the operating wavelength and therefore circuit theory concepts still apply to active-antenna design although these circuit theory concepts must be judiciously combined with electromagnetic theory. The usual formulation couples a high-frequency form of transmission-line theory with circuit theory as applied to microwave/millimeter-wave

²An amplifier is an oscillator biased above threshold, but without feedback. An array of active antennas carefully designed to have no internal feedback can be used to amplify weak signals. This is an alternative to having the array itself generate the initial signal, and the design if such amplifiers is also a part of the field of quasioptical power combining. This topic is reviewed in Ref. 10.

circuits. We will presently work from Maxwell’s theory to high-frequency transmission-line theory as it applies to guidance and radiation. We will introduce the somewhat specialized circuit formulation, which includes transmission lines and planar antennas that is usually applied to the high-frequency integrated active-antenna problem.

Maxwell’s equations are the basic defining equations for all electromagnetic phenomena, and they are expressible in MKSA units as [11]

$$\begin{aligned}\nabla \times \mathbf{E} &= -\frac{\partial \mathbf{B}}{\partial t} \\ \nabla \times \mathbf{H} &= \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \\ \nabla \cdot \mathbf{D} &= \rho \\ \nabla \cdot \mathbf{B} &= 0\end{aligned}$$

where \mathbf{E} is the electric field vector, \mathbf{B} is the magnetic induction vector, \mathbf{H} is the magnetic field vector, \mathbf{D} is the electric displacement vector, \mathbf{J} is the current density vector, and ρ is the volume density of charge. Each of these field quantities is a function of three spatial coordinates, which define a coordinate vector \mathbf{r} , and of the time t . The del operator ∇ and its associated operations of the curl $\nabla \times$ and the divergence $\nabla \cdot$ operate on these spatial coordinates. An additional important quantity is \mathbf{S} , the Poynting vector, defined by

$$\mathbf{S} = \mathbf{E} \times \mathbf{H}$$

If one is to take the divergence of \mathbf{S} , one finds

$$\nabla \cdot \mathbf{S} = \nabla \cdot (\mathbf{E} \times \mathbf{H})$$

where, if one assumes a free-space region

$$\mathbf{D} = \epsilon_0 \mathbf{E}$$

$$\mathbf{B} = \mu_0 \mathbf{H}$$

where free-space implies current-free

$$\mathbf{J} = 0$$

and charge-free

$$\rho = 0$$

where ϵ_0 is the permittivity of free space and μ_0 is the permeability of free space, one can use vector identities and Maxwell’s equations to obtain

$$\nabla \cdot \mathbf{S} = -\frac{\epsilon_0}{2} \frac{\partial}{\partial t} (\mathbf{E} \cdot \mathbf{E}) - \frac{\mu_0}{2} \frac{\partial}{\partial t} (\mathbf{H} \cdot \mathbf{H})$$

Integrating this equation throughout a volume V and using Gauss’ theorem

$$\int \nabla \cdot \mathbf{S} dV = \int \mathbf{S} \cdot d\mathbf{A}$$

where $d\mathbf{A}$ is the unit normal pointing out of the surface of the volume V , one finds that

$$\int \mathbf{S} \cdot d\mathbf{A} = -\frac{\partial}{\partial t} W_e - \frac{\partial}{\partial t} W_m$$

where W_e is the electric energy density

$$W_e = \frac{\epsilon_0}{2} \int \mathbf{E} \cdot \mathbf{E} dV$$

and W_m is the magnetic energy density

$$W_m = \frac{\mu_0}{2} \int \mathbf{H} \cdot \mathbf{H} dV$$

The interpretation of these equations is that the amount of \mathbf{S} flowing out of V is the amount of change of the energy within V . One therefore associates energy flow with $\mathbf{S} = \mathbf{E} \times \mathbf{H}$. This is important in describing energy flow in wires as well as transmission lines and waveguides of all types. As was first described by Heavyside [12], the energy flow in a wire occurs not inside the wire but around it; that is, as the wire is highly conductive, there is essentially no field inside it except at the surface where the outer layer of oscillating charges have no outer shell to cancel their effect. There is therefore a radial electric field emanating from the surface of the wire that combines with an azimuthal magnetic field that rings the current flow to yield an $\mathbf{E} \times \mathbf{H}$ surrounding the wire and pointing down its axis. Likewise, for a structure to radiate electromagnetic power upward from its surface requires that crossed components of \mathbf{E} and \mathbf{H} exist on an upward-pointing surface of the conductor.

Now, we would like to apply Poynting's theorem to the study of circuits that may contain antennas. A circuit, in general, will contain conductors that guide charges and currents, and these conductors will be surrounded by materials that are permeated by electromagnetic fields generated by the charges and currents in the conductors. It was Pocklington in 1897 [13] who made the formal structure of the fields around a wire a bit more explicit and, in the effort, also formed the basis for the approximation on which most of circuit and transmission-line theory rests, the quasistatic approximation. The result of his study of monochromatic (single-frequency) fields on wires could be summarized as follows. If one considers a small enough region around the axis of a wire conductor, one could construct an xyz Cartesian coordinate system where the axis of the wire is the z axis. As the fields close to the wire are stronger than those farther away, one can show that close enough to the wire all of the field quantities $\mathbf{f}(x, y, z, t)$ vary as

$$\mathbf{f}(x, y, z, t) = \Re\{\mathbf{f}(x, y)p(z, t)\}$$

where the propagation function $p(z, t)$ will generally take the form

$$p(z, t) = a_f e^{i\beta z - i\omega t} + a_b e^{-i\beta z - i\omega t}$$

where the a_f and a_b are complex constants, β a propagation constant and ω the angular frequency of the assumed field's source. That is, the above states that the fields consist of forward- and backward-propagating waves multiplied by a transverse field configuration. If one assumes

that the velocity of propagation of the above-defined wave is $v = (\mu\epsilon)^{-1/2}$, where the speed of light the speed of light $c = (\mu_0\epsilon_0)^{-1/2}$ is generally reduced by materials that have μ and ϵ different from their free-space values, then one can write that

$$\beta = \frac{\omega}{v}$$

The result that $\mathbf{f}(x, y)$ is independent of z , when substituted into Maxwell's equations, results in the relations in which

$$\nabla_t \times \mathbf{E}_t = \rho$$

$$\nabla_t \times \mathbf{H}_t = \mathbf{J}_z$$

where

$$\nabla_t = \hat{e}_x \frac{\partial}{\partial x} + \hat{e}_y \frac{\partial}{\partial y}$$

is just the transverse, and therefore two-dimensional, gradient operator and the \mathbf{f}_t are the transverse field quantities. These equations are just the electro- and magneto-static equations for the transverse fields, whereas the propagation equation above shows that these static transverse field configurations can be just propagated forward [if the wire is perfectly terminated such that the a_b of the $p(z, t)$ equation is zero but the a_f , the forward-going coefficient is nonzero] as if they corresponded to a propagating plane-wave field configuration. If the magnetic field is caused by the current in the wire, it rings the wire, whereas if the electric field is static, it must appear to emanate from charges in the wire and point outward at right angles to the magnetic field. The Poynting vector \mathbf{S} then points along the direction of propagation, that is, along the wire. If the wire is somehow terminated, for example in an open or short circuit termination, then the dominant electric field may be along the direction of the wire's axis [this is the case where the a_b may be close to or equal to the a_f in the $p(z, t)$ equation], and the Poynting vector \mathbf{S} may have a significant component at right angles to the propagation direction. In fact, in an antenna structure, one open-terminates a wire at a length (half-wavelength) from a feed-point such that the electric field is strongly and homogeneously pointing along the axis of the wire during each half of the wave period. As the current guided along the wire and also changes direction each half-period, the Poynting vector can be maintained in an upwardly pointing direction throughout the wave period. It is reasonably straightforward to generalize this thin wire theory to more general conductor shapes and non-Cartesian geometries, but always with the result that the conductors can be laid out in such manner that they can be used to control the electromagnetic energy flow through controlling the forward and backward excitation coefficients of transverse field configurations that closely resemble static field structures.

If we wish to guide electromagnetic energy along conductors and radiate energy by changing the guiding structure in a controlled manner, then one must design the guiding and radiating structures such that the quasistatic picture comes close to being the actual one. An approximate theory that is based on Pocklington's quasistatic

Figure 15. A sketch of a two-conductor transmission line where some equipotentials and some current lines are drawn in, as well as a volume V_1 with outward-pointing normal $d\mathbf{A}_1$. There is also an outward-pointing normal $d\mathbf{A}_2$ associated with the area bounded by contour C_2 .

approximation is one called *transmission-line theory*. To derive this theory, first consider the two-wire transmission line of Fig. 15. If we are to have something that we can actually call a transmission line, then we would hope that we can find equiphase fronts of the electromagnetic disturbance propagating in the gap crossing the gap conductor and that we can find lines along which the current flows on the current-carrying conductor. Otherwise, if the equiphases closed on themselves and/or we had eddies in the current, it would be hard to think of the structure as any form of guiding structure. Let's say we form an area in the gap with two walls of the four-sided contour C_1 surrounding this area following equiphases an infinitesimal distance dz from each other. We could then write

$$\int \nabla \times \mathbf{E} \cdot d\mathbf{A}_1 = - \int \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{A}_1$$

where $d\mathbf{A}_1$ corresponds to an upward-pointing normal from the enclosed area. One generally defines the integral as

$$\int \mathbf{B} \cdot d\mathbf{A}_1 = \phi$$

where ϕ is the magnetic flux. We further often define the flux as the inductance of the structure times the current by

$$\phi = Li$$

The integral with the curl in it can be rewritten by Stokes' theorem as

$$\int \nabla \times \mathbf{E} \cdot d\mathbf{A}_1 = \oint_{C_1} \mathbf{E} \cdot d\boldsymbol{\ell}$$

where C_1 is the contour enclosing the area. If we define

$$v = \int \mathbf{E} \cdot d\boldsymbol{\ell}$$

on the two equiphase lines of the contour C_1 , where v is an AC voltage (this is the main approximation shown above, as it is only strictly true for truly static fields), then, noting that v doesn't change along two of the boundaries of the contour (because they are the infinitesimal walls on constant voltage plates) and making the other two connecting lines infinitesimal, we note that the relation between the

curl of \mathbf{E} and the magnetic field reduces to

$$v(z+dz) - v(z) = \frac{\partial}{\partial t}(Li)$$

where it has been tacitly assumed that geometric deviations from rectilinear are small enough that one can approximately use Cartesian coordinates, which could be rewritten in the form

$$\frac{\partial v}{\partial z} = \ell \frac{\partial i}{\partial t} \quad (1)$$

where ℓ is an inductance per unit length, which may vary with longitudinal coordinate z if the line has longitudinal variation of geometry. A similar manipulation can be done with the second and third of Maxwell's equations. Taking

$$\nabla \cdot (\nabla \times \mathbf{H}) = \nabla \cdot \mathbf{J} + \frac{\partial}{\partial t} \nabla \cdot \mathbf{D}$$

and noting that the divergence of a curl is zero, substituting for $\nabla \cdot \mathbf{D}$ we find

$$\nabla \cdot \mathbf{J} + \frac{\partial \rho}{\partial t} = 0$$

which is the equation of charge conservation. Integrating this equation over a volume V_2 that encloses the current-carrying conductor whose walls lie perpendicular to the current lines gives

$$\int \nabla \cdot \mathbf{J} dV_2 = - \frac{\partial}{\partial t} \int \rho dV_2$$

where the total change Q , given by

$$Q = \int \rho dV_2$$

is also sometimes defined in terms of capacitance C and voltage v by

$$Q = Cv$$

Noting that

$$\int \nabla \cdot \mathbf{J} dV_2 = \int \mathbf{J} \cdot d\mathbf{A}_2$$

where $d\mathbf{A}_2$ is the outward-pointing normal to the boundary of the volume V_2 and where one usually defines

$$i = \int \mathbf{J} \cdot d\mathbf{A}_2$$

and letting the volume V have infinitesimal thickness, one finds that

$$\int \mathbf{J} \cdot d\mathbf{A}_2 = i(z+dz) - i(z)$$

Putting this together with the equations above, we find

$$\frac{\partial i}{\partial z} = c \frac{\partial v}{\partial t} \quad (2)$$

where c is the capacitance per length of the structure, where longitudinal variations in line geometry will lead to a longitudinal variation of c . The system of partial differential equations for the voltage and current have a circuit representation, as schematically depicted in Fig. 16a. One can verify this by writing Kirchoff's laws for the nodes

Figure 16. A circuit equivalent for (a) a lossless and (b) a lossy transmission line. The actual stages should be infinitesimally long, and the l s and c s can vary with distance down the line. In reality, one can find closed-form solutions for the waves in nominally constant l and c segments and put them together with boundary conditions.

with $v(z + dz)$ and $v(z)$ using the relations

$$v = \ell \frac{\partial i}{\partial t}$$

and

$$i = c \frac{\partial v}{\partial t}$$

Fig. 16b illustrates the circuit equivalent for a lossy (and therefore dispersive) transmission line, where the r represents the resistance encountered by the current in the metallization and where the g represents any conductance of the substrate material that might allow leakage to ground. A major point of the diagram is that the structure need not be uniform in order to have a transmission-line representation, although one may find that irregularities in the structure will lead to longitudinally varying inductances and capacitances.

Clearly, the solution to the circuit equations will have a wave nature that will exhibit propagation characteristics, which we discussed previously. In a region with constant ℓ and c , one can take a z derivative of Eq. (1) and a t derivative of Eq. (2) and substitute to obtain

$$\frac{\partial^2 v}{\partial z^2} - \ell c \frac{\partial^2 v}{\partial t^2} = 0$$

which is a wave equation with solutions

$$v(z, t) = v_f \cos(\omega t - \beta z + \phi_f) + v_b \cos(\omega t + \beta z + \phi_b) \quad (3)$$

where v_f is the amplitude of a forward-going voltage wave, v_b is the amplitude of a backward-going voltage wave, and

$$\frac{\omega}{\beta} = \sqrt{\ell c}$$

Similarly, taking a t derivative of Eq. (1) and a z derivative of Eq. (2) and substituting gives

$$\frac{\partial^2 i}{\partial z^2} - \ell c \frac{\partial^2 i}{\partial t^2} = 0$$

which will have a solution analogous to the one in Eq. (3), but with

$$v_f = \sqrt{\frac{\ell}{c}} i_f$$

$$v_b = \sqrt{\frac{\ell}{c}} i_b$$

which indicates that we can make the identification that the line phase velocity v_p is given by

$$v_p \triangleq \frac{\omega}{\beta} = \sqrt{\ell c}$$

and the line impedance Z_0 is given by

$$Z_0 = \sqrt{\frac{\ell}{c}}$$

Often, we assume that we can write (the sinusoidal steady-state representation)

$$v(z, t) = \text{Re}[v(z)e^{j\omega t}]$$

$$i(z, t) = \text{Re}[i(z)e^{j\omega t}]$$

such that we can write that

$$\frac{\partial v}{\partial z} = -j\omega \ell i$$

$$\frac{\partial i}{\partial z} = -j\omega c v$$

with solutions

$$v(z) = v_f e^{-j\beta z} + v_b e^{j\beta z}$$

$$i(z) = i_f e^{-j\beta z} + i_b e^{j\beta z}$$

Let's say now that we terminate the line with a lumped impedance Z_ℓ at location ℓ . At the coordinate ℓ , then, the relations

$$Z_\ell i(\ell) = v_f e^{-j\beta \ell} + v_b e^{j\beta \ell}$$

$$Z_0 i(\ell) = v_f e^{-j\beta \ell} - v_b e^{j\beta \ell}$$

hold, and from them we can find

$$v_f = \frac{1}{2}(Z_\ell + Z_0)i(\ell)e^{j\beta \ell}$$

$$v_b = \frac{1}{2}(Z_\ell - Z_0)i(\ell)e^{-j\beta \ell}$$

which gives

$$v(z) = \frac{i(\ell)}{2} [(Z_\ell + Z_0)e^{j\beta(\ell-z)} + (Z_\ell - Z_0)e^{-j\beta(\ell-z)}]$$

$$i(z) = \frac{i(\ell)}{2Z_0} [(Z_\ell + Z_0)e^{j\beta(\ell-z)} - (Z_\ell - Z_0)e^{-j\beta(\ell-z)}]$$

allowing us to write

$$Z(z - \ell) = \frac{v(z - \ell)}{i(z - \ell)} = Z_0 \frac{Z_\ell + jZ_0 \tan \beta(z - \ell)}{Z_0 + jZ_\ell \tan \beta(z - \ell)} \quad (4)$$

This equation allows us to, in essence, move the load from the plane ℓ to any other plane. This transformation can be

used to eliminate line segments and thereby use circuits on them directly. However, note that line lengths in which the line is at least comparable to a wavelength are necessary in order to significantly alter the impedance. At the plane $z = \ell$, then, we can further note that the ratio of the reflected voltage coefficient v_b and the forward-going v_f , which is the voltage reflection coefficient, is given by

$$\mathcal{R} = \frac{Z_\ell - Z_0}{Z_\ell + Z_0}$$

This is the reflection we discussed in the last section, which causes the difference between large and small circuit dimension.

One could question the utility of discussing Poynting vectors and transmission lines when the discussion was on active antennas. The answer really is that any antenna system, at whatever frequency or of whatever design, is a system for directing power from one place to another. To direct power from one place to another requires constantly keeping the Poynting vector pointed in the right direction. As we can surmise from the transmission-line derivation, line irregularities may cause the Poynting vector to wobble (with attendant reflections down the line due to attendant variations in the ℓ and c), but the picture must stay close to “correct” for power to get from one end of the system to another. For this reason, active antennas, even at very high (100s of GHz) frequencies can still be discussed in terms of transmission lines, impedances, and circuit equivalents, although greater care must be used in applying these concepts at increasingly higher frequencies.

The next piece of an active antenna that needs to be discussed is the active element. Without too much loss of generality, we will take our device to be a field-effect transistor (FET). A field-effect transistor (FET) is a device first described by Schockley in 1952 [7], but the MESFET (metal semiconductor FET) was not realized until 1965 [8] when gallium arsenide (GaAs) fabrication techniques became more workable. It should be pointed out that the silicon MOSFET (metal oxide semiconductor FET) is the workhorse device of digital electronics and therefore the most common of all electronic devices presently in existence by a very large margin. The GaAs MESFET was an important structure in the development of discrete microwave components and was used in early development of monolithic microwave circuitry (MMIC). High-electron-mobility transistors (HEMTs) and heterostructure bipolar transistors (HBTs) in such material systems as InP now are replacing GaAs MESFETs as both discrete and integrated components. In the present, though, the FET (and for some characteristics, the GaAs MESFET) will be used as a prototype device as its characteristics are reasonably archetypical of solid-state microwave devices. A top view of an FET might appear as in Fig. 17. As is shown clearly in the figure, an FET is a three-terminal device with gate, drain, and source regions. A cross section of the active region (where the gate is very narrow) might appear as in Fig. 18. The basic idea is that the highly doped n region causes current to flow through the ohmic contacts from drain to source (i.e., electrons flow from source to drain), but the current is controlled in magnitude by the electric field generated by the reverse bias voltage applied to the

Figure 17. Schematic depiction of a top view of the metallized surface of an FET, where G denoted gate, D drain, and S source.

gate electrode. The situation is described a bit more in Fig. 19, where bias voltages are defined and a typical I–V curve for DC operation is given. Typically the bias would be supplied by a circuit such as that of Fig. 20. In what follows, we will simply assume that the biases are properly applied and isolated and consider the AC operation. An AC circuit model is given in Fig. 21. If one uses the proper number of circuit values, these models can be quite accurate, but the values do vary from device to device, even when the devices were fabricated at the same time and even on the same substrate. Usually, the datasheet with a device will, instead of specifying the circuit parameters, specify the device S parameters, which are defined as in Fig. 22 and can be measured in a straightforward manner by a network analyzer. The S parameters are defined by the equation

$$\begin{pmatrix} V_1^- \\ V_2^- \end{pmatrix} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} \begin{pmatrix} V_1^+ \\ V_2^+ \end{pmatrix}. \quad (5)$$

An important parameter is the transfer function of the transistor circuit, which can be defined as the ratio of the v_o to the v_i as defined in Fig. 21. To simplify further analysis, we will ignore the package parasitics R_g and R_d with respect to other circuit parameters, and thereby we will carry out further analysis on the circuit depicted in Fig. 23. The circuit can be solved by writing a simultaneous system of equations for the two nodal voltages v_i and v_o . These sinusoidal steady-state equations become

$$j\omega C_{gd}(v_o - v_i) + g_m v_i + j\omega C_{ds} v_o + \frac{v_o}{R_{ds}} + \frac{v_o}{Z_L} = 0$$

The system can be rewritten in the form

$$v_o \left[j\omega (C_{gd} + C_{ds}) + \frac{1}{R_{ds}} + \frac{1}{Z_L} \right] = v_i [-g_m + j\omega C_{gd}]$$

Figure 18. Schematic depiction of the cross section of the active region of a GaAs FET, Specific designs can vary significantly in the field-effect family.

Figure 19. (a) Circuit element diagram with voltages and currents labeled for (b), where a typical I - V curve is depicted.

which gives us our transfer function T in the form

$$T = \frac{v_o}{v_i} = \frac{-g_m + j\omega C_{gd}}{j\omega(C_{gd} + C_{gs}) + \frac{1}{R_{ds}} + \frac{1}{Z_L}}$$

Often we are interested in open-circuit parameter—that is, the circuit transfer function when Z_L is large compared to other parameters. We often call this parameter G the *open-circuit gain*. We could write this open-circuit gain in the form

$$G = \left. \frac{v_o}{v_i} \right|_{oc} = \frac{-g_m R_{ds} + j\omega C_{gd} R_{ds}}{j\omega(C_{gd} + C_{gs})R_{ds} + 1}$$

It is useful to look at approximate forms. It is generally true that

$$C_{gd} \ll C_{ds}, C_{gs}$$

but for usual operating frequencies it is also generally true that

$$\frac{1}{\omega C_{ds}} \ll R_{ds}$$

Using both of the equations in our equations for T and G , we find

$$T = \frac{-g_m R_{ds}}{1 + \frac{R}{Z_L}}$$

$$G = -g_m R_{ds}$$

Clearly, one sees that the loaded gain will be less than the unloaded gain, as we would expect. Making only the first of our two approximations above, we can write these

Figure 20. Typical FET circuit including the bias voltages v_{gs} and v_{ds} as well as the AC voltages v_i and v_o , where the conductors represent AC blocks and the capacitors DC blocks.

Figure 21. Intrinsic model for a common-source FET with external load and termination impedances and including gate and drain resistive parasitics, where Z_T is the gate termination impedance, R_g is the gate (metallization) resistance, C_{gs} is the gate-to-source capacitance, C_{gd} is the gate-to-drain capacitance, g_m is the channel transconductance, R_{ds} is the channel (drain-to-source) resistance, C_{ds} is the channel capacitance, R_d is the drain (metallization) resistance, and Z_L is the load impedance.

equations as

$$T = \frac{-g_m R_{ds}}{1 + j\omega\tau_{ds} + \frac{R_{ds}}{Z_L}}$$

$$G = \frac{-g_m R_{ds}}{1 + j\omega\tau_{ds}}$$

where the τ_{ds} is a time constant given by

$$\tau_{ds} = \frac{1}{C_{ds} R_{ds}}$$

We see that, in this limit, the high-frequency gain is damped. Also, an interesting observation could be that, at some frequency ω , an inductive load could be used to cancel the damping and obtain a purely real transfer function at that frequency. This effect is the one that allows us to use the transistor in an oscillator.

Let us now consider an oscillator circuit. The basic idea behind the oscillator circuit is illustrated in the one-port diagram of Fig. 24. The transistor's gain, together with feedback to the input loop through the capacitor C_{gd} , can give the transistor an effective negative input impedance that can lead to oscillation if the real and imaginary parts of the total impedance (i.e., Z_T in parallel with the Z_i of the transistor plus load) cancel. The idea is much like that illustrated in Fig. 25 of a feedback network. One sees that the output of the feedback network can be expressed as

$$v_o = G(j\omega)[v_i - H(j\omega)v_o]$$

or, by rearranging terms, one finds that

$$\frac{v_o}{v_i} = \frac{G(j\omega)}{1 + G(j\omega)H(j\omega)}$$

Figure 22. Schematic depiction of an FET as a two-port device that defines the quantities used in the S matrix of Eq. (5).

Figure 23. Simplified transistor circuit used for analyzing rather general amplifier and oscillator circuits, where the circuit parameter definitions are as in Fig. 22.

which clearly will exhibit oscillation—that is, have an output voltage without an applied input voltage—when

$$H(j\omega) = -\frac{1}{G(j\omega)}$$

What we need to do to see if we can achieve oscillation is to investigate the input impedance of our transistor and load seen as a one-port network. Clearly we can write the input current of Fig. 23 as

$$i_i = j\omega C_{gs}v_i + j\omega C_{gd}(v_i - v_o)$$

and then using the full expression for T to express v_o as a function of v_i , one finds

$$Z_i = \frac{i_i}{v_i} = j\omega C_{gs} + j\omega C_{gd} \left(1 + \frac{g_m - j\omega C_{gd}}{j\omega(C_{gd} + C_{ds}) + \frac{1}{R_{ds}} + \frac{1}{Z_L}} \right)$$

which can be somewhat simplified to yield

$$Z_i = j\omega C_{gs} + j\omega C_{gd} \left[\frac{g_m R_{ds} + 1 + j\omega\tau_{ds} + \frac{R_{ds}}{Z_L}}{1 + j\omega\tau_{ds} + \frac{R_d}{Z_L}} \right]$$

We can again invoke a limit in which $\omega\tau_{ds} \ll 1$ and then write

$$Z_i = j\omega C_{gs} + j\omega C_{gd} \left[\frac{Z_L(1 + g_m R_{ds} + R_{ds})}{R_{ds} + Z_L} \right]$$

Perhaps the most interesting thing about this expression is that one notes that if

$$Z_L = j\omega L$$

and

$$g_m R_{ds} \gg 1$$

Figure 24. Diagram depicting the transistor and its load as a one-port device that, when matched to its termination so that there is no real or imaginary part to the total circuit impedance, will allow for oscillations.

Figure 25. Depiction of a simple feedback network.

then clearly

$$R_i < 0$$

Whether X_i can be made to match any termination is another question that we will take up in the next paragraph.

As was mentioned earlier, generally the datasheet one obtains with an FET has plots of the frequency dependence of the S parameters rather than values for the equivalent-circuit parameters. Oscillator analysis is, therefore, usually carried out using a model of the circuit such as that depicted in Fig. 26, where the transistor is represented by its measured S matrix. The condition for oscillation in such a system can be expressed in either of the forms

$$\Gamma_i \Gamma_T = 1$$

or

$$\Gamma_o \Gamma_L = 1$$

where the Γ s are as defined in the caption of Fig. 26. If both Z_T and Z_L were passive loads—that is, loads consisting of resistance, inductance, and capacitance, then we would have that

$$\begin{aligned} |\Gamma_T| &< 1 \\ |\Gamma_L| &< 1 \end{aligned}$$

and the conditions for unconditional stability (nonoscillation at any frequency) would be that

$$\begin{aligned} |\Gamma_i| &< 1 \\ |\Gamma_o| &< 1 \end{aligned}$$

Clearly, we can express Γ_i and Γ_o as series of reflections such that

$$\begin{aligned} \Gamma_i &= S_{11} + S_{12}\Gamma_L S_{21} + S_{12}\Gamma_L S_{22}\Gamma_L S_{21} \\ &\quad + S_{12}\Gamma_L S_{22}\Gamma_L S_{22}\Gamma_L S_{21} + \dots \\ \Gamma_o &= S_{22} + S_{21}\Gamma_T S_{12} + S_{21}\Gamma_T S_{11}\Gamma_T S_{12} \\ &\quad + S_{21}\Gamma_T S_{11}\Gamma_T S_{11}\Gamma_T S_{12} + \dots \end{aligned}$$

Figure 26. Schematic depiction of an oscillator circuit in which the transistor is represented by its S matrix and calculation is done in terms of reflection coefficients Γ_T looking into the gate termination, Γ_i looking into the gate source port of the transistor, Γ_o looking into its drain source port, and Γ_L looking into the load impedance.

Using the fact that

$$\sum_{n=0}^{\infty} x^n = \frac{1}{1-x}$$

we can reexpress the Γ s as

$$\Gamma_i = S_{11} + \frac{S_{12}S_{21}\gamma_L}{1 - S_{22}\Gamma_L}$$

$$\Gamma_o = S_{22} + \frac{S_{12}S_{21}\Gamma_T}{1 - S_{22}\Gamma_T}$$

If we define the determinant of the \mathbf{S} matrix to be Δ and be given by

$$\Delta = S_{11}S_{22} - S_{12}S_{21}$$

and a transistor κ parameter by

$$\kappa = \frac{1 - |S_{11}|^2 - |S_{22}|^2 + |\Delta|^2}{2|S_{12}S_{21}|}$$

then some tedious algebra leads to the result that stability requires

$$\kappa > 1$$

$$\Delta < 1$$

At frequencies where these condition are not satisfied, oscillation can occur if the load and termination impedances, Z_L and Z_T , respectively, are chosen properly. Oscillator design is discussed in various texts [11,14–16]. Generally, though, oscillator design involves finding instability points and not predicting the dynamics once oscillation is achieved. The next paragraph will discuss these dynamics.

If a transistor circuit is designed to be unstable, then as soon as the DC bias is raised to a level whereby the circuit achieves the set of unstable values, the circuit's output within the range of unstable frequencies rises rapidly and dramatically. The values that we took in the equivalent AC circuit, though, were small-signal parameters. As the circuit output increases, the signal will eventually no longer be small. The major thing that changes in this limit is that the input resistance to the transistor saturates, such that [17,18]

$$R_i = -R_{i\phi} + mv^2$$

where the plus sign on the nonlinearity is necessary, for if it were negative the transistor would burn up or else burn up the power supply. Generally, the m has to be determined empirically, as nonlinear circuit models have parameters that vary significantly from device to device. For definiteness, let's assume that the Z_T is resistive and the Z_L is purely inductive. At the oscillation frequency, the internal capacitance of the transistor then should cancel the load inductance, but to consider dynamics we need to put in both the C and L , as dynamics take place in the time domain. The dynamic circuit to consider is then as depicted in Fig. 27. The loop equation for this circuit in the time domain would be

$$L \frac{\partial i}{\partial t} + (R_i + R_T)i + \frac{1}{C} \int idt = 0$$

Recalling the equivalent circuit of Fig. 23 and recalling that

$$C_{gs} \gg C_{gd}$$

Figure 27. Circuit used to determine the dynamical behavior of a transistor oscillator.

we see that, approximately at any rate, we should have the relation between v_i and i_i that

$$i = C_{gs} \frac{\partial v}{\partial t}$$

Using this $i - v$ relation in the preceding, we find that

$$\frac{\partial^2 v}{\partial t^2} - \frac{R_i - R_T}{L} \left(1 - \frac{mv^2}{R_i - R_T}\right) \frac{\partial v}{\partial t} + \frac{v}{LC} = 0$$

which we could rewrite in terms of other parameters as

$$\frac{\partial^2 v}{\partial t^2} - \varepsilon(1 - \gamma^2 v^2) \frac{\partial v}{\partial t} + \omega_0^2 v = 0$$

which is the form of Van der Pol's equation (see, e.g., Refs. 17 and 18), which is an equation that describes the behavior of essentially any oscillator.

Now that we have discussed planar guiding structures and at least one example of a dynamical element that we can insert into a planar circuit, the time has arrived to discuss the planar antenna structures. Perhaps the best way to gain understanding of the operation of a patch antenna is by considering a cavity resonator model of one. A good review of microstrip antennas is given in Carver and Mink [19] and is reprinted in Ref. 20. Let's consider a patch antenna and coordinate system as is illustrated in Fig. 28. The basic idea behind the cavity model is to consider the region between the patch and ground plane as a resonator. If the resonator were a perfect one, an idealized set of boundary conditions would be satisfied that would allow no exchange of energy between the resonator and its surroundings. In actual operation, it is the inaccuracy of the idealized boundary conditions that gives rise to the transduction mechanism whereby an antenna can convert

Figure 28. A patch antenna and Cartesian coordinate system.

guided waves to radiated waves and vice versa. We will assume the idealized conditions that there is only a z -directed electric field underneath the patch and that this field achieves maxima on the edges (open-circuit boundary condition). The magnetic field will be assumed to have both H_x and H_y components (only an H_x component in what we call the fundamental mode), and tangential components of these on the edges will be zero. (This boundary condition is the one consistent with the open circuit condition on the electric field and is exact as the thickness of the layer approaches zero, as there can be no component of current normal to the edge at the edge, and it would be the normal component of the current that generates the transverse \mathbf{H} field.) The electric field satisfying the open circuit condition can be seen to be given by the modes

$$e_{mn} = \frac{\lambda_{mn}}{\sqrt{\epsilon a b t}} \cos k_n x \cos k_m y$$

where

$$k_n = \frac{n\pi}{a}$$

$$k_m = \frac{m\pi}{b}$$

$$\lambda_{mn} = \begin{cases} 1, & m = 0 \text{ and } n = 0 \\ \sqrt{2}, & m = 0 \text{ or } n = 0 \\ 2, & m \neq 0 \text{ and } n \neq 0. \end{cases}$$

The \mathbf{H} field corresponding to the \mathbf{E} field then will consist of modes

$$\mathbf{h}_{mn} = \frac{1}{j\omega\mu} \frac{\lambda_{mn}}{\epsilon a b t} [\hat{e}_x k_m \cos k_n x \sin k_m y - \hat{e}_y k_n \sin k_n x \cos k_m y]$$

Now what we will call the fundamental mode is the one with $m = 1$ and $n = 0$. We can excite such a mode by choosing the dimension b to be resonant, that is, to correspond to a half of a wavelength in the structure. The dimension transverse to this must then be chosen to be nonresonant. This can be achieved by, for example, making this dimension less than a half-wavelength, but this is not the only way by any means. Now the basic transduction operation of the antenna must be due to the fact that the boundary conditions are not quite exact and the antenna can accept energy from the feedline and radiate it into free space. Let us consider this transduction operation in the antenna's fundamental mode. One might recall from the earlier argument that accompanied Fig. 13 that the z -directed field gives rise to a fringe field at the edges $y = 0$ and $y = b$ such that there are strips of y -directed electric field at the substrate surface for $y \leq 0$ and $y \geq b$. Because the boundary conditions are not quite correct on \mathbf{H} , there will also be strips of x -directed magnetic fields in these regions. As the Poynting vector is given by $\mathbf{E} \times \mathbf{H}$, we note that these strips will give rise to a z -directed Poynting vector at each of these edges. As these edges are a half-wavelength apart and the fields are in phase and Poynting-vector-like directed, these radiating edges will give rise to an upward-radiated field. Similar arguments could be applied to the

Figure 29. (a) A transmission-line model for a patch antenna, and (b) its circuitual equivalent as resonance.

edges at $x = 0$ and $x = a$. However, the x -directed field at $x \leq 0$ has a change of sign at the middle of the edge and is pointwise oppositely directed from the x -directed electric field at $x \geq a$. These fields, therefore, only give rise to very weak radiation, as there is significant cancellation. Analysis of the slot antenna requires that we first interchange the role of the \mathbf{E} and \mathbf{H} fields and realize that the radiating edges in the case of the slot are the edges that are along the direction of the feedline structure. Thus, in the CPW structure, the dominant electric fields are in the gaps between the conductors while the dominant magnetic field in the gaps points into the substrate. The end of the center conductor splits the downward-pointing magnetic field into two phases, one to the right of the center conductor and one to the left, defining the radiating edges of the structure in terms of the null of the z -directed magnetic field.

The picture of the patch antenna as two radiating strips allows us to represent it with a transmission line as well as a circuit model. The original idea is due to Munson [21]. The transmission line model is depicted in Fig. 29. The idea is that one feeds onto an edge with an admittance (inverse impedance) of $G_1 + jB_1$ and then propagates to a second edge with admittance $G_2 + jB_2$. When the circuit is resonant, then the length of transmission line will simply complex conjugate the given load [see Eq. (4)], leading to the circuit representation of Fig. 29b. The slot admittance used by Munson [21] was just that derived for radiation from a slit in a waveguide [22] as

$$G_1 + jB_1 = \frac{\pi a}{\lambda_0 Z_0} [1 - j0.636 \ln k_0 t]$$

where Z_0 is the impedance of free space of $377\Omega(\sqrt{\pi_0/\epsilon_0})$, λ_0 is the free-space wavelength, and k_0 is the free-space propagation vector, and where a and t are defined as per Fig. 28. When the edges are identical (as for a rectangular patch), one can write

$$G_2 + jB_2 = G_1 + jB_1$$

to obtain the input impedance in the form

$$Z_i = \frac{1}{Y_i} = \frac{1}{2G_1}$$

We have now considered all of the pieces, and therefore it is time to consider a couple of actual active-antenna designs. Figure 30 depicts one of the early designs from Kai Chang's group at Texas A&M [23]. Essentially, the patch here is being used precisely as the feedback element of an amplifier circuit (as was described in combination with Fig. 9). A more compact design is that of Fig. 14 [9]. There, the transistor is actually mounted directly into the patch antenna. The slit between the gate and drain yields a

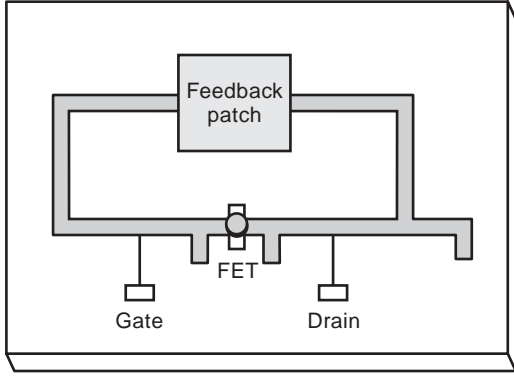

Figure 30. A design of a microstrip active radiating element.

capacitive feedback element such that the effective AC circuit equivalent of this antenna might well appear as depicted in Fig. 31. The capacitor/inductor pair attached to the gate lead form what is often referred to as a *tank circuit*, which (if the load were purely real) defines a natural frequency through the relation

$$\omega = \sqrt{\frac{1}{LC}}$$

As was discussed at some length in Section 1, a major argument for the use of active antennas is that they are sufficiently compact that they can be arrayed together. Arraying is an important method for free-space power combining, which is necessary due to the fact that, as frequency increases, the power-handling capability of active devices decreases. However, element size also decreases with increasing frequency such that use of multiple coherently combined elements can allow one to fix total array size and power more or less independently of frequency even though the number of active elements to combine increases. In the next paragraph, we'll consider some of the basics of arrays. The interested reader might also want to consult a relatively recent review article [10].

Consider a linear array such as is depicted in Fig. 32. Now let's say that the elements are nominally identical apart from phases that are set by the array operator at each of the elements. The complex electric field far from the n th element due to only the n th element would then be given by

$$\mathbf{E}_n = \mathbf{E}_e e^{i\phi_n}$$

where the \mathbf{E}_e is the electric field of a single element. To find out what is radiated in the direction θ due to the

Figure 31. AC circuit equivalent of the active antenna of Fig. 14.

Figure 32. Depiction of a linear array of N identical radiating elements.

whole array, we need to sum the fields from all of the radiators, giving each radiator the proper phase delay. Each element will get a progressive phase shift $kd \sin\theta$ due to its position (see Fig. 32), where k is the free-space propagation factor, given by

$$k = \frac{2\pi}{\lambda}$$

where λ is the free-space wavelength. With this, we can write for the total field radiated into the direction θ due to all n elements

$$\mathbf{E}_t(\theta) = \mathbf{E}_e \sum_{n=0}^{N-1} e^{-inkd \sin \theta} e^{i\phi_n}$$

The sum is generally referred to as the *array factor*. The intensity, then, in the θ direction is

$$I_t(\theta) = I_e \left| \sum_{n=0}^{N-1} e^{-inkd \sin \theta} e^{i\phi_n} \right|^2$$

One notes immediately that, if one sets the phases ϕ_n to

$$\phi_n = nkd \sin \theta$$

then the intensity in the θ direction is N^2 times the intensity due to a single element. This is the effect of coherent addition. One gets a power increase of N plus a directivity increase of N . To illustrate, let's consider the broadside case where we take all the ϕ_n to be zero. In this case, we can write the array factor in the form

$$\left| \sum_{n=0}^{N-1} e^{-ind \sin \theta} \right|^2 = \left| \frac{1 - e^{-iNkd \sin \theta}}{1 - e^{-ikd \sin \theta}} \right|^2$$

which in turn can be written as

$$AF = \frac{\sin^2 \left(N \frac{kd}{2} \sin \theta \right)}{\sin^2 \left(\frac{kd}{2} \sin \theta \right)} \quad (6)$$

which is plotted in Fig. 33. Several interesting things can be noted from the expression and plots. One thing to note is that, for kd less than π , there is only one central lobe in the pattern. Another thing to note is that the pattern becomes increasingly directed with increasing N . This is just the directivity effect. If the array had a power-combining

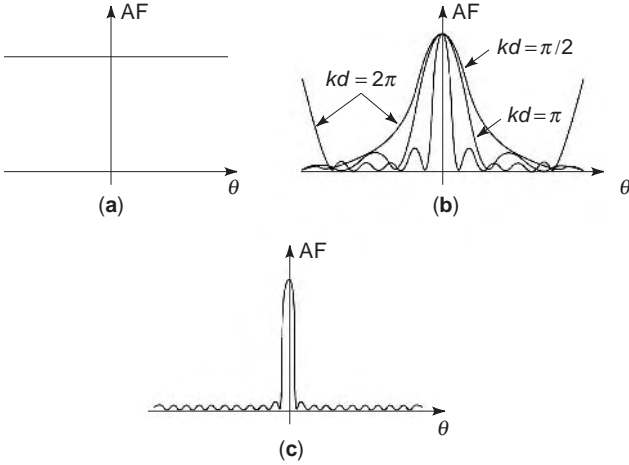

Figure 33. Plots of the array factor of Eq. (6), where (a) $N=1$, (b) $N=5$ and $kd = \pi/2, \pi$, and 2π , and (c) $N=10$ and $kd = \pi$.

efficiency of 100% (which we have built into our equations by ignoring actual couplings, etc.), then the total power radiated could only be N times that of a single element. However, it is radiated into a lobe that is only $1/N$ times as wide as that of a single element.

If we are to realize array gain, however, we need to be certain that the array elements are identical in frequency and have fixed phase relations in time. This can only take place if the elements are locked together. The idea of locking is probably best understood in relation to the Van der Pol equation [24–26], with an injected term, such that

$$\frac{\partial^2 v}{\partial t^2} - \frac{R_{i\phi} - R_T}{L} \left(1 - \frac{mv^2}{R_{i\phi} - R_T} \right) \frac{\partial v}{\partial t} + \omega_0^2 v = A \cos \omega_i t$$

where $R_{i\phi}$ is the input resistance of the transistor circuit as seen looking into the gate–source port and R_T is the external termination resistor placed between the gate and the common source. In the absence of the locking term, one can see that oscillation will take place with a primary frequency (and some harmonics) at angular frequency ω_0 with amplitude $\sqrt{R_{i0} - R_T/m}$ such that

$$v(t) \approx \sqrt{\frac{R_{i0} - R_T}{m}} \cos(\omega_0 t)$$

Without being too quantitative, one can say that, if ω_i is close enough to ω_0 and A is large enough, the oscillation will lock to ω_i in frequency and phase. If ω_i is not quite close enough and A not quite big enough (how big A needs to be is a function of how close ω_i is), then the oscillation frequency ω_0 will be shifted such that

$$v(t) = A_0 \cos((\omega_0 + \Delta\omega)t + \phi)$$

where $\Delta\omega$ and ϕ are functions of ω_i and A . These ideas are discussed in a number of places, including Refs. 1,17,18, and 24–26. In order for our array to operate in a coherent mode, the elements must be truly locked. This locking can occur through mutual coupling or through the injection of an external signal to each of the elements.

Ideally, we would like to be able to steer the locked beam. A number of techniques for doing this are presently

under investigation. A reasonably recent review article covering such techniques is [27]. Much of the thinking stems from the work of Stephan and coworkers [28–31]. One of the ideas brought out in these works was that, if the array were mutually locked and one were to try to inject one of the elements with a given phase, all the elements would lock to that phase. However, if one were to inject two elements at the locked frequency but with different phases, then the other elements would have to adjust themselves to these phases. In particular, if one had a locked linear array and one were to inject the two end elements with phases differing by ϕ , then the other elements would equally share the phase shift such that there would be a linear phase taper of magnitude ϕ uniformly distributed along the array. A different technique was developed by York [32,33] based on work he began when working with Compton [34,35]. In this technique, instead of injecting the end elements with the locked frequency and different phase, one injects the array with frequencies that are detuned from the desired center frequency. If the amplitudes of these injected frequencies are set to values that are not strong enough to lock the elements to these injected frequencies, then the elements would retain their “free-running” frequencies, but would obtain phase shifts from the injected signal as the oscillation within the element attempts to satisfy the contradictory operation instructions that are being fed to the element. If the elements of the array were locked because of mutual feedback, trying to inject either end of the array with “detuned” frequencies would then tend to give the elements a linear taper—that is, one in which the phase varies linearly with distance down the array—with much the same result as the technique of Stephan [28–31]. This will just linearly steer the mainlobe of the array off broadside and to a new direction. Such linear scanning is certainly what is needed for many commercial applications such as tracking or transmitting with minimum power to a given location. Another technique that again uses the locking-type ideas is the technique of changing the biases on each of the array’s active devices [36–38]. Changing the bias of a transistor will alter the free-running frequency at which the active antenna wants to oscillate. For an element locked to another frequency, then, changing the bias will just change the phase. In this way one can individually set the phase on each element. There are problems with this approach (as with all the others to present, which is why this area is still one of active research). One is that addressing each bias line represents a great increase in the complexity that we were trying to minimize by using an active antenna solution. The other is that the maximum phase shift obtainable with this technique is $\pm\pi$ from one end of the array to the other, a limitation that is shared by the phase shifts at the ends technique. In many phased array applications, of which electronic warfare is a typical one, one wants to have “true time delay,” which means that one would like to have as much as a π phase shift between adjacent elements. Essentially none of the techniques addressed to present can seem able to satisfy this requirement. Yet true time delay could open up a set new set of applications that could further drive work in this area. Work, however, continues. But already the

discussion has impinged on the topic of the next section, that of future application areas, and, therefore, now is a propitious time to begin this third section.

3. APPLICATIONS OF AND PROSPECTS FOR ACTIVE ANTENNAS

As was discussed earlier, active antennas were the first antennas of Hertz [4] although perhaps the greatest driver of more recent advances in this area has been power combining at high frequencies [10]. The power-combining area is becoming a subarea of high-power microwave/millimeter-wave devices by itself. However, there are numerous motivations other than simple power combining to pursue the study of active antennas. In this section, the aim is to run through a whole potpourri of past, present, and future applications. The applications to be touched on in this section are by no means exhaustive, but hopefully are representative.

Perhaps the earliest application of the active-antenna concept (following that of Hertz) was aimed at solving the small-antenna problem. As we recall, an antenna can be modeled (roughly) by a series RLC network with the R representing the radiation resistance. The input impedance of such a combination is given by

$$Z_i = \frac{1 - \frac{\omega^2}{\omega_0^2} + j\omega RC}{j\omega C}$$

and so we see that, when the operation frequency ω is well below the resonant frequency

$$\omega_0 = \frac{1}{\sqrt{LC}}$$

and the inverse of the RC time constant

$$\tau = RC$$

then the antenna appears as a capacitor and radiates quite inefficiently. The problem of reception is similar. Apparently, already in 1928 Westinghouse had a mobile antenna receiver that used a pentode as an inductive loading element in order to boost the amount of low-frequency radiation that could be converted to circuit current. In 1974, two works discussed transistor-based solutions to the short aerial problem [39,40]. In Ref. 40, the load circuit appeared as in Fig. 34. The idea was to generate an inductive load whose impedance varied with frequency, unlike a regular inductor, but so as to increase antenna bandwidth. The circuit's operation is not intuitively obvious. It is possible that most AM, shortwave, and FM receivers employ some short antenna solution regardless of whether the actual circuit designers are aware that they are employing active antenna techniques.

More recent efforts aimed at miniaturization have been concentrated on efficient amplification by single active-antenna elements rather than solving the small-antenna problem. For example, handheld wireless communication requires not only compact antenna elements but also compact and efficient amplification at the element. High-efficiency F class amplifiers were already under study in

Figure 34. A circuit taken from Ref. 37 in which a transistor circuit is used to load a short antenna. Analysis shows that, in the frequency regime of interest, the loading circuit appears, when looking toward the antenna from the amplifier terminals, to cancel the strongly capacitive load of the short antenna.

1993 [41] followed by studies of lower-frequency class E amplifiers [42]. Efforts at fabricating integrated active-antenna elements employing high efficiency amplifiers have used resonant (if modified) patch elements, and have therefore in order to remain compact have carried out demonstrations at higher frequencies (S and C bands) where the resonant patches are more compact because of the smaller wavelengths, as is evidenced by work at Tatsuuo Itoh's group at UCLA in [43,44]. Kalialakis et al. attempted to make the active antenna not only efficient but also duplex and thereby a candidate for a transceiver [45].

Another set of applications where active devices are used as loading elements is in the >100 -GHz regime. Developments in this regime are reviewed in Refs. 1 and 46. To date, most work at frequencies greater than 100 GHz has involved radioastronomical receivers. A problem at such frequencies is a lack of components, including circuit elements so basic as waveguides. Microstrip guides already start having extramode problems at Ku band. Coplanar waveguides can go higher, although to present, rectangular metallic waveguides are the preferred guiding structures past about 60 GHz. In W band (normally narrowband, about 94 GHz—see Table 1), there are components, as around 94 GHz there is an atmospheric window of low propagation loss. However, waveguide tolerances, which must be a small percentage of the wavelength, are already severe in W band, where the wavelength is roughly 3 mm. Higher frequencies pretty much have to be handled in free space or, as one says, quasioptically. Receivers must therefore by nature be downconverting in this >100 GHz regime. Indeed, these types of solutions are the ones being demonstrated by the group at Michigan [46], where receivers will contain multipliers and downconverting mixers right in the antenna elements in order that CPW can be used to carry the downconverted signals to the processing electronics. Millimeter-wave/terahertz radioastronomy seems to be a prime niche for quasioptical active-antenna solutions.

The first applications of active antennas where solid-state components were used as gain elements were for power boosting [47–52]. By 1960, solid-state technology had come far enough that antennas integrated with diodes and transistors could be demonstrated. These early demonstrations of *antennafiers* [48] could be considered as the precursors of the high-efficiency integrated antennas we

mentioned in an earlier paragraph, but judging from the reference lists of these more recent works [43,44], there doesn't seem to be much of causal relationship. In fact, this early integrated active-antenna technology was to remain a laboratory curiosity per se until the 1980s, when further improvements in microwave devices were to render the technology more practical. The motivation at that point in time was primarily large gain. Large power gain, however, really requires combining the outputs of multiple solid-state devices. Power combining (see reviews in Refs. 10, 53, and 54), though, can be hard to achieve. There is a theorem that grew out of the early days of radiometry and radiative transfer (in the 1800s) known variously as the *brightness theorem*, the *Lagrange invariant*, or later the (later) *second law of thermodynamics*. (See, for example, Ref. 55 for some discussion of the Lagrange invariant.) The theorem essentially states that one cannot increase the brightness of a source by passive means. This theorem practically means that if one tries to combine two nominally identical but non-phase-locked sources by taking their outputs, and attempting to launch those two outputs into the same direction in space such that the two beams occupy the same spatial location in space, the resulting power density per steradian can be no greater than that of either of the nominally identical sources. Other power that was intended to go into this desired direction will have gone in some other direction. This seems to preclude any form of power combining. There is a proviso here, though. At the time the brightness theorem was first formulated, there were no coherent radiation sources. If one takes the output of a coherent radiation source, splits it in two, and adds it back together in phase, then the brightness, which was halved, can be restored. If two sources are phase locked, they are essentially one source. Therefore, locked sources can be coherently added if they are properly phased. A major portion of the power-combining field is therefore associated with techniques to lock individual radiating elements together into coherent sources and/or to amplify the output of weak sources in arrays of devices that lock to the source and to each other. It turns out that a powerful method with which to carry out such power combining employs the techniques that are generally referred to as *free-space power combining*.

A number of groups are working on developing compact elements for free-space power combining. Examples of free-space power-combining schemes have already appeared in Fig. 14 [9] and 30 [22]. In designs where the elements are spatially packed tightly enough, proximity can lead to strong enough nearest-neighbor coupling so that an array will lock to a common frequency and phase. Closeness of elements is also desirable in that arrays with less than $\lambda/2$ spacing will have no sidelobes sapping power from the central array beam. In designs that don't self-lock, one must either inject a locking signal on bias lines or spatially from a horn to try to lock to all elements simultaneously. A method for carrying out power combining in a self-locking array is to use the so-called *grid oscillator* solution [56,57]. The actual structure of a grid appears as in Fig. 35. The operating principle of the grid is actually quite a bit different from that of the arrays of weakly coupled individual elements. Note that there is no ground

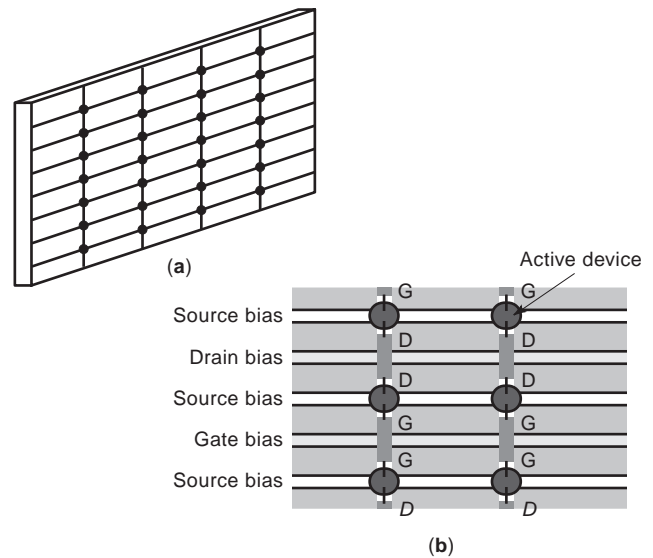

Figure 35. Schematic depiction of (a) the active surface of a grid oscillator and (b) a breakout of an internal region of the grid showing the active device placement relative to the bias lines.

plane at all on the back, and there is no ground plane either, per se, on the front side. Direct optical measurements of the potentials on the various lines of the grid [58], however, show that the source bias lines act somewhat as AC grounds. In this sense, either a drain bias line, together with the two closest source biases, or a gate bias line together with the two horizontally adjacent bias lines appears somewhat like CPW. The CPW lines, however, are periodically loaded ones with periodic active elements alternated with structures that appear like slot antennas. The radiating edges of the slots are, for the drain bias lines, the vertical AC connection lines between drain and drain or, for the gate bias CPW, the horizontal AC gate-to-gate convection lines. Indeed, the grid is known to lock strongly along the rows and more weakly between columns. As adjacent-row elements are sharing a patch radiator, this should be expected behavior. In a major sense, this strong locking behavior of the grid is both an advantage and a disadvantage. It is advantageous that the grid is compact (element spacing can be $\leq \lambda/6$) and further that it is easy to get the rows to lock to each other. However, the compactness is also a disadvantage in that it is quite hard to get any more functionality on the grid. Much effort has been given in this area to generate functionality by stacking various grid-based active surfaces such as amplifying surfaces, varactor surfaces for frequency shifting and modulation, or doubling surfaces. A problem with stacking is, of course, diffraction as well as alignment. Alignment tolerance adds to complexity. Diffraction tends to ease alignment tolerance, but in an inelegant manner. A 100-transistor array with $\lambda/6$ spacing will have an extent of roughly 1.5λ per side. As the diffraction angle is something like the wavelength divided by the array diameter, the diffraction angle for such an array is a major portion of a radian. One can say that grids are quasioptical, but in optics one seldom uses apertures too much smaller than a millimeter, for which the diffraction angle

would be roughly a thousandth of a radian. As far as pure combining efficiency goes, grids are probably the optimal solution. However, more functionality may well be hard to obtain with this solution. But then, as was previously mentioned, free-space power combining is itself becoming a subarea of high-power microwave/millimeter-wave sources as is evidenced by a review article [10].

Another application area of active antennas is that of proximity detection [59]. The idea is that an oscillator in an antenna element can be very sensitive to its nearby (within several wavelengths) environment. As was discussed previously, variation in distances to ground planes change impedances. The proximity of any metal object will, to some extent, cause the oscillator to be aware of another ground plane in parallel with the one in the circuit. This will change the impedance that the oscillator sees and thereby steer the oscillator frequency. The active antenna of Ref. 59 operated as a self-oscillating mixer; that is, the active element used the antenna as a load, whereas the antenna also used a diode mixer between itself and a low-frequency external circuit. The antenna acted both as a transmitting and receiving antenna. If there were something moving near the antenna, the signal reflected off the object and rereceived might well be at a different frequency than the shifting oscillator frequency. These two frequencies would then beat in the mixer, be downconverted, and show up as a low-frequency beat note in the external circuit. If such a composite device were to be used in a controlled environment, one could calibrate the output to determine what is occurring. Although Navarro and Chang [1, p. 130] mention such applications as automatic door openers and burglar alarms, I personally don't know how far the technology has gone into such commercial application. The original paper [59], though, seemed to have a different application in mind, as the term *Doppler sensor* appeared in the title. If one were to carefully control the immediate environment of the self-oscillating mixer, then reflections off more distant objects received by the antenna would beat with the stable frequency of the oscillator. The resulting beat note of the signals would then be the Doppler shift of the outgoing signal on reflection off the surface of the moving object, and from it one could determine the normal component of the object's velocity. It is my understanding that some low-cost radars operate on such a principle. As with other applications, though, the active-antenna principle, if due only to size constraints, becomes even more appealing at millimeter-wave frequencies, and at such frequencies power constraints favor use of arrays.

An older field that seems to be going through an active-antenna renaissance is that of retroreflection. A retro-reflector is a device that, when illuminated from any arbitrary direction, will return a signal directly back to the source. Clearly, retroreflectors are useful for return calibration as well as for various tracking purposes. An archetypical passive retroreflector would be a corner cube. Another idea for a passive reflector is a Van Atta array [60]. Such an array uses wires to interconnect the array elements such that the phase progression of the incident signal is conjugated and thereby returned in the direction of the source. As was pointed out by Friis in the 1930s,

though, phase conjugation is carried out in any mixer in which the local oscillator frequency exceeds the signal frequency [61]. This principle was already being exploited in 1963 for implementing retroreflection [62]. This work didn't seem to catch on, perhaps due to technology. A review in 1994 [63] and designs for such arrays were demonstrated and presented at the 1995 International Microwave Symposium [64,65]. For a more recent demonstration, a group of UCLA researchers borrows from the term *phase conjugation* from the optics literature in order to describe their work [66]. Work in this area of retrodirective arrays continues [67].

Although much has been done in the area of active antennas in general and active integrated antennas in particular, much remains to be done, and the area remains an active one at this point in time. Although the field of active antennas began with the field of radiofrequency, it still seems to be a field in its infancy and one that should continue to grow and change with advances in technology.

ACTIVE FILTERS: OVERVIEW OF ACTIVE-FILTER STRUCTURES

LAURENT BILLONNET

IRCOM University of Limoges
Limoges, Cedex, France

1. INTRODUCTION

Telecommunication services and products fueled by Internet, mobile, and space markets, have grown spectacularly since the early 1990s with no signs of slowing down. The use of microwave, millimeter-wave, and more generally high-frequency circuits, for today's applications, concerns at the same level detection systems (radars, intrusion sensors, etc.), the medical domain, and also various communication systems (e.g., telephone, PCS, data transfer, Internet by satellite, military applications, WLAN, Bluetooth). Such systems employ different RF functions or subsystems. Basic blocks can be divided into two categories. The first category concerns passive blocks or functions such as multiplexers, delays, couplers, isolators and connection sections (e.g., transmission lines). The second category focuses instead on active blocks, that is, blocks that use basic active components (transistors) or more complex subsystems. Basic subsystems to consider in this case are amplifiers, mixers, oscillators, and filters. Amplifiers are generally used to extract the information signal from noise in a front-end receiver or to increase the signal level in a transmitter chain. Mixers are used to upconvert or downconvert (modulate or demodulate) the working frequency of a signal to enable its transmission through a particular media (e.g., for hertzian transmission) or in a particular dedicated frequency band (e.g., in a given channel between a base station and a satellite or as a relay between two satellites). Oscillators are frequency sources most often used in association with mixers. The frequencies generated drive the up- or downconversion during a modulation/demodulation process. Finally, another essential block in a communication system is a filter. What is a filter [1]? A filter performs an electrical function used for a frequency selection process. This process can consist in

preserving a frequency band. We then speak either of low-pass, bandpass, or highpass filters. These filters are used to process a signal that must be transmitted to another part of a chain. The process can also consist in rejecting frequency bands. We speak in this case of bandstop filters. These filters are used to eliminate the effect or influence of a parasitic signal next to the frequency of a working signal. Note that lowpass or highpass filters may be considered, depending on their use (selection or rejection) as rejecting filters.

With the need of compact size and light weight for new satellite and PCS applications, the translation from classical waveguide-type technologies to planar integrated processes has become unavoidable. If passive filters solutions are first considered, reducing insertion losses and, as a result, increasing battery life and noise performance, the use of high- Q volumic resonators is needed. The latter cannot be reached by use of conventional planar MIC or MMIC technologies where unloaded Q factor does not exceed 200–300 and rapidly decreases with increasing frequency. The solution cannot then be found on the basis of conventional frequency selective passive circuits. One well-known limitation is the ratio between insertion loss and bandwidth. Their product is a constant for a given realization of passive filtering structure.

One promising way that naturally comes to mind to overcome these drawbacks, and specifically losses compensation, is the integration of passive filters with active components or devices. As we show it in this article, on the basis of this idea, different configurations of microwave active filters (MAFs) have been developed, and new types are under intensive search and study nowadays.

The key features of MAFs are:

- Gain control without distortion of the frequency response
- Frequency tuning capability (in Hz)
- Frequency agility for fast-tuned filters (in Hz/s)
- Capability of modifying specified poles to improve response selectivity
- Possibility of implementing automatic frequency control techniques
- Easy use of MIC/MMIC and integrated technologies
- Small filter dimensions and weight

However, in comparison to purely passive structures, implementation of active devices is accompanied with undesirable factors to take into account, such as:

- Noise figure increase
- Critical power-handling behavior
- Dynamic range reduction
- Electrical stability
- Stability of active parts under variations of external mechanical, climatic, optical, or electromagnetic conditions

In the design of microwave active filters, first task of researchers has then been to deal with imperfect active devices and lossy passive components [2]. The situation was

similar to that encountered before the advent of high-performance op-amps (operational amplifiers) in the 1950s and 1960s, when audiofrequency active RC filter designs were attempted. By adapting some of the active solutions used at lower frequency, investigators have then devised a number of interesting circuits. In this section, we first talk about the different families of filters. We evaluate different ways of classifying MAFs and show that two main categories can be finally considered. For the first category, we describe, from a general point of view, various compensation techniques and detail more specifically filters based on the use of gyrators and negative-impedance converters (NICs). At this step, we emphasize different problems that must be faced by RF and microwave designers in comparison to low-frequency classical designs. The second category is based on filters resulting from the application of methods and concepts used primarily at low frequency. As an example, this section sums up the different ways of considering and implementing recursive and transversal (R&T) filters for the microwave purpose.

2. MAF CLASSIFICATION

Most MAFs can be classified into several levels of a consideration depending on their basic topology structure, type of passive and active elements used, resonator configurations, guiding structures, application domain, working frequency band, and other factors. Major problem for MAF classification resides in the fact that there is still no systematic method to predict which active solution is the best to fit given specific functional requirements.

From our point of view, active filter structures at microwaves can be divided into two main categories:

- Active filters resulting from the improvement of classical microwave passive structures (category 1)
- Active filters resulting from the application, in the microwave domain, of methods and concepts primarily used at low frequency (category 2)

In fact, active-filter categories can, using the same approach, be defined by considering how the active components or functions improve the basic passive structures:

- If the active parts are used as correction blocks (e.g., for loss compensation), then the corresponding active filter belongs more to the first category;
- If the improvement is done through the benefit of a typical active property (except compensation, e.g., through nonreciprocity, unilaterality, or gain), then the second category is indicated.

Depending on the way the active parts contribute to the response improvement, the resulting filter can belong to one or the other category. As an example, consider the simple case of a classical LC filter for which the response improvement is realized through the use of an “active inductance”:

- If the active inductance consists in a classical passive inductance in which losses are compensated with a

NIC (a negative resistance), the global filter rather belongs to the first category.

- On the other hand, if the active inductance results from the capacitive load of a gyrator (which specific role, as we will see later, is to invert an impedance), then the global filter is of the second category.

Most realizations to date use the compensation principle and then belong to category 1 [3–6]. However, as it will be shown further, original approaches now tends to design circuits of category 2.

3. COMPENSATION TECHNIQUES

Referring to filter category 1, we show here various approaches to compensate (from a general point of view) the response of filter structures. Considering circuits using either distributed elements (in microstrip or coplanar technology) or lumped elements (using, e.g., monolithic integrated processes), compensation can be done in three basic ways.

3.1. Amplifiers for Loss Compensation

A first solution is used for resonator-based planar or volumic structures. It consists in compensating for the passive losses of one or more resonator thanks to the feedback of an amplifier. In terms of the compensation, the two-port amplifier is equivalent to a one-port negative resistance, as will be shown below. Following this principle, an example of a three-pole filter realized on a duroid substrate is given in Fig. 1 [7]. In this case, only the central resonator losses are directly compensated by the amplifier of adequate phase and gain values. These values are calculated to maintain the electrical stability (see Active filters: tools and techniques for active-filter design, Section 2). Input and output coupling values have been chosen to perform a 400 MHz bandwidth at 12 GHz. Figure 2 shows the improvement provided by the amplifier. Measurements of the filter in Fig. 3 show a perfect loss compensation within the passband. Poor input matching is due to a nonperfect matching of the amplifier. The same approach has been applied to volumic structures [8] for a third-order dielectric resonator (DR) filter for which the central resonator is compensated by an active loop [9].

3.2. Active Matching Approach

This active matching technique has already been successfully used and described at lower frequencies for broad-

Figure 1. Topology of a third-order planar active filter.

Figure 2. Simulated passive and compensated third-order planar filter responses.

band matching [10,11]. As an example, the filter consists here of a cascade association of three sections (Fig. 4) [12]. First and last sections act respectively as input and output matching networks. PHEMT active devices in common-gate and common-drain configurations have been used instead of passive elements to achieve wideband matching simultaneously as gain performances. The bandpass filter response is obtained by the intermediate section composed of a passive lumped-element network that sets the filter center frequency. The main goals of the common-gate and common-drain stages are to improve selectivity, compensate for the passive network losses, and match the filter to $50\ \Omega$ external impedances.

At high frequencies, the common-gate configuration is unilateral, whereas the common-drain configuration becomes nonunilateral, thus being capable of achieving both

Figure 3. Measured third-order planar filter response.

input and output matchings to $50\ \Omega$ impedances. It can be shown [13] that the voltage transfer function of the passive section realizes a bandpass filter response. Replacing the common-gate and common-drain transistors in Fig. 4 by their equivalent models, it can be demonstrated that S_{21} is proportional to the voltage transfer function, thus realizing a bandpass filter response. Figure 5 shows the layout of the monolithic microwave integrated circuit (MMIC) using ED02Ah GaAs process from OMMIC [14]. Dimensions of the chip are $1.5 \times 1\ \text{mm}^2$. Total DC power consumption is 80 mW. Figure 6 shows a comparison between computer-simulated and measured results. The active filter operates at 31.825 GHz with 0.5 dB gain and 1.5 GHz with $-3\ \text{dB}$ bandwidth. Active matching approach appears to be suitable to achieve broadband performance with $|S_{ii}| < -12\ \text{dB}$. At the central frequency, the noise factor of the filter is equal to the minimum noise factor of 4 dB. The $-1\ \text{dB}$ compression point occurs for an input power of $+3\ \text{dBm}$. Noise performance and power-handling capabilities are discussed in the article on active-filter design tools and techniques, cited above (in Section 3.1).

3.3. Filtering/Matching Approach with Gain

The method is derived from classical lumped matching technique but it differs in the fact that a preliminary matching step is performed on the active part. This alternative method combines amplification and filtering functions based on the use of an active element with cascaded passive lumped filtering sections also contributing to the matching of the active part. A circuit example using this approach is presented in Fig. 7 [12]. The basic methodology first consists in simply doing a preliminary matching of a single transistor at the central frequency thanks to two inductances at the input and output. Wideband matching and filtering principles are then simultaneously realized by lumped passive filtering sections placed either before or after the preliminary matched active device while maintaining gain in the passband.

In comparison to a classical method, the preliminary matching using only two components achieves a significant reduction in the number of elements of the matching sections that can then be achieved much more simply. The chip size is only $1.5 \times 1\ \text{mm}$. Total DC power consumption is 20 mW. Figure 8 shows a comparison between computer-simulated and measured results. This filter operates at 14.12 GHz. The gain is near 0 dB, and the $-3\ \text{dB}$ bandwidth is 1.77 GHz. Good performances are obtained, especially for the input matching ($|S_{11}| = -17.26\ \text{dB}$). Simulated noise factor is equal to 2.7 dB at the center frequency.

3.4. Gytrators and NICs

The last compensation approach consists in using gyrators or NICs. Gytrators (impedance inverters) and NICs are functions initially used at low frequency. Their role is to build a given impedance through an intermediate load impedance. Thus, the impedance at a gyrator input is inversely proportional to the load impedance of the gyrator. In the NIC case, the input impedance is proportional to the negative of the load impedance of the NIC.

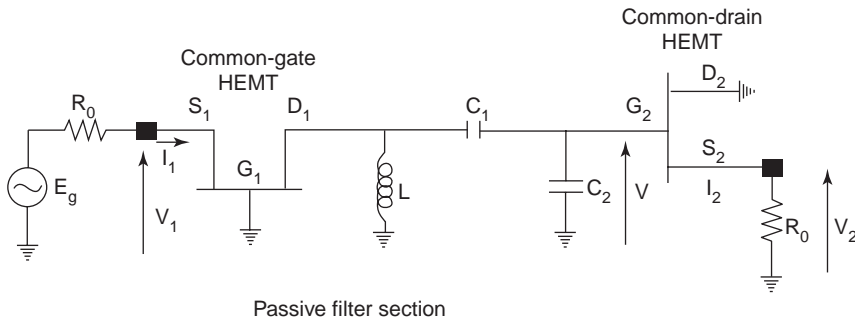

Figure 4. Actively matched passive lumped filter.

In most cases, NICs are dedicated to the compensation of losses and of resistive parts. However, overcompensation has already been used for oscillator design [15,16]. Gytrators are more classically used for high-value reactance design (in particular, for inductances) and for ideal inductances [17,18].

3.4.1. Design Problems at Microwaves. A large number of gyrators and NICs topologies have been investigated. Most of them come from the low frequency domain, where transistors and op amps can be considered as ideal transconductances and amplifiers with infinite gain, respectively.

At microwaves, gyrators and NICs topologies can be divided into two categories. As an example, we consider the NIC case here:

- In Fig. 9, high-gain transistors are considered as high-value transconductances. Input impedance of the global circuit then depends only on the three load impedances Z_1 , Z_2 , Z_3 , and is given by:

$$Z_{in} = -\frac{Z_1 Z_2}{Z_3}$$

- For the second category, transistors are modeled as finite-value transconductances. In Fig. 10, input impedance depends not only on a load impedance Z but

also on the two transconductances g_1 and g_2 , and is given by:

$$Z_{in} = -\frac{1}{g_1 g_2 Z}$$

However, whatever category is considered, investigator has to face some problems inherent to the microwave domain:

- Transconductances values cannot be infinite.
- Transistors cannot be modeled as simply as at low frequency, even in the linear regime.
- Passive components are not ideal and present losses or unwanted distributed effects.
- Interconnecting elements (in general transmission-line sections) lead to nonnegligible effects on the whole circuit response.

Considering the example of Fig. 10 at microwaves, when loaded with a pure resistance R , the circuit can provide a complex input impedance, even with a positive real part. Therefore, even if the idea of a simple transposition of low-frequency concepts to microwaves is promising, more complex compensation means must be considered.

3.4.2. Design Methodologies. In many cases, for negative-resistance circuits, designers just try to fit the negative real part of the desired impedance and accommodate as best as possible with the parasitic or unwanted imag-

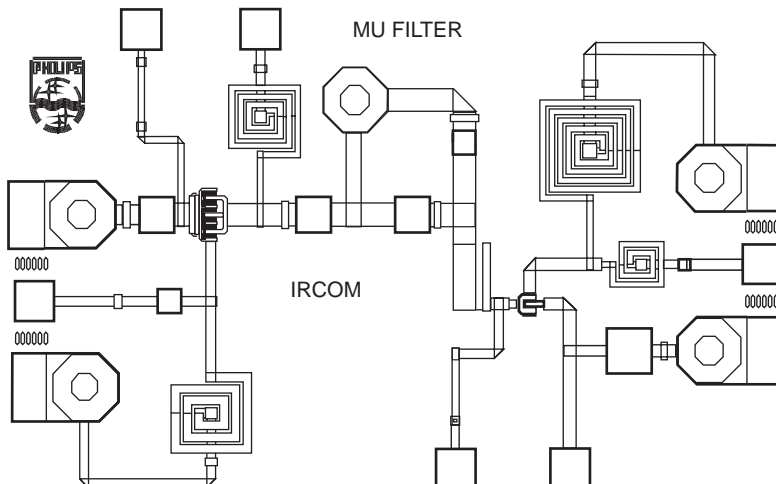

Figure 5. Layout of the actively matched passive lumped filter.

Figure 6. Comparison between simulated and measured S_{21} parameter of the actively matched passive lumped filter.

inary part when associating it to the rest of the filter [19,20]. This is the same for active inductances when designers try to fit only the imaginary part without sufficiently factoring in the parasitic real part, thus leading to poor- Q -factor inductances. Most part of the time, this tendency is only due to the lack of a systematic procedure. Some researchers have derived interesting methodologies to overcome these problems. Among all the attempts, one of the most interesting and simplest has been done by Sussman-Fort [21].

To explain the method, we come back to the topology of Fig. 10. Consider now the two-port NIC represented by its chain matrix (classically four parameters: A , B , C , and D) and loaded with an impedance Z . The input impedance is given by:

$$Z_{in} = \frac{AZ + B}{CZ + D} \quad (1)$$

Considering that a pure load resistance R at port 2 does not lead to $-R$ at the input at microwaves, the question we now consider is whether the corresponding Z_{in} can still be made to be a negative resistance by choosing a special load impedance Z . To answer this, we set $Z_{in} = -R$ in (1) and solve for the required Z as follows:

$$Z = -\frac{DR + B}{CR + A} = -Z' \quad (2)$$

Figure 7. Schematic of the preliminary matched filter structure.

Referring to (2), Z may be interpreted as the negative of the impedance Z' looking into port 2 when port 1 (the input) is terminated with the negative of the desired input impedance (here R is the negative of $-R$).

The design approach then simply consists in terminating the input of the circuit with the negative of the desired impedance, and to synthesize the negative of the impedance seen at port 2 under this condition. In our example, we then first load the input with R , look at the resulting impedance Z' at port 2, and try to synthesize $-Z'$, that is, Z .

A restriction must, however, be emphasized in the fact that the real part of Z must be positive to lead to a passive network to synthesize at port 2. If not, the procedure turns to a nonsense approach since a negative resistance will still have to be synthesized at port 2.

Note that this general procedure can also be applied for the design of ideal inductance. In that case, the procedure leads to synthesize the negative of the impedance seen at port 2 when the input is loaded by a negative inductance. The procedure applies for NICs as well as for gyrators. In any case, the impedance needed at port 2 can be synthesized using any adequate CAD software based, for example, on the real frequency technique.

To further facilitate the design, additional preliminaries can be applied before using this technique:

- In the case of infinite transconductance NICs or gyrators, each transistor can be replaced by a cascade association of two or more transistors to emulate as close as possible an infinite transconductance value [22].
- In the case of a finite-value transconductance NIC or gyrator, each transistor can be substituted with two transistors in a cascade configuration [21]. The desired effect here is to reduce the parasitics of the transistors.

However, in both cases, the synthesis steps cannot be skipped and are not sufficient to get close enough to the ideal case. Moreover, the cascade approach increases power consumption and degrades the power-handling capabilities (and in particular the compression point).

Another interesting design approach [23] can be associated with the Sussman-Fort basic approach for the complex load impedance synthesis. It relies on an original assisted visual representation of the design process.

Until now, there have been two main approaches to synthesize broadband matching and compensation networks for microwave active circuits. The first approach is based on the analytic theory by Fano [24] and Youla [25]; the second is the use of the already mentioned real frequency

Figure 8. Simulated and measured S_{21} parameter of the preliminary matched filter.

technique (RFTs) by Carlin and Yarman [26]. Unfortunately, these approaches involve several limitations:

- It is difficult to apply them directly for the design of complex active circuits (i.e., circuits with several matching/compensation networks).
- With the synthesis techniques above, network configurations and elements result from fully formalized, complicated numerical procedures. Therefore, the designer has only very limited possibilities to control these configurations and elements.
- If distributed-element matching networks have to be designed, both the analytical procedures and RFTs lead to networks made from commensurate transmission lines. However, in practice, it may be

Figure 9. Example of a high-transconductance NIC topology.

Figure 10. Example of a finite-value transconductance NIC topology.

preferable to employ networks consisting of noncommensurate lines, or mixed lumped/distributed-element networks.

To overcome these limitations, a new decomposition synthesis approach has been introduced for designing linear and nonlinear active circuits with passive matching/compensation networks. This method supposes that the design of active circuit is accomplished in two steps:

- Determination of acceptable regions of the matching/compensation networks immittances at sample frequencies over a frequency band of interest, according to a set of circuit specification ranges (noise, gain, matching levels)
- Synthesis of matching/compensation networks based on the acceptable immittance regions.

This technique allows the user to select a suitable network configuration and to directly control all the network elements for successful fabrication. Lumped, distributed noncommensurate line and mixed (lumped/distributed) networks of moderate complexity can then be designed. The approach is implemented in the software tool LOCUS, offering simple and fast means to produce solutions

Figure 11. Simulated and measured imaginary part of the 1.5 nH active inductance.

Figure 12. Basic LC shunt bandpass filter topology.

without the need for complicated circuit theory and mathematics. Other approaches have been developed by Yarman [27].

3.4.3. Circuit Examples. We give here three application examples of the compensation principle. The first example concerns the design of an ideal inductor in the 3.8–4.2 GHz band for a high- Q filter at 4 GHz [28]. Here, a spiral MMIC inductor is cascaded with a negative-impedance converter to obtain a high- Q inductor. Topology used is of infinite transconductance NIC type. The circuit has been drawn with the elements of the HB200 UMS (United Monolithic Semiconductors) process [29]. The size of the MMIC chip is 2.2×1.8 mm. Figure 11 shows simulated and measured results. The imaginary part is close to the expected value and losses are perfectly compensated.

The active inductance can then be used to design selective band-pass filters. Basic topology is presented in Fig. 12 [28]. Coupled lines are used at the input and output of the circuit to decouple the LC resonator and control the filter selectivity. Response of the filter achieves a Q factor of 1000 with a perfect loss compensation at the center frequency. A photograph of the filter is given in Fig. 13. Note the input and output coupling elements and the capacitance in parallel with the compensated spiral inductor.

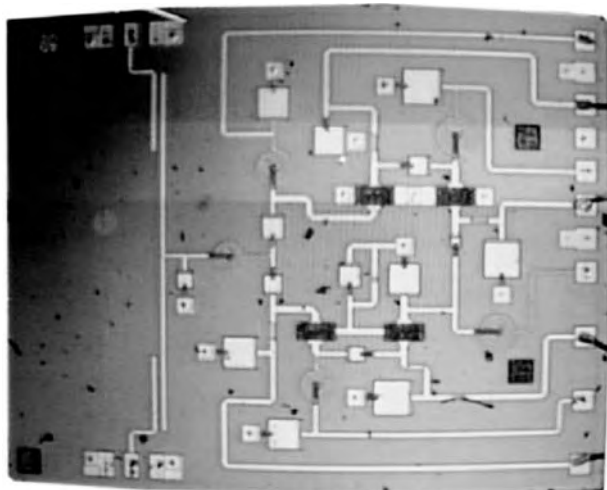

Figure 13. Photograph of the actively compensated LC shunt bandpass filter.

Figure 14. Layout of the tunable compensated bandstop filter.

The second example focuses on an active tunable bandstop filter using lumped elements [28]. We use here pseudolumped inductors built and synthesized in microstrip technology. Center frequency is optimized at 2 GHz. This filter can be tuned in frequency by using a varactor diode. Losses of the microstrip inductors and of the varactor diode are compensated by the negative-resistance circuit of Fig. 10. In a first step, characteristics of lumped inductors are studied according to the different geometric dimensions to determine an electrical equivalent schematic. This study is realized thanks to classical EM-CAD software packages. We use here an alumina substrate ($\epsilon_r = 9.8$; $h_s = 635 \mu\text{m}$). For this filter, the inductor chosen is realized with a single meander of length 1 mm, gap $30 \mu\text{m}$, and strip width $255 \mu\text{m}$. Layout of the filter including the MMIC chip is shown in Fig. 14. Measurements are shown in Fig. 15. Note that this bandstop filter is tunable in frequency over a wide band (nearly one octave). Tunability is also one interesting capability of active filters. It gives the property of being reconfigurable in frequency. Other examples of response tunability will be given and commented in the next sections. In this case, the tuning range varies from 1.3 to 2.6 GHz (66% of center frequency). The losses are well compensated as intended.

Figure 15. Measured tuned response of the compensated bandstop filter.

Figure 16. Layout of the two-pole active bandpass filter.

In the third example, we use the same type of NIC chip to compensate for the losses of a two-pole microstrip bandpass filter [30]. Interdigital capacitors and meander inductors are used to obtain a center frequency at 1.6 GHz. Compensation is made at one end of the inductors as shown in Fig. 16. Figure 17 shows the simulated response of the filter using the measured results of the MMIC chip. This figure also illustrates the response that would be obtained at the same frequency (due to the imaginary part of the MMIC impedance) without the negative real part of the MMICs. As can be seen, the difference of level obtained at the center frequency is more than 16 dB.

4. LOW-FREQUENCY CONCEPTS AT MICROWAVE APPLICATION TO RECURSIVE FILTER DESIGN

This section focuses on filters of category 2: active filters resulting from the application, in the microwave domain, of methods of filtering and concepts firstly used at low frequency.

4.1. Theoretical Background

Active filters have, for many years, focused at low frequency on operational amplifier approaches because of the abilities of such components to compensate for the

intrinsic losses of passive components, and for the overall amplification also provided. Although the physical constraints are strongly different, these advantages carry over to microwave frequencies, thus showing an increasing interest in adapting low-frequency techniques for use in microwave systems. One of these techniques includes the design of recursive and transversal filters. Application of such concepts to filtering structures clearly must employ MMIC technology [31].

Recursive and transversal filters are governed by the following time-domain (3) and frequency-domain (4) equations, where $x(t)$ [$y(t)$] is the input [output] of the system:

$$y(t) = \sum_{k=0}^N a_k x(t - k\tau) - \sum_{p=1}^P b_p y(t - p\tau) \quad (3)$$

$$H(f) = \frac{Y(f)}{X(f)} = \frac{\sum_{k=0}^N a_k e^{-2j\pi f k \tau}}{1 + \sum_{p=1}^P b_p e^{-2j\pi f p \tau}} \quad (4)$$

Implementation of the corresponding (N:P)-order filter requires multiple constant delay increments τ , amplitude weighting elements $\{a_k\}$ and $\{b_p\}$, and a mean of combining the elementary delayed signal components.

Figure 17. Influence of the negative real part of the MMIC on loss compensation of the two-pole bandpass filter.

Figure 18. Topology of the first-order microwave recursive filter.

4.2. Power Matching Approach

Several approaches have been investigated to implement recursive responses. A first approach [31,32] consists in identifying a transversal filter with a distributed amplifier to get a ladder-type structure. However, this technique impose respectively a lowpass filter and a highpass filter before and after each transistor of the structure, to simultaneously realize the necessary delay time τ , and contribute to the response selectivity.

Another simple solution consists in considering combiners at microwaves, as power dividers/combiners [33]. This approach enables filter branches to be easily associated and then to be designed separately, each of them matched to the same impedance (in general, $50\ \Omega$), naturally leading to the identification of the weighting parameters as microwave amplifiers [34–36].

Following these principles for MMIC design purpose, we consider here a first-order recursive filter, shown in Fig. 18 [37]. Power dividers/combiners are built in MMIC technology with lumped-element cells in order to minimize the size of the final device. Each power divider/

combiner requires five lumped components. Delay time τ is built with a lowpass T cell. A one-stage pseudoresistive amplifier, including two RL series circuits for the matching of a single FET, is chosen here [38], thus again reducing the dimensions of the resulting circuit. For electrical stability reasons that we discuss in the article on active-filter design tools and techniques (cited above, in Section 3.1), the amplifier gain is adjusted to obtain the ratio $|S_{21}|_{\max}/|S_{21}|_{\min} = 10$ (20 dB) in the 7.5–12.5 GHz range. Figure 19 shows the layout of the filter, following OMMIC MMIC process design rules [14]. The circuit is implemented on an $100\text{-}\mu\text{m}$ -thick GaAs substrate. Dimensions of the chip are 2.0×1.5 mm. Perfect agreement between simulated and measured results is shown in Fig. 20.

4.3. Voltage Matching Approach

Considering that voltage matching and input/output signals combination can be more easily obtained over wider frequency bands than power matching, an alternative technique consists in synthesizing the filter responses owing to the use of voltage-matched devices [13]. At a last step, the whole circuit is matched to $50\ \Omega$ external impedances using FETs as described in Section 3.2. The classical recursive flow graph can be identified to the idealized series–shunt feedback model where an ideal adder is used to loop a unilateral forward active path $\mu(j\omega)$ with a passive path $\beta(j\omega)$. Under these assumptions, the overall transfer function can be identified as the transfer function of a first-order recursive filter if $\mu(j\omega) = 1$ and $\beta(j\omega) = -b_1 e^{-j\omega\tau}$.

The design procedure begins by first determining the circuit that realizes the voltage summation function at the input of the feedback. Then, the passive feedback device must provide the necessary delay time imposed by the

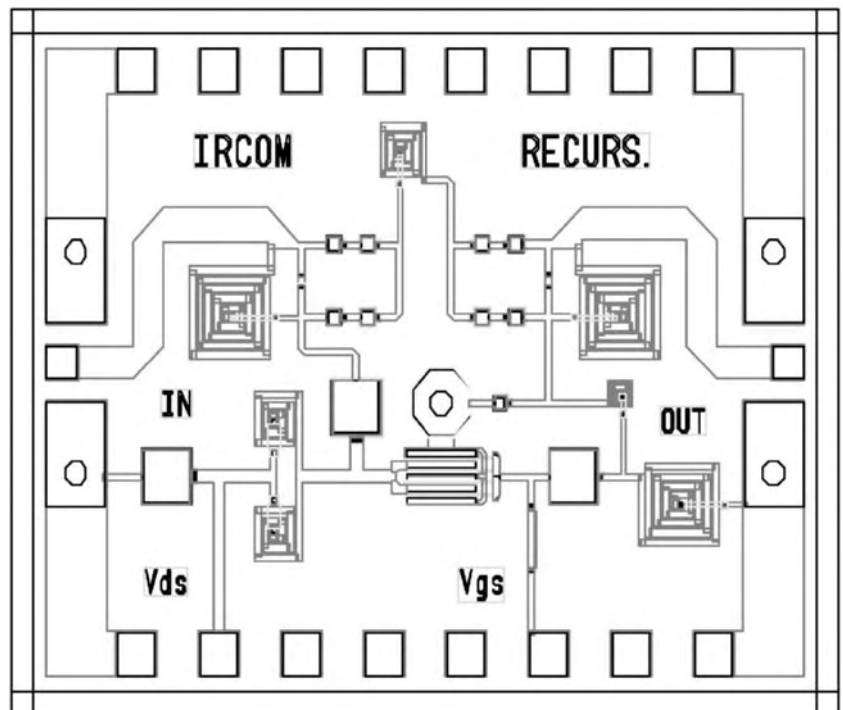

Figure 19. Layout of the first-order microwave recursive filter.

Figure 20. Theoretical, simulated, and measured response of the first-order recursive filter.

recursive process. Finally, a unilateral microwave active device must be employed in the forward branch in order to allow the feedback scheme to operate as intended. By verifying adequate relations between the impedances of the different blocks within the structure [13], the filter voltage gain appears to be of the recursive type:

$$G_V = K \left(\frac{\mu}{1 - \mu e^{-j\omega\tau}} \right)$$

Finally, for integration in microwave systems, two impedance transformers are required to match the filter to $50\ \Omega$ external impedances: a common-gate MESFET at the input and a common-drain MESFET at the output (Fig. 21), which must simultaneously provide a voltage matching of the loop and a power matching of the complete structure. Moreover, an attracting outstanding feature is the capability of the common-gate stage T_1 to produce power gain, making it a significant factor in the composi-

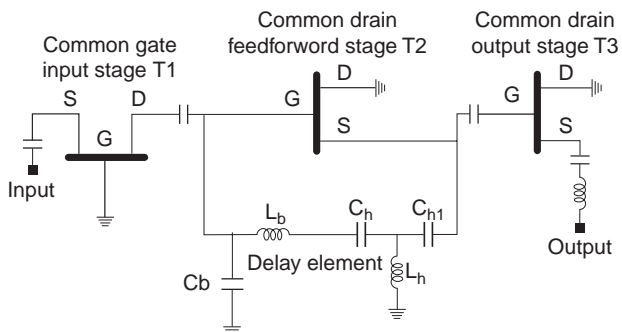

Figure 21. Electrical schematic of the voltage-matched first-order recursive filter.

tion of the overall noise figure of the filter. The loop gain can be controlled by the bias voltage of the common drain amplifier T_2 placed within the feedforward branch of the loop. A conventional lumped highpass cell and a lowpass cell are used to provide the necessary delay time τ for the desired filter center frequency. The filter has been fabricated using a $0.2\text{-}\mu\text{m}$ -gate-length PHEMT foundry process (ED02Ah from OMMIC [14]), and implemented on a $100\text{-}\mu\text{m}$ -thick GaAs substrate. Dimensions of the corresponding MMIC chip are $1 \times 1.5\ \text{mm}^2$. Total DC power consumption of the filter is $30\ \text{mW}$. Figure 22 shows a comparison between measured and simulated responses of the filter.

Figure 22. Simulated and measured voltage-matched first-order recursive filter response.

Figure 23. Photograph of the MMIC varactor-tuned first-order recursive filter.

The circuit is operating at 7 GHz with 5.1 dB gain at the center frequency and 140 MHz at 3 dB bandwidth. The out-of-band rejection is better than 20 dB, with 2 GHz from passband edges. The measured -1 dB compression point occurs for an input power of -15 dBm, and the simulated noise figure is 5.5 dB at the center frequency.

4.4. Frequency Tunable Recursive Filters

Recursive and transversal filters can simply provide tunable responses because of arbitrary analog phase shifter structures. As an example, we present the expression of a recursive transfer function shifted over a frequency band noted Δf :

$$\begin{aligned}
 H(f - \Delta f) &= \frac{\sum_{k=0}^N a_k e^{-2j\pi(f-\Delta f)k\tau}}{1 + \sum_{p=1}^P b_p e^{-2j\pi(f-\Delta f)p\tau}} \\
 &= \frac{\sum_{k=0}^N a_k e^{-2j\pi f k \tau} e^{jk\phi}}{1 + \sum_{p=1}^P b_p e^{-2j\pi f p \tau} e^{jp\phi}}
 \end{aligned}
 \tag{5}$$

with $\phi = 2\pi\Delta f\tau = 2\pi\Delta f/f_0$. This expression clearly shows that recursive responses can be tuned by the introduction of a variable phase shift in each branch of the filter. Consequently, many “recursivelike” filter structures can take advantage of this concept to be turned into tunable versions.

For most applications, 10% of tuning range is not sufficient and emphasizes the need for a real phase shifter function. A phase shifter structure for “recursivelike” filter purpose is proposed in Ref. 39. Maximum phase shift measured is 55° . Gain is near 7.5 dB in the 3–5 GHz frequency band. Noise factor of the phase shifter is 4.5 dB at 4 GHz.

Another tunable filter example is based on the design concepts outlined in Section 4.3. A tunable filter is realized by introducing a phase shift into the feedback loop of a voltage-matched recursive structure [13]. Filter tuning at the desired center frequency is accomplished through variation of the equivalent capacitor of a varactor diode that replaces a capacitance of the initial delay-time section. Correct adjustment of the bias point of the transistor T_2 (see Fig. 21) ensures a constant gain level over the frequency tuning range when the series diode resistance varies with the bias voltage.

A photograph of the filter is shown in Fig. 23. Dimensions of the MMIC chip are 2×1.5 mm². The measured transmission parameter of the filter is shown in Fig. 24. A frequency shift from 7.03 to 9.5 GHz (30% of relative

Figure 24. Measured S_{21} parameter of the tunable first-order recursive filter.

Figure 25. Second-order ring resonator active recursive filter.

tuning band) is achieved with a constant gain level of 3.5 dB across the tuning band. Moreover, the filter exhibits a good $50\ \Omega$ matching over the 2.5-GHz tuning band ($S_{ii} < -10\ \text{dB}$; $i = 1, 2$). The expected noise figure is 5 dB at center frequencies. The measured $-1\ \text{dB}$ compression point occurs for an input power of $-10\ \text{dBm}$. Maximum total DC power consumption is 46 mW.

4.5. High-Order Recursive Filters

For high-order filter design, a first alternative approach consists in coupling microstrip planar ring resonators, each resonator realizing a pole of the recursive transfer function.

The general transfer function of these ring resonator filters, where K and $\{K_n\}$ are functions of the coupling values and the amplifier gains can be expressed as:

$$S_{21}(f) = \frac{Ke^{-j\pi(f/f_0)}}{1 + \sum_{n=1}^N K_n e^{-2n\pi(f/f_0)}}$$

We give here an example of a second-order filter implemented in coplanar technology [40]. Many studies have shown that, in most cases, coplanar waveguides can be a good alternative to microstrip lines because of greater ease and flexibility in the design [41,42]. Because all conductors are located on the same plane, the ground connections for the active chips through via holes or ground report are eliminated, thus leading in more ease for connecting the active parts (here the amplifiers/phase shifters) and in more compact designs. Another advantage

Figure 27. Photograph of the two-pole ring resonator recursive filter on its test fixture.

of coplanar technology is that each element characteristic can be adjusted and improved through additional geometric parameters. According to this degree of freedom, high-directivity couplers can then be easily achieved by minimizing the difference between the phase velocities of the two normal modes [43].

In our example, we consider three pairs of parallel coupled lines with up to two amplifiers within each passive ring resonator to achieve a second-order structure. The considered topology is shown in Fig. 25. With a methodology discussed in the article on active-filter design tools and techniques alluded to above, the noise performance of such structures can be analytically optimized. We use here the same amplifier/phase shifter as in Section 4.4. The

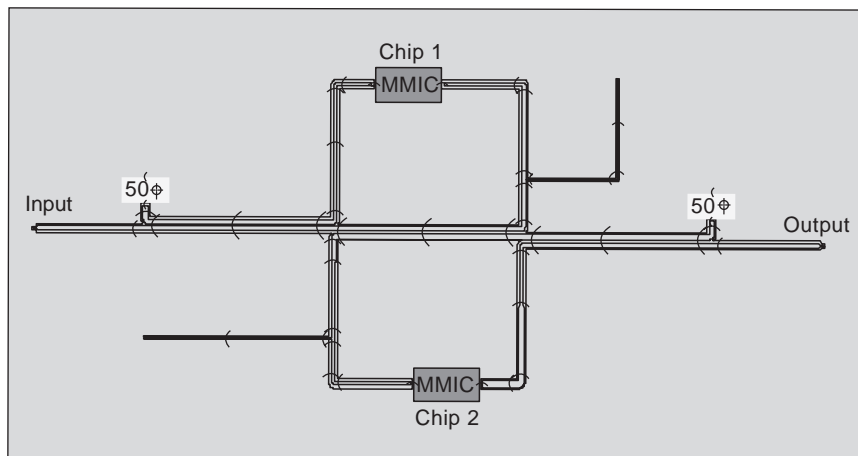

Figure 26. Two-pole ring resonator recursive filter layout in coplanar technology.

Figure 28. Comparison between simulation and measurements of the two-pole active ring resonator filter.

objective is to achieve a bandwidth $\Delta f = 120$ MHz with a ripple $\delta = 0.2$ dB within the passband. With $|G| = 2.2$, $F_A = 4.5$ at 4 GHz, the center frequency, we obtain $|S_{21}| = 13.7$ dB, $|S_{ii}| < -12$ dB. The noise figure is estimated to 6.5 dB. Figure 26 shows the layout of the active filter implemented on a 635- μm -thick alumina substrate ($\epsilon_r = 9.6$). Dimensions of the filter are 38×18 mm. A photograph of the circuit on its test fixture is given in Fig. 27.

Figure 28 shows a perfect agreement between simulated and experimental results. The gain of the filter is equal to 13.6 dB at 4 GHz. At center frequency, S_{11} and S_{22} are less than -10 dB. Power consumption is about 24 mW.

A second alternative for high-order filter design resides on the fact that classical “ladder type” high-order recursive filter design can become greatly complex considering the n -way dividers/combiners and the stability analysis of such multifeedback structures.

In the proposed approach [44], classical recursive filter concepts are extended by decomposing the response as a set of unitary terms. Each of these corresponds to a first-order function characterized by its own weighting coefficients $\{a_i, b_i\}$ and delay-time parameters τ_i . The obvious advantage of this approach is a more flexible way to

Figure 29. Test fixture of the four-cell filter configuration.

Figure 30. Measured S_{21} parameter of the four-cell filter with pairs of pole at 9.7 and 10.3 GHz.

individually control each pole frequency, selectivity, and also stability, thus simultaneously maintaining the global filter stability when cascading n unitary cells for a n th-order response. This also enables a tuning of the bandwidth and of the center frequency, whereas the classical approach does not give such flexibility. At least by cascading several elements of the same type, this approach also takes great advantage of MMIC technology reproducibility.

A physical implementation is shown in Fig. 29. Four 2×2 mm first-order tunable version of the chip of Fig. 19 are cascaded. Various response shapes can be obtained in terms of gain and bandwidth by adjusting center frequencies of the individual poles. Figure 30 shows excellent results obtained in the 4-chip configuration when two poles are located at 9.7 GHz and two at 10.3 GHz. Gain at center frequency is near 6 dB for a 670 MHz bandwidth. Good matching of the structure and -40 dB out-of-band rejection can also be noted in this case.

1. INTRODUCTION

Whatever the application is, all communications systems—whether cellular, PCS, cable or satellite—require, in increasing quantity, a range of microwave filters with near-ideal characteristics to maximize communication capacity and signal processing efficiency and thus lower system costs. To satisfy these demands, engineers try to come up with design innovations and improved manufacturing processes of new filtering devices to reduce the cost of high-frequency communications. Since the early 1990s, engineers have also been increasingly interested in using active techniques for their compatibility with planar integrated monolithic technologies. Since the first microwave circuit was designed using a GaAs-based process, more and more attempts have been done nowadays to switch to silicon-based processes because of the resulting compact size and low-cost aspects.

We follow and gradually illustrate this tendency in this article. We first discuss the use of CAD tools for microwave and RF filter design, focusing particularly on optimization tools. We emphasize that, without any strong microwave design background and experience, this kind of tool unavoidably leads to nonreproducible and nonsystematic solutions. We then show the necessary implementation of analytical procedures to set and verify some essential characteristics of low-noise active devices, with examples of electrical stability criteria and noise performance calculation, prediction, and optimization. These two

examples are illustrated through many integrated filter designs and measurements.

Section 3 deals with the description of tools and techniques for filter improvements. We first begin with an extended consideration of compensation techniques based not only on loss compensation but also on response selectivity and circuit dimensions. The technique is illustrated with the design of a one-pole interdigital filter and a two-pole coplanar filter in which response and size have been improved using this approach. We then generalize this principle to the “active-impedance profile” (AIP) technique and present an example application to multistandard and pseudomultipole filters.

In Section 4, novel approaches and new technologies for new microwave and RF communications needs are detailed. We first discuss the new application constraints driven by new communication standards. We then discuss GaAs processes to silicon-based technologies, emphasizing the differences between the two technologies in terms of processes themselves, and in terms of CAD tools, component implementation, compactness, relative size, and cost with two basic circuit examples. Migration to silicon-based processes also involves novel implementation approaches among which differential circuits. This last approach is illustrated with experimental results.

2. ANALYTICAL TOOLS AND PROCEDURES FOR ACTIVE FILTER DESIGN

2.1. Numerical CAD Optimization Tools

Since 1980, scientific production on microwave filters has grown extensively. This extension finds its sources from a technical perspective in:

- A permanent growth in device complexity
- A constant objective of reduction in size and weight
- The use of new materials and new technologies (superconductor materials, MEMs, planar monolithic technologies, etc.)

However, any experimented engineer knows that this growth of production is fueled mostly by novel modern computing systems and by the extraordinarily growing computation capabilities.

Without this computation power, many application would still be only perspectives:

- The development of precise electromagnetic simulation methods for planar (2D or 2.5D) or volumic (3D) circuits, such as the finite-element method, method of lines, or modal analysis
- The development of numerical synthesis methods taking into account a larger number of parameters such as losses or process limitations
- Global analysis methods simultaneously coupling in a single step various sorts of analysis that are sometimes very different

1. INTRODUCTION

Whatever the application is, all communications systems—whether cellular, PCS, cable or satellite—require, in increasing quantity, a range of microwave filters with near-ideal characteristics to maximize communication capacity and signal processing efficiency and thus lower system costs. To satisfy these demands, engineers try to come up with design innovations and improved manufacturing processes of new filtering devices to reduce the cost of high-frequency communications. Since the early 1990s, engineers have also been increasingly interested in using active techniques for their compatibility with planar integrated monolithic technologies. Since the first microwave circuit was designed using a GaAs-based process, more and more attempts have been done nowadays to switch to silicon-based processes because of the resulting compact size and low-cost aspects.

We follow and gradually illustrate this tendency in this article. We first discuss the use of CAD tools for microwave and RF filter design, focusing particularly on optimization tools. We emphasize that, without any strong microwave design background and experience, this kind of tool unavoidably leads to nonreproducible and nonsystematic solutions. We then show the necessary implementation of analytical procedures to set and verify some essential characteristics of low-noise active devices, with examples of electrical stability criteria and noise performance calculation, prediction, and optimization. These two

examples are illustrated through many integrated filter designs and measurements.

Section 3 deals with the description of tools and techniques for filter improvements. We first begin with an extended consideration of compensation techniques based not only on loss compensation but also on response selectivity and circuit dimensions. The technique is illustrated with the design of a one-pole interdigital filter and a two-pole coplanar filter in which response and size have been improved using this approach. We then generalize this principle to the “active-impedance profile” (AIP) technique and present an example application to multistandard and pseudomultipole filters.

In Section 4, novel approaches and new technologies for new microwave and RF communications needs are detailed. We first discuss the new application constraints driven by new communication standards. We then discuss GaAs processes to silicon-based technologies, emphasizing the differences between the two technologies in terms of processes themselves, and in terms of CAD tools, component implementation, compactness, relative size, and cost with two basic circuit examples. Migration to silicon-based processes also involves novel implementation approaches among which differential circuits. This last approach is illustrated with experimental results.

2. ANALYTICAL TOOLS AND PROCEDURES FOR ACTIVE FILTER DESIGN

2.1. Numerical CAD Optimization Tools

Since 1980, scientific production on microwave filters has grown extensively. This extension finds its sources from a technical perspective in:

- A permanent growth in device complexity
- A constant objective of reduction in size and weight
- The use of new materials and new technologies (superconductor materials, MEMs, planar monolithic technologies, etc.)

However, any experimented engineer knows that this growth of production is fueled mostly by novel modern computing systems and by the extraordinarily growing computation capabilities.

Without this computation power, many application would still be only perspectives:

- The development of precise electromagnetic simulation methods for planar (2D or 2.5D) or volumic (3D) circuits, such as the finite-element method, method of lines, or modal analysis
- The development of numerical synthesis methods taking into account a larger number of parameters such as losses or process limitations
- Global analysis methods simultaneously coupling in a single step various sorts of analysis that are sometimes very different

From the beginning of their careers today's engineers can use numbers of synthesis, analysis, and statistical tools, and more importantly of optimization tools that can strongly help the design. For the beginner, the danger is in believing that this complete set of tools can lead, with security, to synthesis and analysis of any microwave function without either a strong knowledge or preliminary analytical studies. In particular, the riskiest tool is, without any doubt, the optimizer, which is still for some designer a "miracle" (or panacea) tool that always leads to the "best" solution.

In fact, any optimiser must be used with great care and attention:

- In practice, it should be used only at the last step of a design, after the synthesis procedure, to fine-tune the different parameters of the problem. If not, it does not mean any reproducibility in the approach and is based only on a hazardous random starting point. It does not enable any understanding or feedback of the results obtained.
- It never leads in a systematic way to "the" best solution, but usually only to a mathematically local set of parameters.
- Depending on the number of optimization constraints and the nature of each separate constraint (response level, noise, compression point, etc.), the major difficulty is the weight of the different constraints from one to the other. The optimizer then does not permit one to systematically analyze the influence of a given parameter (geometric or electrical) on the whole set of circuit characteristics.

Using such tools without any theoretical background, without experience, or without any preliminary analytical study, even simplified, does not reveal an efficient, fast, and operational investigator. The primary objective must be the implementation of rigorous analytical procedures to investigate any problem that can be encountered at each design step of an active device.

2.2. Examples of Analytical Tools and Procedures at Microwaves

We describe here two examples of analytical procedures that can facilitate understanding of the influence of a parameter on a given filter characteristic. These two examples focus on low-noise circuits in the linear regime.

2.2.1. Analysis and Optimization of Noise Performance.

For any applications using circuits with active elements, the problem of noise performance is a critical point that must be studied. In this subsection, the purpose is not to describe well-known methods or formalisms classically applied at the component level (e.g., how to determine the optimal loads of a transistor to be at the minimum noise power); rather this discussion is dedicated to determining

- The contribution of an active function in terms of system components, to the noise of a more complex structure (e.g., an amplifier within a recursive filter, or a negative resistance within a resonator-based filter)
- The optimal location of an active function within a global structure [1]
- An analytical optimization method of the noise characteristics of a global structure in which is integrated an active function, while maintaining given filtering characteristics

The discussion here is intended to help the designer better predict the influence of active parts or components by analytical means.

Several methodologies have been studied to evaluate or model noise performances, depending on the type of electrical parameters that are considered. Here, we choose to use a noise-wave formalism described by Wedge and Rutledge [2]. This formalism takes advantage of the S -parameter description. However, other formalisms using currents or voltages instead of power waves also exist, based on the same principles.

Analytical derivation of noise performance using the noise-wave formalism is done by gradually reconnecting parts of a global device for which S parameters and the noise matrix are known. An interesting way to illustrate the approach is to evaluate the noise factor of microwave active recursive filters. Other structures are studied in Ref. 3. As shown in Fig. 1, the noise-wave formalism consists in modeling the noise of a two-port device with internal noise-wave generators c_1 and c_2 .

Their contribution to the output scattering waves b_1 and b_2 can be expressed in the following manner, where S is the scattering matrix of the two-port Q :

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix}_Q \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} + \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} \quad (1)$$

Regarding the first-order recursive topology of the article ACTIVE FILTERS: OVERVIEW OF ACTIVE-FILTER STRUCTURES, Section 4.2, the circuit consists in two power dividers/combiners, one delay element, and one amplifier. Depending on where the amplifier is placed within the structure (in the feedback or in the direct branch), two topologies can be derived (Fig. 2). In the passband case, the problem is then to find, for each topology, the gain value G , noise factor value F_A , and the two coupling values

Figure 1. Two-port circuit described by noise waves and scattering parameters.

- A systematic approach for the analytical derivation of noise performances

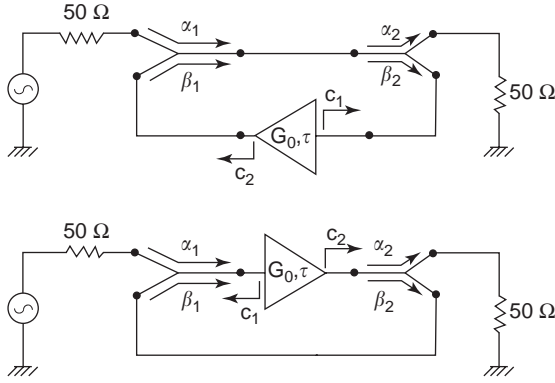

Figure 2. First-order recursive filter topologies: amplifier placed (a) in the feedback branch and (b) in the direct branch.

at the input and output of the filter, to obtain a given response shape with a minimum noise factor at center frequency. To calculate the minimum noise factors of the two topologies, we first consider the R and V selectivity parameters that set the filtering performances. These parameters must not be modified during the improvement process of the noise factor and set the frequency shape of the response. f_0 is the center frequency.

$$R = \frac{|S_{21}|_{\max}}{|S_{21}|_{\min}} = \frac{|S_{21}(f_0)|}{|S_{21}(f_0/2)|}, \quad V = \frac{R-1}{R+1} \quad (2)$$

The two corresponding filters are considered as equivalent when they are characterized by the same V parameter even if they do not achieve the same gain at the center frequency f_0 . The transfer functions of the two topologies can then be expressed as follows with the selectivity parameter $V = \beta_1\beta_2G_0$, $G = G_0 e^{-2j\pi f\tau}$, where G_0 is a positive real gain and the delay time τ is introduced:

$$H_i(f) = \frac{K_i}{1 - V e^{-2j\pi f\tau}} \quad (3)$$

For topology 1 (Fig. 2a), the transfer function and the noise factor at f_0 , the center frequency, are analytically derived through the reconnecting method, as functions of β_1 , G_0 , and F_A (the noise factor of the amplifier that can also be derived from the same noise-wave formalism):

$$H_1(f) = \frac{\alpha_1\alpha_2}{1 - G\beta_1\beta_2}; \quad F_1 = 1 + \left(\frac{\beta_1}{\alpha_1}\right)^2 (F_A - 1)G_0^2 + \left(\frac{\beta_2 - \beta_1G_0}{\alpha_1\alpha_2}\right)^2 \quad (4)$$

F_1 can also be expressed as a function of β_1 , G_0 , F_A and more importantly of V to maintain the filter response shape. For a given amplifier, β_1 appears as a degree of freedom that can be used to optimize the noise factor. It can even be shown that for the optimal value of $\beta_1 = \beta_{1\text{opt}}$, $F_1 < F_A$ when $G_0 \rightarrow \infty$.

Using the same methodology for topology 2, the transfer function $H_2(f)$ and the corresponding noise factor F_2

are given by:

$$H_2(f) = \frac{G\alpha_1\alpha_2}{1 - G\beta_1\beta_2}; \quad F_2 = 1 + \frac{(F_A - 1)}{\alpha_1^2} + \left(\frac{\beta_2 - \beta_1G_0}{\alpha_1\alpha_2G_0}\right)^2 \quad (5)$$

The expression of $\beta_{1\text{opt}}$ is the same as for topology 1 but leads to $F_2 > F_A$ at f_0 . The analytical procedure enables us to find that topology 1 is better than topology 2 in terms of the noise factor, which could not have been derived by using a classical CAD optimizer. Simulations show on one hand the noise factors increase when the selectivity increases, and on the other hand when the gain is increased (for the same F_A of the amplifier), the noise factor of the filter decreases as expected.

To experimentally validate our approach, we have designed a first-order recursive filter from topology 1 in MMIC technology. This filter, the layout of which is given in Fig. 3, has the same filtering performance as that described in Section 4.2 (Fig. 20) of the article over-viewing active-filter structures [cited above, immediately following Eq. (1)]. Couplings (through the use of Lange couplers [4,5]) and gain values are chosen to obtain the lowest noise factor according to the analysis presented. Measured noise figure is equal to 2.1 dB, in contrast to the initial 11.7 dB.

2.2.2. Analytical Tools for Electrical Stability Analysis and Optimization. Several stability criteria are used at microwaves to evaluate the electrical stability of a circuit. Most techniques used are based on the Rollett factor K [6,7] defined through two-port S parameters. However, these factors are not quantitative, and additional parameters must be calculated to get more information. Plots of μ factor [8] or stability circles can then be calculated to give the reader an idea of the stability margin and the location, respectively, of the load impedances that can lead to instability.

In terms of design, these criteria present many disadvantages:

- In most cases, filters are designed to be terminated (directly or in cascade with other modules) with 50 Ω impedances. In case of conditional stability, the

Figure 3. Layout of the low-noise first-order active recursive filter.

Rollett factor does not predict the impedances for which the instability is observed. It is then necessary to plot the stability circles, thus clearly complicating the engineer's work.

- Another important point directly concerns the validity of classical parameters. Indeed, interpretation of classical parameters (including stability circles) leads to a valid evaluation of stability only when the circuit is intrinsically stable, independently of the terminations. The designer must then, in a first step, be sure of the intrinsic stability of the device.
- Finally, for more complex circuits, classical stability parameters cannot analytically predict the influence of a component or a circuit characteristic, and therefore lead to efficient modification of the adequate parameter in case of instability.

Many researchers have attempted to solve the problem with methods derived from Bode's theory [9] among which Ohtomo [10] and Platzker [11]. We describe this last approach here. The normalized determinant function (NDF) approach is an extension of Bode's theory for circuits with more than two ports and multiple feedbacks. Without discussing the details, analysis of a mathematical complex function leads to a plot in an image complex plane. The function considered here is defined as the ratio of the determinant of the nodal description matrix of the circuit when all the sources are in ON state, to the determinant of the same matrix when all the sources are in OFF state. Interpretation of the resulting plot in the image plane results from Cauchy's theorem. If the plot encircles the origin of the image plane in the clockwise direction, then the circuit is unstable. There are as many instabilities as encirclements. Frequencies of instabilities can be extracted by searching the roots of the NDF.

The originality of the method resides in the return ratio (RR) principle [12], which allows analysis with a classical CAD package. With this method, each transistor is modeled as a voltage-controlled current source. All these sources, one by one, are driven by an external voltage instead of their initial internal voltage. The corresponding

RR is then defined as the ratio of the initial internal voltage to the external one. At each step of the calculation, all sources for which the RR has been calculated are turned off. Finally, expression of the NDF is derived from the n RRs (for a n -source or a n -transistor circuit).

Note that this approach, when numerically used through a CAD package, does not allow any interpretation of any parameter on the circuit stability. However, in this case, classical optimization is still possible.

With a strict calculation approach, analytical expression of the NDF can be obtained, thus allowing the evaluation of each parameter influence not only on the stability itself but also on the frequency where instabilities occur. To illustrate this point, we consider the first-order filter discussed in Section 4.2 (Fig. 19) of the article cited above [following Eq. (1)], where Lange couplers are used for division/summation of the signals within the structure [13]. We first model the ideal amplifier of the structure with an equivalent voltage-controlled current source terminated with two $50\ \Omega$ impedances. In Fig. 4, the ideal amplifier has been replaced by its equivalent dependent source. Because of the unilaterality property of this source, we now obtain a new open-loop two-port device loaded by a generator of internal impedance $50\ \Omega$ at the input, and with a $50\ \Omega$ impedance at the output. Initial input and output ports are also assumed to be terminated with a $50\ \Omega$ impedance. The current source is controlled by an external voltage V_{ext} .

The NDF is then derived through the RR calculation. It shows that the zeros location in the complex plane for $\text{NDF}(f)$ (i.e., the location of instabilities) is equivalent to the zeros location of the denominator of the transfer function of the filter $H(f)$. In other words, zeros of the NDF are equivalent to the poles of the response.

Using the same principles, we now consider a second-order recursive filter, for which the two amplifiers G_1 and G_2 are substituted with dependent current sources. Calculation of the NDF is obtained in two steps corresponding to the calculation of the two RRs:

$$\text{NDF}(f) = (1 + \text{RR}_1(f)) \cdot (1 + \text{RR}_2(f))$$

Figure 4. New “open loop” equivalent circuit of a first-order recursive filter.

Figure 5. Unstable case of a second-order recursive filter: NDF plot for $G_1 = -5$ and $G_2 = -2$.

Here again, the NDF is the same as the denominator of the transfer function of the filter, thus validating the NDF calculation process. Figure 5 shows how instability can be predicted when the NDF encircles the origin for $G_1 = -5$ and $G_2 = -2$. In the same manner, Fig. 6 illustrates the stable state of the circuit, when the NDF does not encircle the origin for $G_1 = -4$ and $G_2 = -2$.

3. EXAMPLES OF PERFORMANCE IMPROVEMENT

For most engineers and researchers, the use of active components or functions is limited to loss compensation of passive structures. Nevertheless, active parts can play various roles in a global system. By identifying two main filter families in the active-filter structure overview article cited above, we have underlined a filter category for which active functions play an essential role. Gain, unilaterality or phase shift are directly implicated in the response and do not operate only for a simple loss compensation.

In fact, it is reasonable to imagine that active modules associated to passive filters could enable

- A significant reduction in size of the circuits
- An improvement of the response selectivity, even the control or the reconfigurability of the working band (passband or stopband)
- An automatic control process of frequency and level of the response elicited by external parasitics (e.g., temperature drift)
- Novel topologies for original filter structures
- Improved variable components [14]

In this section, we illustrate the possible improvements of filter responses and size due to such techniques for the

Figure 6. Stable case of a second-order recursive filter: NDF plot for $G_1 = -3$ and $G_2 = -3$.

two filter categories identified in the active-filter structure overview article cited above. We also describe automatic frequency control techniques and show an experimental validation.

3.1. Loss Compensation and Size Reduction

Miniaturized high-selectivity microwave bandpass filters are highly desirable for the next generation of satellite and mobile communications systems. Traditional interdigital and combline filters [15] based on TEM mode coupling are well suited for the design of narrowband passive filters. Unfortunately, the design of such filters with classical technologies (e.g., microstrip technology) leads to very high insertion losses in the operating band, especially when high selectivity is required. Indeed, due to low unloaded Q factors, it is not possible to obtain narrowband bandpass filters achieving 0 dB insertion losses with only passive elements, except with superconducting techniques.

An original technique is presented here, using classical passive interdigital filters in association with a MMIC active component circuit. Two filters, one of the first order and one of the second order, are discussed in reference to microstrip and coplanar technologies, respectively [16].

3.1.1. First-Order Microstrip Filter. A very classical first-order filter is studied using a standard design procedure [16]. The initial passive structure is designed to fit the following characteristics: 3.46 GHz for the center frequency and 91 MHz for the 3 dB bandwidth (2.63%). Measured insertion losses of the passive filter are about 7 dB at the center frequency. In a second step, the passive filter is geometrically modified in order to insert the MMIC circuit, while keeping the same center frequency. By taking into account the value of the imaginary part of the active

Figure 7. Photograph of the active one-pole microstrip filter.

component, the length of the resonator can be approximately divided by 2. A photograph of the active microstrip filter is shown in Fig. 7. Comparison of passive parts of the two versions are compared in Fig. 8. Measurements in Fig. 9 show a 3.27 GHz central frequency at a 85 MHz 3 dB bandwidth (2.6%). The insertion losses have been compensated at 0 dB.

3.1.2. Second-Order Coplanar Bandpass Filter. Many studies have shown that coplanar wave-guides can be considered as a good alternative to microstrip lines for many applications [17]. It is well known that low-level coupling coefficients are needed when designing narrowband bandpass filters. In the case of interdigital filters, a separating ground plane can be placed between the two coupled strips in order to obtain low-level couplings. With this approach, it is possible to efficiently control low coupling coefficients by adjusting the dimension of this ground plane. This method allows one to design compact low-coupled sections [18]. Another advantage of the coplanar technology is the flexibility in the design of the passive circuits. Indeed, a large number of geometric parameters can be chosen to design any transmission line with a given impedance. Electrical characteristics can then be improved by properly defining the ratio of the strip length to the slot length.

By taking into account all these advantages, a second-order filter is designed in coplanar technology. In this case, two MMIC components are placed at the open end of each resonator. A layout and a photograph of the coplanar active filter are respectively shown in Figs. 10 and 11. Measurements have been made over a wide frequency range in order to verify the bandstop responses (Fig. 12). No spurious resonances appear up to 9.5 GHz. Measurements also show a 1.98 GHz center frequency and a 75 MHz 3 dB

Figure 8. Comparison of the initial and optimized passive parts of the one-pole filter.

bandwidth (3.8%). In comparison to the purely passive case, the imaginary part of the MMIC chip has increased the response selectivity; 0 dB insertion losses have also been measured. In order to compare the reduction in size provided by the imaginary part of the active component, the same filter without the active components has been simulated. The center frequency of the filter is shifted to 2.6 GHz, resulting in a size reduction of about 0.8. Insertion losses are -7 dB in this case.

3.2. Active-Impedance Profile

In the previous subsection, interdigital structures were presented and improved in microstrip and coplanar technologies. However, these structures are not adequate when frequency switching or tuning is needed. Generally, the response of a passive filter is optimal at a given frequency. Tunability of the center frequency then implies a variation of one of the filter component parameters (such as electrical lengths) that can damage one or more electrical characteristics of the filters (matching, losses, bandwidth, etc.). In particular, for all planar filters using a varactor-based tuning or a switching process, any decrease of the center frequency is associated with a proportional reduction in bandwidth [19,20].

Nevertheless, beyond loss compensation and circuit size reduction, results presented above indicate a significant

Figure 9. Experimental results of the active one-pole microstrip filter.

Figure 10. Layout of the compensated coplanar two-pole filter.

increase of the response selectivity in comparison to the corresponding passive filters. It should then be possible, using the same approach, to control simultaneously the bandwidth and the center frequency owing to the imaginary parts presented by compensation circuits.

In particular, it can easily be verified by simulations that these imaginary parts contribute to the improvement of the response in two ways:

- The value of the imaginary part at the input of the compensation circuit sets or corrects the center frequency of the filter. At a given frequency, this value is equivalent to a resonator length added to or withdrawn from a passive resonator.
- For this filter topology, the slope of the imaginary part around the chosen center frequency directly commands the response selectivity.

We now show two examples to illustrate how these simple impedance considerations, called active-impedance-profile (AIP), can be interpreted and applied for the design of multistandard and pseudomultipole filters.

3.2.1. Application of AIP to Multistandard Filters for Mobile Communications. The objective here is to build electrically tunable filters for multistandard mobile communication applications. To do this, frequency tuning must be achieved while maintaining a correct and constant level within the passband. Losses due to the passive

Figure 11. Photograph of the compensated coplanar two-pole filter.

parts of the circuit, but also those introduced by the tuning elements, must be compensated and controlled.

Generally, the response of a passive filter is optimal at a given frequency. To control the effects of one of the tuning parameters on filter performance, the filter structure has to be selected in reference to the target application. In our case, several tests on various elementary resonator-based structures have shown that interdigital filter structures exhibit an acceptable tolerance concerning the center frequency variation [21]. For example, a 10% increase of the resonator electrical length (by means of an additional capacitor at the end of the resonator or by the physical modification of the resonator length) achieves a 10% decrease of f_0 with a limited effect (less than 3%) on the bandwidth.

We apply our technique to the design of a second-order interdigital bandpass filter in coplanar technology. The filter topology is the same as in Fig. 10. The center frequency is electronically tuned in relation to the biasing voltages supplied to the varactor diodes located on the resonators. Each NIC-based AIP circuit is placed onto the ground plane (near the open end of each resonator) and is connected in series (using a bounding wire) with a varactor diode at the open end of the resonator. The filter is intended here to cover three telecommunications standards at

Figure 12. Experimental results of the compensated coplanar two-pole filter over a wide frequency range.

Figure 13. Objective and simulated AIP+diode impedance: (a) imaginary part; (b) real part.

- 1748 MHz (DCS1800 transmission band)
- 1950 MHz (UMTS transmission band)
- 2140 MHz (UMTS reception band)

For all standards, the objective bandwidth is set to 60 MHz relative to the UMTS standard. The design process is then done in four steps:

1. The designer sets the circuit dimensions referring to the desired center frequencies for the different communication standards and to the desired circuit size reduction.
2. This step focuses on the search, for each standard (three in this example), of the impedance characteristics in terms of real and imaginary parts to produce through the AIP associated with the varactor diode.
3. Considering that the switching between the standards is made through the varactor diode, one varactor bias voltage must be chosen in a third step for each standard. These choices can be set by the designer, but in a more general approach, an optimization process can help in finding the most adequate biasing points.
4. This last step consists in finding the real and imaginary part profiles over a frequency band covering all the standards. This impedance profile is obtained by deembedding the varactor diode impedance from the one obtained in step 3 around each standard center frequency.

Figure 13 shows the imaginary and real parts of the set AIP/varactor diode obtained at step 3 with classical packaged abrupt junction varactor diodes and for the three chosen bias voltages. A good agreement is obtained for each bias point between the objective correction impedance around each standard center frequency and the impedance performed.

Figure 14 shows the excellent results obtained for the global filter. A constant bandwidth of 60 MHz is obtained for each standard with a perfect loss compensation within the passbands.

3.2.2. Application of AIP to Pseudomultipole Filter. We now present the design of a pseudomultipole filter, based

on a one-pole passive filter topology. We apply the AIP technique to enlarge the bandwidth of the response. We start from the passive one-pole topology of Fig. 15. Transmission response initially presents a poor selectivity and a nonnegligible loss level at the center frequency (about 5 dB).

The idea is now to use the impedance profile principle to enlarge the response bandwidth. The objective is to search for the imaginary part to add to the passive filter, by means of the AIP, to reproduce the one-pole resonance not only at the initial central frequency but also at different frequency points in the objective passband. Figure 16 presents the imaginary parts of the AIP respectively necessary for a simple loss compensation (no effect of the imaginary part) and for a pseudomultipole effect. With this imaginary part profile, the resonance condition is reproduced for each frequency of the objective bandwidth. The result is a pseudomultipole filter based on a one-pole topology. The real part of the AIP allows for loss compensation, while the corresponding imaginary part increases the bandwidth with a flat gain, and with good rejection levels. The bandwidth of the filter is then 240 MHz for the same center frequency. Filter response is presented in Fig. 17 and validates the approach.

Figure 14. Simulated results of the 3-standard active filter.

Figure 15. Distributed one-pole filter topology.

3.3. Automatic Frequency Control Techniques

This section deals with the application of phase-locked and magnitude-locked loops to achieve the automatic frequency control of microwave active filters. Indeed, analog filters are characteristically vulnerable to fabrication tolerances and temperature drifts and must be stabilized and controlled. Automatic frequency control (AFC) using the popular master–slave approach is the most feasible solution to control these characteristics [22]. This problem has been solved for a microwave filter [23–25] by using a typical phase-locked loop (PLL) based on a voltage-controlled oscillator (VCO) matched to the slave filter.

In contrast to the VCO-PLL, we propose here automatic frequency control based on the use of a voltage-controlled filter (VCF) PLL. We also propose an AFC based on the use of a VCF-based magnitude locked loop (MLL). These two techniques are attractive because they simplify the frequency control circuitry. They are applied to control the center frequency of a microwave bandpass VCF, implemented in planar hybrid technology on a duroid substrate and tunable over the 3.8–4.9 GHz range.

We first present a theoretical analysis establishing the control technique principles using a VCF and a MLL or a PLL. A transient-time analysis validates these results at low frequencies. We present measured results for a microwave tunable bandpass filter.

3.3.1. Theoretical Analysis. Figures 18 and 19 present an automatic tuning schemes using VCFs based on a MLL

Figure 16. Loss compensation and pseudomultipole (AIP) profile imaginary parts for the distributed one-pole filter.

Figure 17. Global pseudomultipole AIP-based filter response.

and a PLL, respectively. Theoretical principles of the two techniques are pointed out by considering the particular case of an ideal second-order biquadratic band-pass VCF.

The voltage-controlled center frequency expression is given by $\omega_0(t) = \omega_0(t=0) + KV_c(t)$, where K is the VCF conversion factor (in radians per second per volt) and V_c the control voltage (volts). In the MLL-based AFC circuit scheme of Fig. 18, the amplitude of the reference signal is compared to VCF signal. The magnitude error is amplified and returned to control the filter center frequency ω_0 . The loop is magnitude-locked when the term $\Delta\omega = \omega_r - \omega_0$ is minimized ($\Delta\omega \rightarrow 0$) with ω_r , the reference signal frequency.

In the PLL-based AFC circuit of Fig. 19, the master filter is phase-locked to the reference signal. The phase of the reference signal is compared to the phase of the signal after the biquad filter by a phase comparator. The phase error is filtered out by the lowpass filter, then amplified and fed back to adjust the center frequency ω_0 of the filter. The loop is locked when the difference between the phase of the bandpass filter output signal and the phase of the reference signal is minimized, resulting in $\omega_0 \approx \omega_r$.

The differential equations that govern the control system based on a MLL or a PLL are given by Quintanel et al. [26]. The control response can be characterized for different tracking signal shapes by numerically solving the equations. Results given in Figs. 20 and 21 are obtained by considering $f_r(t)$ as frequency steps. Others results show that the system based on a MLL or a PLL is able to accurately track different time-variable reference frequencies, like ramps or steps. It is also shown that for the same parameter values, the PLL method is more accurate than the MLL technique. In Figs. 20 and 21, the control system based on a MLL is not able to track the reference signal for negative variations. The control system locks on a nonvalid solution. A method to solve this problem consists in taking a smaller $f_0(t=0)$ value to be sure to start with a positive variation and avoid a negative one.

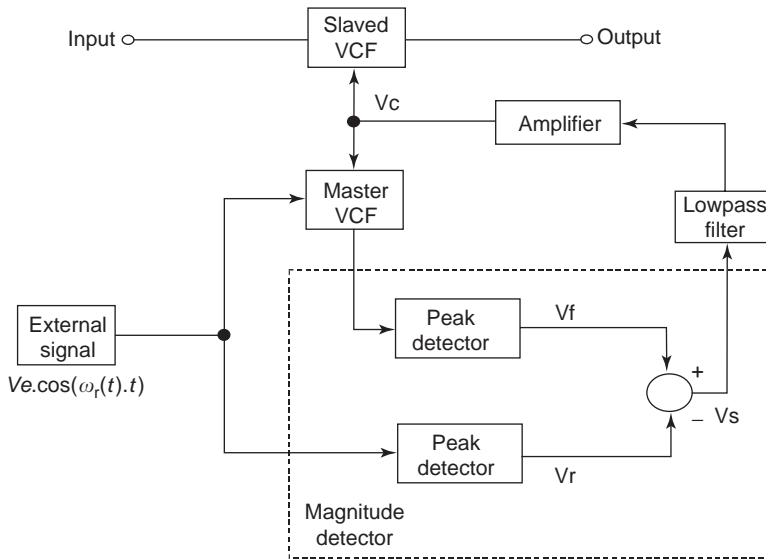

Figure 18. Automatic tuning scheme using a VCF based on a MLL.

3.3.2. AFC Systems Applied at Microwave Frequencies. In this section, we present an application of the AFC methods discussed above to a tunable microwave filter. Figure 22 presents the final functional scheme using the MLL or the PLL techniques. The VCF is a microwave bandpass planar filter based on a distributed half-wave hybrid resonant structure. The tunable element is a varactor diode used as a voltage-controlled capacitor (VCC). It is placed at the middle of the resonator to electronically tune the filter center frequency. The filter is implemented on a duroid substrate with a thickness of 0.5 mm and a dielectric constant of 2.43. It is tunable over the 3.8–4.9 GHz range. The VCC is a MACOM beam-lead constant-gamma GaAs varactor (MA46580).

To split the power reference signal between the reference and the filtered channels, we use a two-way Wilkinson power divider. The Wilkinson divider is fabricated on a duroid substrate and matched to $50\ \Omega$ at all ports. It exhibits a good isolation between output ports over the

3–5 GHz range. Phase detection is realized by using a microwave double-balanced mixer. Magnitude detection is achieved with zero-bias Schottky diodes. All RF elements are implemented on a duroid substrate. A DC amplifier is used to amplify the error signal of the loop.

Measurements are performed for different external reference frequencies and for each control technique. Table 1 summarizes the tracking performances of the two control techniques. The results demonstrate that the AFC based on a PLL or a MLL is possible and feasible in the microwave frequency domain. The PLL method offers a precision error varying from 0% to 0.19% over the 4.0–4.6 GHz range. Finally, the MLL method has a precision of 0.5–3.6% over the same frequency range. The control technique based on a PLL offers a better precision than does the MLL method because the losses of the microwave filter at the center frequency are not constant over the tuning frequency range. Nevertheless, the MLL technique is attractive for microwave applications

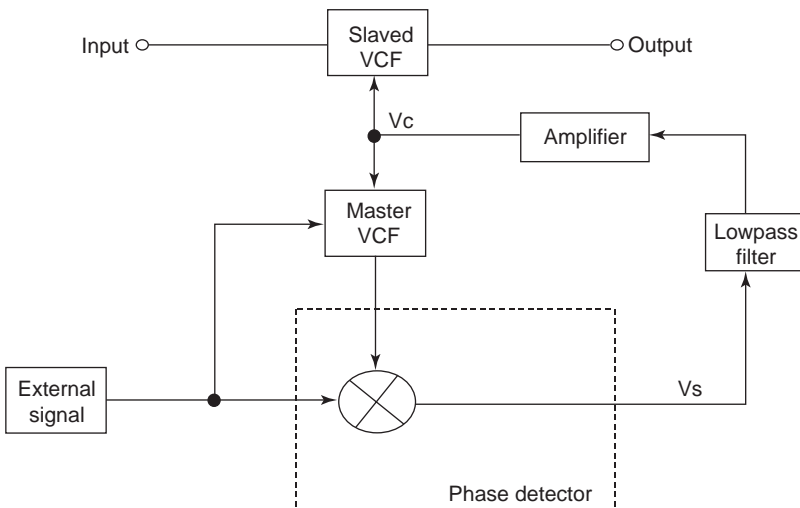

Figure 19. Automatic tuning scheme using a VCF based on a PLL.

Figure 20. System response to frequency steps with a MLL control system.

Figure 21. System response to frequency steps with a PLL control system.

because it avoids the critical phase sensitivity of the PLL method.

4. NEW APPROACHES AND NEW TECHNOLOGIES

The preceding paragraphs have shown that microwave and RF filter design is a complex art because it involves a nonnegligible number of steps, each step needing a wide spectrum of competences. In addition to a strong theoretical background, this diversity supposes the definition of a rigorous and efficient work methodology. However, even when all these tools are well known and effectively used, designers must keep in mind that, around all these skills and competences, new technologies and new needs that can modify their own approaches arise daily.

In this section, we give a brief review of new needs and new technologies in which planar active filters can be involved.

4.1. New needs and constraints

Migration of microwave systems for public market applications, in particular for mobile communications, has led to new unavoidable constraints:

- For mass production, cost considerations are essential. In practice, it is necessary to minimize the design time, and to make the design processes more reliable. Inherently, this is based on reliable low-cost integrated technologies.
- From the communication standards point of view, frequency bands allocated to different services are increasingly narrow, while the demand is always increasing. So the objective is to use at best these frequency bands in order, on one hand, to avoid interferences between services, and on the other hand, to augment the systems capabilities.

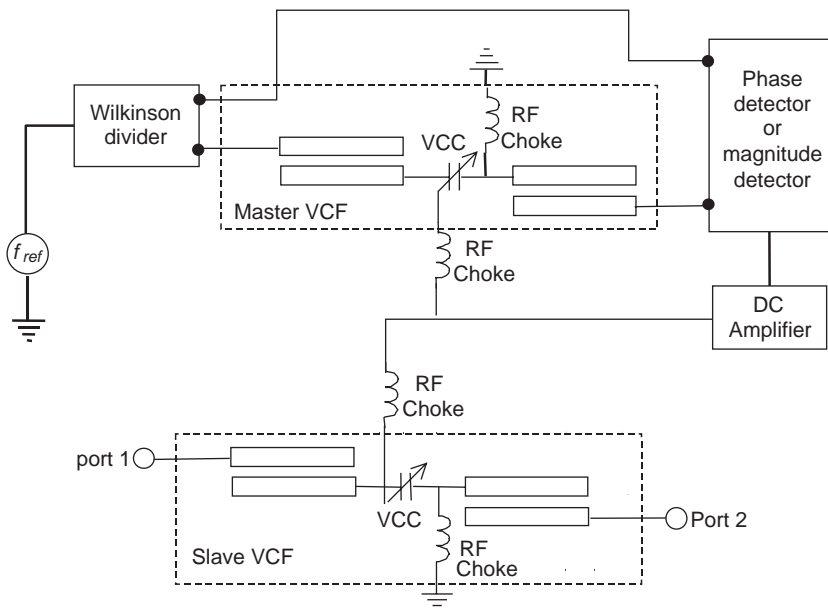

Figure 22. Microwave filter slaved to control system based on a PLL or a MLL.

Table 1. Tracking Performance of the Control Systems

F_{ref} (GHz)	4	4.1	4.2	4.3	4.4	4.5	4.6
f_0 (GHz) PLL method	4.005	4.092	4.197	4.302	4.398	4.503	4.600
f_0 (GHz) MLL method	4.005	4.092	4.171	4.250	4.363	4.495	4.635
ε_r % PLL method	0.12	0.19	0.007	0.004	0.004	0.006	0
ε_r % MLL method	0.12	0.19	0.6	1.1	0.8	0.1	0.7

- Device miniaturization is an essential constraint, synonymous with commercial success, especially for mobile handsets. From a technical perspective, this miniaturization involves a capability of integrating pre- or postprocessing digital circuits with analog microwave functions. At this step, mixed analog–digital technologies and methods are required.
- Finally, in terms of daily use, acceptable power autonomy of mobile handsets involves the use of low-current and low-consumption processes and circuits.

In any recent telecommunication system, filters take in a large number an important place in front-end transmitters/receivers; For example

- A duplexer located after an antenna is classically composed of two filters separating the transmission/reception frequency bands.
- In the reception channel, a filter can be found before the input low-noise amplifier (LNA) to improve its high-level signal performances, and simultaneously eliminate parasitic frequencies coming at the input of the front-end receiver.
- In the same channel, two other filters can be found, one after the LNA before the first downconversion mixer, and another one at intermediate frequency before the baseband downconversion.
- In the transmission channel, a filter can be found after each element of the chain, to eliminate or reduce noise and other possible distortions, linear or nonlinear.

With these considerations, and with the wide diversity of mobile telecommunication standards, it has rapidly become necessary to design multimode/multistandard portable terminals that could allow users to roam on a global scale. For this reason, frequency-tunable active filters have found an increasing interest. Indeed, tunable filter capabilities obviously lead to

- Elimination of redundant functions such as standard switches or analog/digital converters (ADCs)
- Considerable reduction in size of the global system
- Lower system complexity, and associated constraints

Because of their interesting gain capability, tunable active filters can replace very advantageously the LNAs and their associated filters. This approach can then permit (1) Elimination of one or more amplifiers in the transmission/reception chain and (2) Distribution of different constraints of noise, power-handling behavior, and response performance imposed on the other functions, thus relaxing

these specific constraints and providing more ease in the design of each functional block.

In this way, the use of tunable active filters is very attractive. However, to apply this principle with success, it is necessary to adapt the design tools, even to create new ones, but more importantly to adapt the original design method to new technologies.

4.2. New Integrated Technologies for Microwave Design: Silicon versus Gallium Arsenide

Even though some technologies have existed basically unchanged for decades, they can be seen in a totally novel aspect when used at frequencies for which they were not originally implemented. In this way, silicon-based technologies (Si and SiGe technologies) can be considered as novel for microwave active-filter applications.

Silicon-based technologies have been widely used at low frequencies for both digital and analog applications [27]. Because of the great advances of silicon and silicon–germanium technologies since the mid-1990s, silicon-based ICs have found an increasing importance for RF and microwave applications. Since 1998 only, some articles on the international scientific production have reported some interesting elements concerning the transposition of circuits classically implemented on GaAs to silicon-based processes [28,29]. Table 2 presents some general comparison elements between GaAs and SiGe capabilities.

The term *SiGe BiCMOS HBT* refers to heterojunction bipolar transistor, for which the base is doped with germanium. With this technology, chips work much faster while ensuring the reliability and the stability of such a process. These chips can be designed for wireless applications, increasing the performance of these products while decreasing their size and power consumption. Besides, the BiCMOS HBT SiGe technology takes advantage of the integration capability of CMOS process, which leads to greater compactness.

There are two different ideas on the issue of using SiGe technology. On one hand, Si and SiGe technologies are found to be very advantageous, because of their capability to achieve more compact and cost-effective circuits. On the other hand, the degree of maturity of Si/SiGe technologies is still not comparable to that of GaAs technologies. According to some designers, Si technology does not enable

Table 2. Comparison Elements of GaAs versus SiGe

Substrate type	Transistors	f_t (GHz)	F_{min} (dB)	Cost (\$/mm ²)
GaAs	PHEMT	>70	0.9 at 12 GHz	1000
SiGe	HBT-CMOS	>40	0.7 at 2 GHz	700
	BiCMOS	>50		

integration of a complete microwave system. It may then be necessary to use mixed technologies, which tends to be more expensive than a complete development on GaAs.

Moreover, in spite of obvious advantages of cost-effectiveness and compactness, SiGe technology involves some nonnegligible constraints, one of the most important of which is still the lack of a proper library model in conventional microwave and high-frequency circuit simulators. To become more familiar with Si and SiGe technologies, and before confronting the realization of circuits, designers will often have to test several processes through their design kits to have in mind the problems that have to be faced:

1. The first major problem is encountered at the level of the CAD tools. Because of the classical use of silicon technology for digital and analog applications at low frequencies, most component libraries were developed primarily for CAD software using the same approach. Of course, the design philosophy of these circuits is very far from that used for microwave analog circuits.
2. The second problem arises from the fact that some component models are sometimes not available in simulator libraries or not parameterized, thus making any optimization a difficult task. As a result, some components such as inductors are not available because they are not classically used at low frequencies. They have to be designed using specific tools. In some processes, this is also the case for varactor diodes.
3. From the design perspective, this third problem arises from the specific conductivity of the doped silicon (SiGe) substrate and its poor isolation (some tenths of an $\Omega \cdot \text{cm}$ compared to $10^5 \Omega \cdot \text{cm}$ for pure silicon). This leads to considerable increase in the number of parasitic capacitors in a circuit. For example, in the case of the MOSFET, it is necessary to take into account not only the parasitic capacitors C_{gs} and C_{gd} but also capacitors C_{db} , C_{bs} , and C_{gb} (parasitic capacitors between the substrate and respectively the drain, the source, and the gate). These capacitances are nonnegligible regarding the other capacitances of the circuits.

Note that these problems are now partially solved; some SiGe foundries now supply models for classical CAD packages, with microwave design facilities such as constant gain, stability, and noise circles.

Design rules of Si-based technology are also very different from those used with GaAs processes, even for the design of simple circuits. For technological reasons, the ground plane of a circuit on silicon is located on the top of the substrate. It is then not possible to strictly consider microstrip lines. However, some reports have shown the feasibility of transmission lines in polymers, such as benzocyclobutene (BCB), allowing performances close to those obtained with GaAs [28]. Particular attention should be also paid to the leakage currents due to the specific conductivity of the substrate. To solve this problem, many manufacturers use guard rings. These guard rings are buried layers, surrounding partially or totally the component to be protected by acting as a p-n junction biased in inverse. All these protection processes clearly allow a more

compact implementation in comparison to GaAs, leading to very different design rules and component placement than those applied for conventional microwave GaAs technology. This mainly explains the differences in size that can be observed for the same function from one technology to the other. To illustrate these differences in terms of component implementation, size, consumption, and cost, we now give two comparative design examples and the corresponding layouts.

Example 1. In a first-order filter based on a parallel LC resonator, ports are decoupled by low-value capacitances. [The GaAs version is discussed in Section 3.4.3 (see also Fig. 12) of the active-filter structure overview article cited above; see also Ref. 30 of this present article.] In the same way, a SiGe version has been realized [30] using the BYR process from AMS [31]. This filter is designed to work in the UMTS reception band (2110–2170 MHz). Transistors are BiCMOS HBTs and PMOS. Losses are perfectly compensated within the passband. Figures 23a and 23b

(a)

(b)

Figure 23. Layouts of the active LC filter in (a) GaAs and (b) SiGe (+ zoom) technologies.

compare the two circuit layouts. The high-compactness of the SiGe version can be easily noted. The reduction in surface is done with a ratio of 150 corresponding to a reduction of cost of 170. With other circuits found in the literature, the mean reduction ratio in surface and in cost can be estimated respectively at 50 and 55. With the technologies used, the power consumption ratio is ~ 21 (48 mW for SiGe version against 1040 mW for the GaAs version).

Example 2. In this example, two different NIC topologies have voluntarily been chosen to try to emphasize one or the other technology. The GaAs version uses the ED02Ah process from OMMIC [32] with HEMT transistors. The circuit works in the 1.9–2.3 GHz range and belongs to the infinite transconductance NIC category (see active-filter structure overview article cited above). The SiGe version has been realized with the AT46000 from ATMEL [33]. It is based on a classical differential topology using BiCMOS transistors. This circuit works in the 0.1–3 GHz range. Figures 24a and 24b compare the two circuit layouts. The reduction in size here is ~ 55 , corresponding to a cost ratio

of 65. Power consumption is divided by 4 (18 mW for the SiGe version vs. 73 mW for the GaAs version). Simulation results of these two NICs inserted within a filter give a clear advantage to the SiGe version.

4.3. Realisation Examples

Example 1 focuses on a topology proposed in Refs. 34 and 35. It consists of a grounded active inductor using a low-cost 0.8- μm BiCMOS HBT technology [30]. This inductor topology is based on the use of two HBTs in a feedback configuration. Note that in this case there is no need for an integrated inductor (Fig. 25).

The quality factor Q_1 is biased by a voltage-controlled current source built with bipolar transistors. V_{tune} allows tuning of the associated real part while maintaining the inductance value. Using this approach, a quality factor of some thousands can be performed for an inductance value of 9.20 nH.

By associating a capacitor in parallel with the active inductance, a bandpass response can also be obtained. The active LC resonator is decoupled by two small value capacitors. Figures 26 and 27 respectively present the layout of

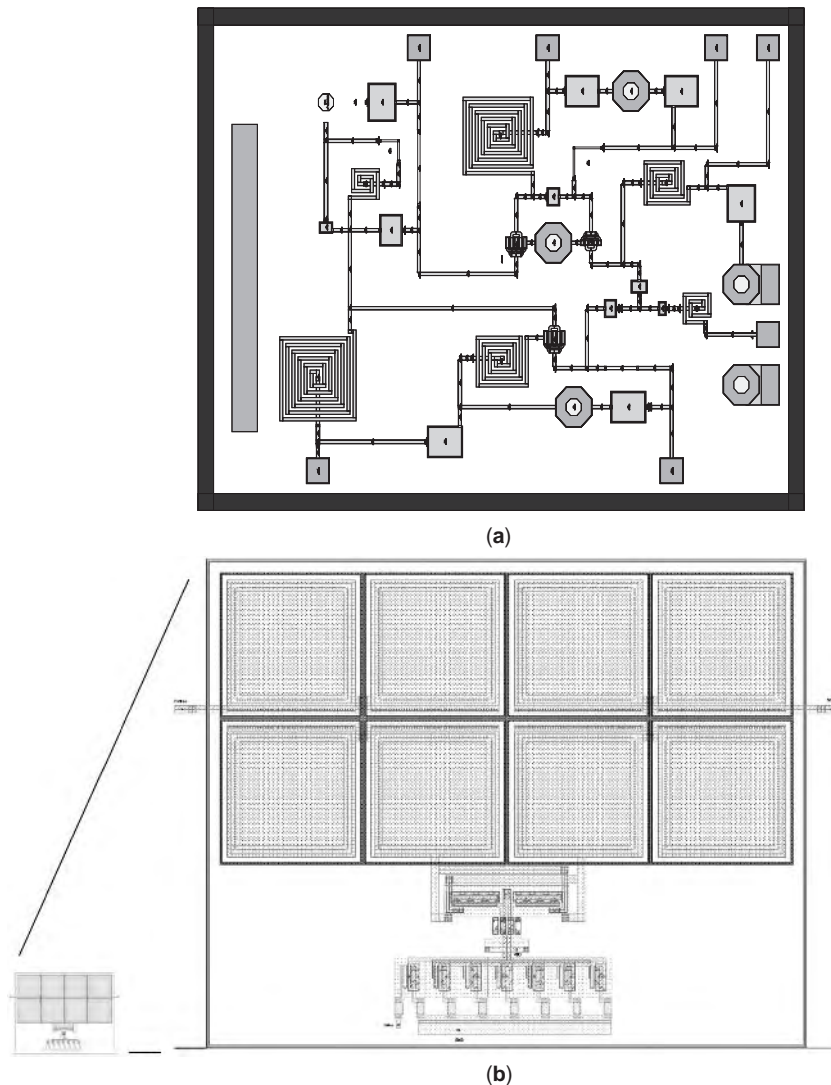

Figure 24. Layouts of the two negative-resistance chips in (a) GaAs and (b) SiGe (+ zoom) technologies.

Figure 25. Schematic of the active inductor.

the filter and the simulated response. Dimensions of this circuit are $150 \times 170 \mu\text{m}$. Total consumption is about 15 mW. Losses are totally compensated at 1.86 GHz, with a quality factor of ~ 150 .

4.4. Differential Circuits

For many years, differential structures have been limited to low-frequency applications. Differential structures have the following advantages compared to single-ended topologies:

- They are insensitive to noise and interference coupled through supply lines and substrate.

Figure 27. Layout-based simulated results of the integrated active LC filter.

- Many linearization methods used for transconductance stages can also be used for low-noise amplifiers and filters using this approach.
- They have smaller even-order distortion.

Figure 26. Layout of the integrated active LC filter in BiCMOS HBT technology.

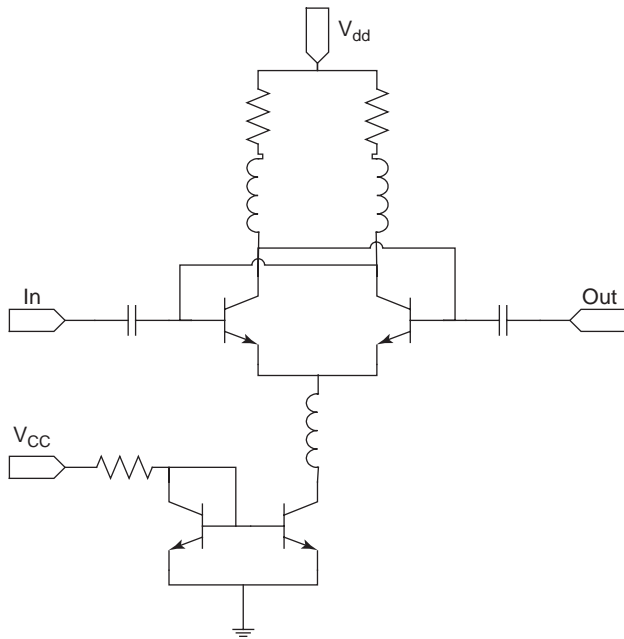

Figure 28. Schematic of the differential negative resistance.

Example 1 (above) focuses on a differential LC active filter in which losses are compensated with a differential negative resistance [36]. We begin with a brief description of the negative-resistance topology. The circuit uses a BiCMOS SiGe HBT technology. Such topologies generally present a real part of the impedance not strongly frequency-dependent and are recommended for wideband applications. A schematic and the layout of the circuit are presented in Figs. 28 and 29, respectively. Three integrated inductors are used to bias and stabilize HBTs. A current source sets the emitter current. Symmetric performances are obtained between the two ports. The imaginary part can be considered as a negative capacitance. Circuit dimensions are $690 \times 800 \mu\text{m}$. The negative resistance performed is about -10Ω at 1.8 GHz. The imaginary part is equivalent to a -2.4 pF negative capacitance. Power consumption is about 46 mW.

A differential LC filter circuit is now presented. The previous differential negative resistance is used to compensate for insertion losses introduced by the inductors of the resonator. Two transconductances are also used to tune the center frequency and the gain of the filter. A schematic of this circuit is presented in Fig. 30. A band-pass response is obtained with a quality factor of ~ 125 at 2 GHz. The S parameters are presented in Fig. 31. The noise figure is $\sim 4.5 \text{ dB}$ at 2 GHz.

Finally, we show a 2-GHz single-ended first-order recursive filter integrated using the QuBIC4 silicon MMIC

Figure 29. Layout of the differential negative resistance.

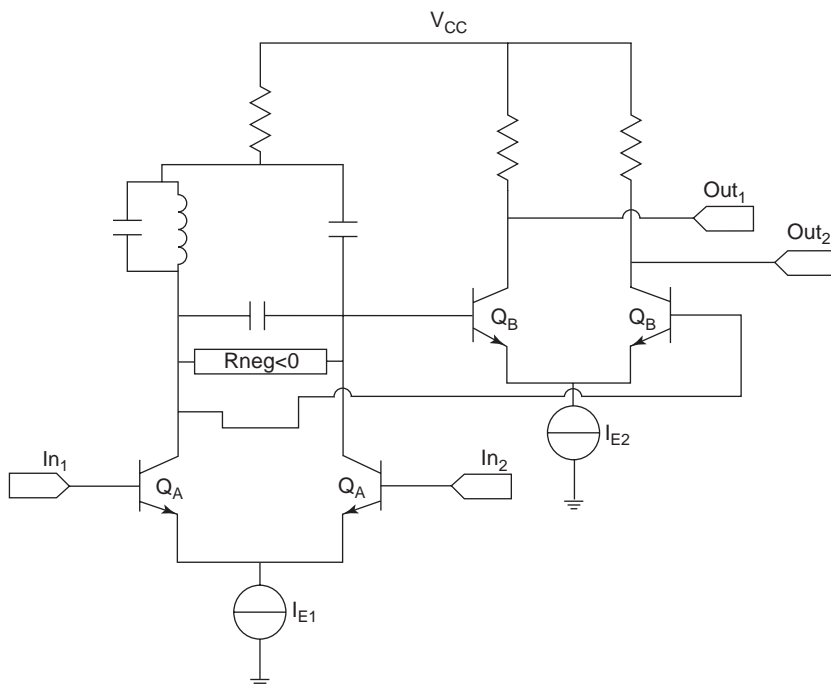

Figure 30. Schematic of the differential filter.

process from Philips [37]. The differential property is used here for an original recombination of input and delayed feedback signals within a first-order recursive structure. Figure 32 presents the basic principle of the circuit. With A_d , the differential-mode voltage gain of the amplifier structure, the voltage gain of the filter can be expressed as a first-order recursive filter response:

$$G_v(f) = \frac{V_{out}(f)}{V_{in}(f)} = \frac{-\frac{A_d}{2}}{1 + \frac{A_d}{2} e^{-j2\pi f\tau}}$$

The circuit layout is shown in Fig. 33. Dimensions of the chip are 1.12×1 mm. Measurements presented in Fig. 34 are in good agreement with simulations. Input/output matching is less than -12 dB within the passband. The filter exhibits a 260 MHz 3 dB bandwidth at 1.94 GHz, with a gain close to 10 dB for a power consumption of 32 mW. Input/output matchings are lower than -12 dB for 1 GHz around the center frequency. Isolation, which is not

Figure 31. S parameters of the differential filter.

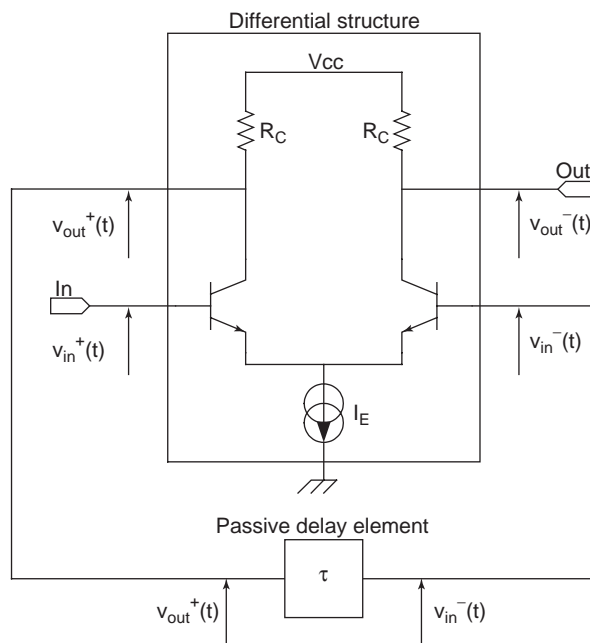

Figure 32. Schematic of a differential-based recursive filter.

Figure 33. Differential-based recursive filter layout.

presented here, is greater than 30 dB in the 0.5–3.5 GHz range. The noise figure is equal to 4.6 dB at the center frequency. The -1 dB compression point is obtained for an output power of -11.7 dBm.

1. INTRODUCTION

Demands for better-quality and new value-added services of existing wireless communication infrastructures have risen beyond all expectations. It is estimated that half a billion handsets will be put into the context of the third-generation system (UMTS, IMT 2000), which will provide an up to 2 MB (megabytes of) bandwidth for each user [1]. The challenging demand is to increase the spectrum efficiency and the system capacity of the current wireless networks. These demands have brought technological challenges to service providers. Because of the ability of suppressing interference and combating against fading and providing new services, adaptive array antennas or “smart” antennas have become one of the key technologies to realize third-generation (3G) and even fourth-generation (4G) wireless communications. We start with an overview of the evolution of wireless communication systems, calling for new technologies to support its new applications and improved qualities. Adaptive array antennas or smart antennas turn out to be solutions in the process of the evolution. We will present various applications of smart antenna technologies in wireless communications.

After that, different architectures of adaptive array antennas are presented with illustrations followed by descriptions of some algorithms. Finally, we compare the adaptive array antennas architectures and their suitability to different applications.

2. DEMANDS FOR ADAPTIVE ARRAY ANTENNAS

In 1899, Guglielmo Marconi transmitted signals across the English Channel, between Wimereux and Dover. In 1901, the first transatlantic wireless transmission was demonstrated [2]. Intrigued by that, scientists and engineers had been investigating new wireless communications methods and services. The era of wireless communications had just begun.

The wireless communication industry has experienced phenomenal technological advancement manifested in various application scenarios, including wireless remote control, codeless telephony, paging, wireless networks, terrestrial cellular telephone systems, and satellite communications [3]. Among them, the cellular telephone systems have been developing from the first-generation systems that were deployed firstly by Nippon Telephone and Telegraph (NTT). Through the 2G systems [i.e., Global System for Mobile Communications (GSM) and Digital Cellular System 1800 (DCS 1800) in Europe, Personal Communication System 1900 (PCS 1900), interim standard 95 (IS-95) and IS-136 in North America and Personal Digital Cellular (PDC) in Japan], the wireless system is evolving to the 3G system [i.e., wideband code-division multiple access (WCDMA) and CDMA 2000], and will approach the 4G system in the near future [3–5].

The 3G system is a universal, multifunctional, globally compatible digital mobile radio system. It allows users to communicate anyone, anywhere, at anytime. The system integrates paging, cordless, cellular, wireless network, and satellite communication systems into a single mobile terminal. The user can use the 3G terminal for conventional voice phonecall, broadband access to the Internet, high-speed package data services, and position tracking [3–12].

The main features of 3G and beyond communications systems are

- *High-Data-Rate Communications.* The minimum requirements of the user data rates in different environments are 144 kbps (kilobits per second) for vehicular applications, 384 kbps for pedestrian, 2 Mbps for indoor office, and 9.6 kbps for satellite communications. These goals require a significantly increased frequency efficiency that is measured by the bps/Hz.
- *New Services.* New services include intelligent transportation, position location (PL) services, and ad hoc networks. These location-aware services require new techniques to provide position information.
- *More Subscribers.* The wireless communications will be so ubiquitous that more subscribers or users are accommodated. This feature demands a dramatic increase in the mobile radio system capacity measured by the number of users within a given frequency spectrum.

During the migration from the 2G system to the 3G system, great efforts have been directed toward the development of the modulation, coding, and protocols on the 2G systems, such as code-division multiple access (CDMA) with IS-95, time-division multiple access (TDMA) with IS-136, and GSM. These techniques have been exhausted to the limit because of the large number of subscribers within the limited channel capacity. Antennas have gained much interest among researchers. The smart antenna system, in the form of adaptive arrays, can mitigate three major impairments caused by wireless channels: *fading*, *delay spread*, and *cochannel interference*. It can also bring many benefits to the existing wireless communication system, such as the enhancement of coverage for portable mobile applications, improved signal-to-interference ratio (SIR) and an increased channel capacity [13,14], lower transmitted power, and higher transmission data rate. Employing adaptive array antennas into current wireless communication infrastructures also brings value-added services, such as general packet radio service (GPRS), users' PL, and the intelligent transportation system [13,15].

3. CURRENT APPLICATIONS OF ADAPTIVE ARRAY ANTENNAS

Along with the evolving development of smart antenna technologies, the applications of adaptive array antennas have extended from the early forms such as diversity and sectoring to the recent employment such as space-division multiple access (SDMA) and multiple-input multiple-output (MIMO) communications. In this section, we give a brief introduction on some applications of adaptive array antennas in the wireless communications.

3.1. Diversity Scheme

The earliest application of adaptive array antennas is diversity. The scheme has found many applications over the years. It has been in wide use in a variety of present-day microwave systems [16–20]. The aims of this scheme are to extract information from several independent signal paths, to combine the multiple signals, and to reduce the effect of excessively high signal fade [21]. Because the probability of two independent signals having a deep fade at the same time is rare, combining them reduces the effect of the fades.

There are many mechanisms to provide diversity. They are space diversity (with spaced array elements), frequency diversity [multicarrier CDMA, orthogonal frequency division multiplexing (OFDM)], angle of arrival (AOA) or angular diversity (impinging waves with different directions), polarization diversity (transmitting signals with different polarized waves), time diversity (signal repetition), and multipath diversity (rake receiver technique) [16]. Among them, space diversity is the easiest one to implement. However, space diversity needs an array antenna with sufficient interelement spacing. Therefore, considering space limitation in a mobile phone, the polarization diversity provides a compact installation [22–26].

Geographically there are two kinds of diversity schemes: the macroscopic diversity scheme and the microscopic

Figure 1. Rayleigh fading envelope.

diversity scheme. A *macroscopic diversity scheme* is used to combat against random shadowing effects where the signal power may drop to a point lower than the value predicted by a long-distance path loss model. The undulation of terrain contours determines the duration of the envelope variations during a long-term fading. The diversity scheme is employed by selecting signals from two separated base stations. On the other hand, in the *microscope cells*, clusters surround mobile users. Time dispersion caused by multipath propagation delays and the random frequency modulation due to varying Doppler shifts on different multiple signals result in fluctuations of the signal power at both base stations (BSs) and mobile terminals. This is commonly known as *Rayleigh fading* (see Fig. 1) [21]. Figure 2 shows the envelope correlation of two signal samples at distance/spacing ζ , where λ is wavelength of the carrier signal. The model assumes that the direction of arrivals (DoAs) of multipath signals are

Figure 2. Envelope correlation spacing in a two-dimensional (2D) Clarke scenario.

uniformly distributed over 360° . Spacing of 0.13λ achieves a correlation lower than 0.7. For practical implementations of a microscopic diversity scheme, array antennas with interelement spacing of 0.38λ for a mobile station (MS) or tens of wavelength for a BS can provide independent signals at separate elements [17]. Ericsson has proved the improvement of the uplink performance employing both space and polarization diversities [27,28]. The international team of Ericsson has built a testbed to study the performance of the smart antenna receiver for digital advanced mobile phone service (AMPS). The uplink receiver uses space and polarization diversities. The interelement spacing is 15λ . The system provides a 3.5 dB gain in signal-to-noise ratio (SNR).

3.2. Sectoring

The ultimate goal of implementing a wireless cellular system is to achieve high capacity while satisfying quality-of-service (QoS) expectations. Cell splitting is a simple way to reduce cochannel interference (CCI). Currently most existing cellular and personal communication service (PCS) systems [3] make use of the sectoring technique in addition to the spatial diversity scheme. Each cell is divided into radial sectors with widebeam directional antennas installed at the BS [3,4,18,29]. Typically, those cells are divided into three sectors, which are 120° wide or six sectors that are 60° wide. Let us consider a cellular system with the cluster size of 7. The 120° cell sectoring reduces the number of the first-tier CCIs from 6 to 2 and brings a 6.8 dB SIR gain [1]. In addition to CCI suppression, another attractive benefit of sectoring is that frequency resources can be reused more frequently; thereby each cell can accommodate a larger traffic density without adding extra base stations.

Higher-order sectorization can be employed via beamforming or employing directional panel antennas to increase the frequency reuse and thus further improve the system capacity [29]. Sectoring via adaptive beamforming even allows more flexible allocation of transmit power at the BS [29]. However, handover will be initiated more frequently. Therefore, the system complexity is also increased.

3.3. Interference Suppression with Adaptive Beamforming

Adaptive antennas date back to 1959. The original work was attributed to L. C. Van Atta's work, *Electromagnetic Reflection* [U.S. Patent 29,080,002 (1959)]. Since then, adaptive beamforming techniques have been employed to remove unwanted noise and jamming from the output, mainly in military applications [4]. With the thriving commercial wireless communication industry and the advancing microprocessor technologies, the adaptive beamforming techniques have found their applications in commercial wireless communications. With powerful DSP hardware at the baseband, algorithms could control antenna beam patterns adaptively to the real signal environment, forming beams toward the desired signals while forming nulls to cochannel interferers. Thus, the system performance is optimized in terms of link quality and system capacity.

Field trials of both multibeam antennas and adaptive arrays have demonstrated performance improvements. Promising results substantiate the potential benefits of the adaptive beamforming technologies [30–37]. Meta-wave has extensively studied the range increase of multibeam antennas. Employing a 24-beam 15° beamwidth system, switching combining from two strongest directional beams achieves a 5 dB gain in a typical cellular environment [30]. An increased interference tolerance of 9 dB in the IS-136 system with a four-element adaptive antenna is demonstrated by Ericsson [31–33,37]. Lucent/AT&T has demonstrated the operation with an equal-power interferer next to the desired mobile terminal several miles from the base station in an IS-136 system with a four-element adaptive antenna [33]. Field trials have also been done for Digital European Cordless Telecommunications (DECT) system under the European TSUNAMI project [34]. Commercial products include a four-beam smart antenna incorporated into a GSM base station product by Nortel, and adaptive array processing using two base-station antennas incorporated into an IS-136 base station product by Ericsson [33–36].

However, the extensive implementation of adaptive antennas has been a problem. Because of system complexity, the fabrication cost, and the operational expenditure, adaptive antennas are limited to base stations or military applications. Researchers are endeavoring to make low-profile and low-power-consumption antennas for mobile terminals. Parasitic array antennas have become an active research topic. The antennas normally has one active element connected to the radiofrequency (RF) port, and beam pattern adaptation is achieved by switching among parasitic elements or by adjusting the loaded reactance at the passive elements. Being a less complicated structure, it offers an economical way to design low power consumption adaptive array antennas.

3.4. Space-Division Multiple Access

Filtering in the space domain separates spectrally and temporally overlapping signals from multiple MSs. Thus, the spatial dimension can be exploited as a hybrid multiple-access technique complementing existing multiple access schemes such as frequency-division multiple access (FDMA), TDMA, and CDMA. This approach is usually referred to as *space-division multiple access* (SDMA). The realization of this filtering technique is accomplished by using a smart antenna, which is capable of modifying its time, frequency, and spatial response by means of the amplitude and phase weighting and the internal feedback control (see Fig. 3). The SDMA scheme enables multiple users within the same radio cell to be accommodated on the same frequency or timeslot. Thus, it will increase the system capacity significantly [13,38–43]. The concept of the SDMA scheme is demonstrated by the TSUNAMI project. A uniform linear array consists of eight elements with a beamforming card developed by ERA Technology [44] used at the BS. The multiple signal classification (MUSIC) algorithm is used to find the direction of the MS. The Kalman filter is used to track the MS [34].

Figure 3. Space-division multiplexing (SDM) using spot beams at BS.

In addition to applications at terrestrial cellular systems, the SDMA scheme has been employed in satellite communications where each spot beam services a geographic area [39]. For an L-band mobile satellite communication system, to increase the frequency reuse in the spatial domain, multiple-beam satellite antennas are used for coverage of Canada and the United States. In comparison with a single-beam antenna, frequency reuse is increased by a factor of 4/3 using a four-beam antenna and 12/3 using a 12-beam antenna [39]. In Japan, a six-beam satellite antenna is used for 22-GHz band satellite broadcasting [45].

4. INCOMING APPLICATIONS OF ADAPTIVE ARRAY ANTENNAS

In addition to the aforementioned applications, new applications will be incorporated into future wireless communications standards of the 3G and 4G systems. Extensive investigations have been carried out to bring these new applications into reality.

4.1. Ad Hoc Networks

An ad hoc network is a dynamic wireless network established by peer-to-peer communications among mobile nodes (e.g., laptops, PDAs) without the help of any infrastructure such as a wire/wireless backbone [9,46–50]. The concept is shown in Fig. 4, in which each mobile terminal directs its beam toward the neighboring node to form a mesh where each node is a potential router. Changing together a sequence of neighboring nodes dynamically changes the routing of an information packet from an information source to a destination. Researchers are investigating media access control (MAC) protocols of ad hoc networks. Adaptive array antennas are a critical part, as many MAC protocol designs include the antenna beam pattern control [47,48]. With a properly oriented beam (toward the desired node), each node can resolve signals from neighboring nodes. The idea is the same as for an SDMA system. The DoA information from the antenna is used in routing selection. Another important issue of the ad hoc network is power consumption. Because mobile terminals for an ad hoc network have a limited battery life (around 3–4 h for a laptop), adaptive array

Figure 4. Ad hoc network with directional antenna at each mobile terminal.

antennas for this application are also required to have easy beam pattern control and consume as little power as possible.

4.2. Position-Location-Based Services

Safety is the primary motivation for PL services. In the United States, the Federal Communications Commission has mandated PL services within 125m accuracy on wireless emergency calls [13,18,51]. Using adaptive antennas, direction finding systems provide a mobile user’s position information. This location information aids emergency rescue, law enforcement, and other emergency calls. With the position location information, other promising applications such as accident reporting, navigational services, automated billing, fraud detection, roadside assistance, and cargo tracking are also becoming reality [15].

Currently, there are many existing PL systems, including the Global Positioning System (GPS), Global Navigation Satellite System (GLONASS), signpost navigation, and cellular geolocation [13]. Among them, cellular geolocation is the most attractive. It only needs to implement the smart antenna system, which has DoA estimation ability, into the existing wireless communication systems. The realization is based mainly on three mechanisms [51]: beacon location methods, DoA estimation techniques, and time-difference-of-arrival (TDoA) techniques. The concept of geolocation technique is shown in Fig. 5. The BSs located near the MSs estimate the DoA of the impinging wave from the terminal. From the DoA estimate, a line of bearing (LoB) from the base station to the mobile transmitter can be drawn. Multiple LoBs, drawn from different BS locations, intersect at the estimated location of the mobile terminal.

4.3. High-Data-Rate Transmission over MIMO Systems

The goal of the 3G communications systems is to provide high-data-rate transmission [5–8,11,52]. The goal urges a significant increase of channel capacity or, say, spectrum efficiency. MIMO systems have shed light in the tunnel to higher-data-rate transmissions. In commercial and

economical aspects the MIMO system is the most promising candidate as it offers such a significant capacity upgrade that high-data-rate transmission can be achieved [52–59].

Multipath fading has long been viewed as impairment to the wireless communications link. Techniques such as diversity combining, equalization, and adaptive beamforming have been investigated to reduce the fading. A different view is that exploiting multipath fading realizes higher-data-rate transmission. In a multipath-rich environment, antenna arrays that provide uncorrelated signal outputs are installed at both transmitters and receivers to build MIMO wireless communication channels [60–65]. The multipath phenomenon achieves an information-theoretic channel capacity that increases with the number of array antenna elements. In Fig. 6, Tx and Rx are the numbers of transmit antennas and receive antennas. We observe that the capacity grows significantly when Tx and Rx increase.

Transmission STC through MIMO systems takes advantage of spatial and temporal diversities to increase the data rate over fading channels [53]. Field tests and experimental results substantiate the capacity gain achieved by MIMO systems [66,67]. Lucent Technologies has achieved

Figure 5. Concept of cellular geolocation.

Figure 6. MIMO information-theoretic channel capacities with different numbers of transmit antenna and receive antennas.

a transmission data rate of 40 bps/Hz at a 30 dB SNR indoor flat fading environment using 8 transmit and 12 receive antennas vertical Bell Labs layered spacetime (V-BLAST) architecture [68,69].

5. ARCHITECTURES AND IMPLEMENTATIONS OF ADAPTIVE ARRAY ANTENNAS

In the previous section, we presented the applications of smart antenna technologies. Various applications require different functions from adaptive array antennas. For example, SDMA requires fine beamforming ability. PL services demand for DoA estimation, and MIMO systems require decorrelation among signal samples. In this section, we examine various realizations and implementation issues of adaptive array antennas. Figure 7 shows the tree structure of various smart antenna implementation architectures.

5.1. Switched-Beam Antennas

A switched-beam antenna system consists of several highly directive, fixed, predefined beams [13,14,18,63,70–72]. In practice, multiple beams can be formed by a beamforming

network, which consists of an involved feeding system and multiple input ports. The feeding network that provides adequate excitation to the array elements can steer the beam pattern to the desired direction. It can be implemented at either RF stage or intermediate-frequency (IF) stage. The functional block diagram of a switched-beam antenna is shown in Fig. 8. An example of the beam-forming network is the Butler matrix [14,18,71,73], which consists of power splitters and phase shifters. It has been used extensively over the years in radar, electronic warfare (electronic support measures), and satellite systems. Figure 9 depicts a 4 × 4 Butler matrix. Figure 10 illustrates the produced beam patterns with the 4 × 4 Butler matrix.

The receiver chooses from the one of the several beams to give the best performance. The decision making stage can be implemented at the IF stage, based on the criterion of the maximum received power using a received signal strength indicator (RSSI) or at the baseband digital stage by examining the lowest signal bit error rate (BER). In Ref. 74, an 8 × 8 Butler matrix is used to generate eight Woodward Lawson beams. Microstrip patch antennas are chosen as the array elements. Mutual coupling between elements is reduced to a level of less than – 15 dB by using H-shaped slot feeding technique. Measurement results show that 13 dBi directivity gain is achieved for the eight beams covering a 114° angular range. A beam selector chooses either one of the eight fixed beams or two neighboring beams by examining the output signal BER.

In a sense, a switched beam is an extension of the conventional sector beam antenna in that it divides a sector into several microsectors [63]. Therefore, the switched-beam antenna system is the easiest solution to upgrade the existing system, which employs 120° sector antennas and dual diversity per sector. However, switched-beam antennas also have drawbacks. They do not exploit multipath. In addition, the signal power from the mobile terminal drops greatly when the mobile terminal moves into the margin of a beam or the area between two beams. Furthermore, owing to the inability to distinguish a desired user from interferers, switched-beam antennas are not effective in combating against CCI. If a strong interfering signal is at the center of a selected beam and the desired user is away from the center of that beam, the interfering signal can be enhanced far more than the desired signal. One solution of the aforementioned problems has

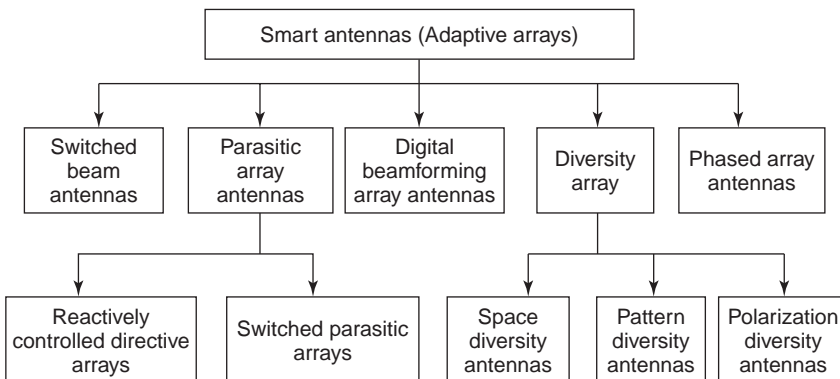

Figure 7. Various architectures of adaptive array antennas.

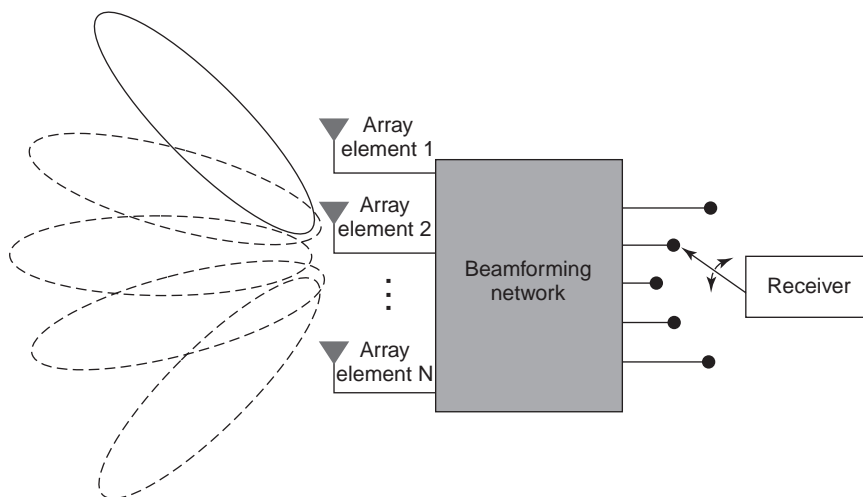

Figure 8. Functional block diagram of switched-beam antennas.

been presented in Refs. 75–77, where phase shifters are added to the switching system. The structure achieves a smoother transition from one beam to another.

5.2. Phased-Array Antennas

Research and development (R&D) of phased-array antennas for radar systems has been ongoing in the United States since 1950s [78]. Since then, phased-array antennas have been extensively utilized in radar, military scenarios, and satellite communications. Now the antennas are used more for space-based communications applications because of their advantages in scanning, reconfigurability, weight, and power. In satellite communications, adaptive array antennas function as input–output ports of the link at both satellite and ground segments. In Japan, phased-array antennas were first applied when Japanese Defense developed a passive array antenna consisting of element antennas equipped with phase shifters and power divider/combiners in the 1960s [78]. The Communication Research laboratory (CRL) and National Space Development Agency of Japan (NASDA) developed an onboard Ka-band (20/30-GHz) scanning spot beam active phased array

antenna for the experimental high data rate (gigabit) communication satellite [79]. Both the transmit and receive antennas use a meanderline polarizer and 64 pyramidal horn element antennas, and realize circularly polarized scanning spot beams. Each antenna is connected with four independent 4-bit digital phase shifters to achieve four independent beams, respectively. In Australia a 12-element land mobile terminal phased-array antenna is designed for continuous tracking of the Mobilesat satellite while the terminal is moving [80]. The role of a phased-array antenna for mobile terminal in satellite communication scenario is to enable transmission and reception of microwave signals and to track the satellite while the vehicle is moving. As shown in Fig. 11, the terminal is equipped with phased-array antenna as the mobile antenna, an antenna electronic unit (AEU), a transceiving unit, and a satellite tracking unit. The functional block diagram of the mobile antenna is depicted in Fig. 12. The beamforming network consists of power dividers, couplers, switches, phase shifters, biasing networks, and

Figure 9. A four-port Butler matrix for fixed beamforming [71].

Figure 10. A set of four beams produced using a 4 × 4 Butler matrix. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 11. Functional block diagram of a mobile satellite communication terminal and a phased-array antenna mounted on a car.

circularly polarized (CP) patch antennas as array elements. The system conforms with the Australian mobile satellite specifications:

- *Polarization.* right-hand circular
- *Frequency.* 1646.5–1660.5 MHz for transmission; 1545.0–1559.0 MHz for reception
- *Coverage.* full 360° in azimuth and 28–66° in elevation
- *Gain.* 10–12 dBi desirable with a minimum of 7 dBi

In the design presented in Ref. 80, single-feed stacked patch elements presented in Ref. 75 (see Fig. 13) are selected as the best candidates for constructing the planar phased array. The detailed view of the developed multilayer phased-array antenna is shown in Fig. 14. The multilayer design includes stacked CP patch antenna arrays and two foam layers to achieve an increased antenna beamwidth, a slotted ground layer for coupling, and an antenna beamforming network layer as shown in Fig. 15. The beamforming network layer consists of a 12-way feed power division/combination network as required for 12 patch antenna elements arranged in two rings of 8 and 4 elements. Twelve 3-bit digital phase shifters (including a 180° switched-line phase shifter and 45° and 90° loaded line phase shifters), located at the outputs of the 12-way divider, are coupled to individual antenna elements via aperture coupling.

Phased-array antennas contain a multitude of radiating elements, typically arranged in a rectangular or triangular tessellation. Beam pattern steering of phased-array antennas is achieved by implementing phase shift of signals from array elements [18,63,70,75,80–82]. Dynamic phased arrays make use of the DoA information from a desired user and steer a beam maximum toward that user, thus improving the capabilities of a switched-beam antenna [63]. Tracking is needed to continuously steer the beam toward the desired user. However, the disadvantage of the phased-array antenna is the relatively high cost as expensive PIN diodes are used in phase shifters required by beamforming networks [75].

5.3. Digital Beamforming Array Antennas

The technological progress of DSP has introduced the concept of beamforming in the digital stage [14,18,37,39,63,70,82–84]. In comparison with switched-beam antennas and phased-array antennas, smoother pattern direction tuning and higher-resolution direction finding can be achieved with high-speed DSP and high-resolution ADC. The functional block diagram of a DBF array antenna is shown in Fig. 16. Each downconversion channel has a low-noise amplifier, a frequency converter, and an ADC. Signals received by individual antenna elements are downconverted to the baseband, digitized, and then fed into a DSP chip where algorithms are carried out. A fine steering is achievable by employing high-resolution sampling and

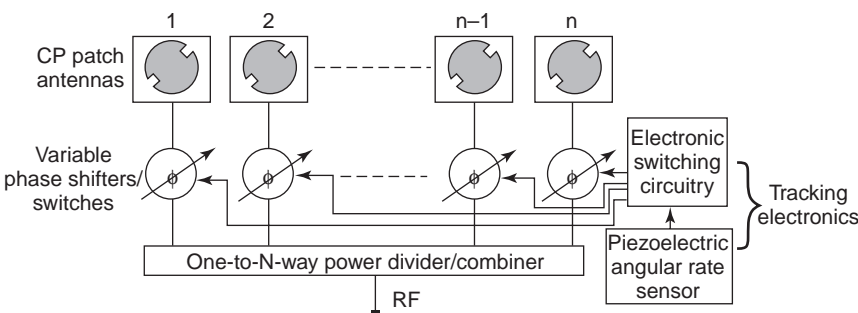

Figure 12. Functional block diagram of a phased-array antenna at land mobiles for satellite communications.

Figure 13. Stacked patch with perturbation segments [75].

quantization in an A/D conversion process. Many beamforming and DoA estimation algorithms have been studied [3,4,8,37,39,63,85–89]. Simulations and tests show that they are fruitful in improving the system capacity and enhancing system performance [37,39,87].

However, high-resolution A/D conversion dissipates a substantial amount of DC power. Furthermore, since a DBF antenna needs the same number of A/D converters as does the number of antenna elements, the fabrication cost increases with the number of antenna elements. In addition, because A/D conversion cannot be carried out directly in the RF stage, same amount of power are also consumed at the frequency converters [14,82,90]. For these reasons, the use of DBF antennas has been restricted to military applications, satellite communications, or at the base station for terrestrial wireless communications.

5.4. Parasitic Array Antennas

To circumvent the disadvantages of the aforementioned systems, adaptive beamforming based on parasitic antennas has been explored [82,90–107]. In a parasitic array antenna, the active element, which is excited by the transmitted or

Figure 14. Detailed view of the developed multilayer phased-array antenna.

Figure 15. Detailed view of the beamforming layer.

the received signal sources, is surrounded by a number of parasitic elements, which are not connected to the signal source. In the presence of neighboring elements, the performance of each element depends not only on that element’s current but also the currents of neighboring elements. For resonant elements with no current excitation of their own, a substantial current could be induced by radiation from another source [108]. The far-field radiation pattern is formed by superposition of the radiation of all antenna array elements [109]. Thus, by changing the radiation of each element, it is possible to direct the antenna beam toward desired directions.

The use of parasitic elements for controlling antenna beam patterns goes back to the work of Yagi and Uda during the 1930s [108]. This antenna array has been patented in various forms for numerous applications. Various electronically steered Yagi–Uda arrays have been designed. A reflector formed by short-circuited elements is arranged behind the active element. Figure 17 illustrates the formation of Yagi-Uda array with the switched parasitic elements. By controlling the states (ON or OFF) of the PIN diode switches of the parasitic elements, different sets of short-circuited monopoles function as directors and reflectors around the active central monopole. Therefore, directive beams are steered toward the desired directions [91–93,96,97,100,102,103]. Instead of using one active element at a fixed position, multiple active elements give more choices of producing multiple beams [97,98,101,107]. Similar to those wire antenna elements switched by diodes, it is also possible to use switches to control the radiation pattern of parasitic patch elements and thereby change the beam direction of a parasitic patch array antenna [99]. The aforementioned antennas are categorized as “switched parasitic antennas” [105]. Using switched parasitic antennas, beam directions can be selected only among predefined directions. Analogous to switched-beam antennas, this limits performance.

Another category of parasitic array antennas is the “reactively controlled directive array antenna,” which

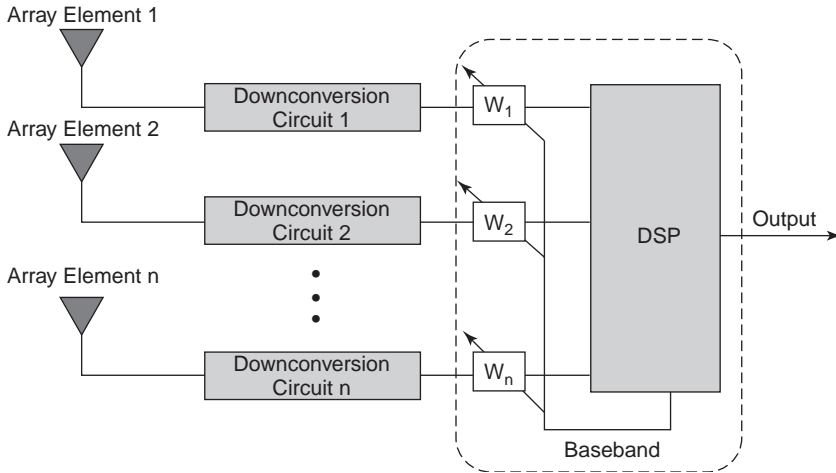

Figure 16. Functional block diagram of DBF array antennas.

dates back to Harrington’s work in 1978 [94]. The parasitic array is formed with one active and several surrounding monopoles on the ground plane. The functional block diagram is shown in Fig. 18. Changing the reactance of the parasitic elements alters the radiation of each element. Therefore, by adjusting the reactance loaded on the parasitic elements, directive beam patterns can be formed. With this configuration, it is possible to achieve a smoother beam pattern tuning. In Ref. 95, the array elements are realized microstrip patches. The loads on the parasitic elements are carried out by terminating a transmission line by a variable-reflection phase shifter. Adaptive beamforming is realized by the steepest-gradient optimization method. More recently, extensive investigations on adaptive beamforming and DoA estimation using this type of structure are carried out. A seven-element antenna called the *electronically steerable parasitic array radiator* (ESPAR) [90,104,110–112] has been developed.

Figure 19 shows the configuration of a seven-element ESPAR antenna. One active central element (monopole) is surrounded by six parasitic elements uniformly placed on a circular grid of radius R on a circular grounded baseplate. The length of each monopole L and the radius R of the circular grid are one-quarter wavelength ($\lambda/4$) of the transmitting RF signal at 2.484 GHz. According to Harrington [94], wide spacing among elements (e.g., $\lambda/2$) leads to reduced gain and significant backlobes. Moreover, further reduction of interelement spacing to $\lambda/8$ leads to a

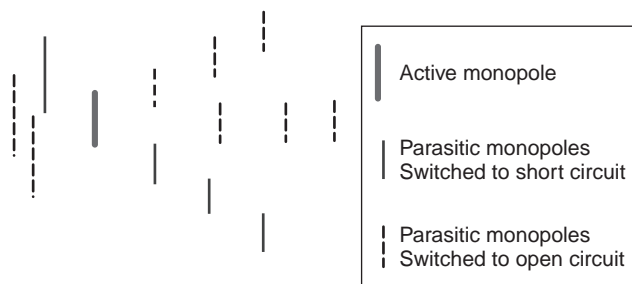

Figure 17. Structure of a switched parasitic array antenna.

supergain array. Therefore, a realistic design for spacing $= \lambda/4$ is chosen. The baseplate transforms monopoles with their images to dipoles with a length of $2L$. The central monopole is connected to a RF receiver, and each parasitic monopole is loaded with a tunable varactor that is realized with a reversely biased diode.

The working principle of ESPAR antennas is different from that for DBF array antennas. The antenna generates a directional beam based on tuning load reactances (x_1, x_2, \dots, x_6) on the parasitic monopoles. Signals received or transmitted from the central RF port excite the parasitic monopoles with substantial induced mutual currents on them. Let us first assume that the antenna is working in transmitting mode, where vectors \mathbf{i} and \mathbf{v} represent the currents and the voltages on the monopoles, respectively:

$$\mathbf{i} = [i_0 \ i_1 \ i_2 \ i_3 \ i_4 \ i_5 \ i_6]^T \quad (1)$$

$$\mathbf{v} = [v_0 \ v_1 \ v_2 \ v_3 \ v_4 \ v_5 \ v_6]^T \quad (2)$$

The superscript “T” represents the transpose; i_0 and v_0 represent the current and the voltage on the active central

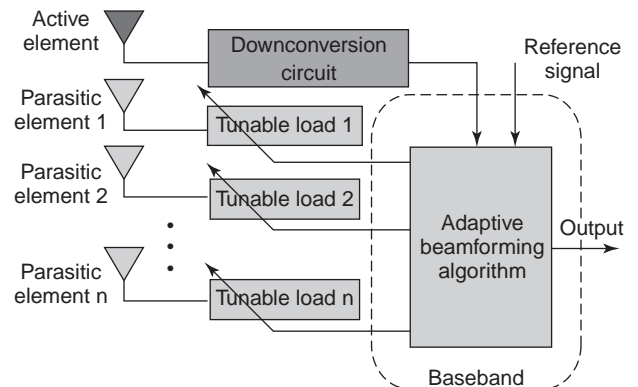

Figure 18. Functional block diagram of reactively controlled directive array antennas.

Figure 19. Configuration of a seven-element ESPAR antenna. The length of each monopole L and the radius R of the circular grid are one-quarter wavelength $\lambda/4$ of the transmitting RF signal at 2.484 GHz.

element (0), respectively. Mutual admittances are represented by the matrix \mathbf{Y}_C with each entity y_{ij} denoting the mutual admittance between the i th element and the j th element. The induced currents are represented with mutual admittances:

$$\mathbf{i} = \mathbf{Y}_C \mathbf{v} = \begin{bmatrix} y_{00} & y_{01} & y_{02} & y_{03} & y_{04} & y_{05} & y_{06} \\ y_{10} & y_{11} & y_{12} & y_{13} & y_{14} & y_{15} & y_{16} \\ y_{20} & y_{21} & y_{22} & y_{23} & y_{24} & y_{25} & y_{26} \\ y_{30} & y_{31} & y_{32} & y_{33} & y_{34} & y_{35} & y_{36} \\ y_{40} & y_{41} & y_{42} & y_{43} & y_{44} & y_{45} & y_{46} \\ y_{50} & y_{51} & y_{52} & y_{53} & y_{54} & y_{55} & y_{56} \\ y_{60} & y_{61} & y_{62} & y_{63} & y_{64} & y_{65} & y_{66} \end{bmatrix} \begin{bmatrix} v_0 \\ v_1 \\ v_2 \\ v_3 \\ v_4 \\ v_5 \\ v_6 \end{bmatrix}. \quad (3)$$

These values can be obtained using a numerical electromagnetic code (NEC) simulator [113]. The voltages on the active central monopole and the m th parasitic monopole are represented by v_0 and v_m , respectively. Let z_0 be the characteristic impedance at the RF port and v_s represent the transmitted voltage signal source with the amplitude and the phase from the driving RF port at the central element. Following the analysis in [90], we obtain

$$\mathbf{i} = v_s (\mathbf{Y}_C^{-1} + \mathbf{X}_L)^{-1} \mathbf{u}_1 \quad (4)$$

where $\mathbf{X}_L = \text{diag}[z_0, jx_1, \dots, jx_6]$ and $\mathbf{u}_1 = [1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0]^T$. The far-field radiation pattern is the superposition of all monopoles' radiation patterns [108]. Therefore, the far-field current signal in the azimuthal direction ϕ with its amplitude and the phase is represented as

$$y_{\text{far}}(\phi) = \mathbf{i}^T \mathbf{p} \mathbf{h} \alpha(\phi) = [(\mathbf{Y}_C^{-1} + \mathbf{X}_L)^{-1} \mathbf{u}_1]^T \mathbf{p} \mathbf{h} \alpha(\phi) v_s \quad (5)$$

where $\alpha(\phi)$ is the 7×1 dimensional steering vector corresponding to azimuth angle ϕ . It is expressed as

follows:

$$\alpha(\phi) = \begin{bmatrix} 1 & e^{j(\pi/2) \cos(\phi)} & e^{j(\pi/2) \cos(\phi - (\pi/3))} & e^{j(\pi/2) \cos(\phi - (2\pi/3))} \\ e^{j(\pi/2) \cos(\phi - \pi)} & e^{j(\pi/2) \cos(\phi - (4\pi/3))} & e^{j(\pi/2) \cos(\phi - (5\pi/3))} \end{bmatrix}^T \quad (6)$$

In (5), we denote $(\mathbf{Y}_C^{-1} + \mathbf{X}_L)^{-1} \mathbf{u}_1$ as \mathbf{w}_E and term it the “equivalent-weight vector” because of its resemblance to a (7×1) -dimensional beamforming weight vector in the array processing literature [90]. According to the reciprocity theory for radiation patterns [108], if the antenna is working in the receiving mode, the voltage signal, say, $y(t)$ at the RF port is expressed as

$$y(t) = \mathbf{w}_E^T \alpha(\phi) s(t) \quad (7)$$

where $s(t)$ represents the far-field impinging current waves with the amplitude and the phase in the azimuthal direction ϕ . It is clear that \mathbf{w}_E is dependent on the reactance values of the reactances at those parasitic elements; therefore a beamsteering pattern is achieved by properly adjusting reactance values. For the designed ESPAR antenna, the adjustable load reactances at the parasitic elements are realized with reversely biased diodes as shown in Fig. 20. The implementation achieves a frequency-dependent reactance value ranging from $-45.8j\Omega$ to $-3.6j\Omega$.

Since the load reactances and switches are realized by the diodes, there is only a small leakage current. Therefore, the power consumption of the parasitic array antennas is very small. Furthermore, the system normally has only one RF port and one subsequent downconversion circuit. In terms of power consumption and fabrication cost, it is obvious that parasitic array antennas are suitable for mass implementations of adaptive array antennas, especially for battery-powered portable mobile terminals.

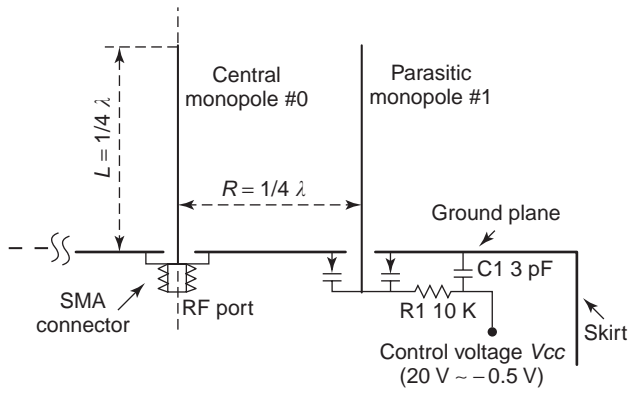

Figure 20. Vertical cross-sectional view of ESPAR antenna and a reactance circuit of one of the six parasitic elements. The length of each monopole is one-quarter wavelength ($\lambda/4$) of the transmitting RF signal at the frequency of 2.484 GHz [90].

5.5. Diversity Antennas

Diversity antennas combat against multipath fading and improve channel quality for a given radio spectrum in comparison with that from a single-port antenna [13,20,35,105,114]. Because the correlation among signals from the multiple ports of array antennas undermines diversity combining performance [16,20], the challenge of diversity antenna design is how to achieve signal decorrelation. This is particularly difficult in handphones where antenna elements are mounted within small spacing, for a given incident wave distribution scenario.

Colburn et al. [115] have presented three candidate dual-diversity antenna configurations: two side-mounted

planar-inverted F antennas (PIFAs), a back-mounted PIFA with a top-mounted helix, and a top-mounted PIFA with a flip monopole. Experimental results show sufficient signal decorrelation of these configurations. The diversity gain obtained with polarization diversity has been demonstrated with dual-polarized diversity obtained by an aperture-coupled patch antenna or by two slanted dipoles over an infinite ground plane [24]. Vaughan [102] presented diversity antennas using various parasitic array antenna structures. In one of the designs, three directional patterns are formed with three subsets of a parasitic array as shown in Fig. 17. By selecting one of the patterns pointing in different directions, angular diversity advantage is achieved. In another design, 16 parasitic monopoles are placed uniformly in the circle of radius 0.25 wavelength, and an active monopole is located at the center of the circle. The directional beam pattern with 90° half-power beamwidth (HPBW) is rotated, 360/16° each step, by shifting switch setting of parasitic elements. For adjacent beam patterns with 22.5° angular spacing, the envelope correlation of complex beam patterns is 0.91. For patterns with larger angular separation, say, 45°, the envelope correlation of 0.7 is achieved. The Virginia Tech Antenna Group has evaluated the envelope correlation, power imbalance, and diversity gain with space diversity, polarization diversity, and pattern diversity at handheld terminals [116]. The spatial diversity is achieved with two parallel half-wavelength dipoles with inter-element spacing variable from 0.1 to 0.5 wavelength. The dual-polarization diversity antenna is constructed with a dipole and a printed wheel antenna separated vertically by 0.3 wavelength. As for the pattern diversity, it is achieved with two dipoles, with 0.25 wavelength interelement

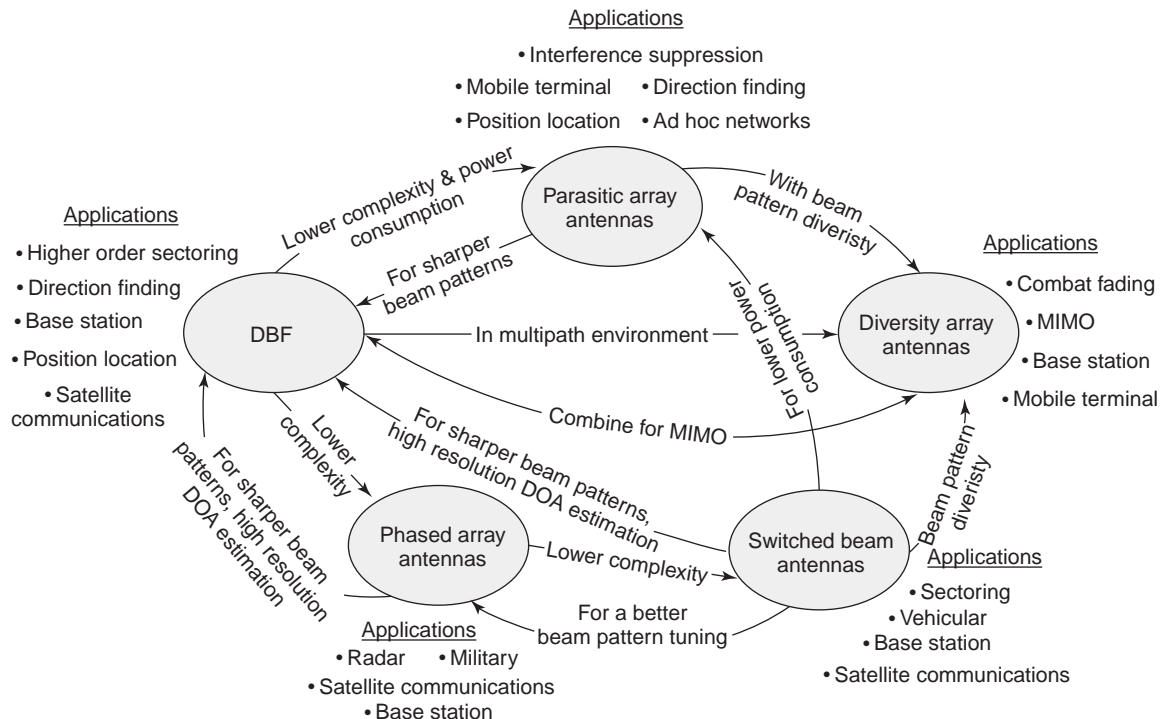

Figure 21. Relation of various adaptive array antenna structures and their applications.

Table 1. Comparison of Various Adaptive Array Antennas and Related References

Adaptive Array Architecture	Implementation stage	Decision–Control Stage	Applications	Refs.
Switched-beam antenna	RF/IF	Baseband/IF	Cellular base station, satellite communications	13, 14, 18, 63, 70–77
Phased-array antenna	RF	Baseband	Military, radar, satellite communications	18, 63, 70, 78–82
Digital beamforming (DBF)	Baseband DSP	Baseband	Cellular base station, satellite communications, radar, high-resolution direction finding	3, 4, 8, 14, 18, 37, 39, 63, 70, 82–89
Parasitic array	RF	Baseband	Power consumption limited mobile terminal, direction finding	82, 90–108, 110–112
Diversity array	Providing uncorrelated signals at RF stage	Baseband/IF	Mobile terminals, combating multipath fading, MIMO communications	20, 24, 105, 115, 116

spacing, connected to a quadrature (90°) hybrid (see Fig. 9). The structure provides two orthogonal beams at the two ports. Measured results in various multipath environments have clearly justified the feasibility of diversity at handheld terminals.

6. CONCLUSIONS

The wireless communications system is evolving with a fast pace. Better-quality wireless communications, new services and applications will become available with the technological advances. With different structures, adaptive array antennas play important roles in the evolution of wireless communications systems. Figure 21 and Table 1 generalize the tradeoff between the performance and complexities of various forms of adaptive array antennas, implementation stages and some of their applications. For applications where cost and power consumption are the main limiting factors, parasitic array antennas and switched-beam antennas are suitable. DBF array antennas and phased-array antennas dominate in the applications such as satellite communications and BS applications, where high performance is desired. In addition to combating fading, diversity antennas can also be employed to realize high-speed MIMO wireless transmissions.

ALTIMETERS

HALIT EREN
Curtin University of Technology
Bentley, Australia

1. INTRODUCTION

Altitude, for the purposes of this article, is the elevation of an object above a given level. (In astronomy, navigation, and surveying, altitude means the angular height of a celestial body above the plane of the horizon.) *Altimeters* are instruments that measure altitude. Altimeters represent an advanced technology, finding diverse commercial and military applications ranging from air transport to space exploration. Many companies (Table 1) offer a wide range of altimeters and altimeter-related products.

There are three main types of altimeter:

1. The pressure altimeter, which uses changes in the atmospheric pressure to infer altitudes.
2. The radio detection and ranging (or *radar*) altimeter, which measures the time required for a continuous wave (CW) or pulse of radio energy to travel from an object in the atmosphere to the ground and back.
3. The optical altimeter, based on laser optics, operating mainly on pulsed energy transmission, as in the case of laser radar (LIDAR).

Altimeters are usually associated with aircraft, but they are also used in applications such as geodesy and surveying, navigation weapon guidance systems, parachute jumping, and mountaineering. The accuracy and the sophistication of the sensors and the associated electronics and computing power of altimeters depend on the measurement requirements. For example, in remote sensing applications, the selection of the sensors depends on the platform of the operation, as illustrated in Fig. 1.

Altimeters can be divided into two categories:

1. Instruments that measure the altitude of an object above a fixed Earth reference level (e.g., sea level).
2. Instruments that measure the distance between an object and some earth reference.

Instruments in the first category are of the barometric types that use the static air pressure at some altitude to infer height above a reference level. The second category is much broader and is based on the use of electromagnetic waves to determine altitudes. Some devices in this category are radar altimeters, laser altimeters, and the Global Positioning System (GPS).

2. BAROMETRIC ALTIMETERS

Barometric altimeters are based on the measurement of pressure, which varies depending on the atmospheric layers. Atmosphere of the Earth may be divided into several layers: troposphere (0–16 km from sea level),

stratosphere (16–50 km), mesosphere (50–80 km), thermosphere (80–640 km), and exosphere (outer space). To determine the altitude of an object, the atmospheric pressure is compared with a reference pressure by a mechanism such as shown in Fig. 2. Over the years, many different mechanisms have been developed for barometric

altitude measurements. However, they all rely on the use of a relation between air pressure and altitude.

In most modern barometric altimeters, integrated circuit (IC) pressure transducers are used, as shown in Fig. 3. A wide variety of pressure transducers are available with different specifications that are suitable

Figure 1. Use of altimeters at various altitudes. Altimeters are designed to operate accurately at certain ranges. Developed in recent (as of 2003) years, the altimeters carried by the geostationary satellites offer very high accuracy.

for a large range of barometric altimeter applications. The performance of pressure transducers depends on the characteristics of the atmospheric pressure.

2.1. Principles of Operation and the Effect of Atmospheric Pressure

Certain assumptions are made to allow the altitude–pressure relationship to be simplified so that the altitude above sea level at any point in Earth’s atmosphere can be related to air pressure by a single-valued function. The assumptions are often referred to as a *standard atmosphere* and are primarily concerned with the atmospheric conditions at sea level, chemical composition of the atmosphere, and atmospheric temperature distribution. These assumptions are based on a mixture of observations, measurements, and theories that are internationally accepted.

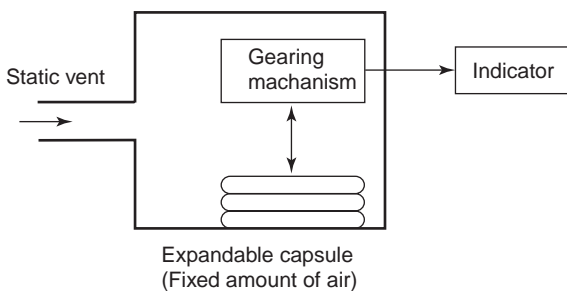

Figure 2. A typical barometric altimeter. In this type a constant volume of air is trapped in the bellows. Depending on the air pressure in the chamber, the bellows changes its volume. The change in volume is scaled by a gearing mechanism connected to an analog indicator.

Figure 3. A barometric altimeter based on piezoresistive integrated circuit. The characteristics of silicon allow construction of a thin diaphragm that can be deflected by an applied pressure, thus resulting in changes in resistance of the piezoresistive elements located on the diaphragm. The signal-processing and voltage regulation circuits are also integrated in the IC chip.

The concept of the standard atmosphere has a threefold purpose: (1) it sets a reference for testing, design, and performance comparisons between instruments and the body carrying the altimeter, such as an aircraft, a balloon, or a parachute jumper; (2) it allows the derivation of the pressure–altitude relationship to be simplified both mathematically and physically within the altimeter; and (3) finally, if all objects with altitude-measuring devices are set to the same reference, the vertical separation between these objects when they are in common airspace can be reliably inferred and safety can be increased. The International Standard Atmosphere (ISA) assumptions are summarized as follows:

1. The temperature at sea level T_0 and the pressure at sea level P_{s0} are assumed to be constant at $T_0 = 288.15$ K and $P_{s0} = 101,325$ Pa (1013.25 mbar, 29.92 in.Hg).
2. The temperature decreases linearly with increasing height until a height known as the *tropopause* is reached, above which the temperature remains constant until the *stratopause* height is reached. The region below the tropopause is known as the *troposphere*. The law relating temperature T to altitude H to the tropopause height is given by

$$T = T_0 - LH \tag{1}$$

where L is the temperature decrease rate and is defined to be -6.5×10^{-3} K/m. At and above the tropopause (11,000 m), T remains constant at $T = T_T = 216.65$ K (-56.5°C).

3. The stratopause is defined to occur at 20,000 m. The region between the tropopause and the stratopause is known as the *stratosphere*.
4. At heights above the stratopause the temperature starts to increase linearly with height; this region is known as the *chemosphere* (top of the stratosphere, all of the mesosphere, and lower part of the thermosphere). The temperature increase rate is defined to be 1.0×10^{-3} K/m. The chemosphere is defined to have a height limit of 32,004 m. The temperature in

Figure 4. Change in the atmospheric pressure due to air density. These changes in the air pressure can be related to altitude by using the gas laws.

the chemosphere is given by

$$T = T_T + L(H - H_S) \tag{2}$$

where H_S is the height of the stratopause.

Using these assumptions, the altitude–static pressure relationship can now be derived by considering Fig. 4. A small change in pressure dp of air with density ρ , due to a small change in height dH , can be found by equating the forces acting in the vertical plane on an elemental volume of air, so that

$$-dp = \rho g dH \tag{3}$$

where g is the gravitational acceleration. From the ideal gas law

$$p = \rho R_a T \tag{4}$$

where T is the air temperature (in Kelvins) and R_a is the gas constant for a unit mass of dry air.

Combining Eqs. (1) and (2) through the variable ρ results in the following equation:

$$\frac{-dp}{p} = \frac{g}{R_a T} dH \tag{5}$$

The value of g , the gravitational acceleration, is known to decrease with increasing distance from the center of Earth. The equation governing this is

$$g = \frac{R^2}{(R + H)^2} g_0 \tag{6}$$

where R is the radius of Earth and g_0 is the gravitational acceleration at Earth’s surface, where its value is approximately equal to 9.807 m/s^2 . This degradation of g ,

however, can be assumed to be insignificant in the evaluation of the pressure altitude. This additional assumption further simplifies the derivation.

The assumptions stated imply that the relation between the pressure altitude and the static pressure must be derived separately in three regions, namely the troposphere, the stratosphere, and the chemosphere. First, considering the troposphere, by substitution of Eq. (1) into Eq. (5), and integrating both sides to eliminate the dp and dH , we obtain

$$-\int_{P_{s0}}^{P_s} \frac{1}{p} dp = \frac{g_0}{R_a} \int_0^H \frac{1}{T_0 - LH} dH \tag{7a}$$

where P_{s0} is the pressure at height $H = 0$ and P_s is the pressure at height H . Using the integration rule $(1/u)du = \ln|u| + c$ and the equality $\ln A - \ln B = \ln(A/B)$, we have

$$\ln \frac{P_s}{P_{s0}} = \frac{g_0}{R_a L} \ln \frac{T_0 - LH}{T_0} \tag{7b}$$

Solving for P_s gives

$$P_s = P_{s0} \left(1 - \frac{L}{T_0} H\right)^{g_0/LR_a} \tag{8}$$

Similarly, for the two other regions of concern, their appropriate temperature equations, $T = T_T$ and Eq. (2) can be substituted into Eq. (5) and integrated.

Considering the constants implied in the ISA and additionally noting that $R_a = 287.053 \text{ J/(K} \cdot \text{kg)}$, the following equations are found to relate the static pressure to the pressure altitude H_p

1. Troposphere (– 914.4 to 11,000 m):

$$P_s = 1013.25(1 - 2.25577 \times 10^{-5} H_p)^{5.255879} \text{ mbar} \tag{9}$$

2. Stratosphere (11,000 m to 20,000 m):

$$P_s = 226.32e^{0.0001576885(H_p - 11,000)} \text{ mbar} \tag{10}$$

3. Chemosphere (20,000–32,004 m):

$$P_s = 54.7482[1 + 4.61574 \times 10^{-6}(H_p - 20,000)]^{-34.163215} \text{ mbar} \tag{11}$$

It can be seen that these relationships are nonlinear. The nonlinearity can be observed graphically by plotting altitude on the horizontal axis against pressure as shown in Fig. 5.

2.2. Construction, Errors, and Use of Barometric Altimeters

A barometric altimeter must be able to display altitude linearly; therefore, a linearization, such as the gain adjustment, is necessary. The linearization is usually done by a calibratable mechanism to allow for variations in aneroid chambers. This mechanism introduces a gain that counters the nonlinear effects of pressure versus height, by means of nonlinear compression/expansion of the aneroid chamber. Gearing is also introduced, so that one

Figure 5. Static pressure versus pressure altitude. The pressure changes in a nonlinear manner. Linearization techniques must be employed to measure and display altitudes by barometric methods.

revolution of the altimeter pointer is equivalent to a 330 m height displacement.

The linearizing part of the mechanism of an aneroid barometric altimeter is usually located at the center of the altimeter body. The temperature compensation is realized via a bimetallic strip, which alters its curvature as temperature increases. These features are necessary to compensate for the changes in the modulus of elasticity of the material that the aneroid chamber is made from. For example, if the sea-level temperature of an aneroid chamber were to decrease, its elasticity would increase. Since the chamber has a vacuum, it is in natural shape when fully expanded (i.e., at very low atmospheric pressure). If the chamber material becomes more elastic, it tries to resume its original shape. This results in the display of a height greater than the actual height. Since the atmospheric pressure decreases as the chamber is moved away from sea level, the extra height effect of the elasticity of the chamber increases as the altitude increases.

The static pressure port is placed on the backplate of the altimeter for use in a small aircraft. In modern aircraft this port is connected to a line that is in turn connected to either a pitot tube or a static vent. The pitot tube is often seen as a small probe-like object pointed forward and located at the front of the aircraft to measure the airspeed. In altitude measurements, it fulfills the function of supplying a static pressure that is independent of the velocity of the aircraft.

It is important to note that pitot tubes can introduce errors into altitude measurements. The tubes are mechanically designed to introduce minimum errors and also are positioned on the aircraft so that the attitude does not affect the airflow onto the tube. A badly designed or positioned pitot tube can cause shockwaves to occur at high air velocities and also cause extra air to be forced into the static measurement holes, thus increasing the pressure.

In an effort to attempt to alleviate some of the problems caused by pitot tubes, the use of static vents has become common in modern aviation. They are designed to be mounted flush on the fuselage of an aircraft. In particular, these vents find extensive use in military applications where the removal of the probe-like pitot tube has improved stealth capabilities.

One problem common to all types of static-pressure-driven instruments is ice formation and water buildup inside the tubes or vents. To prevent ice formation, these tubes and vents contain heating elements. Where there is ice, there can be water. Variations in pressure and temperature can cause water to condense in tubes and ports. In the interests of instrument functionality and minimization of errors, there must be provisions to check static lines for water and remove it.

A typical modern barometric altimeter is approximately 35×30 mm and has a liquid crystal display (LCD). It can also function as a barometer and can be set for the minimum and maximum altitudes, the absolute altitude, the speed of ascent and descent, the reduced and absolute air pressures, the weather forecast, and time and altitude alarms. Typically, the range of measurement of the barometric altimeter is -700 to $10,000$ m, and it updates information once every second. It has a pressure range from 600 to 1100 mbar with $\pm 0.5\%$ accuracy and 0.1 mbar resolution. The altitude resolution is about 0.1 m. Altimeters with high precision find applications in geosciences, surveying, aviation, meteorology, recreation, and the laboratory.

2.3. Further Comments on Application of Barometric Altimeters in Aircraft

Barometric altimeters find extensive use in most modern aircraft as backup instruments. These altimeters are composed mechanically of sector gears, pinion, backlash springs, crankshafts, aneroid capsules, and pointers on a dial. A series of pointers on a graduated dial may be used to indicate altitude in hundreds, thousands, or tens of thousands of feet or meters. The barometric dial records the air pressure in millibars. Because atmospheric pressure is measured relative to sea level, the pressure altimeter must be manually adjusted in order to compensate for variations in pressure caused by weather changes.

In aircraft, the barometric altimeters can be set to show either altitude above sea level or altitude above an airfield once the height of the airfield above the sea level is known. If the pilot wishes to adjust the altimeter to display the height above sea level, the corrected sea-level pressure needs to be entered. When the corrected sea-level pressure is compared with the pressure at the airfield, the height of the airfield from sea level can be found. The sea-level pressure at that particular time must be known, however, because it may differ from the ISA assumption, indicating that the height of the airfield is higher or lower than what it actually is. Airfields continuously broadcast updated information on the pressure so that the pilot may correct the altimeter. The correct setting is called QNH, the adjusted sea-level pressure.

On the other hand, a pilot may wish to set the altimeter so that it displays the altitude above a particular airfield. To do this the pressure height of the airfield needs to be entered into the altimeter. Such pressures are denoted QFE and are given relative to the sea-level pressure. For example, an airfield 304.8 m above sea level, on a day when the sea-level pressure is as per ISA (1013.25 mbar), has a QFE of 977.4 mbar. This value is calculated from

Eq. (9). In summary, the barometric pressure knob is used to correct any variation in the sea-level pressure from the ISA assumed value of 1013.25 mbar.

Recalling the ISA assumptions, the temperature variations and airspeed effects are ignored. However, these effects can be taken into account by the application of computers and suitable analog-to-digital converters (ADCs) to the real-time signals generated by the instruments. The computers use complex models to take into account many variables affecting the altitude measurements. This means that the computer-driven altitude display can be corrected in real time, so that the pilot has a very accurate altitude reading at all times.

Altimeters are prone to the following errors: (1) instrument errors due to manufacture, installation, maintenance, and so on; (2) instrument lag; and (3) position error due to placement of vents and blockage of the static vents by ice. In response, the availability of computers has prompted the development of advanced pressure-measuring devices, such as the vibrating pressure sensor and the solid-state capsule pressure sensor.

As illustrated in Fig. 6, vibrating sensors work on the principles of detecting change in the natural resonant frequency of a vibrating system within a cylinder as the air pressure changes. This means that the electrical output of this sensor, when amplified, will be a frequency that changes proportionally with the pressure it is exposed to. Modern ADCs can detect very small differences in output frequency due to density variations as well as the large frequency variations due to pressure changes. This type of setup, which is enclosed, is very rugged and is in wide use today in commercial aircraft.

The second type of sensor, the capsule type, typically uses a vacuum chamber. The difference between these and the older aneroid chambers is in the materials from which the diaphragm is constructed. Typical materials are silicon, quartz, or ceramic compounds. These newer diaphragm materials are chemically engineered to have perfect mechanical properties in that they are very linear, do not suffer from hysteresis, and have a very stable modulus of elasticity.

The capsule-type transducers rely on two main methods. The first method involves the impregnation of the

Figure 6. Vibrating sensor barometric altimeter. The natural frequency of the vibrating element depends on the air pressure inside a cylinder chamber. The signal of natural vibration is picked up and processed to obtain the pressure, and hence the altitude of the mechanism above sea level.

diaphragm with a Wheatstone bridge, thus allowing an excitation to be applied and a pressure-dependent voltage to appear at the output. This voltage varies with the change in resistance of the impregnated resistors as the diaphragm flexes due to pressure, similarly to a resistive strain gauge. The second method is to form an area of metallization on the bottom side of the diaphragm and the bottom of the vacuum chamber. This creates a capacitor, and these sensors are highly sensitive to small variations in its capacitance. However, temperature variations and accelerations can severely affect both these types of sensors. Thus the temperature is measured near the device and fed into the ADC for correction. For the acceleration effect, ensuring that the device is mounted so that its axis of movement is orthogonal to the acceleration is sufficient compensation. It should be noted that these devices are designed to be minimally sensitive to gravitational effects.

It can be concluded that barometric altimeters are likely to continue to be used extensively in the near future to measure altitudes of up to 15,000 m. Radar altimeters are expected to expand their role of providing accurate landing references, and low-altitude radar altimeters will continue to be used mainly for special-purpose military operations.

3. RADAR (RADIO) ALTIMETRY

Radar and laser altimeters, also termed *active ranging sensors*, are based on the transmission of electromagnetic or optical energy directed at an object and the detection of the reflected energy from the object. The reflected energy is suitably processed to reveal information about the altitude as well as other parameters such as the atmospheric conditions, including pollution. Radar altimeters can provide height information at high altitudes, where barometric systems are not effective. They can also provide high-quality images, as illustrated in Fig. 7.

Aviation radar altimeters, which have been in use for many years, measure height above the ground or sea. They transmit either continuous waves (CW) or pulsed waves and normally operate in the 4.2–4.4-GHz band to provide inputs to, for example, automatic landing systems or autostabilization systems for aircraft and helicopters. The basic operating principles of radio and radar altimeters are similar. The only difference is that the term *radio altimeter* often refers to continuously modulated waves, whereas the term *radar altimeter* refers to pulsed waves, mainly used in aircraft, spacecraft, and satellites.

3.1. Radar Altimeters Used in Satellites

The radar altimeter is a single-frequency radar system that broadcasts a pulsed tone directly downward, as illustrated in Fig. 8. It has highly sensitive devices for signal detection and processing. A satellite altimeter is a nadir-pointing active microwave sensor designed to measure characteristics of the surface of Earth. The time it takes for the reflected signal to be received directly is translated into the height above the terrain.

Figure 7. A typical example of remote sensing. Active remote sensors transmit electromagnetic energy and pick up the return signals. By appropriate data processing three-dimensional images can be constructed.

If a pulse is transmitted toward a target surface at an accurately measured time t_1 , it reflects back to the source after a time t_2 . The time difference $t_d = t_1 - t_2$ is equal to the round-trip distance to the reflecting surface divided by the propagation speed c :

$$t_d = \frac{2h}{c} \text{ or } h = \frac{ct_d}{2} \tag{12}$$

The accuracy of the measured distance h can be expressed by

$$\Delta h = \Delta c \frac{t_d}{2} + c \frac{\Delta t_d}{2} \tag{13}$$

Here, the time difference accuracy Δt_d depends mainly on the sharpness of the pulse, which is equal to

$$\Delta t = \frac{1}{B} \tag{14}$$

where B is the signal bandwidth.

If the speed of the pulse is taken to be constant, the range resolution can be found from

$$\Delta h = \frac{c}{2B} \tag{15}$$

Higher accuracy is achieved by detailed analysis of the received signal; this is achieved by averaging a large number

Figure 8. Geometry of a pulse-limited radar altimeter. The pulse intersects the nearest point on the ground, and the illuminated disk spreads rapidly. This gives a maximum size for the footprint. The geometry of the beam-limited altimeter is similar.

of echoes. Range errors can arise from pulse dispersion due to backscattering from the rough surface and to the propagation characteristics of the atmosphere. Consequently, the returned pulse is distorted and fading occurs, as illustrated in Fig. 9. The distortion in the waveform of the echo signal makes the altimeter signal less than perfect.

There are different types of radar altimeters, such as beam-limited altimeters, pulse-limited altimeters, synthetic aperture radar altimeters, imaging altimeters, and scanning altimeters. The operation principles of the altimeters are similar, but they vary in size of footprint, direction of the beam, and purpose of usage. The details in the differences of these altimeters are not given in this article, but interested readers can find further information in the references (e.g., Elachi [1]).

Figure 9. Waveforms of returned pulses: (a) ideal power distribution and typical power distribution of the returned signal—the distortion is due to imperfect mirroring of the signal back to the sensor; (b) pulse shape of wide-beam, narrow-pulse altimeter.

In most modern radar altimeters, high measurement accuracy is required. This necessitates good information on the effect of the ionosphere and atmosphere as well as sound understanding of the errors introduced by the sensor dynamics and signal-processing electronics. The signal-processing electronics comprises many components such as oscillators, modulators, mixers, power amplifiers, filters, demodulators, digitizers, compressors, and computers. All these devices have to be of good quality and highly accurate. Judicious selection of all the discrete components and circuits is necessary for good conformity and matching.

The first satellite altimeter was tested in 1973, as parts of several Skylab missions conducted by the United States. At that time, a typical resolution was 1–2 m; modern altimeters are capable of resolutions down to 2 cm (TOPEX/Poseidon). As an example, the discussion here focuses on one of the latest satellite altimeters, for the NASA TOPEX/Poseidon satellite used in oceanic applications.

The TOPEX/Poseidon mission, a joint mission between NASA and the Centre Nationale d'Etudes Spatiales (CNES), the French space agency, was designed to make high-precision measurements of the ocean surface possible. The application areas of this system are mainly for weather reports and predictions, in geodesy and geophysics. The TOPEX altimeter was the first dual-frequency satellite altimeter operating in space to perform these important measurements. The TOPEX used several methods for determining distance, such as the round-trip time discussed previously, and the shape of the reflected pulse. In particular, the shape of the reflected pulse provided a wealth of information on wave height in the ocean and the sea-surface windspeeds.

The TOPEX altimeter uses a 13.6-GHz signal as its primary pulse, and a secondary frequency of 5.3 GHz. The use of two frequencies is helpful in removing the adverse effects of variations in the propagation speed of the pulse due to variations in the atmospheric conditions of Earth.

NASA has built a self-calibration mechanism into the TOPEX altimeter. While over land, twice a day, the altimeter spends 5 min calibrating itself. The TOPEX is known to be extremely reliable and robust because of this self-calibration capability and its ability to compensate for ionospheric effects.

To obtain a high degree of precision, the satellite that carries TOPEX needs to know its exact position relative to points on Earth. The GPS helps the satellite determine its position with a precision of about 2 cm. A laser Doppler system and a ground station are also used to verify this reading. Another satellite system with importance for altitude measurements has been the Geosat follow-on meteorological-oceanographic (GFO METOC) satellite. It is owned by the U.S. Navy and is used for determining thermal fronts, eddies, ice edge locations, surface windspeeds, and wave heights.

The GFO and the GPS systems mentioned above are also used for position and altitude determinations, but their design is more elaborate than is needed for the accuracy of TOPEX. In these systems, an onboard water vapor detector is used to help correct ionospheric interference. Essentially,

the GFO was a test to determine whether a low-cost, light-weight, and compact satellite could be used to provide the U.S. Navy and its associated agencies with real-time ocean data. But the expectations for the GFO to replace TOPEX in a cost-effective manner have failed so far.

Spaceborne altimeters are primarily pulse-limited, and therefore they cannot deliver the required accuracy of surface height measurements over icy land. This is because the spreading and slope of the reflected pulse cause severe errors. In addition, during land height measurements, sudden changes in the slopes of the topography often result in a loss of tracking. Although techniques have been developed to improve the spatial resolution of radar altimeters for accurate elevation estimates over the terrain, most of them result in a significant increase in cost and complexity compared with a conventional altimeter.

In a typical noise-modulated radar altimeter, the principle of operation is based on the dependence of the cross-correlation function of the random modulation (Gaussian noise) on the finite correlator bandwidth, smoothing methods, extraneous noise disturbance, component characteristics, and changes in altitude during measurements.

3.2. Radio Altimeters

Like radar altimetry, radio altimetry is based on the use of electromagnetic (EM) waves to determine the distance between a reference point and an object that reflects the waves. Radio altimeters are used mostly in aircraft. Unlike radar altimetry, radio altimetry is based on continuous EM waves. Generally, it uses a frequency-modulated (FM) carrier, whose frequency is varied at a constant rate. The carrier reaches the surface below and reflects back to the transmitter with a delay. The reflection appears as a time-shifted version of the transmitted signal; thus the phase shift can be utilized. This time difference equates to a frequency difference, which can easily be detected using a superheterodyne receiver. Figure 10 illustrates the time difference in the transmitted and received signals. A typical radio altimeter operates at about 4.3 GHz. A low-frequency (100-Hz) triangular waveform modulates the carrier over a range of about ± 50 MHz.

Figure 10. The transmitted and received waveforms of a radio altimeter. The time difference between the transmitted waveform and the reflected wave from the target is an indication of the distance between the two objects.

All radio and radar altimeters have three basic components: one or two antennas, a transmitter receiver, and an indicator. The type of antenna varies, depending on where it is fixed on the aircraft (on a flat or skewed area under the fuselage). Antennas are designed specifically for each system, so changing the unit also involves changing the antenna. The transmitter–receiver is the core of the device. The indicator consists of an electronic digital display or a common analog display.

As mentioned before, frequency differences can be measured using a superheterodyne receiver. In the signal-processing section, the received signal is multiplied with the transmitted signal on an instantaneous basis. In this way, according to the superheterodyne principle, a sum and a difference frequency are created. A lowpass filter is used to remove the component containing the sum of the frequencies, leaving only the difference, as required for further processing. The difference frequency can then be applied to a signal processor for digital display, or perhaps to a frequency-to-voltage converter allowing the altitude to be displayed in analog form. This technique allows the display of instantaneous altitudes as well as changes in altitude.

It is important to note that in the determination of altitudes by radar altimeters the speed of an EM wave in air is assumed to be constant: 3×10^8 m/s. Although this assumption may be valid in some situations, the presence of water vapor in the atmosphere can affect the speed and introduce serious errors in the measurements. Apart from this common shortcoming of radio altimeters, specific altimeters have their own. For example, a conventional FM counter radio altimeter has the following shortcomings: (1) the step error can be severe, (2) an upper measurable limit is introduced by the spurious beat, and (3) there is a tendency to overcount because of unwanted far-distance propagation. The step errors can be reduced by the *modulation synchronous phase-switching method*, using switching-type phase shifters placed at the transmitting (or receiving) antenna feeders. This results in an increase in the phase at every period of the frequency modulation. The upper limits and overcounting errors can be eliminated by the *frequency offset method*. In this method, the time-varying phase shifts are made at higher rates than the modulation repetitions.

Used in an aircraft, the radio altimeter measures its distance above the ground rather than above sea level. A cathode-ray tube indicates the time that a pulse of radio energy takes to travel from the aircraft to the ground and back to the aircraft. The altitude is equal to one-half the time multiplied by the speed of the pulse. Radio altimeters are used especially in automatic navigation and instrument landing systems (ILSs). They are also used in remote sensing applications for military intelligence gathering, mapping, and surveying.

4. LASER ALTIMETERS

Laser altimeters are essentially a form of laser range finding devices, and are used widely for accurate distance measurements. The operation principles are similar to

those of radar altimeters in depending on the time difference between the transmitted and received signals. Thus, the distance is measured by timing a light pulse traveling from a laser light emitter and back to a detector located in the vicinity of the transmitter.

Laser rangefinders are commonly used in land surveying. Airborne laser measurements can be used to directly measure topography, stream channel cross sections, gully cross sections, soil surface roughness, vegetation canopy heights, and vegetation cover and distributions. These laser measurements can be used for the estimation of forest biomass and volume, aerodynamic roughness, and leaf area indices. Airborne laser altimeters provide quick and accurate measurements for evaluating changes in land surface features and can be an additional and useful tool for remote sensing of watershed properties and water resource management.

In laser altimeter applications, three measurement techniques are used: (1) the interferometric method, which is extensively used in short-distance measurements, up to 100 m in free air; (2) amplitude-modulated laser beam telemetry, suitable for distances of 100 m–50 km; and (3) the pulsed laser radar method, for altitudes over 10 km. All these methods are based on the measurement of the propagation time of the laser pulse over the distance under investigation. Therefore, the evaluation of the true geometric distance depends on corrections for factors such as the air refractivity, the beam angles, and the signal processing techniques. On the basis of these principles, various types of laser altimeters are available commercially, depending on the application requirements and the range of the altitudes. In extra-long-range applications, optical radar altimeters, which are based on sending infrared pulses of about 5 ns duration, are found to be accurate.

4.1. Amplitude-Modulated Laser Beam Altimeters

Although interferometric methods for distance measurements are extensively used for short-distance applications, they are clearly not suitable for long-range distance measurements. For those a common method involves amplitude modulation of the laser beam. In this method the modulated beam is projected toward the target and the light returned from the target is collected by a telescope to be sent to a detector, as illustrated in Fig. 11. The phase of the amplitude modulation of the returning light is compared with that of the emitted light. The differences in the phases occur because of the time required for the light to travel to the target and back to the telescope. To describe the operations, an equation can be written in terms of intensities of transmitted beam $I(t)$ and the received beam $I(t - \tau)$

$$I(t) = \alpha I(t - \tau) \quad (16)$$

where τ is the transit time, or propagation time delay, of the lightbeam, and α is the attenuation coefficient, which takes into account propagation efficiency and losses during transmission. The transit time for the sinusoidal modulation, the geometric distances, and the refractive index

Figure 11. A laser-beam-modulated altimeter. The phase difference between the transmitted and returned signals is measured. The phase comparison technique allows the evaluation of altitudes at high precision from distances of several hundred kilometers.

of the spectral distribution of the lightbeam can be used to find the relationship between the phase shift Φ and the total pathlength L

$$\Phi = \frac{2\pi n_g L}{\lambda_v} \quad (17)$$

where n_g is the group index of refraction of air and the λ_v is the wavelength in vacuum.

4.2. Pulsed Laser Radar

Another approach to laser-based altitude measurement is to make use of the round-trip transit time for a very short pulse, as illustrated in Fig. 9b. Often the acronym LIDAR (light detection and ranging) is used, as an optical counterpart of “radar.” Using lasers to measure altitude results in good accuracy and spatial resolution, but in doing so the advantage of all-weather capability of a microwave altimeter is lost. Such measurements can only be carried out in favorable atmospheric conditions.

Pulsed laser radars commonly use Q -switched laser switches with high peak power. The accuracy of the time measurement depends on the characteristics of the propagation medium and on the resolving capabilities of the photodetector and the timing system. In topographical applications, the statistical characteristics of the received signals for the short-pulse laser altimeters can be directly related to the statistics of the surface profile. In the signal analysis the effects of laser speckle, shot noise, and the surface profile of the ground target need to be considered carefully.

In pulsed radar applications, the altitude to be measured can be found from the expression

$$E_R = \frac{E_0 A_R \eta A_T t^2}{\Omega_0 L^2 \Omega_T} \quad (18)$$

where E_0 is the transmitted pulse energy, A_T and A_R are the areas of the target and the received system, Ω_0 and Ω_T are the solid angles over which the emitted and reflected energy are spread, t is the atmospheric transmission time, η is the diffusion or reflection coefficient, and E_R is the received energy. This equation indicates that the energy follows an inverse-square law. If the intensity of the returned signal is high, Eq. (18) can be used for altitude measurements. If it is low, various probability methods (e.g., the Poisson distribution) are used to estimate the number of photoelectrons.

Solid-state lasers can deliver pulses with time duration of typically 20 ns and peak power up to 1000 MW. Semi-

conductor laser diodes provide high-efficiency pumping of solid-state lasers with the promise of long-lived, reliable operation. In the next generation of laser altimeters, 100-W quasi-CW laser diode bars are likely to find applications. Even with the use of power laser equipment to generate the transmitted signals, the pulse intensity of the returned signals is very weak. To overcome this problem, highly sensitive photodiodes and photomultipliers are used for detection.

In this article, two different systems are discussed in order to explain the scope and the potential of practical laser altimeters: the shuttle laser altimeter (SLA) and the raster scanning airborne laser (RASCAL). The first type, the SLA, is in its second generation of development. Constructed by NASA, this altimeter is used to determine the shape of land surfaces and vegetation canopies. At present, the accuracy of the SLA-2 is within ≈ 1.5 m (vertically) for each 100-m-diameter footprint. The signal-processing component of the system is able to recognize the differences between the reflection from the soil surface and the reflections from other objects; hence the information can be separated and relief plots can be computed.

The mission objective was to compile a database of laser echo returns for every possible surface condition on Earth. The SLA-2 is constructed as an engineering experiment, and NASA is planning the introduction of a third-generation altimeter, the SLA-3. This instrument is planned to have an ultrahigh repetition rate, a smaller footprint than SLA-2, and the ability to penetrate vegetation canopies so that it can provide a contour of the surface under the canopy.

Operation of the SLA-2 is very complex, but it can be broken down into the following three major components: the laser transmitter (a Q -switched, diode-pumped Nd:YAG device, by McDonnell-Douglas), the 38-cm-diameter telescope antenna, and the altimeter receiver connected to a waveform digitizer. A variable-gain amplifier is used to accommodate a greater range of return amplitudes of the returned signals, thus increasing the accuracy and the altitude range. The actual laser return-pulse detection is performed via a silicon avalanche photodiode detector, which in turn is connected directly to the waveform digitizer.

The second altimeter is the RASCAL, also from NASA. The operational principle of the RASCAL is similar to that of the SLA, but the device is configured specifically to operate in aircraft. The RASCAL sensor was developed in 1995 at the Goddard Space Flight Center for airborne mapping of surface topography. The RASCAL is a

second-generation laser altimeter with application to both Earth (airborne) and other planetary surface (space-based) topography determinations. It differs from earlier nadir-profiling laser altimeters by an increase in pulse repetition rate by two orders of magnitude and provision for a near-contiguous scan pattern. It was first operated in a NASA airborne remote sensing program station in California in September 1995, where its high spatial resolution (better than 2 m) in three-dimensional images of topography was demonstrated.

The complicated part of RASCAL is the need for accurate positioning of the laser relative to the aircraft and Earth. Through the use of the aircraft's GPS and inertial navigation system, the NASA team has, in its words, "brute-forced" the solution to this problem and gained a reliable model for exact positioning information. The accuracy of this system has been described as "not as good as [it] should be," and there are plans to build a laser capable of 1 ns pulse width at 10 kHz to help correct this. The return-pulse energy-sampling system is not at its optimum yet, either. By the use of the RASCAL, so far, postprocessed data have been used to re-create many footprints with diameters of 1 m, spaced approximately every 1.5 m in both directions in a pattern 100 m wide. An average accuracy of better than 20 cm with a precision of ± 5 cm is achievable.

A plot obtained from the RASCAL system data is shown Fig. 7. It showed up in postprocessing, when the analyzing team apparently did not realize that they had flown over a satellite tracking station. Although the desired accuracy is lacking, this typical plot shows the potential of the system.

Besides terrestrial applications, laser altimeters, LIDARs, and other ranging systems have been important parts of space missions to the Earth's moon, asteroids, and Mars; and more are planned and contemplated in the future exploration of the solar system. In 1997 the *Mars Global Surveyor* (MGS) entered into orbit around Mars. One of the four scientific instruments on the MGS is the Mars orbiter laser altimeter (MOLA), which has started to map the topography of the planet with unprecedented accuracy. In 1999 the *Near Earth Asteroid Rendezvous* (NEAR) spacecraft, which carries the NEAR laser rangefinder (NLR), arrived at the asteroid Eros. The NLR was to study the shape and the dynamics of the body of Eros for a period of a year. The MOLA and the NLR, along with the Clementine laser altimeter that went to the moon in 1992, represent a new class of active remote sensing instruments for investigations of science in the solar system.

5. GLOBAL POSITIONING SYSTEM (GPS)

The GPS was begun 1978 and completed in 1994 with 21 active and 3 spare satellites. The GPS allows users to determine their exact position, velocity, and time at any time of day, in any weather conditions, free of charge. In discussions of the GPS, it is convenient to break the system into three blocks or segments: the space segment, the user segment, and the control segment.

5.1. The Space Segment

The GPS satellites orbit Earth at an approximate altitude of 20,000 km, and have an orbit period of 12 sidereal hours. The orbits have been arranged so that a user can have a direct line of sight to at least four satellites at all times at any place on Earth.

Each satellite transmits a unique code, which is based on a pseudorandom sequence allocated before launching. Having received this code, the users can employ autocorrelation techniques to recover these sequences. Given an accurate time reference and the propagation time from the satellite to the receiver, the distance can be determined. If the distances from each satellite in sight and the locations of satellites are known, the relative position and thus the coordinates of the receiver can be calculated easily. For precise calculations, the clock references of the GPS satellites must be known exactly. The clocks on the satellites are known to be stable within 0.003 s per 1000 years.

The satellites transmit signals at 1575.42 and 1227.60 MHz; these two transmissions are known as the L1 and L2 signals. The L1 signal is described as being made up of a *precision* code (P) and a *coarse acquisition* code (C/A). The L2 contains only the P code, which when encrypted is called the "Y code."

5.2. The User Segment

Users of the GPS often have handheld GPS receivers. A receiver determines a pseudorange to work out the time that the signal takes to reach to the receiver. Performing this operation for more satellites in sight, the receiver can work out where the user is either on the face of or above Earth.

The P and C/A codes are sometimes referred as the *precise positioning service* (PPS) and the *standard positioning service* (SPS), respectively. As these names would suggest, the PPS is more accurate than the SPS; this is due to a smaller bit period in the P code. The PPS has been withheld from public use, but is earmarked to be released for civilian use in the near future. A third frequency, which will give better accuracy, is planned to be released for the public. However, the Russian Global Navigation Satellite System (GLONASS) uses a single frequency, thus giving better accuracy for civilian use.

5.3. The Control Segment

The control segment consists of operators of the GPS network at a number of stations on Earth. The requirement of this segment is to maintain the GPS time, monitor and control the satellite orbit positions, and predict variations for compensation of any detected inaccuracies. The network has a master control station situated in Colorado Springs in the United States, and five additional monitoring stations. The positions of these stations are known precisely, and they are used to check and calibrate the GPS. The stations are distributed roughly along the equator and are geographically suitable for general system maintenance. At the moment, the number of stations is said not to be sufficient; however, more stations are being

planned to allow the determination of precise orbital paths of the satellites.

5.4. Theory of Operation

The theory of operation of the GPS is too complicated for detailed treatment in this article. Here, a brief explanation will be given to provide a basic understanding of GPS-based altimeters, particularly concerning accuracy and errors.

The GPS makes use of the time of arrival; that is, the satellites send out signals that contain some information such as the exact time of signal transmission and satellite locations. Once received, the information in the signal can be processed to calculate the time taken for the signal to arrive from the satellite at the receiver. By repeating this operation with the information from at least four satellites, the latitude, longitude, and height of the user can be determined in reference to the satellites and thus, in turn, in reference to fixed points on Earth.

Each satellite transmits a binary phase shift-keyed sequence that is spread spectrally, by its pseudorandom code; this allows all of the satellites to transmit on the same L1 and L2 carriers. They all use the same bandwidths at 2.0463 MHz for the C/A codes and 20.98 MHz for the P codes. This is called *code-division multiple access* (CDMA), and it relies on the properties of pseudorandom codes to work.

Pseudorandom codes have the property of strong autocorrelation. This means that when a pseudorandom code is overlaid on itself and correlated, the result will be slightly negative for all positions except an identical overlaying, in which the result becomes positive. A delay time is added to the internally generated pseudorandom code, to provide a positive, strong correlation with the received signal.

If the internal clock of the GPS receiver were exactly synchronized with the satellite's clock, the measured time delay would be representative of the actual physical distance between the satellite and the receiver. It is very unlikely, however, that the satellite and receiver clocks will be synchronized exactly. As a result, some differences in time, called *clock bias*, arise. The GPS receivers must determine the magnitude of the clock bias by taking delay times of the other satellites into consideration. This means that the measured delay times are the combination (physical distance)/(speed of light) + (clock bias) as explained above.

It is convenient to define a *pseudorange*, which is the delay time multiplied by the speed of light. This is a pseudodistance from the receiver to the satellite, with clock bias factored in. The actual process that the receiver executes can be summarized as follows:

1. The receiver tracks four or more satellites and determines the delay time from each satellite.
2. The receiver calculates all the pseudoranges (i.e., multiplies the times by c).
3. The receiver then corrects the pseudorange results for errors such as the satellite clock difference, the clock bias, the ionospheric effects, and time.

The information sent by satellites, for the computation, is in the form of 50-bps (bits per second) frames superimposed on the C/A and P codes, called the *NAV messages*. It takes about 12.5 min to download 25 of the 1500-bit frames to the receiver. The precise position of the satellite, the clock time, and other relevant information is included in the NAV message. Because of the time required to download the message, the NAV message is defined to be valid for 4 h.

4. When all of the pseudoranges have been corrected, the receiver performs a simultaneous solution of four equations with four unknowns. The four unknown quantities are the Cartesian coordinates x, y, z and the time.

Now that the receiver has solved the equations, the latitude, longitude, and altitude of the user can be calculated and displayed. The accuracy of these results depends on statistical analysis, and thus on the percentage of time of availability of satellites.

The GPS has a number of errors that need to be considered in altitude determinations. Some of these are the receiver clock error, the multipath error, and the ionospheric and tropospheric propagation errors.

As mentioned, the U.S. Department of Defense (DoD) is planning to allow civilian users to use the PPS system instead of the SPS. This will give substantial improvement in accuracy of the position and altitude determinations, as shown in Table 2. In this table, the formal specified accuracies are shown in bold. The percentages 50%, 63%, and 95% are the probable fractions of time for the receiver to be located within the given distances of an exact position calculated statistically. For example, the measured vertical height of the receiver in the SPS system is within 140 m of the central value 95% of the time. This can be compared with 28 m for the PPS system. The distance error of 140 m is clearly too large to be useful in aircraft applications, at low altitudes, but may be acceptable at high altitudes.

A method of improving this accuracy is called *differential GPS* (DGPS), and it can help provide an SPS user with subcentimeter accuracy in many cases. The DGPS uses a ground station that is geodetically fixed (with exact latitude and longitude), and it continuously tracks all visible satellites. Given the precise location and altitude of the DGPS station, and that the satellites transmit their

Table 2. Accuracy in GPS Systems

	Accuracy					
	50% of Time		63% of Time		95% of Time	
	PPS	SPS	PPS	SPS	PPS	SPS
Position (m)						
Horizontal	8	40	10.5	50	21	100
Vertical	9	47	14	70	28	140
Spherical	16	76	18	86	36	172
Velocity (x, y, z) (m/s)	0.07	—	0.1	—	0.2	—
Time (ns)	68	115	100	170	100	340

positions in the NAV message, the DGPS can apply corrections based on the measured delay times. By transmitting corrected information about the visible satellite positions to a GPS receiver via a radio channel, the computation at the receiver can be improved.

The GPS is a powerful tool for accurate determination of altitudes if one has access to a PPS system, and an altitude accuracy better than 100 m can be achieved even with the SPS system. Handheld GPS receivers are now commonly available for a few hundred dollars in consumer retail outlets.

6. REMOTE SENSING

Remote sensing is the science of detecting, measuring, and analyzing an object on the ground from a distance. It comprises mainly measurements of electromagnetic radiation from the ground, in the form of energy reflected by active sensors or emitted by passive sensors in various spectral ranges picked up by aircraft or satellites. Also, remote sensing may encompass aerial photography and similar methods whose results are generally displayed in the form of photographlike images. In aircraft applications, images from different flight paths can be combined to allow an interpreter to perceive features in three dimensions, and identify specific types of rock, soil, vegetation, and other entities, where they have distinctive reflectance values in different spectral regions of the electromagnetic radiation.

Remote sensing systems are made from distinct components as shown in Fig. 12: (1) an active or a passive remote sensor that employs detecting mechanisms to sense or scan the object, (2) a device for recording and imaging of the information received, and (3) the analysis and display system that makes the information useful. In some cases, analysis and display systems are combined and operate concurrently with the sensing system to process and display the data instantaneously. In other cases, the data are recorded and analyzed later. The displays are usually in the form of aerial photographs or television pictures.

An important feature of remote sensing is the identification of signatures, which is used to sense the desired objects against a complex background or surroundings. For example, it may be necessary to identify a particular mineral, crop blight, or type of air or water pollution. Signature, as applied to imagery, usually refers to visual characteristics that identify the subject and separate it from other similar objects.

Image formation is another important aspect of remote sensing. In this regard, there are two categories of

systems: (1) imaging sensor systems, which can be subdivided into framing systems (e.g., aerial photographic cameras, vidicons) and scanning systems, (e.g., radar), and (2) nonimaging sensor systems, also known as spectral data systems (e.g., spectroradiometers, radar scatterometers).

Remote sensors may be surface-based and stationary or mobile, or airborne in aircraft, helicopters, or balloons; or carried aboard spacecraft, such as satellites, a space shuttle, or a space station. These bases are known as the *sensor platforms*. The resolution, or detail, with which a remote sensor can monitor a subject generally depends on the distance from the sensor platform to the object. Generally, remote sensors that employ the shortest wavelengths provide the best resolution. For example, microwave sensors, which operate at wavelengths longer than those of thermal infrared sensors, can be expected to have poorer resolution. However, the longer wavelengths have the best penetrating power. Microwaves, for example, can penetrate through clouds, whereas visible light and infrared light do not. Therefore, microwave radar systems are often used to sense subjects that are not visible to optical wavelength laser radar systems. Also, microwave systems can be used to penetrate vegetation for geologic mapping, to monitor snow depths, to indicate soil moisture, and so on.

Remote sensing finds many applications, such as in military equipment; air transport; deep-space research; geography; environmental monitoring such as oceanography, hydrology, meteorology, and pollution control; monitoring snow depth and ice cover, flood control, hydroelectric generation, and water transport management; agriculture and forestry; and lightning and fire sensing. The geographic and geologic applications include land-use and terrain mapping, geological mapping, and detection of mineral deposits. Oceanographic applications encompass monitoring of waves, currents, temperatures, salinity, turbidity, and other parameters and phenomena related to oceans and seas.

The technology of remote sensors varies from system to system. For example, in a typical infrared remote sensing system, the thermal infrared energy is detected by an optical-mechanical scanner. The detector is cooled by a liquid nitrogen or liquid helium jacket that encloses it, and a rotating mirror directs radiation coming from various directions onto the sensor. Infrared radiation permits mapping surface temperatures to a precision of less than a degree and thus shows the effects of phenomena that produce temperature variations, such as groundwater movements.

In another system, Landsat images are commonly used. They are produced with data obtained from a multispectral scanner carried aboard certain U.S. Landsat satellites orbiting Earth at an altitude of about 900 km. Images covering an area of over 185 km² are available for virtually every part of Earth's surface. Scanner measurements are made in four spectral bands: green and red in the visible portion of the spectrum, and two infrared bands. The data are usually displayed by arbitrarily assigning different colors to the bands and then superimposing these to make representative images.

Figure 12. Components of remote sensing for image processing. The sensed signals are stored and processed either online or offline.

Figure 13. The geometry of a scanning beam altimeter. The scanning is realized either electronically or mechanically. Processing of the returned signals from each scan gives accurate three-dimensional images.

Topographic mapping of the earth, moon, and planets can be accomplished with high resolution and accuracy using satellite laser altimeters. These systems employ nanosecond laser pulses and microradian beam divergences to achieve submeter vertical range resolution from orbital altitudes of several hundred kilometers.

Conventional altimeters provide a topographic surface profile. In most cases the surface topography is required over an area. This can be achieved by multiple orbit traces displaced across the track by successive revolutions of an element making a large number of accurately positioned orbital passes. Often a multibeam or scanning beam altimeter is used to provide three-dimensional images. The corresponding geometry is illustrated in Fig. 13. The accurate performance of the altimeter depends on the effects of the target surface characteristics, spacecraft pointing jitter, and waveform digitizer characteristics. The ranging accuracy is critically dependent on the pointing accuracy and stability of the altimeter, especially over high-relief terrain where surface slopes are large. At typical orbital altitudes of several hundred kilometers, single-shot accuracy of a few centimeters can be achieved when the pointing jitter is on the order of 10μ rad or less.

7. SURFACE HEIGHT MEASUREMENT AND HEIGHT ACCURACY

Surface height measurement is an important concept associated with altimeter technology. In general, height measurement has many applications, ranging from the microscopic scale of measuring step heights in wafers in integrated circuits and height measurements of machined metal surfaces, to the very large scales of ice formation on Earth's surface and wave heights in the oceans. Consequently, the instrumentation suitable for these measurements ranges from microscopes and interferometers to GPS and satellite radar.

In large-scale applications, many methods are used to determine heights on land: (1) spirit leveling (most accurate but slow), (2) measuring vertical angles and distances

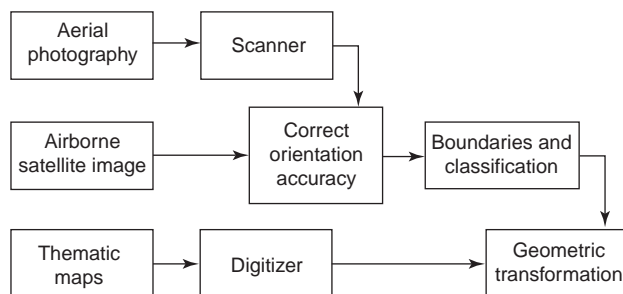

Figure 14. Use of different methods in remote sensing. Several methods are combined electronically to give extremely accurate mapping. In this particular case aerial photography, airborne satellite images, and digitized thematic maps are combined.

(accurate and faster), (3) measuring differences in atmospheric pressure, (4) using photographic techniques such as aerial surveying, and (5) using radar and satellite systems. The last two techniques are accurate but require expensive and sophisticated equipment, as discussed earlier. Often, more than one technique is employed to obtain accurate geographic information, as illustrated in Fig. 14.

In spirit leveling, a horizontal telescope fitted with crosshairs, rotating around a vertical axis on a tripod, is used to adjust a bubble, which is exactly centered. The reading on a graduated vertical staff is observed through the telescope. If such staffs are placed on successive ground points, and the telescope is truly leveled, the difference between the readings at the crosshairs will equal that between the heights of the points. By moving the level and the staffs alternately along a path or road and repeating this procedure, differences in height can be measured accurately over long horizontal distances. In some stringent surveys, the error may be kept to less than a centimeter over a distance of 100 km.

For faster work in hilly areas, where lower accuracy is usually acceptable, trigonometric height determination is employed, using a theodolite to measure vertical angles and measuring or calculating the distances by triangulation. To increase precision, the observations are made simultaneously in both directions so that aerial refraction is eliminated.

The third method of height determination depends on measurements of atmospheric pressure differences with a sensitive aneroid barometer, which can respond to pressure differences small enough to correspond to 0.3–0.6 m in height. To obtain reliable results, it is necessary to use a reference barometer, as the air pressure changes constantly. An alternative to the barometer for the pressure measurements is the use of an apparatus for measuring the boiling point of a liquid, since the boiling temperature depends on the atmospheric pressure.

A relatively new method of surface height measurement is the use of satellite and radar systems. The analysis of the signals received simultaneously from several satellites gives heights as accurately as positions. Heights determined in this way are useful in previously unmapped areas as a check on results obtained by faster relative

methods, but they are not accurate enough for mapping developed areas or for engineering projects. For example, absolute and relative height measurements with the differential GPS systems are accurate to about 30 m, whereas in photogrammetric surveys subcentimeter accuracy can be achieved over a wide area, typically 5 km^2 .

Another application of the satellite systems is in the oceans, to measure the sea level, since the surface of the sea acts as a reflector for radar waves. The accuracy of the measurements depends on how precisely the satellite orbit is known, and on the reduction of dynamic effects on the sea surface such as semidiurnal and diurnal tides.

A typical application of altimeters is in aircraft to determine their height above the surface. Radar systems are often used for geometric height estimation of civil and military aircraft. A typical system consists of a standard altimeter backed up with secondary surveillance radar (SSR) operating on mode S coupled to an omnidirectional antenna fixed under the airplane. The geometric height is derived by various methods, such as the trilateration method, and the systematic errors are compensated for by deriving the profile of the effect on height measurements of the bias in range measurements. Various curve-fitting techniques are used, which estimate both the geometric height and any nonzero systematic errors.

High single-point precision and high point density can be obtained by airborne laser altimetry, using GPS positioning and inertial navigation system (INS) attitude determination. However, these methods are subject to various error sources, which include (1) internal laser sensor errors; (2) GPS and INS errors; (3) atmospheric effects; (4) terrain roughness, reflectivity, and slope; (5) presence, height, and type of vegetation; and (6) integration and synchronization of laser, GPS, and INS. When well calibrated, laser altimeters can give subcentimeter accuracy. However, the accuracy may be very sensitive to terrain type, terrain coverage, and filters used to remove undesired objects, such as buildings and trees. In particular, pointing accuracy, which depends on the pointing jitter of the scanning mirror and INS attitude determination, is a main error source, especially over high-relief terrain.

AMPLITUDE SHIFT KEYING

Cleveland, Ohio

1. INTRODUCTION

In some digital communication systems, such as satellite communication and cellular telephone systems, digital message data, such as binary 0 and 1, must be impressed on a high-frequency carrier signal before being transmitted. The carrier is usually a voltage signal such as a cosine function of time t

$$s(t) = A \cos(2\pi f_c t + \theta)$$

where A is the amplitude, f_c is the carrier frequency, and θ is the initial phase. Each of these three parameters or a combination of some of them can be used to carrier the message data. The process of impressing a message on to a carrier by associating one or more parameters of the carrier with the message is called modulation, and the process of extracting the message from the modulated signal is called demodulation.

The most important properties of a modulation scheme are the bandwidth efficiency, bit error probability, and system complexity.

The *bandwidth efficiency* is defined as number of bits per unit bandwidth (1 Hz) that a modulation scheme communicates, and it is determined by the power spectral

density (PSD) of a digitally modulated signal. Even though the carrier signal of a digitally modulated signal is a deterministic signal, the data bits that modulate the carrier are typically random. Therefore the digitally modulated signal is typically a random signal. For random signals, their spectral property is described by PSD [1, App. A], unlike that for deterministic signals where spectrum can be found using Fourier series or Fourier transform, depending on whether the signal is periodical or aperiodic, respectively.

Bit error probability is also commonly referred as *bit error rate* (BER), although the latter is only an approximation of the former. It is largely determined by the signal energy to noise energy ratio or simply signal-to-noise ratio (SNR), as well as signaling format. One modulation scheme may need less SNR than the other for the same BER, then we say the former is more power efficient than the latter.

System complexity refers to mainly complexities of the modulator, demodulator, and synchronization subsystems, which are also determined by signalling format.

The three basic digital modulations are the amplitude shift keying (ASK), frequency shift keying (FSK), and phase shift keying (PSK). As these terms suggest, while keeping all other parameters of the carrier unchanged, ASK uses the data to vary the amplitude, FSK uses the data to change the frequency, and PSK uses the data to control the phase of the carrier, respectively. Binary forms of all three of them are the simplest ones, where the modulating digital message are binary. If the messages are M -ary, where M is an integer, then the modulations are MASK, MFSK, or MPSK.

Both ASK and FSK are the simplest to implement, but ASK is more bandwidth-efficient; that is, for the same system bandwidth ASK can transmit more data. ASK and PSK have the same bandwidth efficiency, but PSK is more power-efficient, that is, for the same SNR (signal-to-noise ratio), the PSK has a lower bit error rate. However, PSK is more difficult to implement than ASK. Even though PSK has gained more popularity, ASK and FSK are still used in many communication systems because of their implementation simplicity.

This article is about ASK. We will first introduce the simplest ASK, the On-Off keying (OOK), in Section 2. After that we will describe a general form M -ary ASK (MASK) in Section 3, where a general form of the power spectral density expression is given and optimum detection and its error probability expression is derived. In Section 4, bipolar symmetric MASK and its PSD, BER, modulator, and demodulator are presented. Section 5 discusses unipolar MASK and its PSD, BER, modulator and demodulator. MASK and MPSK are compared in Section 6. Finally, in Section 7, two advanced forms of modulations related to ASK, the QAM, and ASK-OFDM are briefly discussed.

2. ON-OFF KEYING

The simplest ASK scheme is the binary unipolar ASK also known as *on-off keying* (OOK), where binary data 1 and 0

Figure 1. OOK waveforms: (a) data waveform; (b) modulated OOK signal waveform.

are represented by the presence and the absence of a carrier burst, respectively. The OOK signal set is

$$\begin{aligned} s_1(t) &= A \cos 2\pi f_c t \text{ for } a = 1, \quad 0 \leq t \leq T \\ s_2(t) &= 0 \text{ for } a = 0, \quad 0 \leq t \leq T \end{aligned} \quad (1)$$

where a is the binary data. Figure 1 illustrates an OOK signal, where (b) is the baseband data waveform corresponding to the data sequence (10110). The baseband waveform voltage is either A volts or 0, depending on whether the data bit is 1 or 0. When the data bit is 1, there is a burst of carrier signal of A volts in (b), otherwise there is not.

In the following we examine the properties of OOK in terms of its spectrum and bit error probability. We will give expressions without derivations. We defer the derivations to the section on noncoherent unipolar M -ary ASK, of which OOK is only one special case.

2.1. Power Spectral Density and Bandwidth

It is well known that for a bandpass random signal $s(t)$, the PSD is completely determined by the PSD of its complex envelope or equivalent baseband signal [1–3]

$$\Psi_s(f) = \frac{1}{2} [\Psi_{\tilde{s}}(f - f_c) + \Psi_{\tilde{s}}(-f - f_c)] \quad (2)$$

where $\Psi_{\tilde{s}}(f)$ is the PSD of the complex envelope. Thus it suffices to have $\Psi_{\tilde{s}}(f)$ instead of $\Psi_s(f)$.

Assuming that the random data bits are uncorrelated and equally likely, the baseband PSD expression of OOK is given by [1, p. 422]

$$\Psi_{\tilde{s}}(f) = \frac{A^2 T}{4} \left(\frac{\sin \pi f T}{\pi f T} \right)^2 + \frac{A^2}{4} \delta(f) \quad (3)$$

where $\delta(f)$ is the Dirac delta function, which is a discrete spectral line at zero frequency, reflecting the DC component

Figure 2. PSD of OOK and unipolar MASK with a rectangular pulse, from Eqs. (3) and (2), with $A = \sqrt{2}$ and $T = 1$.

of the baseband signal. The rest is a continuous part of the PSD, representing the variation in the data sequence.

Figure 2 shows the PSD of OOK. In the figure we set $A = \sqrt{2}$ and $T = 1$ for unity average symbol pulse energy and $f_c = 4/T$. In fact, the shape of the PSD in this figure is for any unipolar M -ary ASK with rectangular pulse. From the figure we can see that the main spectral components are within the null-to-null bandwidth, which is $2/T$. That is, the null-to-null bandwidth is twice the symbol rate.

2.2. Modulator and Demodulator

The modulator of OOK is very simple (Fig. 3a). The binary data sequence is used as a control signal that connects the output with the oscillator through the switch when the bit is 1 and disconnects the switch when the bit is 0. The demodulator can be in two different forms: the coherent (Fig. 3b) and the noncoherent (Fig. 3c). The coherent demodulator requires a carrier recovery circuit that synchronizes in frequency and phase the local oscillator in the receiver with the received signal

$$r(t) = s(t) + n(t)$$

where $n(t)$ is the additive white Gaussian noise (AWGN) whose two-sided power spectral density is $N_0/2$. The

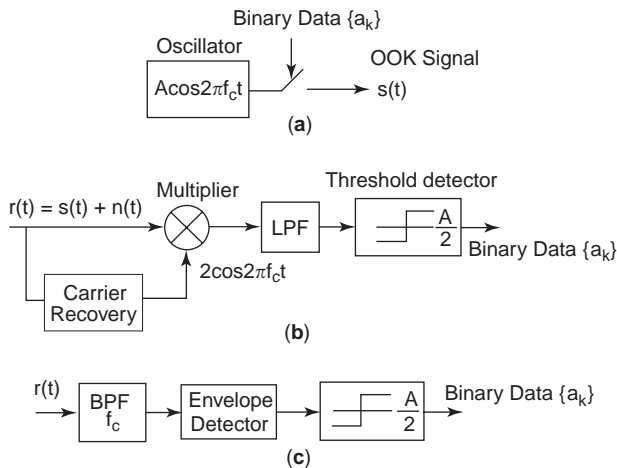

Figure 3. OOK modem: (a) modulator; (b) coherent demodulator; (c) noncoherent demodulator.

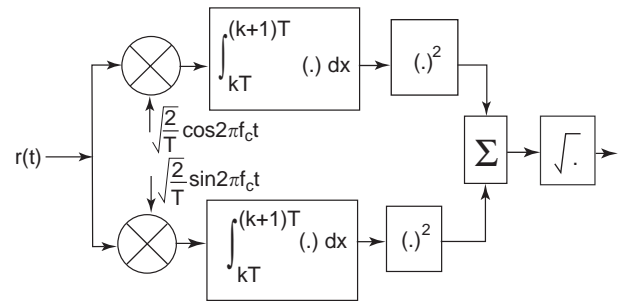

Figure 4. Quadrature envelope detector.

received signal is first multiplied with the recovered carrier $2 \cos 2\pi f_c t$, and the product then passes a lowpass filter (LPF). The LPF rejects the double-frequency part of the product and high-frequency noise. The result is $A + n$, where n is the residual noise. This signal is sent to the threshold detector, whose threshold is set at $A/2$. If the signal is above $A/2$ threshold, the output is set to 1; otherwise the output is set to 0. In the noncoherent demodulator, the first stage is a bandpass filter (BPF) with a center frequency of f_c and adequate bandwidth. This BPF has the function of selecting the desired signal and rejecting the noise. The filtered signal then passes an envelope detector, which extracts the envelope of the modulated carrier, namely, the noise-corrupted baseband pulses. Finally, the noise-corrupted baseband pulses pass the threshold detector to produce the binary data sequence.

The envelope detector can be implemented in the form of a quadrature detector as shown in Fig. 4. It can also be approximately implemented in other forms. For example, the well-known AM demodulator consisting of a diode followed by a resistor and a capacitor in parallel is an envelope detector.

2.3. Bit Error Probability

Bit error probability expressions for OOK are given below without proof. Later we can see that these expressions can be derived as special cases from M -ary cases.

The bit error probability for coherent demodulation of OOK is

$$P_b = Q\left(\sqrt{\frac{E_b}{N_0}}\right) \quad (4)$$

where E_b is the average bit energy and

$$Q(x) = \int_x^\infty \frac{1}{\sqrt{2\pi}} e^{-\frac{u^2}{2}} du \quad (5)$$

is the Q function. The bit error probability for noncoherent demodulation of OOK is [5].

$$P_b = \frac{1}{2} \exp\left(-\frac{E_b}{2N_0}\right) + \frac{1}{2} Q\left(\sqrt{\frac{E_b}{N_0}}\right) \quad (6)$$

Figure 5. OOK bit error probabilities: solid line—coherent demodulation; dotted line—noncoherent demodulation.

Figure 5 shows the BERs of coherent and noncoherent OOK; the former demodulator has a better BER. The noncoherent is relatively easier to implement since it does not require the carrier synchronization. The noncoherent demodulator is more robust against channel impairments such as fading and also is suitable for systems where synchronization is difficult such as a frequency-hopping multiple-access system.

3. M -ARY ASK (MASK)

OOK is simple but not bandwidth-efficient. To improve bandwidth efficiency, we need to go from binary to M -ary, where M is usually a power of 2.

In M -ary ASK (MASK), data bits are grouped into n -tuples, where $n = \log_2 M$. Each n -tuple is mapped into an amplitude A_i . Thus a symbol in MASK is a burst of carrier signal with an amplitude determined by the n -tuple and it represents n bits instead of only one bit as in OOK. As we will see later (Sections 4.1 and 5.1), the bandwidth of the MASK signal's PSD is determined by the symbol duration. By keeping the symbol duration the same, an MASK system and an OOK system will need the same bandwidth, but the bit rate of the MASK system will be n times that of the OOK system.

In the basic symbol period $[0, T]$, an MASK signal with a pulseshape $p(t)$ can be expressed as

$$s_i(t) = A_i p(t) \cos 2\pi f_c t, \quad 0 \leq t \leq T \quad (7)$$

for $i = 1, 2, \dots, M$. The distribution of amplitudes varies. The most common choices are the symmetric uniform spacing bipolar distribution and uniform spacing unipolar distribution. The amplitudes of the symmetric uniform spacing bipolar distribution is given by

$$A_i = (2i - 1 - M)A, \quad i = 1, 2, \dots, M \quad (8)$$

where $A > 0$. The amplitude spacing is $2A$. For example, if $M = 4$, then $A_i \in (-3A, -A, A, 3A)$. The amplitude distribution of the uniform spacing unipolar distribution is given by

$$A_i = (i - 1)A, \quad i = 1, 2, \dots, M \quad (9)$$

The amplitude spacing is A . If $M = 4$, then $A_i \in (0, A, 2A, 3A)$. OOK is just a special case of the unipolar MASK when $M = 2$.

A bipolar MASK can be demodulated only coherently since noncoherent demodulation cannot distinguish the sign of the signal. A unipolar MASK can be demodulated noncoherently as well as coherently. However, it is generally used in a system where coherent demodulation is difficult; thus noncoherent demodulation is preferred. If coherent demodulation is feasible, the symmetric uniform spacing bipolar MASK is preferred over the uniform spacing unipolar MASK since the former has better BER performance. In the following two sections, we will discuss coherent symmetric uniform spacing bipolar MASK and noncoherent uniform spacing unipolar MASK. But first, we examine the power spectral densities of both.

3.1. Power Spectral Density

Consider a sequence of MASK symbols in the form of

$$s(t) = \sum_{k=-\infty}^{\infty} A_k p(t - kT \cos 2\pi f_c t), \quad -\infty < t < \infty \quad (10)$$

where A_k are the amplitudes controlled by the data n -tuples. Assuming that the data are uncorrelated, the PSD of the complex envelope of the bandpass MASK signal is [1, (A.18)]

$$\Psi_s(f) = \frac{\sigma_A^2 |P(f)|^2}{T} + \left(\frac{m_A}{T}\right)^2 \sum_{k=-\infty}^{\infty} \left|P\left(\frac{k}{T}\right)\right|^2 \delta\left(f - \frac{k}{T}\right) \quad (11)$$

where $P(f)$ is the Fourier transform of $p(t)$, σ_A^2 is the variance of A_k , and m_A is the mean value of A_k .

Now let us assume that $p(t)$ is rectangular with unit amplitude; then

$$|P(f)| = \left| T \frac{\sin \pi f T}{\pi f T} \right| \quad (12)$$

and

$$P \frac{k}{T} = T \frac{\sin \pi k}{\pi k} = \begin{cases} T, & k = 0 \\ 0, & k \neq 0 \end{cases}$$

then the PSD of the complex envelope of the bandpass MASK signal is

$$\Psi_s(f) = \sigma_A^2 T \left(\frac{\sin \pi f T}{\pi f T} \right)^2 + (m_A)^2 \delta(f) \quad (13)$$

3.2. Optimum Detection and Error Probability

It is well known from detection theory that for a noise-corrupted signal, the optimum detection starts by correlating the signal with a set of orthonormal basis functions from which the signal is constructed [4, Chap. 2] [1, App. B]. The outputs of the correlators are called sufficient statistics. Then, based on the probability distributions of the sufficient statistics and the detection criterion (usually minimum error probability), the detection rule is established.

To derive the optimum demodulator of the MASK, we first assume that the pulse shaping function is the unit amplitude rectangular pulse; then we can rewrite (7) in terms of an orthonormal basis function $\phi(t)$

$$s_i(t) = A_i \cos 2\pi f_c t = s_i \phi(t), \quad 0 \leq t \leq T \quad (14)$$

Note that there is only one basis function

$$\phi(t) = \sqrt{\frac{2}{T}} \cos 2\pi f_c t \quad (15)$$

and its energy is normalized, that is, $\int_0^T \phi^2(t) dt = 1$ and s_i is the projection of $s(t)$ onto the orthonormal basis function, given by

$$s_i = \int_0^T s_i(t) \phi(t) dt = A_i \sqrt{\frac{T}{2}} \quad (16)$$

Assuming that the received signal is

$$r(t) = s_i(t) + n(t)$$

then the sufficient statistic is the correlator output

$$r = \int_0^T r(t) \phi(t) dt \quad (17)$$

and the detector compares r to s_i and chooses the closest (minimum distance decision rule) [1].

The error probability of the coherent detection for an MASK with equal amplitude spacings can be derived as follows. Assuming an AWGN channel with two-sided noise PSD of $N_0/2$, we obtain

$$r = \int_0^T r(t) \phi(t) dt = \int_0^T [s_i(t) + n(t)] \phi(t) dt = s_i + n$$

where n is Gaussian with zero mean and a variance of $N_0/2$ [1, App. B]. Thus r is Gaussian with mean s_i and variance $N_0/2$.

$$f(r/s_i) = \frac{1}{\sqrt{\pi N_0}} \exp \left[-\frac{(r - s_i)^2}{N_0} \right] \quad (18)$$

Figure 6. Thresholds and decision regions for MASK. (From Xiong [1], copyright © 2000 Artech House.)

Now we assume that signals s_i are equally spaced. Figure 6 shows the probability distribution densities of r conditioned on equally spaced s_i , where τ_i are thresholds. This figure can help us derive the error probability.

Assuming that, s_i is transmitted, a symbol error occurs when the noise n exceeds in magnitude one-half the distance between two adjacent levels. This probability is the same for each s_i except for the two outside levels, where an error can occur in one direction only. Assuming all amplitude levels are equally likely, the average symbol error probability is

$$P_s = \frac{M-1}{M} \Pr \left(|r - s_i| > \frac{\Delta}{2} \right)$$

where Δ is the distance between adjacent signal levels, and also is the distance between adjacent thresholds. Thus

$$\begin{aligned} P_s &= \frac{M-1}{M} \Pr \left(|r - s_i| > \frac{\Delta}{2} \right) \\ &= \frac{M-1}{M} \frac{2}{\sqrt{\pi N_0}} \int_{\Delta/2}^{\infty} e^{-x^2/N_0} dx \\ &= \frac{M-1}{M} \frac{2}{\sqrt{2\pi}} \int_{\Delta/\sqrt{2N_0}}^{\infty} e^{-x^2/2} dx \end{aligned}$$

That is

$$P_s = \frac{2(M-1)}{M} Q \left(\sqrt{\frac{\Delta^2}{2N_0}} \right) \quad (19)$$

Note that this expression is applicable to any uniformly spaced MASK, whether it is bipolar or unipolar, symmetric or asymmetric.

Now if the MASK signal's pulse shaping function is an arbitrary energy function rather than rectangular, we can write (7) as

$$s_i(t) = A_i p(t) \cos 2\pi f_c t = s_i \phi(t), \quad 0 \leq t \leq T \quad (20)$$

where

$$\begin{aligned} \phi(t) &= \sqrt{2/E_p} p(t) \cos 2\pi f_c t \\ s_i &= A_i \sqrt{E_p}/2 \end{aligned} \tag{21}$$

where E_p is the energy of pulseshaping signal $p(t)$ in $[0, T]$. Note that $\int_0^T \phi^2(t) dt \cong 1$ for $f_c \gg 1/T$. Thus for most practical cases where $f_c \gg 1/T$, the optimum demodulator for the rectangular pulse case is still applicable for other pulseshapes and the symbol error probability expression (19) is still valid.

4. BIPOLAR SYMMETRIC M-ARY ASK

As mentioned in the previous section, a bipolar MASK can be demodulated only coherently and is preferred over the unipolar MASK since the former has better BER performance. In this section, we will examine coherent symmetric uniform-spacing bipolar MASK in terms of its PSD, system structure, and BER.

4.1. Power Spectral Density and Bandwidth

The PSD of the complex envelope of the symmetric bipolar MASK (not necessarily uniformly spaced) is obtained by setting $m_A = 0$ in (11):

$$\Psi_s(f) = \frac{\sigma_A^2 |P(f)|^2}{T} \tag{22}$$

The above shows that the PSD of symmetric bipolar MASK is determined by the PSD of the pulseshaping function $p(t)$. If the pulse is rectangular, then, from (13), we have

$$\Psi_s(f) = \sigma_A^2 T \left(\frac{\sin \pi f T}{\pi f T} \right)^2 \tag{23}$$

The passband PSD can be obtained by substituting the baseband PSD expressions into (2). Figure 7 shows the passband PSD of the bipolar MASK with rectangular pulse (where we set $\sigma_A^2 T = \frac{1}{2}$). The null-to-null bandwidth is $2/T$. Note that unlike the PSD for OOK there is no discrete spectral line at the carrier frequency.

Figure 7. PSD of bipolar MASK with rectangular pulse, and $\sigma_A^2 T = \frac{1}{2}$.

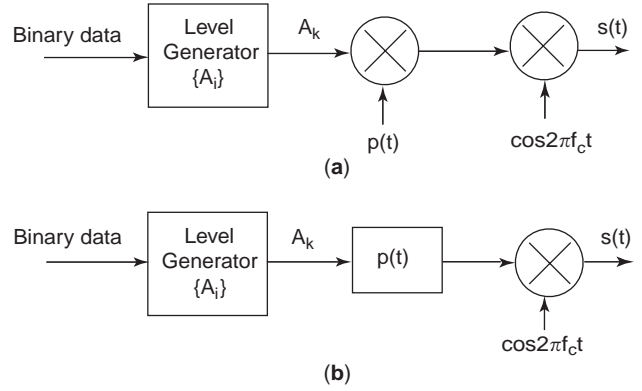

Figure 8. MASK modulator. (From Xiong [1], copyright © 2000 Artech House.)

4.2. Modulator and Demodulator

The modulator is shown in Fig. 8. Figure 8a is a direct implementation of (7). The level generator takes $n = \log_2 M$ bits from the binary datastream and maps them into an amplitude level $A_k \in \{A_i\}$, where the subscript k indicates the k th symbol interval. The mapping is preferably gray-coding so that the n -tuples representing the adjacent amplitudes differ by only one bit. The functions of the remaining blocks are self-explanatory. The equivalent implementation is shown in Fig. 8b. It is more practical for hardware implementation. The $p(t)$ multiplier is replaced with a filter with an impulse response $p(t)$. In order to generate a pulse $A_i p(t)$, the input to the filter must be an impulse $A_i \delta(t)$. In practice, this can be realized by a very narrow pulse with amplitude A_i .

The optimum receiver implementing the minimum distance rule is shown in Fig. 9, where the last block is a threshold detector. Figure 9a is a direct implementation of (17) and the minimum distance rule. In Fig. 9b, the correlation with $p(t)$ is replaced by a matched filter and a sampler [1, p. 419]. Figure 9b is more practical for hardware implementation.

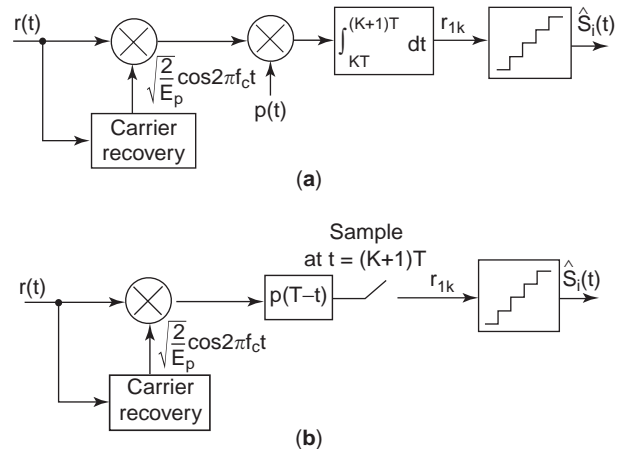

Figure 9. Optimum coherent demodulators for MASK. (From Xiong [1], copyright © 2000 Artech House.)

The threshold detector has $M-1$ thresholds, each placed in the middle of two signal points (refer to Fig. 7). The correlator computes the r , and the threshold detector is actually computing the distance of r to the amplitudes s_i , $i=1, 2, \dots, M$ and chooses the smallest. Note that the reference signal can be any scaled version of $\phi(t)$ as long as the thresholds are scaled accordingly.

The recovery of coherent carrier and the symbol timing clock are assumed in the coherent demodulator. A description of techniques of carrier and timing recovery is beyond the scope of this article, but it can be found in common communication books.

4.3. Error Probability

The error probability of bipolar symmetric uniformly spaced MASK is obtained from (19), but we need to figure out what Δ is. For bipolar symmetric uniformly spaced MASK, the amplitudes A_i are given in (8). In terms of signal projection s_i , from (21) we can write

$$\begin{aligned} s_i &= A_i \sqrt{E_p/2} = (2i-1-M)A \sqrt{E_p/2} \\ &= (2i-1-M)A_0, \quad i=1, 2, \dots, M \end{aligned} \quad (24)$$

where $A_0 = A \sqrt{E_p/2}$. Then

$$\Delta = |s_i - s_{i-1}| = 2A_0$$

Thus from (19) we have

$$P_s = \frac{2(M-1)}{M} Q \left(\sqrt{\frac{2A_0^2}{N_0}} \right) \quad (25)$$

The symbol error probability can be expressed in terms of the average energy of the signals. The average symbol energy of the signals is

$$\begin{aligned} E_s &= \frac{1}{M} \sum_{i=1}^M E_i = \frac{1}{M} \sum_{i=1}^M s_i^2 \\ &= \frac{1}{M} \sum_{i=1}^M (2i-1-M)^2 A_0^2 = \frac{1}{M} \frac{M(M^2-1)A_0^2}{3} \\ &= \frac{1}{3} (M^2-1)A_0^2 \end{aligned} \quad (26)$$

As a result, (25) becomes

$$P_s = \frac{2(M-1)}{M} Q \left(\sqrt{\frac{6E_s}{(M^2-1)N_0}} \right) \quad (27)$$

Since the average energy per bit is $E_b = E_s / \log_2 M$, (27) can be written as

$$P_s = \frac{2(M-1)}{M} Q \left(\sqrt{\frac{6(\log_2 M)E_b}{(M^2-1)N_0}} \right) \quad (28)$$

Figure 10. Symbol error probability of coherent bipolar symmetric uniformly spaced MASK (solid line) and coherent unipolar uniformly spaced MASK (dotted line).

Figure 10 shows the curves of the symbol error probability of the bipolar symmetric uniformly spaced MASK versus E_b/N_0 . We emphasize that (27) to (28) depend on only average energy of the signal symbols, not the function form of $p(t)$. In general, bit error probability is not simply related to symbol error probability. However, for Gray coded¹ n -tuple-to-amplitude mapping, the adjacent symbols differ by only one bit. At high signal-to-noise ratios, the most likely errors are the adjacent symbols, so in this case

$$P_b \approx \frac{P_s}{\log_2 M} \quad (29)$$

5. UNIPOLAR M -ARY ASK

As pointed out in Section 2, a unipolar MASK can be demodulated noncoherently as well as coherently. Even though coherent unipolar MASK is not a usual choice since the symmetric bipolar MASK is better in terms of BER, for the sake of completeness and also because of the ease in doing this, we will present the error probability expression. Then we will focus on the noncoherent unipolar MASK. But first we examine its power spectral density.

¹The bits-to-amplitude mapping could be arbitrary as long as the mapping is one-to-one. However, a method called Gray coding is usually used. Gray coding assigns n -tuples with only one-bit difference to two adjacent amplitudes. When an M -ary symbol error occurs, it is most likely that the signal is detected as one of the signals with the adjacent amplitudes; thus only one of the n bits is in error. Gray coding keeps the bit error rate at the minimum for a given symbol error rate.

5.1. Power Spectral Density and Bandwidth

In general, the PSD of unipolar MASK is given by (11). For uniformly spaced amplitudes and rectangular symbol pulse, the PSD of the complex envelope is given in (13). The passband PSD shape is shown in Fig. 2.

For the amplitudes given in (9), the mean value of the amplitudes is

$$m_A = \frac{1}{M} (0 + A + \dots + (M-1)A) = \frac{(M-1)A}{2}$$

and then

$$\Psi_s(f) = \sigma_A^2 T \left(\frac{\sin \pi f T}{\pi f T} \right)^2 + \frac{(M-1)^2 A^2}{4} \delta(f) \quad (30)$$

5.2. Modulator and Demodulator

The structure of modulator for unipolar MASK is almost the same as that for bipolar MASK as shown in Fig. 8. The difference is only in the settings of the level generator due to the signal's unipolarity. The signal levels are now only positive and equally spaced.

The structure of coherent demodulator for unipolar MASK is almost the same as that for bipolar MASK as shown in Fig. 9. The difference is only in the settings of the threshold detector due to the signal's unipolarity. The thresholds now are only positive and equally spaced.

The structure of noncoherent demodulator for unipolar MASK is almost the same as that for OOK as shown in Fig. 3. The difference is in the threshold detector, which must now have multiple equally-spaced thresholds.

5.3. Coherent Demodulation and Error Probability

The symbol error probability is again given by (19), but we need to figure out what Δ is. For unipolar uniformly spaced MASK, the amplitudes are given in (9). In terms of signal projection s_i , from (21) we can write

$$s_i = A_i \sqrt{E_p/2} = (i-1)A \sqrt{E_p/2} \quad (31)$$

$$= (i-1)A_0, \quad i = 1, 2, \dots, M$$

where $A_0 = A \sqrt{E_p/2}$. Then

$$\Delta = |s_i - s_{i-1}| = A_0$$

Thus from (19) we have

$$P_s = \frac{2(M-1)}{M} Q \left(\sqrt{\frac{A_0^2}{2N_0}} \right) \quad (32)$$

The average symbol energy of the signals is

$$\begin{aligned} E_s &= \frac{1}{M} \sum_{i=1}^M E_i = \frac{1}{M} \sum_{i=1}^M s_i^2 \\ &= \frac{1}{M} \sum_{i=1}^M (i-1)^2 A_0^2 = \frac{1}{M} \sum_{j=0}^{M-1} j^2 A_0^2 \\ &= \frac{1}{6} (2M^2 - 3M + 1) A_0^2 \end{aligned}$$

Table 1. Comparison between Bipolar and Unipolar Uniformly Spaced MASK

M	2	4	8	16	32	64	∞
$R(M)$	2	2.8	3.333	3.647	3.818	3.908	4
$10 \log R(M)$ (dB)	3.01	4.472	5.229	5.619	5.819	5.919	6.02

As a result, (32) becomes

$$P_s = \frac{2(M-1)}{M} Q \left(\sqrt{\frac{3E_s}{(2M^2 - 3M + 1)N_0}} \right) \quad (33)$$

In terms of average energy per bit, (33) can be written as

$$P_s = \frac{2(M-1)}{M} Q \left(\sqrt{\frac{3(\log_2 M)E_b}{(2M^2 - 3M + 1)N_0}} \right) \quad (34)$$

This expression is plotted in Fig. 10 (dotted line). The P_b at high SNRs can be estimated by (29). When $M=2$, the unipolar MASK is OOK, $P_s = P_b$. Substituting $M=2$ into (34), we obtain the exact expression in (4).

Comparing (28) and (34) reveals that the ratio of the expression in the square root sign of (28) over that of (34) is

$$R(M) = \frac{2(2M^2 - 3M + 1)}{M^2 - 1}$$

Table 1 shows some values of $R(M)$. It shows that the bipolar uniformly spaced MASK is superior to the unipolar uniformly spaced MASK. The asymptotic ratio is 4 or 6 dB. This confirms the statement we said earlier that coherent unipolar MASK is not a usual choice since the symmetric bipolar MASK is better in terms of BER.

5.4. Noncoherent Demodulation and Error Probability

When carrier synchronization is difficult or beyond simple system complexity, noncoherent unipolar MASK can be used. The noncoherent demodulator is the same as that for OOK in Fig. 3c except that the threshold detector must have multiple thresholds. The thresholds and symbol error probability for noncoherent demodulation of the unipolar uniformly spaced MASK in AWGN channel has been derived [6]. We summarize the derivation here and present the results.

Recall that the unipolar uniformly spaced MASK signal set is $(0, A, 2A, \dots, (M-1)A)$. When the amplitude $A_0 = 0$ is transmitted, the output of the envelope detector (Fig. 4), denoted as η , has Rayleigh distribution (the first probability density function (pdf) in Fig. 11). An error will occur if the envelope η has a value greater than the threshold γ . The probability of error for this case will be

$$p(e|A_0) = \int_{\gamma}^{\infty} \frac{\eta}{\sigma^2} \exp\left(-\frac{\eta^2}{2\sigma^2}\right) d\eta$$

Figure 11. Threshold and decision regions for unipolar noncoherent MASK ($M=4$).

where $\sigma^2 = N_0/2$ is the variance² of the AWGN [1,7]. At high signal-to-noise ratio, the optimum threshold (γ_0) can be closely approximated by $\sqrt{E_{\min}}/2$ [8], where $E_{\min} = A^2 T/2$ is the energy of the symbol with the minimum non-zero amplitude. Therefore

$$p(e|A_0) = \exp\left(-\frac{E_{\min}}{4N_0}\right)$$

The other case that should be considered separately is the case when the symbol A_{M-1} is transmitted (see the last pdf in Fig. 11). In this case, the probability density function of the envelope η is Rician and is centered at $(M-1)\sqrt{E_{\min}}$. An error will occur if the value of the envelope η has a value less than the threshold. At high signal-to-noise ratio, the Rician distribution is closely approximated by a Gaussian distribution [8]. Using the Gaussian approximation, the probability of error for this case will be

$$p(e|A_{M-1}) \approx \int_{-\infty}^{\gamma_{M-2}} \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(\eta - (M-1)\sqrt{E_{\min}})^2}{2\sigma^2}\right] d\eta$$

Since we have used the Gaussian approximation, the threshold will be taken as the intersection of the adjacent probability density functions $p(\eta|A_{M-1})$ and $p(\eta|A_{M-2})$, that is, $\gamma_{M-2} = (M-1.5)\sqrt{E_{\min}}$, then

$$p(e|A_{M-1}) \approx Q\left(\sqrt{\frac{E_{\min}}{2N_0}}\right)$$

All other transmitted symbols have the same Rician distribution with different means. Because of the equal spacing of these signals and their thresholds, they have equal probability of error. Regardless of what symbol was transmitted, we can assume that the Rician pdf is centered at the zero point and an error will occur if η exceeds the upper or lower threshold, that is, if $\eta > \sqrt{E_{\min}}/2$ or $\eta < -\sqrt{E_{\min}}/2$. Since the Gaussian approximation has symmetric pdf around its mean, the average probability

²The envelope detector must be a quadrature receiver with orthonormal reference carriers.

of error can be expressed as

$$\begin{aligned} p(e|A_i) &\approx 2 \int_{\gamma_i}^{\infty} \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{\eta^2}{2\sigma^2}\right) d\eta \\ &= 2Q\left(\sqrt{\frac{E_{\min}}{2N_0}}\right), \quad i=1, \dots, M-2 \end{aligned}$$

Multiplying the three conditional probabilities by $(1/M)$, $(1/M)$ and $[(M-2)/M]$, respectively, and adding them will give

$$P_s = \frac{1}{M} \left[\exp\left(-\frac{E_{\min}}{4N_0}\right) + (2M-3)Q\left(\sqrt{\frac{E_{\min}}{2N_0}}\right) \right]$$

The average symbol energy E_s is related to the minimum symbol energy by

$$\begin{aligned} E_s &= \frac{1}{M} \sum_{i=1}^M E_i = \frac{1}{M} \sum_{i=1}^M (i-1)^2 \left(A^2 \frac{T}{2}\right) = \frac{1}{M} \sum_{j=0}^{M-1} j^2 \left(A^2 \frac{T}{2}\right) \\ &= \frac{1}{6} (2M^2 - 3M + 1) \left(A^2 \frac{T}{2}\right) = \frac{1}{6} (2M^2 - 3M + 1) E_{\min} \end{aligned}$$

or

$$E_{\min} = \frac{6E_s}{2M^2 - 3M + 1} = 2B_M E_s$$

where

$$B_M = \frac{3}{2M^2 - 3M + 1} \quad (35)$$

This equation can be written in terms of E_s/N_0 using the following equation

$$P_s = \frac{1}{M} \left[\exp\left(-\frac{E_s}{2N_0} B_M\right) + (2M-3)Q\left(\sqrt{\frac{E_s}{N_0} B_M}\right) \right] \quad (36)$$

or in terms of E_b/N_0

$$\begin{aligned} P_s &= \frac{1}{M} \left[\exp\left(-\frac{1}{2} (\log_2 M) B_M \frac{E_b}{N_0}\right) \right. \\ &\quad \left. + (2M-3)Q\left(\sqrt{(\log_2 M) B_M \frac{E_b}{N_0}}\right) \right] \end{aligned} \quad (37)$$

where E_b is the average energy per bit. When $M=2$, the above reduces to the P_b expression for OOK (6). Figure 12 shows the symbol error probability given above for noncoherent demodulation (dotted lines), together with those for coherent demodulation. From the figure we can see that the noncoherent demodulation incurs a small performance degradation. When M is high, the degradation is negligible.

Figure 12. Symbol error probability of unipolar uniformly spaced MASK: solid line—coherently demodulated; dotted line—noncoherently demodulated.

6. COMPARISON WITH MPSK

For the same symbol rate and the pulshape, MPSK and MASK have the same PSD and hence the same bandwidth. Thus it makes sense to compare their BER performances.

In comparison to MPSK, starting from $M = 4$, the error probability of bipolar MASK is inferior to that of the MPSK. The P_s of the MPSK is given by [1, (4.24)]

$$P_s \approx 2Q\left(\sqrt{\frac{2E_s}{N_0}} \sin \frac{\pi}{M}\right) \tag{38}$$

Comparing (38) and (27), the ratio (MASK over MPSK) of the arguments inside the square root sign of the Q function is

$$R_M = \frac{3}{(M^2 - 1) \sin^2 \frac{\pi}{M}} \tag{39}$$

and is tabulated in Table 2. If $M \geq 32$ the degradation is constantly 5.17 dB. This is easily seen from (39). For

Table 2. Power Penalty of MASK over MPSK

M	2	4	8	16	32	64	128
$R(M)$	1	0.4	0.325	0.309	0.305	0.304	0.304
$10 \log R(M)$ (dB)	0	-3.98	-4.88	-5.10	-5.16	-5.17	-5.17

large M , $\sin \pi/M \cong \pi/M$, and $R_M \cong 3/\pi^2 \cong 0.304$. Another fact is that in both bipolar MASK and MPSK, for the same error probability, the power increase is 6 dB for doubling M for large M . This means in terms of increasing bandwidth efficiency with increased M , both schemes pay the same penalty in BER performance. However, MASK still has a fixed 5.17 dB disadvantage against MPSK. This shows MASK is inferior to MPSK in terms of error probability. However, we will see that going to two-dimensional MASK, namely, QAM, improves error rate performance significantly. As a result, QAM is superior to MPSK when $M > 4$. We will briefly discuss QAM in the next section.

7. ADVANCED MODULATIONS RELATED TO ASK

Two important modulations arise from ASK. One is the quadrature amplitude modulation or QAM. Another is the ASK-OFDM (orthogonal frequency division multiplexing).

QAM is constructed by adding two MASK signals together as below [$p(t)$ is pulshape]

$$s_i(t) = A_{i1}p(t) \cos 2\pi f_c t - A_{i2}p(t) \sin 2\pi f_c t$$

As can be seen, the second carrier is a sine function that is orthogonal to the first carrier. The first component is the in-phase or I component, and the second component is the quadrature or Q component. The system complexity of QAM doubles that of MASK since it requires I and Q branches in its modulator and demodulator. However, the BER performance of QAM is much better than MASK. In fact, the BER performance of an M -ary QAM is exactly the same as that of a \sqrt{M} -ary MASK whose bandwidth efficiency is only half that of QAM [13]. Also the BER performance of an M -ary QAM is even better than that of MPSK when $M > 4$. For example, for the same BER, the MPSK needs 1.65, 4.20, and 7.02 dB more SNR for $M = 8, 16,$ and 32 , respectively [1].

Orthogonal frequency-division multiplexing is a bandwidth-efficient multiple-carrier modulation scheme, especially good for frequency-selective fading channels, where data are separated into N datastreams. Each of them modulates a subcarrier. Then these N modulated signals are summed to form the final signal, which in turn modulates a higher-frequency carrier for transmission. The common modulations used in OFDM are QAM or MPSK [9]. Noncoherent OOK or MASK were also proposed to be used in frequency-hopping multiple-access system since carrier synchronization is difficult in such system [11,12]. An OFDM scheme that uses QAM or MPSK or noncoherent MASK (including OOK) requires that the N subcarriers be separated in frequency by $1/T$ for them to be orthogonal to each other so that they can be separated in the demodulator. These types of OFDM can be conveniently implemented by the pair of inverse fast Fourier transform (IFFT) for modulation and FFT for demodulation [10]. MASK-OFDM has been proposed [13], where coherent MASK is used for modulation that requires a frequency separation of only $1/2 T$ and can be conveniently implemented by the pair of fast cosine transform (FCT)

and inverse FCT (IFCT) for modulation and demodulation, respectively. Since the BER performance of MASK is inferior to that of QAM, the order of the MASK has to be reduced to \sqrt{M} to match the BER performance of QAM. By doing so, the bandwidth advantage of MASK-OFDM is lost. However, the system complexity of MASK-OFDM is reduced in comparison to that of QAM-OFDM.

ANALYTICAL AND ADAPTIVE MODELING OF NONLINEAR HIGH-POWER AMPLIFIERS

MOHAMED IBNKAHLA
Queen's University
Kingston, Ontario, Canada

1. INTRODUCTION

Communication channels are equipped with high-power amplifiers (HPA), which are used to amplify the transmit-

Figure 1. Example of amplitude conversion of a TWT amplifier.

ted signal in order to reach an acceptable signal-to-noise ratio (SNR). In general, these amplifiers have nonlinear characteristics. For example, traveling-wave-tube (TWT) amplifiers (see examples of amplitude and phase conversions in TWT amplifiers in Figs. 1 and 2, respectively) and solid-state power (SSP) amplifiers are widely used in satellite communications for their excellent power efficiency [15]. However, these amplifiers cause nonlinear distortions to the transmitted signals, due to their nonlinear behavior.

For low input levels, the output power of a nonlinear HPA is essentially a linear function of the input power. As the input drive increases, the output power increases nonlinearly until the point of maximum power output is reached. Beyond this point (referred to as “saturation”), any additional increase in the input power level does not result in an additional increase in output power (see, e.g., Fig. 1). The operating point of the TWT is usually given in terms of input or output backoff from saturation. Generally, an amplifier will be most efficient when it operates at or near saturation.

Figure 2. Example of phase conversion of a TWT amplifier.

The closer an amplifier is driven to saturation, the greater the amount of distortion it produces. Distortion may also be produced in the phase, which may change nonlinearly with the input power level.

HPA modeling serves a variety of purposes. For example, if the required measured physical data are unavailable, an analytical model is desirable. This model can be used in order to run computer simulations that measure a variety of signal and channel configurations without imposing instrumentation limitations. The analytical expressions derived by the model can be used in order to conduct performance analysis of the communication channel, to study the efficiency of the design through computer simulations, or to optimize the channel resources over various amplifier and channel conditions. Moreover, analytical models can be used in order to design and optimize the different parts of the transmitter and the receiver, such as modulation scheme and predistortion technique at the transmitter; and demodulation scheme, detection device, and equalization algorithm at the receiver. This article presents a survey of nonlinear amplifier models, including memoryless amplifiers and amplifiers with memory. There is a special focus on adaptive neural network (NN) approaches.

2. NONLINEAR MEMORYLESS HIGH-POWER AMPLIFIERS

2.1. Signal Representation

TWT amplifiers exhibit two nonlinear conversions: amplitude-to-amplitude (AM/AM) and amplitude-to-phase (AM/PM) conversions. Two equivalent frequency-independent representations have been proposed for these nonlinearities: amplitude-phase (A-P) representation and in-phase – quadrature (I-Q) representation [24].

Let the TWT input wave be expressed as

$$x(t) = r(t) \cos(\omega_0 t + \phi_0) \quad (1)$$

where ω_0 is the carrier frequency and $r(t)$ and ϕ_0 are the input signal amplitude and phase, respectively.

For the A-P representation, the output signal is expressed as

$$y(t) = A(r(t)) \cos(\omega_0 t + \phi(r(t)) + \phi_0) \quad (2)$$

where $A(r)$ and $\phi(r)$ are the AM/AM and AM/PM conversions, respectively.

For the I-Q representation, the output signal is represented by its in-phase and quadrature components

$$p(t) = P(r(t)) \cos(\omega_0 t + \phi_0) \quad (3)$$

$$q(t) = -Q(r(t)) \sin(\omega_0 t + \phi_0) \quad (4)$$

where $P(r)$ and $Q(r)$ are the in-phase and quadrature conversions, respectively. These can be shown from the

AM/AM and AM/PM conversions to be:

$$P(r) = A(r) \cos(\phi(r)) \quad (5)$$

$$Q(r) = A(r) \sin(\phi(r)) \quad (6)$$

2.2. Nonlinear Distortion Effect on Digitally Modulated Signals

When the input signal is digitally modulated, the HPA nonlinearity rotates the signal constellation. This causes an alteration in the decision region. Figure 3 displays the effect of nonlinearity on the constellation of a 16-quadrature amplitude modulation (16-QAM) signal. The decision regions are used by the receiver to decode the received symbols. If a received symbol falls in the decision region of a certain constellation point, then the receiver decides that the transmitted symbol is that particular constellation point.

Figure 3. TWT input (a) and output (b) constellations with amplifier working close to saturation.

Figure 4. Example of spectral regrowth generated by a TWT amplifier.

When the decision regions are distorted, the receiver can no longer use the ideal decision regions of the transmitted constellation in order to decode the received signal. The receiver must know the constellation at the output of the amplifier, which is difficult since the characteristics and the operating point of the amplifier may change. Moreover, as can be seen in Fig. 3b, some symbols become closer to each other in the distorted constellation, leading to an increase in the symbol error rate (SER).

2.3. Intermodulation Distortions and Spectral Regrowth

Another major consequence of amplifier nonlinearities is the generation of intermodulation distortion (IMD) products [17]. IMD products are located at frequencies above and below those of the input carriers, and at frequency intervals equal to separations between input carriers. IMD products cannot be easily eliminated through filtering, as they are located close to the desired input signal bandwidth. IMD products not only corrupt the amplified signal itself but also cause adjacent-channel interference due to spectral regrowth (Fig. 4), which is more serious because it acts as interference to the adjacent channels. This interference is tightly controlled by the communications standards being used, and must be reduced to the allowable limit. Thus, this phenomenon has a direct impact on the system capacity and performance.

Distortion is most often evaluated in terms of the ratio of the carrier to the third-order IMD products (i.e., IMD terms closest to the carrier). IMD terms can also be non-symmetric. This imbalance is due to the presence of both amplitude- and phase-induced IMD products [17].

Interference produced in the adjacent channel is characterized by the adjacent-channel power ratio (ACPR), which is the power in the main channel divided by the power in the lower plus upper adjacent channels [25].

HPA amplifier design depends on tradeoffs between three main performance indicators: output power, efficiency, and sideband regrowth. However, a certain amount of power amplifier nonlinearity has to be accepted in order to guarantee satisfactory amplifier efficiency.

Moreover, these amplifiers not only are nonlinear, but also can possess memory. If the reciprocal of the bandwidth of the input signal is much larger than the memory of the amplifier (as is the case for most amplifiers driven with narrowband signals), then the amplifier can be modeled as memoryless for that particular input signal. This means that the output is a function of the input at the present time only.

An accurate and verified simulation model for an HPA is required to reliably study the effects of the nonlinearity on the system level, and to give an insight into the problem of finding an appropriate tradeoff between power amplifier efficiency and system capacity. Therefore, an optimal operating point is imperative in order to maximize the output power and minimize the degradation due to distortions.

2.4. Amplifier Backoff

Backoff (BO) defines how far the HPA is operating from the saturation point. The *input saturation power* is defined as the maximum power that can be provided by the amplifier with the highest efficiency. Beyond saturation, the amplifier has no more gain in power. There are two ways of defining backoff: (1) relative to the input [input backoff (IBO)] and (2) relative to the output [output backoff (OBO)]. IBO is the ratio of the saturation power to the desired drive (input) power. OBO is the ratio of the saturation power to the actual output power. Increasing the IBO or OBO reduces nonlinear distortions, but also leads to less output power.

3. ANALYTICAL MODELS

Considerable work has been done in the literature for developing analytical expressions of TWT characteristics. The analytical models have been categorized based on the form of the mathematical representation to elucidate the general characteristics of the models falling in each category.

3.1. Power Series

The power series representation is one of the most commonly used methods to represent nonlinear devices because it identifies the contribution of different power terms. Since the AM/AM conversion, $A(r)$, is an odd function of r , and the AM/PM conversion, $\phi(r)$, is an even function, the following expansion is generally assumed

$$A(r) = \sum_{m=0}^{\infty} a_m r^{2m+1} \quad (7)$$

$$\phi(r) = \sum_{m=0}^{\infty} p_m r^{2m} \quad (8)$$

where parameters $\{a_m\}$ and $\{p_m\}$ have to be determined (e.g., through an optimization procedure).

The power series or Taylor expression must be used with some caution because the series may not converge for all values and sometimes converges slowly. The series requires a large number of terms and heavy computation. The power series model can closely approximate the amplifier curve for a limited range. A common drawback with this model is the explosion of the predicted variable magnitude. This occurs when large values are assigned to some predictions. This type of behavior necessitates the censoring of the predicted variable value. Hence, it is difficult to test strong nonlinearities in simulation when there is a very large envelope variation in the input signal.

The classic work using this model was performed by Chapman and Millard [4]. They accounted for the effect of the AM/PM conversion, which was represented by a single constant coefficient k determined through a measured technique:

$$\phi(r) = kr^2 \quad (9)$$

This relation does not hold over the complete operating region of the TWT amplifier.

Medhurst and Roberts [21] proposed a representation of the AM/AM characteristic by using the sum of the linear and cubic terms and used a two-tone test for verification:

$$y(t) = a_1 x(t) + a_3 x^3(t) \quad (10)$$

3.2. Softlimiter Approach

The input/output relationship can simply be modeled as an ideal softlimiter that has two distinct regions: the perfect linear region and the saturation region. However, the linear region of a practical TWT amplifier is not as perfectly linear as that of the soft limiter. Moreover, this representation does not give a completely realistic model

of the TWT. The limitation of this model is that it requires the envelope amplitude function $A(r)$ not to fall off beyond saturation.

3.3. Exponential Expression

Berman and Mahle [2] gave a three-parameter analytical expression of the AM/PM conversion, which gives reasonably good agreement over the whole range, especially for small input power and above saturation

$$\phi(r) = k_1(1 - \exp(-k_2 r^2)) + k_3 r^2 \quad (11)$$

where k_1 , k_2 , k_3 are the TWT constants obtained from a measured transfer characteristic by a cut-and-dry method or by an optimization routine. The slope for zero input power is given by $2k_1 k_2$. Moreover, for a large input signal power, $\phi(r)$ approaches $k_3 r^2$.

Thomas et al. [27] proposed a four-parameter formula for $A(r)$. The amplitude nonlinearity was analytically modeled by fitting the single-carrier input/output power data with a portion of cosine centered around saturation. This leads to the following function representation

$$A(r) = \begin{cases} 10^{\alpha[\cos(\log_{10}(r/r_s)/\beta)-1]}, & r > r_s \\ r, & r < r_s \end{cases} \quad (12)$$

where r_s is the input saturation power and α and β are constants chosen to fit the data that can be calculated through optimization routines.

3.4. Error Function

The error function closely follows the AM-AM characteristics of a typical TWT amplifier. However, this approach can result in higher error for different amplifiers which may not follow the typical characteristic closely. Pawula [22] presented the input-output relationship of nonlinearity by an error function characteristic using

$$A(r) = \alpha \sqrt{\frac{\pi}{2}} \operatorname{erf}\left(\frac{r}{\beta}\right) \quad (13)$$

where α is the gain parameter and β is the limiter parameter.

3.5. Bessel Functions

The Bessel function was also considered for analytical modeling because of its analytical and numerical convenience as it simplifies the calculation of the output spectrum. However, it requires a large number of terms to fit the measured data.

Kaye et al. [18] came up with the quadrature model and used a sum of Bessel functions of the first kind of order 1. In order to compute the power spectra of the outputs of the nonlinearities in the I-Q representation, they suggested to represent them by a convergent series of functions that are, on one hand, simple to determine from the measured data and, on the other hand, convenient for the power spectrum calculations. This model is

expressed as

$$P(r)[\text{or } Q(r)] = \sqrt{2} \sum_{m=1}^L b_m J_1 \left(\frac{\sqrt{2}r(2m-1)\pi}{R} \right), \quad (14)$$

$$r \leq \frac{R}{2\sqrt{2}}$$

where $J_1(\cdot)$ is the Bessel function of the first kind of order 1.

Simbo and Potano [26] used a complex Bessel function expansion to simultaneously account for the AM/AM and AM/PM conversion of the TWT. Group delay and amplitude variation preceding the input of the nonlinear device was modeled using a Fourier series expression. However, the function has a high computational complexity for the calculation of the coefficients:

$$A(r)e^{j\phi(r)} = \sum_{m=1}^L b_k J_1(\alpha m r) \quad (15)$$

where $\{b_m\}$ are complex coefficients, and α is a constant that scales the input level.

For the I-Q representation, Hetrakul and Taylor [9] proposed two-parameter formulas using a modified Bessel function of the first kind

$$P(r) = C_1 r e^{-C_2 r^2} J_0(C_2 r^2) \quad (16)$$

$$Q(r) = S_1 r e^{-S_2 r^2} J_1(S_2 r^2) \quad (17)$$

where, $J_k(\cdot)$ is the modified Bessel function of the first kind of order k . The coefficients C_1 , C_2 , S_1 , S_2 are computed from a conventional optimization subroutine, so as to yield the least-squares fit to the actual measured data. The Bessel function approximation needs four coefficients to give a good fit to the TWT nonlinearity, up to and beyond saturation. Note that for large input power values, the formulas approach certain constants.

3.6. Rational Functions: Saleh's Model

A very comprehensive work was published by Saleh [24] for both A-P and I-Q representations. The model presented by Saleh is widely used in the literature. It is a frequency-independent model and can be made frequency-dependent by adding filters that reflect the frequency selectivity:

A-P Representation. The AM/AM and AM/PM curves are modeled as

$$A(r) = \frac{\alpha_a r}{1 + \beta_a r^2} \quad (18)$$

$$\phi(r) = \frac{\alpha_p r^2}{1 + \beta_p r^2} \quad (19)$$

Note that for a large value of r , $A(r)$ is proportional to $1/r$ and $\phi(r)$ approaches a constant.

I-Q Representation. The in-phase and quadrature curves are modeled as follows:

$$P(r) = \frac{\alpha_P r}{1 + \beta_P r^2} \quad (20)$$

$$Q(r) = \frac{\alpha_Q r^3}{(1 + \beta_Q r^2)^2} \quad (21)$$

Note that for a large value of r , both $P(r)$ and $Q(r)$ are proportional to $\frac{1}{r}$.

Saleh used a minimum mean-square-error (MMSE) procedure for fitting the formulas to the experimental data. With only two parameters, this is the most widely used model for TWT amplifiers in the literature. Note that, for high input power signals, $A(r)$ and $\phi(r)$ approach $\alpha_a/\beta_a r$ and α_p/β_p , respectively. Therefore, this model is suited for amplifiers that have these specific asymptotic behaviors.

4. NEURAL NETWORKS FOR MODELING MEMORYLESS TWT AMPLIFIERS

This section employs multilayer neural networks [8] to model TWT amplifiers. The main advantage of NN models over classical models is that they offer better MSE approximation performance than do classical TWT models [12]. NNs are adaptive, which makes them appropriate for online modeling. Classical models are based on offline optimization procedures that do not allow online modeling. Moreover, NNs can model a variety of nonlinear amplifiers using the same parametrized structure (e.g., a structure with five neurons). Only the NN weight values change from one TWT model to another. On the contrary, most classical models have been designed for specific families of TWT amplifiers (e.g., TWTs having a given asymptotic behavior). Therefore, they may not always be appropriate for emerging generations of TWT and SSP amplifiers.

4.1. NN Structure and Learning Algorithms:

Figure 5 shows the modeling scheme of a TWT characteristic using a two-layer neural network (NN) [10]. The NN has a scalar input, M neurons in the first layer, and a scalar output. A set of input-output data (collected from the physical TWT measurements, or from the transmission channel input-output signals) is presented to the NN. The network output at time n is expressed as

$$s(n) = \sum_{k=1}^M c_k f(w_k x(n) + b_k) \quad (22)$$

where $x(n)$ is the input sample at time n and f is the activation function (which is taken in this article as the hyperbolic tangent function); $\{w_k\}$, $\{b_k\}$, and $\{c_k\}$, $k = 1, \dots, M$, are the NN weights. We denote the vector containing the network weights by θ : $\theta = [w_1, \dots, w_M, b_1, \dots, b_M, c_1, \dots, c_M]^T$ where $(\cdot)^T$ denotes the transpose.

To perform the modeling task, the NN weights are updated using a learning algorithm that minimizes the squared error between the TWT output and the NN outputs

$$J(n) = \frac{1}{2} \|e(n)\|^2 \quad (23)$$

where

$$e(n) = y(n) + N_0(n) - s(n) \quad (24)$$

where $y(n)$ is the TWT output and $N_0(n)$ is a zero-mean white Gaussian noise with variance σ^2 .

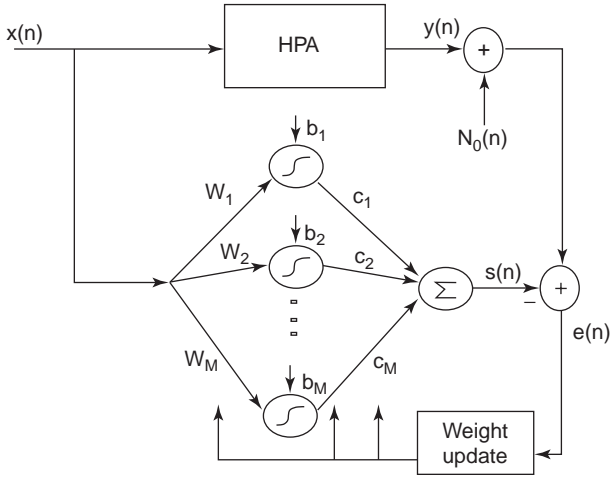

Figure 5. NN adaptive modeling of a nonlinear TWT amplifier.

In the following, we present two approaches to update the NN weights: the classical backpropagation (BP) algorithm and natural gradient (NG) algorithm.

The BP algorithm follows the ordinary gradient descent to update the weight vector θ :

$$\theta(n+1) = \theta(n) - \mu \nabla_{\theta}(J(n)) \quad (25)$$

where μ is a small positive constant, and ∇_{θ} is the ordinary gradient with respect to θ :

$$\nabla_{\theta}(J(n)) = -e(n) \cdot \nabla_{\theta} s(n) \quad (26)$$

$$= -e(n) \cdot \begin{pmatrix} x(n)c_1 f'(w_1 x(n) + b_1) \\ \vdots \\ x(n)c_M f'(w_M x(n) + b_M) \\ f(w_1 x(n) + b_1) \\ \vdots \\ f(w_M x(n) + b_M) \\ c_1 f'(w_1 x(n) + b_1) \\ \vdots \\ c_M f'(w_M x(n) + b_M) \end{pmatrix}$$

The NG algorithm follows the steepest-descent direction of the loss function, which is given by [1]

$$-\tilde{\nabla}_{\theta} J(n) = -G^{-1} \nabla_{\theta} J(n) \quad (27)$$

where G^{-1} is the inverse of the Fisher information matrix (FIM):

$$G = [g_{ij}(\theta)] = \left[E \left(\frac{\partial J(n)}{\partial \theta_i} \frac{\partial J(n)}{\partial \theta_j} \right) \right] \quad (28)$$

Therefore, the NG algorithm adjusts the NN weights as follows:

$$\theta(n+1) = \theta(n) - \mu G^{-1} \nabla_{\theta}(J(n)) \quad (29)$$

The calculation of the expectations in the FIM requires knowledge of the probability distribution functions (pdf values) of x and s , which are not always available. Moreover, the calculation of the inverse of the FIM is computationally very costly. A modified Kalman filter technique has been proposed [1] for an online estimation of the FIM inverse

$$\hat{G}^{-1}(n+1) = (1 + \varepsilon_n) \hat{G}^{-1}(n) - \varepsilon_n \hat{G}^{-1}(n) \nabla_{\theta} s(n) (\nabla_{\theta} s(n))^t \hat{G}^{-1}(n) \quad (30)$$

where $\nabla_{\theta} s(n)$ is the ordinary gradient of s [see Eq. (26)], and ε_n is a positive updating rate. The choice of ε_n depends on how fast/stable the algorithm is desired to be. For example, if $\varepsilon_n = c_e/n$ (where c_e is a small positive constant), then Kalman filtering is equivalent to an online calculation of the arithmetic mean. However, when ε_n is a constant, the convergence is faster but the algorithm may be less stable.

In order to reach a good tradeoff between convergence speed and stability, we will use a search-and-converge method in which ε_n is defined by

$$\varepsilon_n = \frac{\varepsilon_0 + \frac{c_e n}{\tau}}{1 + \frac{c_e n}{\tau \varepsilon_0} + \frac{n^2}{\tau}} \quad (31)$$

where τ is a positive time constant, and ε_0 is a small positive constant. Here, small n corresponds to a “search” phase (where ε_n is close to ε_0), and large n corresponds to a “converge” phase (ε_n is equivalent to c_e/n).

Simulation Example 1. Here, a neural network composed of $M = 5$ neurons is used to model the AM/AM characteristic of a TWT amplifier. The NG and the BP algorithms are compared. The simulations show that the value of $\mu = 0.005$ represents a good tradeoff (for each algorithm) between convergence speed and stability. Figure 6a shows the learning curve for each algorithm. It can be seen that the NG descent has a much faster convergence. The resulting MSE approximation performances are 9×10^{-6} and 3.0×10^{-5} for the NG and BP algorithms, respectively. Figure 6b illustrates the resulting AM/AM models and the original TWT input–output data that have been used for learning. Note that, for this amplifier, classical models such as Saleh [24] and Thomas [27] expressions give 1.4×10^{-4} and 2.0×10^{-4} as MSE errors, respectively. Therefore, the NG approach outperforms both the classical models and the BP algorithm. For asymptotic behavior, NN models approach a constant (due to the shape of the neuron activation function), which is desirable in TWT modeling as it ensures stability for high input power fluctuations. The desired asymptotic constant can be included as an additional constraint value during the learning process. Finally, the odd and even BP algorithms can be employed (if needed by the user to ensure strict even

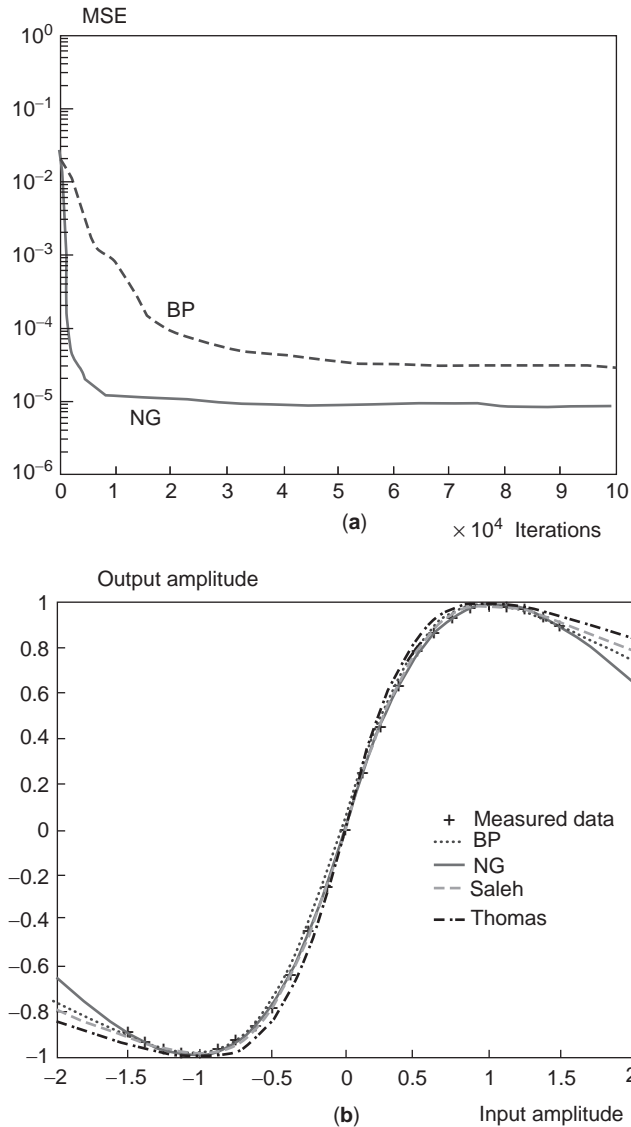

Figure 6. Modeling the AM/AM conversion of Intelsat IV TWT amplifier: (a) learning curves of the BP and NG algorithms; (b) comparison between the different models. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

or odd characteristics) [10]. See Table 1 for additional computer simulation results.

5. MODELING AND IDENTIFICATION OF NONLINEAR AMPLIFIERS WITH MEMORY

As discussed above, some nonlinear amplifiers may contain a memory that cannot be neglected. Moreover, the

transmission channel may also be considered as a nonlinear system with memory. This is because the uplink and downlink channels may introduce some memory because of thermal and electrical effects, multi-path propagation, or other filtering processes in the channel [15]. Several approaches, including those discussed below, have been proposed in the literature to model nonlinear amplifiers with memory.

5.1. Volterra Model

In the Volterra model, the input–output relationship is expressed as follows

$$\begin{aligned}
 y(t) = & h_0 + \int_{-\infty}^{+\infty} h_1(\tau_1)x(t - \tau_1)d\tau_1 \\
 & + \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} h_2(\tau_1, \tau_2)x(t - \tau_1) \\
 & \times x(t - \tau_2)d\tau_1d\tau_2 \\
 & + \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} h_3(\tau_1, \tau_2, \tau_3)x(t - \tau_1) \\
 & \times x(t - \tau_2)x(t - \tau_3)d\tau_1d\tau_2d\tau_3 + \dots
 \end{aligned} \tag{32}$$

where the Volterra kernels $\{h_1(\tau_1), h_2(\tau_1, \tau_2), h_3(\tau_1, \tau_2, \tau_3), \dots\}$ have to be obtained through an optimization or adaptive procedure.

Volterra series can approximate nonlinear amplifier characteristics [3,16,28,30] and predistortion devices [3,6,16] relatively well. The major drawback of this model is its complexity, which increases immensely with the length of the memory and the order of the nonlinearity.

5.2. Wiener Model (Filter–Memoryless Nonlinearity or Two-Box Model)

In this model, the amplifier is modeled by a linear filter followed by a memoryless nonlinearity (Fig. 7). This model is very simple and can provide a good approximation of the memory and the nonlinearity. The characterization of the filter and nonlinearity can be made through adaptive or optimization procedures [11,24].

5.3. Wiener–Hammerstein Model (Three-Box Model)

The amplifier is modeled by a linear filter followed by a memoryless nonlinearity followed by a linear filter (Fig. 8). This model has been shown to accurately predict intermodulation products and yield excellent characterization of several TWT and SSP amplifier behaviors. The different boxes can be determined through measurement and data processing [5], or they can be determined

Table 1. MSE Performance of Different Models for Approximation of I-Q and A-P TWT Characteristics

Characteristic	BP NN	NG NN	Saleh [24]	Hetrakul–Taylor [9]	Thomas et al. [27]	Berman and Mahle [2]
In-phase	6.1×10^{-3}	2.6×10^{-4}	3.20×10^{-3}	3.30×10^{-3}	—	—
Quadrature	6.2×10^{-3}	2.7×10^{-4}	5.20×10^{-4}	1.60×10^{-3}	—	—
AM/AM	3.0×10^{-5}	9.0×10^{-6}	1.40×10^{-4}	—	2.00×10^{-4}	—
AM/PM	8.1×10^{-5}	3.2×10^{-6}	1.38×10^{-4}	—	—	8.00×10^{-4}

Figure 7. Wiener model.

adaptively (e.g., using neural networks and adaptive filtering) [11]. In this model, a physical interpretation of the different parts of the model can be easily made. This leads to an easy design and optimization of communication system (predistortion, equalization, IMD calculation, etc.).

5.4. Parallel Wiener Model

This model is composed of several parallel Wiener blocks that are summed together to yield the output. These models are more complicated than the two-box and the three-box models, but may yield better accuracy if the nonlinearity is complicated [19].

5.5. Memory Polynomial

The memory polynomial model (see Fig. 9) is composed of a cascade of polynomials separated by unit delays. The output can be expressed in discrete time as

$$y(n) = \sum_{k=0}^L F_k(x(n-k)) \tag{33}$$

where $F_k(x)$ is the k^{th} polynomial.

An extension of this model has been proposed in Ref. 20, allowing the unit delays to be sparse delay taps. This allows longer-time-constant memory effects to be modeled in parallel with short-time-constant effects using fewer parameters. The different parameters in this model can be characterized using an adaptive sliding-window approach.

The following section details the Wiener modeling approach using neural networks and adaptive filtering.

6. WIENER MODELING USING ADAPTIVE FILTERING AND NEURAL NETWORKS

The nonlinear channel to be modeled in this section is a nonlinear Wiener system composed of a linear filter $H(z) = \sum_{k=0}^{N_h-1} h_k z^{-k}$ followed by a zero-memory amplitude nonlinearity $g(\cdot)$ (Fig. 10). The phase nonlinearity is not considered in this section, but it can easily be included in the scheme with small changes to the algorithm [11,13,14].

The nonlinear system output signal is corrupted by a zero-mean additive white Gaussian noise (AWGN) $N_0(n)$. It can be expressed at time n as

$$d(n) = y(n) + N_0(n)$$

Figure 8. Wiener-Hammerstein model (three-box model).

Figure 9. Memory polynomial model.

where

$$y(n) = g\left(\sum_{k=0}^{N_h-1} h_k x(n-k)\right) \tag{34}$$

The NN model (Fig. 10) is composed of an adaptive filter, $Q(z) = \sum_{k=0}^{N_q-1} q_k z^{-k}$, followed by a two-layer (zero-memory) adaptive neural network. The two-layer NN is composed of a scalar (real-valued) input, M neurons in the input layer, and a scalar output.

The adaptive structure has two goals:

1. Identify the linear filter H by the adaptive filter Q .
2. Model the nonlinearity $g(\cdot)$ by the zero-memory nonlinear NN.

The learning is performed by using the input-output signals only (i.e., we consider the unknown nonlinear system as a blackbox).

The NN output at time n is expressed as

$$\begin{aligned} s(n) &= \sum_{k=1}^M c_k f\left(w_k \sum_{i=0}^{N_q-1} q_i x(n-i) + b_k\right) \\ &= \sum_{k=1}^M c_k f(w_k Q^t X(n) + b_k) \end{aligned} \tag{35}$$

where $\{w_k\}$, $\{b_k\}$, and $\{c_k\}$ (where $k=1, \dots, M$) are the NN weights, $Q = [q_0 \ q_1 \ \dots \ q_{N_q-1}]^T$, and $X(n) = [x(n) \ x(n-1) \ \dots \ x(n-N_Q+1)]^T$.

The network and filter parameters are updated in order to minimize the loss function J_n (or squared error) between the system output and the NN output

$$J(n) = \frac{1}{2} \|e(n)\|^2 \tag{36}$$

where

$$e(n) = d(n) - s(n) \tag{37}$$

We denote the system parameter vector to be updated by $\theta = [w_1 w_2 \dots w_M b_1 b_2 \dots b_M c_1 c_2 \dots c_M q_0 q_1 \dots q_{N_q-1}]^T$. The BP and NG approaches that can be used to update the system are

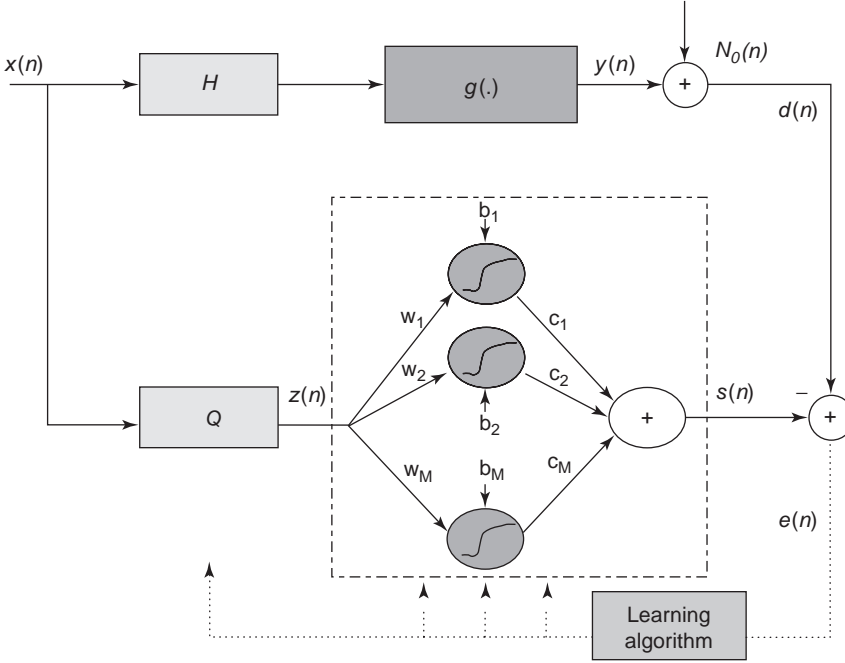

Figure 10. Neural network modeling and identification structure.

BP Algorithm. The BP algorithm updates the weights according to the ordinary gradient descent

$$\theta(n+1) = \theta(n) - \mu \nabla_{\theta} J(n) \quad (38)$$

where μ is a small positive constant, and ∇_{θ} represents the ordinary gradient with respect to vector θ , which is expressed as

$$\nabla_{\theta} J(n) = -e(n) \nabla_{\theta} s(n) \quad (39)$$

where

$$\nabla_{\theta} s(n) = \begin{pmatrix} c_1 \mathbf{Q}^t \mathbf{X}(n) f'(w_1 \mathbf{Q}^t \mathbf{X}(n) + b_1) \\ \vdots \\ c_M \mathbf{Q}^t \mathbf{X}(n) f'(w_M \mathbf{Q}^t \mathbf{X}(n) + b_M) \\ c_1 f'(w_1 \mathbf{Q}^t \mathbf{X}(n) + b_1) \\ \vdots \\ c_M f'(w_M \mathbf{Q}^t \mathbf{X}(n) + b_M) \\ f(w_1 \mathbf{Q}^t \mathbf{X}(n) + b_1) \\ \vdots \\ f(w_M \mathbf{Q}^t \mathbf{X}(n) + b_M) \\ x(n) \sum_{k=1}^M c_k w_k f'(w_k \mathbf{Q}^t \mathbf{X}(n) + b_k) \\ \vdots \\ x(n - N_Q + 1) \sum_{k=1}^M c_k w_k f'(w_k \mathbf{Q}^t \mathbf{X}(n) + b_k) \end{pmatrix} \quad (40)$$

where f' denotes the first derivative of f .

The NG Algorithm. The NN weights are updated according to the NG descent

$$\theta(n+1) = \theta(n) - \mu \tilde{\nabla}_{\theta} J(n) \quad (41)$$

where $\tilde{\nabla}_{\theta}$ represents the NG

$$-\tilde{\nabla}_{\theta} J(n) = -\Gamma^{-1} \nabla_{\theta} J(n)$$

where Γ^{-1} is the FIM inverse:

$$\Gamma = [\gamma_{i,j}] = \left[E \left(\frac{\partial J(n)}{\partial \theta_i} \frac{\partial J(n)}{\partial \theta_j} \right) \right] \quad (42)$$

Here again, the FIM can be approximated online using a modified Kalman technique

$$\hat{\Gamma}^{-1}(n+1) = (1 + \varepsilon_n) \hat{\Gamma}^{-1}(n) - \varepsilon_n \hat{\Gamma}^{-1}(n) \times \nabla_{\theta} s(n) (\nabla_{\theta} s(n))^t \hat{\Gamma}^{-1}(n) \quad (43)$$

where $\nabla_{\theta} s(n)$ is the (ordinary) gradient of $s(n)$ [see Eq. (40)].

Simulation Example 2. For the unknown structure to be identified, the following amplitude nonlinearity is taken:

$$g(x) = \frac{\alpha x}{1 + \beta x^2}, \quad \alpha = 2, \quad \beta = 1$$

The input signal has been taken as a white Gaussian sequence with variance 1 and filter H is taken as $H = [1.49 \ 1.36 \ 1.07 \ 0.67 \ 0.27 \ -0.057 \ -0.263 \ -0.325 \ -0.263 \ -0.125]^T$. The noise variance is $\sigma = 0.002$ and the learning rate is fixed to $\mu = 0.007$.

Filter Q is composed of 10 weights that have been initialized with 0 values. The NN is composed of $M = 5$ neurons. Figure 11 displays the learning curves of the BP and NG algorithms. The NG algorithm is faster and yields a lower MSE than does the BP algorithm (the MSE after

Figure 11. MSE learning curve for identification of the filter nonlinearity model. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

convergence equals 5×10^{-5} for the NG and 5.5×10^{-4} for the BP.

Figure 12 shows the frequency responses of the exact filter and the models obtained through the BP and NG algorithms, respectively. The frequency responses of the models are scaled versions of the exact filter frequency response. The amplitude conversion model obtained by the memoryless NN compensates for the scaling factor introduced by the adaptive filter. Figure 13 shows the AM/AM curves obtained through the NG and BP algorithms, respectively, which fit very well with the exact nonlinearity.

One major advantage of this NN adaptive approach is that it allows one to identify (or extract) the memoryless nonlinearity and estimate the memory of the amplifier, even in the case where the amplifier is not physically composed of separated blocks (i.e., a linear filter followed by a memoryless nonlinearity).

In Ref. 11, an adaptive structure composed of an adaptive filter, followed by a memoryless NN followed by an adaptive filter, has been used to characterize an SSP amplifier using physical measured data. The adaptive structure was able to extract the amplifier memoryless nonlinearity and characterize its frequency response. See also Refs. 7, 23, and 29 for other NN and adaptive

approaches used to efficiently model, identify, simulate, and characterize nonlinear microwave circuits with memory.

1. LINEAR ANISOTROPY AND BIANISOTROPY

Free space or vacuum is isotropic. Its electromagnetic response characteristics are contained in the frequency-domain constitutive relations

$$\left. \begin{aligned} \underline{D}(\underline{r}, \omega) &= \varepsilon_0 \underline{E}(\underline{r}, \omega) \\ \underline{H}(\underline{r}, \omega) &= \mu_0^{-1} \underline{B}(\underline{r}, \omega) \end{aligned} \right\} \quad (1)$$

wherein \underline{r} is the position vector and ω is the angular frequency. The induction field phasors $\underline{D}(\underline{r}, \omega)$ and $\underline{H}(\underline{r}, \omega)$ are scalar multiples of the primitive field phasors $\underline{E}(\underline{r}, \omega)$ and $\underline{B}(\underline{r}, \omega)$, respectively. The constants of proportionality—the permittivity $\varepsilon_0 = 8.854 \times 10^{-12}$ F/m and the permeability $\mu_0 = 4\pi \times 10^{-7}$ H/m of free space—are fundamental to the structure of modern electromagnetic theory [1].

The dielectric media that students are introduced to in their first electromagnetism course are also isotropic, with

$$\left. \begin{aligned} \underline{D}(\underline{r}, \omega) &= \varepsilon(\omega) \underline{E}(\underline{r}, \omega) \\ \underline{H}(\underline{r}, \omega) &= \mu_0^{-1} \underline{B}(\underline{r}, \omega) \end{aligned} \right\} \quad (2)$$

as the constitutive relations. The permittivity scalar ε must be complex-valued and frequency-dependent due to causality. Isotropic magnetic media are described by the constitutive relations

$$\left. \begin{aligned} \underline{D}(\underline{r}, \omega) &= \varepsilon_0 \underline{E}(\underline{r}, \omega) \\ \underline{H}(\underline{r}, \omega) &= \mu^{-1}(\omega) \underline{B}(\underline{r}, \omega) \end{aligned} \right\} \quad (3)$$

wherein the permeability scalar μ is frequency-dependent and complex-valued. Electromagnetically, the most complex of all isotropic media are the isotropic chiral media [2] whose constitutive relations

$$\left. \begin{aligned} \underline{D}(\underline{r}, \omega) &= \varepsilon(\omega) \underline{E}(\underline{r}, \omega) + \chi(\omega) \underline{B}(\underline{r}, \omega) \\ \underline{H}(\underline{r}, \omega) &= \mu^{-1}(\omega) \underline{B}(\underline{r}, \omega) + \chi(\omega) \underline{E}(\underline{r}, \omega) \end{aligned} \right\} \quad (4)$$

employ three complex-valued scalars: ε , μ , and χ .

The induction and the primitive field phasors are aligned in all linear isotropic media, because the constants of proportionality in Eqs. (1)–(4) are scalars. In contrast, the macroscopic properties of anisotropy and bianisotropy denote the directionality of the primitive field phasors relative to the induction field phasors. Specifically, a medium is termed *dielectrically anisotropic* if $\underline{D}(\underline{r}, \omega)$ is not aligned with $\underline{E}(\underline{r}, \omega)$, and *magnetically anisotropic* if $\underline{H}(\underline{r}, \omega)$ is not aligned with $\underline{B}(\underline{r}, \omega)$. In a linear dielectric-magnetic medium, the field phasors are related in the frequency-domain constitutive relations¹

$$\left. \begin{aligned} \underline{D}(\underline{r}, \omega) &= \underline{\varepsilon}(\omega) \cdot \underline{E}(\underline{r}, \omega) \\ \underline{B}(\underline{r}, \omega) &= \underline{\mu}(\omega) \cdot \underline{H}(\underline{r}, \omega) \end{aligned} \right\} \quad (5)$$

by the 3×3 dyadics (i.e., second-rank Cartesian tensors) of permittivity $\underline{\varepsilon}$ and permeability $\underline{\mu}$. Any $n \times n$ dyadic can be interpreted as a $n \times n$ matrix throughout this article [3, Chapter 1].

Many examples of anisotropic dielectric media arise in the context of crystal optics [4,5]. The uniaxial and orthorhombic biaxial crystals, which may be characterized by the permittivity dyadics

$$\underline{\varepsilon}_{\text{uni}}(\omega) = \varepsilon_{11}(\omega) \underline{\hat{x}\hat{x}} + \underline{\hat{y}\hat{y}} + \varepsilon_{33}(\omega) \underline{\hat{z}\hat{z}} \quad (6)$$

and

$$\underline{\varepsilon}_{\text{ortho}}(\omega) = \varepsilon_{11}(\omega) \underline{\hat{x}\hat{x}} + \varepsilon_{22}(\omega) \underline{\hat{y}\hat{y}} + \varepsilon_{33}(\omega) \underline{\hat{z}\hat{z}} \quad (7)$$

respectively, are widely studied; here and hereafter, the Cartesian unit vectors are denoted by $\underline{\hat{x}}$, $\underline{\hat{y}}$, and $\underline{\hat{z}}$. Nematic and smectic liquid crystals are also described by Eqs. (6) and (7), respectively [6,7]. Permeability dyadics with forms analogous to (6) and (7) may be employed to describe diamagnetic and paramagnetic crystals [5]. An important noncrystalline example of anisotropic dielectric behavior is provided by an electron plasma in thermal motion, biased by a static magnetic field [3, Chapter 7]. The corresponding permittivity dyadic has the gyrotropic form

$$\underline{\varepsilon}_{\text{gyro}}(\omega) = \varepsilon_{11}(\omega) (\underline{\hat{x}\hat{x}} + \underline{\hat{y}\hat{y}}) + \varepsilon_{33}(\omega) \underline{\hat{z}\hat{z}} + \varepsilon_{12}(\omega) (\underline{\hat{x}\hat{y}} - \underline{\hat{y}\hat{x}}) \quad (8)$$

¹It is convenient for the solution of boundary-value problems in engineering practice to interchange the roles of $\underline{B}(\underline{r}, \omega)$ and $\underline{H}(\underline{r}, \omega)$ in frequency-domain constitutive relations.

when the biasing magnetostatic field is oriented parallel to $\underline{\hat{z}}$. Magnetically biased ferrites may be characterized in terms of a permeability dyadic analogous to the $\underline{\varepsilon}_{\text{gyro}}$ of (8) [3, Chapter 7].

The generalization from anisotropy to bianisotropy is achieved through the introduction of the magnetoelectric dyadics $\underline{\zeta}(\omega)$ and $\underline{\xi}(\omega)$; thereby, the bianisotropic constitutive relations emerge as [8,9]

$$\left. \begin{aligned} \underline{D}(\underline{r}, \omega) &= \underline{\varepsilon}(\omega) \cdot \underline{E}(\underline{r}, \omega) + \underline{\zeta}(\omega) \cdot \underline{H}(\underline{r}, \omega) \\ \underline{B}(\underline{r}, \omega) &= \underline{\zeta}(\omega) \cdot \underline{E}(\underline{r}, \omega) + \underline{\mu}(\omega) \cdot \underline{H}(\underline{r}, \omega) \end{aligned} \right\} \quad (9)$$

If a particular medium is nonhomogeneous, its constitutive dyadics are functions of the position vector \underline{r} ; thus, the nonhomogeneous counterparts of (9) are as follows:

$$\left. \begin{aligned} \underline{D}(\underline{r}, \omega) &= \underline{\varepsilon}(\underline{r}, \omega) \cdot \underline{E}(\underline{r}, \omega) + \underline{\zeta}(\underline{r}, \omega) \cdot \underline{H}(\underline{r}, \omega) \\ \underline{B}(\underline{r}, \omega) &= \underline{\zeta}(\underline{r}, \omega) \cdot \underline{E}(\underline{r}, \omega) + \underline{\mu}(\underline{r}, \omega) \cdot \underline{H}(\underline{r}, \omega) \end{aligned} \right\} \quad (10)$$

In the remainder of this article, unless stated otherwise, homogeneity is assumed.

The most commonplace example of bianisotropy arises when a linear isotropic dielectric and/or magnetic medium rigidly attached to a constantly moving reference frame is considered from a stationary reference frame. From the perspective of a stationary observer, the moving medium is bianisotropic [3,10]. Thus, if an isotropic dielectric-magnetic medium with permittivity ε and permeability μ is traveling with uniform velocity \underline{v} , then the constitutive dyadics of the moving medium from the perspective of a stationary observer are

$$\left. \begin{aligned} \underline{\varepsilon}_{\text{mov}} &= \varepsilon [\alpha \underline{I} + (1 - \alpha) \underline{\hat{v}\hat{v}}] \\ \underline{\zeta}_{\text{mov}} &= \beta \underline{\hat{v}} \times \underline{I} \\ \underline{\zeta}_{\text{mov}} &= -\beta \underline{\hat{v}} \times \underline{I} \\ \underline{\mu}_{\text{mov}} &= \mu [\alpha \underline{I} + (1 - \alpha) \underline{\hat{v}\hat{v}}] \end{aligned} \right\} \quad (11)$$

where $\underline{I} = \underline{\hat{x}\hat{x}} + \underline{\hat{y}\hat{y}} + \underline{\hat{z}\hat{z}}$ denotes the 3×3 identity dyadic and

$$\alpha = \frac{1 - \varepsilon_0 \mu_0 |\underline{v}|^2}{1 - \varepsilon \mu |\underline{v}|^2}, \quad \beta = \frac{|\underline{v}| (\varepsilon \mu - \varepsilon_0 \mu_0)}{1 - \varepsilon \mu |\underline{v}|^2}, \quad \underline{\hat{v}} = \frac{1}{|\underline{v}|} \underline{v} \quad (12)$$

More exotic examples of bianisotropy arise from direct generalizations of the anisotropic forms (6)–(8). For example, (7) leads to the conceptualization of the orthorhombic biaxial bianisotropic form [11,12]

$$\underline{\gamma}_{\text{ortho}} = \gamma_{11} \underline{\hat{x}\hat{x}} + \gamma_{22} \underline{\hat{y}\hat{y}} + \gamma_{33} \underline{\hat{z}\hat{z}}, \quad (\gamma = \varepsilon, \xi, \zeta, \mu) \quad (13)$$

Media described by the gyrotropic form (8), when mixed with isotropic chiral media [2] and homogenized, give rise to the class of bianisotropic media known as *Faraday chiral media* (FCM) [13,14]. These are described by the constitutive dyadics

$$\underline{\gamma}_{\text{FCM}} = \gamma_{11} (\underline{\hat{x}\hat{x}} + \underline{\hat{y}\hat{y}}) + \gamma_{33} \underline{\hat{z}\hat{z}} + \gamma_{12} (\underline{\hat{x}\hat{y}} - \underline{\hat{y}\hat{x}}), \quad (14)$$

$$(\gamma = \varepsilon, \xi, \zeta, \mu)$$

with $\underline{\xi}_{\text{FCM}} = -\underline{\zeta}_{\text{FCM}}$.

Artificial bianisotropic media have been fabricated since at least the 1890s, when Bose [15] reported experimental results on the passage of microwaves through an ensemble of jute spirals. But the fabrication of artificial bianisotropic media intensified only about a century later, following renewal of interest in chirality [2]. Electrically small wire structures with twists have to be represented by both electric and magnetic dipoles, insofar as scattering is concerned [16]. Hence, ensembles of twisted wires—which can be fabricated in many ways [17,18]—are effectively bianisotropic continua at sufficiently low frequencies.

In the most general linear scenario, each of the four constitutive dyadics $\underline{\underline{\varepsilon}}$, $\underline{\underline{\zeta}}$, $\underline{\underline{\xi}}$, and $\underline{\underline{\mu}}$ contains nine complex-valued scalars; in matrix notation, we obtain

$$\underline{\underline{\gamma}} = \begin{pmatrix} \gamma_{11} & \gamma_{12} & \gamma_{13} \\ \gamma_{21} & \gamma_{22} & \gamma_{23} \\ \gamma_{31} & \gamma_{32} & \gamma_{33} \end{pmatrix}, \quad (\gamma = \varepsilon, \zeta, \xi, \mu) \quad (15)$$

However, for consistency with the special theory of relativity, all linear media must satisfy the Post constraint [19,20]

$$\text{Trace} \left[(\underline{\underline{\mu}})^{-1} \cdot (\underline{\underline{\zeta}} + \underline{\underline{\xi}}) \right] = 0 \quad (16)$$

Hence, a maximum of 35 independent, complex-valued, frequency-dependent parameters are needed to characterize a bianisotropic medium. The number of parameters may be further reduced by imposing conditions such as Lorentz reciprocity [21]

$$\underline{\underline{\varepsilon}} = \underline{\underline{\varepsilon}}^T, \quad \underline{\underline{\zeta}} = -\underline{\underline{\zeta}}^T, \quad \underline{\underline{\mu}} = \underline{\underline{\mu}}^T \quad (17)$$

where the superscript ^T denotes the *transpose*. Also, if the effects of dissipation are neglected, then the approximation [3, Section 2.5]

$$\underline{\underline{\varepsilon}} = \underline{\underline{\varepsilon}}^+, \quad \underline{\underline{\zeta}} = \underline{\underline{\zeta}}^+, \quad \underline{\underline{\mu}} = \underline{\underline{\mu}}^+ \quad (18)$$

may be implemented, with the superscript ⁺ indicating the *conjugate transpose*.

2. POINT GROUPS FOR LINEAR CONSTITUTIVE DYADICS

The specific form of the constitutive dyadics of a medium reflects the spacetime symmetry of the underlying medium physics. In particular, it is the *point group symmetry* of the anisotropic or bianisotropic medium that determines the form of Eq. (15) [22]. Each point group consists of all those space, time and spacetime transformations that bring the medium into self-coincidence. The number of different point groups is 122. These are conventionally divided into the three classes [23,24]: G_1 and G_2 containing 32 point groups each, and G_3 containing 58 point groups. Class G_1 describes those media which are invariant under the time-reversal operation. Lorentz-reciprocal media (17), including anisotropic diamagnetic and paramagnetic media, belong to G_1 . The 32 point groups of G_1 give rise to the seven classical crystallographic systems—

triclinic, monoclinic, orthorhombic, tetragonal, trigonal, hexagonal and cubic [5]—whose point groups and associated constitutive dyadic forms are listed in Table 1. (The 230 *space groups* corresponding to the 32 point groups of G_1 —which specify the symmetry elements of the underlying Bravais lattice—may be found in standard sources such as Ref. 25. The class G_2 does not contain the time reversal operation, whereas point groups of G_3 contain the time-reversal operation in combination with rotation–reflection operations. The classes G_2 and G_3 describe magnetic media (ferromagnetics, antiferromagnetics and ferrimagnetics [23]) and the most general bianisotropic media [26]. The 90 point groups belonging to G_2 and G_3 , together with their corresponding constitutive dyadic forms, are cataloged elsewhere [22,24].

3. PLANE-WAVE PROPAGATION

In the frequency domain, the source-free Maxwell curl postulates are given as [3]

$$\left. \begin{aligned} \nabla \times \underline{\underline{H}}(\underline{\underline{r}}, \omega) + i\omega \underline{\underline{D}}(\underline{\underline{r}}, \omega) &= \underline{\underline{0}} \\ \nabla \times \underline{\underline{E}}(\underline{\underline{r}}, \omega) - i\omega \underline{\underline{B}}(\underline{\underline{r}}, \omega) &= \underline{\underline{0}} \end{aligned} \right\} \quad (19)$$

wherein an $\exp(-i\omega t)$ time dependency has been assumed for the field phasors. The combination of (19) with the bianisotropic constitutive relations (9) yields a self-consistent system of differential equations that may be conveniently expressed in six-vector/dyadic notation as

$$[\underline{\underline{L}}(\nabla) + i\omega \underline{\underline{K}}(\omega)] \cdot \underline{\underline{F}}(\underline{\underline{r}}, \omega) = \underline{\underline{0}} \quad (20)$$

The linear differential operator $\underline{\underline{L}}(\nabla)$ and 6×6 constitutive dyadic $\underline{\underline{K}}(\omega)$ have the representations

$$\underline{\underline{L}}(\nabla) = \begin{bmatrix} \underline{\underline{0}} & \nabla \times \underline{\underline{I}} \\ -\nabla \times \underline{\underline{I}} & \underline{\underline{0}} \end{bmatrix}, \quad \underline{\underline{K}}(\omega) = \begin{bmatrix} \underline{\underline{\varepsilon}}(\omega) & \underline{\underline{\zeta}}(\omega) \\ \underline{\underline{\xi}}(\omega) & \underline{\underline{\mu}}(\omega) \end{bmatrix} \quad (21)$$

and the 6-vector electromagnetic field phasor $\underline{\underline{F}}(\underline{\underline{r}}, \omega)$ is defined as

$$\underline{\underline{F}}(\underline{\underline{r}}, \omega) = \begin{bmatrix} \underline{\underline{E}}(\underline{\underline{r}}, \omega) \\ \underline{\underline{H}}(\underline{\underline{r}}, \omega) \end{bmatrix} \quad (22)$$

Eigenanalysis of the system

$$[\underline{\underline{L}}(i\mathbf{k}) + i\omega \underline{\underline{K}}(\omega)] \cdot \underline{\underline{F}}_0 = \underline{\underline{0}} \quad (23)$$

is very fruitful for the development of plane-wave solutions

$$\underline{\underline{F}}(\underline{\underline{r}}, \omega) = \underline{\underline{F}}_0 \exp(i\mathbf{k} \cdot \underline{\underline{r}}) \quad (24)$$

of (20), where \mathbf{k} is the wavevector. In general, the associated dispersion relation

$$\det[\underline{\underline{L}}(i\mathbf{k}) + i\omega \underline{\underline{K}}(\omega)] = 0 \quad (25)$$

provides a polynomial of degree four in the components of \mathbf{k} . While the derivation of the roots \mathbf{k} of (25) and the

Table 1. The 32 Point Groups of G_1 in the International Notation^a

Medium Type	Crystal System	Point Group	Constitutive Dyadic Form	Number of real-valued scalars

^aThe conventional constitutive dyadic forms are also listed [5]; therein, c_n denotes a complex-valued constitutive parameter whereas r_n denotes a real-valued constitutive parameter. Source: Ref. 23.

associated eigenvectors \mathbf{F}_0 is mathematically straightforward, it is a task best undertaken with the aid of a symbolic manipulation package because the process involves unwieldy expressions.

Propagation in a direction parallel to the unit vector $\hat{\mathbf{a}}$ requires determination of the wavenumber k , which is the magnitude of the wavevector $\underline{\mathbf{k}} = k\hat{\mathbf{a}}$. In general, two distinct complex-valued solutions—say, k_1 and k_2 —emerge for every $\hat{\mathbf{a}}$. This phenomenon is known as *birefringence*, and every anisotropic/bianisotropic medium is generally birefringent. The difference between the real parts of k_1 and k_2 gives rise to optical rotation, which is the change in the tilt angle of the vibration ellipse of a plane wave on either reflection from or transmission through a birefringent layer. This phenomenon is commonly exploited in the construction of optical waveplates, polarizers, and prisms [4, Chapter 14], as well as microwave gyrators, isolators, and circulators [27, Section 6.8]. The operations of many liquid crystal devices are also based on birefringence [28]. The difference between the imaginary parts of k_1 and k_2 , called *dichroism*, is a measure of differential absorption of two orthogonally polarized plane waves incident on a birefringent layer.

If a wavenumber is independent of $\hat{\mathbf{a}}$, the corresponding solution $\mathbf{F}_0 \exp(ik\hat{\mathbf{a}} \cdot \mathbf{r})$ represents an *ordinary* plane wave;

otherwise, the solution represents an *extraordinary* plane wave. The amplitude vectors $\underline{\mathbf{E}}_0$ and $\underline{\mathbf{H}}_0$ of an ordinary plane wave are always normal to the direction of propagation, but those of an extraordinary plane wave may not be. The amplitude vectors $\underline{\mathbf{D}}_0$ and $\underline{\mathbf{B}}_0$ of both ordinary and extraordinary plane waves are normal to $\hat{\mathbf{a}}$. The time-averaged Poynting vector of an ordinary plane wave is aligned with the direction of propagation, but that of an extraordinary plane wave is generally not. Incidental unirefringence (i.e., $k_2 = k_1$) may arise for a specific $\hat{\mathbf{a}}$ —for instance, when $\hat{\mathbf{a}} = \hat{\mathbf{z}}$ in a uniaxial dielectric medium with permittivity specified by (6). Pathological unirefringence (i.e., $k_2 = k_1$ for all $\hat{\mathbf{a}}$) can also arise, for example, in a uniaxial dielectric–magnetic medium whose permittivity dyadic is a scalar multiple of its permeability dyadic [29]. Anomalous unirefringence is also possible for a specific $\hat{\mathbf{a}}$, when, in addition to $k_2 = k_1$, the amplitude vector $\mathbf{F}_{0_2} = ik_1 \mathbf{r} \cdot \hat{\mathbf{a}} \mathbf{F}_{0_1}$ turns out to be a function of \mathbf{r} whereas \mathbf{F}_{0_1} is spatially uniform [30]; the coalescence of the two plane waves—which exhibits a linear dependence on propagation distance—is known as a *Voigt wave* [31].

Many accounts of plane-wave propagation in complex media are available in the scientific literature. For comprehensive descriptions of plane-wave solutions in

anisotropic media, Ref. 3 is recommended. Propagation in bianisotropic media is an active area of research, using standard eigenanalysis [32], and results are also available for nonhomogeneous examples such as cholesteric liquid crystals [6,7] and helicoidal bianisotropic media [2,33]. The exquisitely beautiful palette of electromagnetic consequences of anisotropy and bianisotropy becomes evident in crystal optics [34,35].

4. DYADIC GREEN FUNCTIONS IN SPECTRAL FORM

In the presence of a six-vector electromagnetic source term $\underline{\mathbf{S}}(\underline{\mathbf{r}}, \omega)$, the Maxwell curl postulates (20) become

$$[\underline{\mathbf{L}}(\nabla) + i\omega\underline{\mathbf{K}}(\omega)] \cdot \underline{\mathbf{F}}(\underline{\mathbf{r}}, \omega) = \underline{\mathbf{S}}(\underline{\mathbf{r}}, \omega) \quad (26)$$

The linearity of (26) implies that its solution may be expressed in terms of a dyadic Green function $\underline{\mathbf{G}}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega)$ as

$$\underline{\mathbf{F}}(\underline{\mathbf{r}}, \omega) = \underline{\mathbf{F}}_h(\underline{\mathbf{r}}, \omega) + \int_{V'} \underline{\mathbf{G}}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) \cdot \underline{\mathbf{S}}(\underline{\mathbf{r}}', \omega) d^3\underline{\mathbf{r}}' \quad (27)$$

where field and source points are represented by $\underline{\mathbf{r}}$ and $\underline{\mathbf{r}}'$, respectively, with all source points confined to the region V' . The field $\underline{\mathbf{F}}_h(\underline{\mathbf{r}}, \omega)$ represents the solution to the source-free version of (26); thus, $\underline{\mathbf{F}}_h(\underline{\mathbf{r}}, \omega)$ is the complementary function. The dyadic Green function itself arises as the solution to the differential equation

$$[\underline{\mathbf{L}}(\nabla) + i\omega\underline{\mathbf{K}}(\omega)] \cdot \underline{\mathbf{G}}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) = \delta(\underline{\mathbf{r}} - \underline{\mathbf{r}}') \underline{\mathbf{I}} \quad (28)$$

in which the role of the source term is taken by the product of the Dirac delta function $\delta(\underline{\mathbf{r}} - \underline{\mathbf{r}}')$ and the 6×6 identity dyadic $\underline{\mathbf{I}}$. As the present context is that of unbounded space completely filled by a homogeneous medium, $\underline{\mathbf{G}}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega)$ is also required to satisfy the Sommerfeld radiation condition [36].

The method of Green functions is a powerful tool in the analysis of electromagnetic fields. However, the explicit delineation of the dyadic Green function for anisotropic and bianisotropic media continues to provide a

the Fourier transform of (28) yields

$$\underline{\tilde{\mathbf{G}}}(\underline{\mathbf{q}}, \omega) = \frac{1}{i\omega} \frac{\text{adj}[\underline{\tilde{\mathbf{A}}}(\underline{\mathbf{q}}, \omega)]}{\det[\underline{\tilde{\mathbf{A}}}(\underline{\mathbf{q}}, \omega)]} \quad (30)$$

where

$$\underline{\tilde{\mathbf{A}}}(\underline{\mathbf{q}}, \omega) = \begin{bmatrix} \underline{\mathbf{0}} & \frac{1}{\omega}(\underline{\mathbf{q}} \times \underline{\mathbf{I}}) \\ -\frac{1}{\omega}(\underline{\mathbf{q}} \times \underline{\mathbf{I}}) & \underline{\mathbf{0}} \end{bmatrix} + \underline{\mathbf{K}}(\omega) \quad (31)$$

While the analytic properties of the inverse Fourier transform

$$\underline{\mathbf{G}}(\underline{\mathbf{R}}, \omega) = \left(\frac{1}{2\pi}\right)^3 \frac{1}{i\omega} \int_q \frac{\text{adj}[\underline{\tilde{\mathbf{A}}}(\underline{\mathbf{q}}, \omega)]}{\det[\underline{\tilde{\mathbf{A}}}(\underline{\mathbf{q}}, \omega)]} \exp(i\underline{\mathbf{q}} \cdot \underline{\mathbf{R}}) d^3\underline{\mathbf{q}} \quad (32)$$

for anisotropic media are known [40], numerical techniques are needed to explicitly evaluate (32).

5. DYADIC GREEN FUNCTIONS IN CLOSED FORM

Closed-form representations of dyadic Green functions are available for all isotropic media [2]. In contrast, those representations have been found for only a limited set of anisotropic and bianisotropic media [37,39].

For a uniaxial dielectric-magnetic medium characterized by the constitutive dyadics

$$\left. \begin{aligned} \underline{\varepsilon}_{\text{uni}} &= \varepsilon_{11} \left(\hat{\mathbf{x}}\hat{\mathbf{x}} + \hat{\mathbf{y}}\hat{\mathbf{y}} \right) + \varepsilon_{33} \hat{\mathbf{z}}\hat{\mathbf{z}} \\ \underline{\mu}_{\text{uni}} &= \mu_{11} \left(\hat{\mathbf{x}}\hat{\mathbf{x}} + \hat{\mathbf{y}}\hat{\mathbf{y}} \right) + \mu_{33} \hat{\mathbf{z}}\hat{\mathbf{z}} \end{aligned} \right\} \quad (33)$$

the 3×3 dyadic components of the 6×6 dyadic Green function

$$\underline{\mathbf{G}}_{\text{uni}}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) = \begin{bmatrix} \underline{\mathbf{G}}_{\text{uni}}^{ee}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) & \underline{\mathbf{G}}_{\text{uni}}^{em}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) \\ \underline{\mathbf{G}}_{\text{uni}}^{me}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) & \underline{\mathbf{G}}_{\text{uni}}^{mm}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) \end{bmatrix} \quad (34)$$

are given as [41]

$$\left. \begin{aligned} \underline{\mathbf{G}}_{\text{uni}}^{ee}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) &= -i\omega\mu_{11} \left[\left(\varepsilon_{33}\varepsilon_{\text{uni}}^{-1} + \frac{\nabla\nabla}{\omega^2\varepsilon_{11}\mu_{11}} \right) \underline{\mathbf{g}}_e(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) - \underline{\mathbf{T}}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) \right] \\ \underline{\mathbf{G}}_{\text{uni}}^{em}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) &= -\varepsilon_{11}\varepsilon_{\text{uni}}^{-1} \cdot (\nabla \times \underline{\mathbf{I}}) \cdot \left[\mu_{33}\underline{\mathbf{g}}_\mu(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega)\underline{\mu}_{\text{uni}}^{-1} + \underline{\mathbf{T}}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) \right] \\ \underline{\mathbf{G}}_{\text{uni}}^{me}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) &= -\mu_{11}\underline{\mu}_{\text{uni}}^{-1} \cdot (\nabla \times \underline{\mathbf{I}}) \cdot \left[-\varepsilon_{33}\underline{\mathbf{g}}_e(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega)\varepsilon_{\text{uni}}^{-1} + \underline{\mathbf{T}}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) \right] \\ \underline{\mathbf{G}}_{\text{uni}}^{mm}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) &= -i\omega\varepsilon_{11} \left[\left(\mu_{33}\underline{\mu}_{\text{uni}}^{-1} + \frac{\nabla\nabla}{\omega^2\varepsilon_{11}\mu_{11}} \right) \underline{\mathbf{g}}_\mu(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) + \underline{\mathbf{T}}(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega) \right] \end{aligned} \right\} \quad (35)$$

formidable challenge to theoreticians [37–39]. A spectral representation may be provided as the spatial Fourier transform [8]

$$\underline{\tilde{\mathbf{G}}}(\underline{\mathbf{q}}, \omega) = \int_{\underline{\mathbf{R}}} \underline{\mathbf{G}}(\underline{\mathbf{R}}, \omega) \exp(-i\underline{\mathbf{q}} \cdot \underline{\mathbf{R}}) d^3\underline{\mathbf{R}} \quad (29)$$

with $\underline{\mathbf{R}} = \underline{\mathbf{r}} - \underline{\mathbf{r}}'$. For the homogeneous bianisotropic medium characterized by the 6×6 constitutive dyadic $\underline{\mathbf{K}}(\omega)$,

The scalar Green functions $\underline{\mathbf{g}}_e(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega)$ and $\underline{\mathbf{g}}_\mu(\underline{\mathbf{r}} - \underline{\mathbf{r}}', \omega)$ in (35) are defined by

$$\underline{\mathbf{g}}_\gamma(\underline{\mathbf{R}}, \omega) = \frac{\exp\left(-i\omega^2\varepsilon_{11}\mu_{11}\sqrt{\gamma_{33}\underline{\mathbf{R}} \cdot \underline{\gamma}_{\text{uni}}^{-1} \cdot \underline{\mathbf{R}}}\right)}{4\pi\sqrt{\gamma_{33}\underline{\mathbf{R}} \cdot \underline{\gamma}_{\text{uni}}^{-1} \cdot \underline{\mathbf{R}}}}, \quad (36)$$

($\gamma = \varepsilon, \mu$)

while the dyadic $\underline{T}(\underline{r} - \underline{r}', \omega)$ is specified as

$$\begin{aligned} \underline{T}(\underline{R}, \omega) &= \left(\frac{\varepsilon_{33}}{\varepsilon_{11}} \underline{g}_\varepsilon - \frac{\mu_{33}}{\mu_{11}} \underline{g}_\mu \right) \frac{(\underline{R} \times \hat{\underline{z}})(\underline{R} \times \hat{\underline{z}})}{(\underline{R} \times \hat{\underline{z}})^2} \\ &+ \left[\underline{I} - \hat{\underline{z}}\hat{\underline{z}} - \frac{2(\underline{R} \times \hat{\underline{z}})(\underline{R} \times \hat{\underline{z}})}{(\underline{R} \times \hat{\underline{z}})^2} \right] \\ &\times \frac{g_\varepsilon \sqrt{\varepsilon_{33} \underline{R} \cdot \underline{\varepsilon}_{\text{uni}}^{-1} \cdot \underline{R}} - g_\mu \sqrt{\mu_{33} \underline{R} \cdot \underline{\mu}_{\text{uni}}^{-1} \cdot \underline{R}}}{i\omega \sqrt{\varepsilon_{11} \mu_{11}} (\underline{R} \times \hat{\underline{z}})^2} \end{aligned} \quad (37)$$

Although analytical progress has been reported towards closed-form dyadic Green functions for general uniaxial bianisotropic media described by the constitutive dyadics

$$\underline{\gamma}_{\text{uni}} = \gamma_{11} \underline{I} + (\gamma_{33} - \gamma_{11}) \hat{\underline{z}}\hat{\underline{z}}, \quad (\gamma = \varepsilon, \zeta, \zeta, \mu) \quad (38)$$

the case remains unsolved [39,42].

Closed-form representations of dyadic Green functions are available for the bianisotropic example provided by a uniformly moving isotropic dielectric–magnetic medium. In the case where $|\underline{v}|$ in (11) is smaller than the phase velocity of a wave in the stationary medium, the 3×3 dyadic Green functions (34) of the moving medium are [3,37]

$$\left. \begin{aligned} \underline{G}_{\text{mov}}^{ee}(\underline{r} - \underline{r}', \omega) &= -i\omega\mu\sqrt{\alpha^3} \left(\underline{I} + \frac{\underline{\varepsilon}_{\text{mov}} \cdot \nabla \nabla}{\mu(\omega\varepsilon\alpha)^2} \right) \frac{\exp(-i\omega\varepsilon\alpha\sqrt{\underline{\mu}\underline{R} \cdot \underline{\varepsilon}_{\text{mov}}^{-1} \cdot \underline{R}})}{4\pi\sqrt{\varepsilon\underline{R} \cdot \underline{\varepsilon}_{\text{mov}}^{-1} \cdot \underline{R}}} \\ \underline{G}_{\text{mov}}^{em}(\underline{r} - \underline{r}', \omega) &= \frac{1}{i\omega} \underline{\varepsilon}_{\text{mov}}^{-1} \cdot [\nabla \times \underline{I} - i\omega(\hat{\underline{v}} \times \underline{I})] \cdot \underline{G}_{\text{mov}}^{mm}(\underline{r} - \underline{r}', \omega) \\ \underline{G}_{\text{mov}}^{me}(\underline{r} - \underline{r}', \omega) &= -\frac{1}{i\omega} \underline{\mu}_{\text{mov}}^{-1} \cdot [\nabla \times \underline{I} - i\omega(\hat{\underline{v}} \times \underline{I})] \cdot \underline{G}_{\text{mov}}^{ee}(\underline{r} - \underline{r}', \omega) \\ \underline{G}_{\text{mov}}^{mm}(\underline{r} - \underline{r}', \omega) &= -i\omega\varepsilon\sqrt{\alpha^3} \left(\underline{I} + \frac{\underline{\mu}_{\text{mov}} \cdot \nabla \nabla}{\varepsilon(\omega\mu\alpha)^2} \right) \frac{\exp(-i\omega\mu\alpha\sqrt{\varepsilon\underline{R} \cdot \underline{\mu}_{\text{mov}}^{-1} \cdot \underline{R}})}{4\pi\sqrt{\underline{\mu}\underline{R} \cdot \underline{\mu}_{\text{mov}}^{-1} \cdot \underline{R}}} \end{aligned} \right\} \quad (39)$$

Dyadic scalarization and factorization techniques are commonly implemented in establishing solutions to (28). In outline, the procedure is as follows. Formally

$$\underline{G}(\underline{r} - \underline{r}', \omega) = [\underline{L}(\nabla) + i\omega\underline{K}(\omega)]^\dagger \underline{W}(\underline{r} - \underline{r}', \omega) \quad (40)$$

where the adjoint operation indicated by superscript \dagger is defined implicitly via

$$[\underline{L}(\nabla) + i\omega\underline{K}(\omega)]^\dagger \cdot [\underline{L}(\nabla) + i\omega\underline{K}(\omega)] = \mathcal{H}(\nabla, \underline{r}, \omega) \underline{I} \quad (41)$$

The scalar Green function $W(\underline{r} - \underline{r}', \omega)$ in (40) is specified by the action of the scalar fourth-order operator $\mathcal{H}(\nabla, \underline{r}, \omega)$ in (41) as

$$\mathcal{H}(\nabla, \underline{r}, \omega) W(\underline{r} - \underline{r}', \omega) = \delta(\underline{r} - \underline{r}') \quad (42)$$

The construction of the adjoint operator $[\underline{L}(\nabla) + i\omega\underline{K}(\omega)]^\dagger$ for anisotropic and bianisotropic media involves straightforward, albeit lengthy, matrix–algebraic operations.

However, solutions to the fourth-order partial differential equation represented by (42) are generally elusive.

The general unavailability of the dyadic Green functions in closed form has meant that a cornerstone of electromagnetic scattering theory—the Huygens principle—has been formulated exactly only for the simplest of anisotropic media [43,44]. Field representations in non-Cartesian coordinate systems are generally unavailable; and the very few counterexamples [45,46] are exceedingly awkward to handle and restricted in scope.

6. DEPOLARIZATION DYADICS

Although closed-form representations of dyadic Green functions are relatively scarce, often in electromagnetic analyses it is sufficient to construct approximative solutions of restricted validity. An important example occurs in the homogenization of particulate composite materials [47,48], wherein the scattering response of an electrically small particle embedded within a homogeneous ambient medium is required. Relative to Eqs. (26) and (27), the particle represents an equivalent source $\underline{S}(\underline{r}, \omega)$; and the field $\underline{F}(\underline{r}, \omega)$ is sought for $\underline{r} \in V$ (i.e., in the source region). Provided the particle is sufficiently small compared with the electromagnetic wavelengths, the Rayleigh

approximation

$$\underline{F}(\underline{r}, \omega) \approx \underline{F}_h(\underline{r}, \omega) + \underline{D}(\underline{r}, \omega) \cdot \underline{S}(\underline{r}, \omega) \quad (43)$$

may be implemented, where

$$\underline{D}(\underline{r}, \omega) = \int_V \underline{G}(\underline{r} - \underline{r}', \omega) d^3 \underline{r}' \quad (44)$$

is the 6×6 *depolarization dyadic* of a region of the same shape, orientation, and size as the particle [48]. In the limiting case of a vanishingly small particle, the depolarization dyadic is nonzero because of the singularity of the Green function at the origin.

Consider an ellipsoidal particle with surface parameterized as

$$\underline{r}_e(\theta, \phi) = \eta \underline{U} \cdot \hat{\underline{r}}(\theta, \phi) \quad (45)$$

where $\hat{\underline{r}}(\theta, \phi)$ is the radial unit vector specified by the spherical polar coordinates θ and ϕ . The shape dyadic \underline{U} is a real-valued 3×3 dyadic with positive eigenvalues [49]; the normalized lengths of the ellipsoid semi-axes are specified by the eigenvalues of \underline{U} . In the limit $\eta \rightarrow 0$, the 6×6

depolarization dyadic for the ellipsoidal particle embedded within a homogeneous bianisotropic medium (with 3×3 constitutive dyadics $\underline{\underline{\epsilon}}_{\text{amb}}, \underline{\underline{\xi}}_{\text{amb}}, \underline{\underline{\zeta}}_{\text{amb}}$, and $\underline{\underline{\mu}}_{\text{amb}}$) is given as [50]

$$\underline{\underline{\mathbf{D}}}^{U/\text{amb}} = \begin{bmatrix} \underline{\underline{D}}_{ee}^{U/\text{amb}} & \underline{\underline{D}}_{em}^{U/\text{amb}} \\ \underline{\underline{D}}_{me}^{U/\text{amb}} & \underline{\underline{D}}_{mm}^{U/\text{amb}} \end{bmatrix} \quad (46)$$

where

$$\underline{\underline{D}}_{\lambda\lambda'}^{U/\text{amb}} = \underline{\underline{U}}^{-1} \cdot \underline{\underline{\tilde{D}}}_{\lambda\lambda'}^{U/\text{amb}} \cdot \underline{\underline{U}}^{-1}, \quad (\lambda, \lambda' = e, m) \quad (47)$$

$$\begin{aligned} & \underline{\underline{\tilde{D}}}_{\lambda\lambda'}^{U/\text{amb}} \\ &= \frac{1}{4\pi i \omega} \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} \frac{(\hat{\mathbf{q}} \cdot \underline{\underline{\tau}}_{\lambda\lambda'} \cdot \hat{\mathbf{q}}) \hat{\mathbf{q}} \hat{\mathbf{q}} \sin \theta d\theta d\phi}{(\hat{\mathbf{q}} \cdot \underline{\underline{\epsilon}}_{\text{amb}} \cdot \hat{\mathbf{q}})(\hat{\mathbf{q}} \cdot \underline{\underline{\mu}}_{\text{amb}} \cdot \hat{\mathbf{q}}) - (\hat{\mathbf{q}} \cdot \underline{\underline{\xi}}_{\text{amb}} \cdot \hat{\mathbf{q}})(\hat{\mathbf{q}} \cdot \underline{\underline{\zeta}}_{\text{amb}} \cdot \hat{\mathbf{q}})} \end{aligned} \quad (48)$$

$$\underline{\underline{\tau}}_{ee} = \underline{\underline{\mu}}_{\text{amb}}, \quad \underline{\underline{\tau}}_{em} = -\underline{\underline{\xi}}_{\text{amb}}, \quad \underline{\underline{\tau}}_{me} = -\underline{\underline{\zeta}}_{\text{amb}}, \quad \underline{\underline{\tau}}_{mm} = \underline{\underline{\epsilon}}_{\text{amb}} \quad (49)$$

$$\underline{\underline{\tilde{\gamma}}}_{\text{amb}} = \underline{\underline{U}}^{-1} \cdot \underline{\underline{\gamma}}_{\text{amb}} \cdot \underline{\underline{U}}^{-1}, \quad (\gamma = \epsilon, \xi, \zeta, \mu) \quad (50)$$

and

$$\hat{\mathbf{q}} = \hat{\mathbf{x}} \sin \theta \cos \phi + \hat{\mathbf{y}} \sin \theta \sin \phi + \hat{\mathbf{z}} \cos \theta \quad (51)$$

Thus, (48) provides the components of the integrated singularity of the dyadic Green function.

Explicit evaluations of the surface integrals in (48) are available for several classes of anisotropic media. For a spherical particle (i.e., $\underline{\underline{U}} = \underline{\underline{I}}$) immersed in the orthorhombic biaxial dielectric medium described by (7), the 3×3 depolarization dyadics are [51]

$$\left. \begin{aligned} \underline{\underline{D}}_{ee}^{I/\text{ortho}} &= \frac{1}{i\omega\epsilon_0} (D_x \hat{\mathbf{x}}\hat{\mathbf{x}} + D_y \hat{\mathbf{y}}\hat{\mathbf{y}} + D_z \hat{\mathbf{z}}\hat{\mathbf{z}}) \\ \underline{\underline{D}}_{em}^{I/\text{ortho}} &= \underline{\underline{D}}_{me}^{I/\text{ortho}} = \underline{\underline{0}} \\ \underline{\underline{D}}_{mm}^{I/\text{ortho}} &= \frac{1}{3i\omega\mu_0} \underline{\underline{I}} \end{aligned} \right\} \quad (52)$$

with

$$\left. \begin{aligned} D_x &= \frac{\sqrt{\epsilon_{22}}}{(\epsilon_{22} - \epsilon_{11})\sqrt{\epsilon_{33} - \epsilon_{11}}} [F(v_1, v_2) - E(v_1, v_2)] \\ D_y &= \frac{1}{\epsilon_{22} - \epsilon_{11}} \left\{ \frac{\epsilon_{11} - \epsilon_{22}}{\epsilon_{33} - \epsilon_{22}} - \sqrt{\frac{\epsilon_{33} - \epsilon_{11}}{\epsilon_{22}}} \right. \\ & \left. \left[\frac{\epsilon_{11}}{\epsilon_{33} - \epsilon_{11}} F(v_1, v_2) - \frac{\epsilon_{22}}{\epsilon_{33} - \epsilon_{22}} E(v_1, v_2) \right] \right\} \\ D_z &= \frac{1}{\epsilon_{33} - \epsilon_{22}} \left[1 - \sqrt{\frac{\epsilon_{22}}{\epsilon_{22} - \epsilon_{11}}} E(v_1, v_2) \right] \end{aligned} \right\} \quad (53)$$

where $F(v_1, v_2)$ and $E(v_1, v_2)$ are elliptic integrals of the first and second kinds [52], respectively, and their arguments are

$$v_1 = \tan^{-1} \sqrt{\frac{\epsilon_{33} - \epsilon_{11}}{\epsilon_{11}}}, \quad v_2 = \sqrt{\frac{\epsilon_{33}(\epsilon_{22} - \epsilon_{11})}{\epsilon_{22}(\epsilon_{33} - \epsilon_{11})}} \quad (54)$$

The form of the depolarization dyadics (52) also arises for an ellipsoidal particle embedded in an isotropic dielectric

medium [51,53]. The depolarization dyadics for uniaxial dielectric media follow from (52) as special cases (e.g., $\epsilon_{11} = \epsilon_{22}$) [54]. Furthermore, the depolarization dyadics for gyrotropic dielectric media (8) are precisely the same as those for uniaxial dielectric media, since the surface integrals in (48) are insensitive to skew-symmetric dyadic components [50]. In addition to the representation (52) for spherical/ellipsoidal particles, depolarization dyadics associated with certain infinitely long cylindrical particles in biaxial anisotropic media have also been derived [55,56]. Closed-form representations of depolarization dyadics are not available for the general bianisotropic medium (15), but are established for certain ellipsoidal particles embedded in uniaxial bianisotropic media [50].

7. HOMOGENIZATION

Consider the electromagnetic response of an assembly of particulate media. Provided that the component particles are small compared with the electromagnetic wavelengths, the assembly may be viewed as an effectively homogeneous composite medium (HCM) [47,48]. By the process of homogenization, complex anisotropic and bianisotropic media may be conceptualized—and fabricated—even when the component media themselves are relatively simple. A variety of formalisms have been developed for the purpose of estimating the constitutive properties of HCMs. Three widely used homogenization formalisms—namely, those of Maxwell Garnett, Bruggeman and the strong property fluctuation theory (SPFT)—are outlined in this section. The HCM considered is that arising from two particulate component media, labeled as a and b , which are characterized by the 6×6 constitutive dyadics $\underline{\underline{\mathbf{K}}}_a$ and $\underline{\underline{\mathbf{K}}}_b$, respectively, at the angular frequency ω of interest. The volume fractions of the media a and b are denoted by f_a and $f_b = 1 - f_a$, respectively.

The Maxwell Garnett homogenization formalism is perhaps the simplest and most often utilized formalism. If medium a is present as identically oriented, ellipsoidal particles described by the shape dyadic $\underline{\underline{U}}^a$, then the Maxwell Garnett estimate of the HCM constitutive dyadic is [57]

$$\underline{\underline{\mathbf{K}}}_{\text{MG}} = \underline{\underline{\mathbf{K}}}_b + f_a \underline{\underline{\alpha}}^{a/b} \cdot \left(\underline{\underline{I}} - i\omega f_a \underline{\underline{D}}^{I/b} \cdot \underline{\underline{\alpha}}^{a/b} \right)^{-1} \quad (55)$$

The 6×6 depolarization dyadic $\underline{\underline{D}}^{I/b}$ is that associated with a sphere embedded in medium b , while the dyadic $\underline{\underline{\alpha}}^{a/b}$ is the generalized polarizability density dyadic

$$\underline{\underline{\alpha}}^{a/b} = (\underline{\underline{\mathbf{K}}}_a - \underline{\underline{\mathbf{K}}}_b) \cdot \left[\underline{\underline{I}} + i\omega \underline{\underline{D}}^{U^a/b} \cdot (\underline{\underline{\mathbf{K}}}_a - \underline{\underline{\mathbf{K}}}_b) \right]^{-1} \quad (56)$$

of a particle of medium a embedded in medium b . The estimate (55) is valid for $f_a < 0.3$ only. However, this limitation has been overcome in recent (as of 2004) incremental and differential refinements to the Maxwell Garnett formalism [58]. If $\underline{\underline{D}}^{I/b}$ is replaced by $\underline{\underline{D}}^{U^a/b}$ in (55), then the HCM constitutive dyadic estimate of the Bragg-Pippard formalism [59] results.

The Bruggeman formalism rests on the assertion that the net polarizability density is zero throughout the HCM.

A characteristic feature is that the component media a and b are treated symmetrically. Thus, the Bruggeman homogenization formalism has the advantage over the Maxwell Garnett formalism of being applicable for all volume fractions $f_a \in (0,1)$ [47]. For component media a and b distributed as ellipsoids with shape dyadics $\underline{\underline{U}}^a$ and $\underline{\underline{U}}^b$, respectively, the Bruggeman estimate of the HCM constitutive dyadic $\underline{\underline{K}}_{\text{Br}}$ is obtained by solving the equation [57]

$$f_a \underline{\underline{\alpha}}^{a/\text{Br}} + f_b \underline{\underline{\alpha}}^{b/\text{Br}} = \underline{\underline{0}} \quad (57)$$

with $\underline{\underline{\alpha}}^{a/\text{Br}}$ and $\underline{\underline{\alpha}}^{b/\text{Br}}$ defined and interpreted similarly to $\underline{\underline{\alpha}}^{a/b}$. Half a century after its intuitive initial enunciation [60], Eq. (57) was found to arise naturally within the SPFT [61,62]. For isotropic dielectric–magnetic media, the HCM permittivity and permeability may be extracted simply from (57) as roots of quadratic polynomials. But for anisotropic and bianisotropic media, (57) represents a nonlinear relation in terms of the HCM constitutive parameters embodied in $\underline{\underline{K}}_{\text{Br}}$. Iterative solutions to the nonlinear forms of (57) are straightforwardly computed by applying the Jacobi method [63], for example.

The SPFT provides an approach to homogenization based on the iterative refinement of the Bruggeman estimate $\underline{\underline{K}}_{\text{Br}}$. Unlike the Maxwell Garnett and Bruggeman formalisms, the SPFT accommodates a comprehensive description of the distributional statistics of the component media [61]. Thereby, coherent scattering losses may be accounted for. Successive SPFT iterates recruit successively higher-order spatial correlation functions. Suppose that the particulate geometries of both component media a and b are characterized by the ellipsoidal shape dyadic $\underline{\underline{U}}$. Then the n th-order SPFT estimate of the HCM constitutive dyadic is obtained as [62]

$$\underline{\underline{K}}_{\text{Dy}}^{[n]} = \underline{\underline{K}}_{\text{Br}} - \frac{1}{i\omega} \left(\underline{\underline{I}} + \underline{\underline{\Sigma}}^{[n]} \cdot \underline{\underline{D}}^{U/\text{Br}} \right)^{-1} \cdot \underline{\underline{\Sigma}}^{[n]} \quad (58)$$

wherein the subscript Dy on $\underline{\underline{K}}_{\text{Dy}}^{[n]}$ derives from the central equation in the SPFT, namely, the Dyson equation [61]. The mass operator term $\underline{\underline{\Sigma}}^{[n]}$ —which is an infinite series—is defined in terms of the dyadic Green function $\underline{\underline{G}}_{\text{Br}}(\underline{\underline{R}}, \omega)$ associated with $\underline{\underline{K}}_{\text{Br}}$, together with the normalized polarizability density dyadic $\underline{\underline{\chi}}_l = -i\omega \underline{\underline{\alpha}}^{l/\text{Br}}$ ($l = a, b$). In the derivation of (58), the long-wavelength approximation is invoked. For $n = 0$ and $n = 1$, the SPFT estimates of the HCM constitutive dyadic are degenerate with those of the Bruggeman formalism:

$$\underline{\underline{K}}_{\text{Dy}}^{[0]} = \underline{\underline{K}}_{\text{Dy}}^{[1]} = \underline{\underline{K}}_{\text{Br}} \quad (59)$$

At the level of the so-called bilocal approximation (i.e., $n = 2$), the mass operator is given by

$$\underline{\underline{\Sigma}}^{[2]} = \left(\underline{\underline{\chi}}_a - \underline{\underline{\chi}}_b \right) \cdot \left[\mathcal{P} \int \Gamma(\underline{\underline{R}}) \underline{\underline{G}}_{\text{Br}}(\underline{\underline{R}}) d^3 \underline{\underline{R}} \right] \cdot \left(\underline{\underline{\chi}}_a - \underline{\underline{\chi}}_b \right) \quad (60)$$

and $\underline{\underline{K}}_{\text{Dy}}^{[2]}$ is thus delivered by (58). In (60), \mathcal{P} denotes principal value integration and $\Gamma(\underline{\underline{R}})$ is a two-point covariance function. Evaluations of the mass operator (60) for physically motivated choices of $\Gamma(\underline{\underline{R}})$ have revealed that $\underline{\underline{K}}_{\text{Dy}}^{[2]}$ is largely insensitive to the precise form of the

covariance function [64]. Finite integral representations of $\underline{\underline{K}}_{\text{Dy}}^{[2]}$ are available for both anisotropic [64,65] and bianisotropic [62] composites. In addition, the SPFT iterative procedure converges at the level $n = 2$, at least for weakly anisotropic composites [66].

The constitutive dyadic forms that result from homogenization processes have been extensively investigated [63]. HCMs with biaxial symmetry have come under particular scrutiny [67]. A biaxial HCM arises when the component media present two distinct distinguished axes. These distinguished axes can have either a geometric origin (e.g., component media present as spheroids) or an electromagnetic origin (e.g., component media characterized by uniaxial constitutive dyadics). Furthermore, orthorhombic biaxial HCM structures generally develop, provided that the distinguished axes of the component media are mutually perpendicular; for nonperpendicular distinguished axes, the more general monoclinic or triclinic biaxial HCM form arises.

8. NONLINEAR ANISOTROPY

A general description of bianisotropic nonlinearity (and, therefore, also anisotropic nonlinearity) proceeds as follows: The nonlinear constitutive relations are expressed in six-vector/dyadic notation as [68]

$$\underline{\underline{C}}(\underline{\underline{r}}, \omega) = \underline{\underline{K}}_0 \cdot \underline{\underline{F}}(\underline{\underline{r}}, \omega) + \underline{\underline{Q}}(\underline{\underline{r}}, \omega) \quad (61)$$

where $\underline{\underline{K}}_0$ is the 6×6 constitutive dyadic of free space, and the six-vector

$$\underline{\underline{C}}(\underline{\underline{r}}, \omega) = \begin{bmatrix} D(\underline{\underline{r}}, \omega) \\ B(\underline{\underline{r}}, \omega) \end{bmatrix}. \quad (62)$$

The six-vector $\underline{\underline{Q}}(\underline{\underline{r}}, \omega)$ is the sum of linear and nonlinear parts

$$\underline{\underline{Q}}(\underline{\underline{r}}, \omega) = \underline{\underline{Q}}^{\text{lin}}(\underline{\underline{r}}, \omega) + \underline{\underline{Q}}^{\text{nl}}(\underline{\underline{r}}, \omega) \quad (63)$$

The linear part

$$\underline{\underline{Q}}^{\text{lin}}(\underline{\underline{r}}, \omega) = \left(\underline{\underline{K}}^{\text{lin}}(\omega) - \underline{\underline{K}}_0 \right) \cdot \underline{\underline{F}}(\underline{\underline{r}}, \omega) \quad (64)$$

involves $\underline{\underline{K}}^{\text{lin}}$ as the 6×6 constitutive dyadic to characterize the linear response of the nonlinear medium. The exclusively nonlinear response of the medium, under the simultaneous stimulation by an ensemble of $M > 1$ fields $\underline{\underline{F}}(\underline{\underline{r}}, \omega_m)$, ($m = 1, 2, \dots, M$), is characterized by the six-vector $\underline{\underline{Q}}^{\text{nl}}(\underline{\underline{r}}, \omega)$. At the frequency $\omega = \omega_{\text{nl}}$, the j th element of $\underline{\underline{Q}}^{\text{nl}}(\underline{\underline{r}}, \omega_{\text{NL}})$ is given by

$$\begin{aligned} & \mathcal{Q}_j^{\text{nl}}(\underline{\underline{r}}, \omega_{\text{nl}}) \\ &= \sum_{j_1=1}^6 \sum_{j_2=1}^6 \cdots \sum_{j_m=1}^6 \cdots \sum_{j_M=1}^6 \\ & \times \left\{ \chi_{jj_1 j_2 \dots j_m \dots j_M}^{\text{nl}}(\omega_{\text{nl}}; \mathcal{W}) \prod_{n=1}^M [F_{j_n}(\underline{\underline{r}}, \omega_n)] \right\} \end{aligned} \quad (65)$$

for $j \in [1, 6]$, where $\mathcal{W} = \{\omega_1, \omega_2, \dots, \omega_M\}$ and not all members of \mathcal{W} have to be distinct. The angular frequency ω_{nl} is the

sum

$$\omega_{\text{nl}} = \sum_{m=1}^M a_m \omega_m, \quad a_m = \pm 1 \quad (66)$$

If $a_n = -1$, then $F_{j_n}(r, \omega)$ in (65) should be replaced by its complex conjugate. The nonlinear susceptibility tensor

$$\chi_{j_1 j_2 \dots j_M}^{\text{nl}}(\omega_{\text{nl}}; \mathcal{W}) \quad (67)$$

delineates the nonlinear constitutive properties. A vast range of nonlinear electromagnetic phenomena may be described in terms of (65) [69,70].

The homogenization of nonlinear anisotropic composites has been carried out with various homogenization formalisms [71,72], including the Maxwell Garnett [68,73] and Bruggeman [73,74] formalisms, and the SPFT [75]. For example, the anisotropic dielectric HCM with permittivity dyadic given by the sum of linear and nonlinear contributions

$$\underline{\underline{\epsilon}}(\omega) = \underline{\underline{\epsilon}}^{\text{lin}}(\omega) + \underline{\underline{\chi}}^{\text{nl}}(\omega) |\underline{\underline{E}}(\omega)|^2 \quad (68)$$

is found to arise from isotropic nonlinear component media distributed as ellipsoidal particles [74,75]. Furthermore, the degree of nonlinearity exhibited by the HCM described by (68) can exceed the degree of nonlinearity present in the component phases. This nonlinearity enhancement—which is itself an anisotropic phenomenon—has significant potential for technological applications [76].

1. ATTENUATORS

Attenuators are circuits designed to introduce a well-known loss between input and output ports [1]. The power ratio, expressed in decibels, between input and output represents the loss in these circuits. The main use of attenuators is in measurement of the standing-wave ratio (SWR) in antennas and of the transmission coefficient. In the case of the SWR measurement [2], a variable-loss attenuator is used between the generator and the slotline. One adjusts the attenuation value to maintain equal outputs in the stationary wave detector at the maximum and minimum points. SWR in decibels is, then, equal to the difference between the readings of the attenuator.

The external circuits connected to the input and output ports of the attenuator should present purely resistive impedances. These will always be matched to the input and output impedances of the component. Therefore, the resistors always constitute the attenuator circuit. In general, these resistive circuits use the T and Π circuit topologies. Figure 1 shows the T topology, where R_1 , R_2 , and R_3 form the circuit. The external circuitry presents purely resistive impedances (Z_i , Z_o) at the input and output of the attenuator. Figure 2 shows the configuration of the section Π . If the input and output impedances are the same ($Z_i = Z_o$), the circuits T and Π become symmetric, that is, $R_1 = R_2$.

1.1. Attenuator Design

The designer has two concerns in the project of an attenuator: (1) attenuation in decibels and (2) input and output impedances. The attenuation is

$$ATT = 10 \log_{10} N \tag{1}$$

Figure 1. Resistors configuration for the T attenuator; Z_i and Z_o are the input and output resistive impedances presented to the attenuator by external circuits.

Figure 2. Resistors configuration for the Π attenuator; Z_i and Z_o are input and output resistive impedances presented to the attenuator by external circuits.

where ATT it is attenuation (in dB) and N is the ratio between the power absorbed by the circuit (from the generator) and the power delivered to the load.

The design starts from the desired input and output impedances, and from the value of obtained in Eq. (1). Equations (2)–(4) give the resistance that composes the T circuit:

$$R_3 = \frac{2(NZ_i Z_o)^{1/2}}{N - 1} \tag{2}$$

$$R_1 = Z_i \frac{N + 1}{N - 1} - R_3 \tag{3}$$

$$R_2 = Z_o \frac{N + 1}{N - 1} - R_3 \tag{4}$$

Equations (5)–(7) give the resistance for type Π circuits:

$$R_3 = \frac{1}{2(N - 1)} \left(\frac{Z_i Z_o}{N} \right)^{1/2} \tag{5}$$

$$\frac{1}{R_1} = \frac{1}{Z_i} \frac{N + 1}{N - 1} - \frac{1}{R_3} \tag{6}$$

$$\frac{1}{R_2} = \frac{1}{Z_o} \frac{N + 1}{N - 1} - \frac{1}{R_3} \tag{7}$$

Equations (2)–(7) are also valid for symmetric circuits (it is sufficient that $Z_i = Z_o$).

The T and Π attenuators are applied to unbalanced systems such as coaxial cable. Bifilar lines feed many antennas that are intrinsically balanced, such as the dipole antennas. In this case, the T and Π circuits change into the balanced version and are designated as H and O sections, respectively. Figure 3 shows the H-circuit resistor configuration and Fig. 4, the O-circuit configuration. In relation to the T and Π circuits, the resistors R_3 and R_1 , R_2 are distributed in the inferior branch. All project equations shown above are valid for this case. However, it is necessary to take the half of the values of the respective

Figure 3. Balanced attenuator of H type. The R_1 and R_2 resistors from the T circuit are distributed in the inferior arms.

resistors and distribute them in the superior and inferior branches of their circuits.

1.2. Attenuators in Waveguides

Waveguides usually feed high-frequency antennas. In this case, the attenuators are built starting from a very thin tapered geometry resistive card. Figure 5 displays the construction of the waveguide attenuator and shows, how the attenuator device introduces this card in a section of slotted guide. The double-arrow shown in the upper part of the midsection of the figure illustrates the card displacement. The adjustment of the penetration depth in the slot allows one to control the dissipation of power and the desired attenuation. The slot should be made in the middle of the broad wall, as this is the area where it propagates the maximum power inside the guide and therefore where introduction of the resistive card allows the greatest dynamic control of attenuation. The attenua-

Figure 5. Waveguide attenuator.

tion variation with the depth of insertion of the card is nonlinear for this attenuator type. Figure 5, illustrates that SWR in the input and output ports of the attenuator can be improved if the extremities of the card are tapered.

2. BALUNS

Although knowledge of the impedance values between two terminals, is important, it is not enough to connect this impedance correctly to a transmission line, because of the existence of couplings between the terminals and ground.

The equivalent circuit of Fig. 6 represents these couplings to ground. Two special cases are considered in detail [3]:

1. When $Z_2 = Z_3$ in magnitude and phase. In this case, the impedance AB is balanced. Therefore, the voltages between A to ground and B to ground have the same magnitude and opposite phase.
2. When either Z_2 or Z_3 is zero. In this case, one side is at ground potential and the impedance is unbalanced. An example of a balanced line is a parallel wire line (twin lead). The unbalanced lines are generally coaxial. Other types of line can exist,

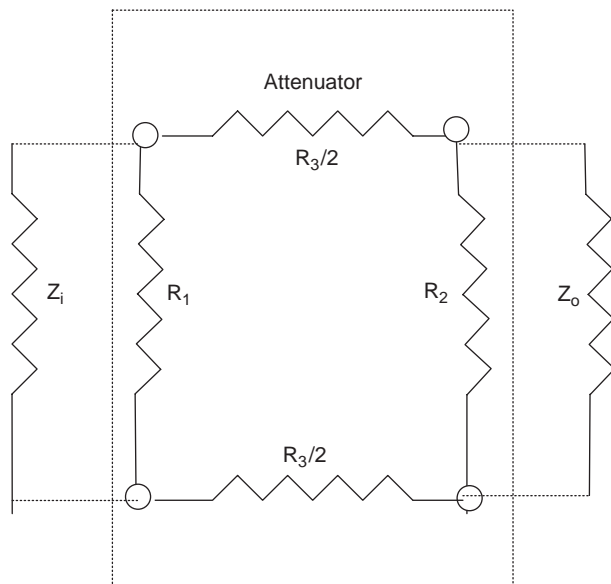

Figure 4. Balanced attenuator of O type. The R_3 resistor from the Π circuit is distributed in the inferior arm.

Figure 6. Equivalent circuit of impedance AB .

Figure 7. (a) Dipole antenna with symmetric feeding; (b) monopole antenna fed in the base; (c) dipole antenna with asymmetric feeding.

where the conductors present different couplings to the ground. An unusual example of this case is the twin lead with conductors of different thicknesses.

Since conductors have different potentials with respect to ground, the capacitance of the each conductor to the ground is also different. Therefore, the current in both conductors can vary.

The antennas are generally designed for balanced or unbalanced input impedances. This simplifies connection of the lines to the antenna. Connection to a symmetric antenna requires a balanced line, while an antenna where one of the feeding points is at ground potential requires an unbalanced input.

A simple example of a balanced antenna is the dipole antenna shown in Fig. 7a. Figure 7b illustrates a monopole, which is an unbalanced antenna. Figure 7c shows a dipole antenna with the feeding point between the center and the end (this is a procedure used to achieve different input impedance values); this antenna has a current imbalance, which prevents it from being fed satisfactorily by either a balanced or unbalanced line.

It is usually necessary to feed a balanced antenna with a coaxial cable and (although less frequent) an unbalanced antenna, with a balanced line. Such connections require special components to ensure satisfactory operation of the system [4]. These devices are balanced-to-unbalanced converters, also known as *baluns*, which ensure that the voltages and/or currents in the two lines are similar in magnitude.

If a coax cable is connected directly in a balanced antenna, currents will be induced in the external part of the external mesh of the cable. This will cause radiation of electromagnetic fields in unwanted directions. These currents cause an imbalance in the current distribution of the antenna. This affects the radiation diagram by altering the mainlobe (sometimes drastically) and the gain of the antenna. In the reception case, interference signals can be induced in the external part of the coaxial and coupled inside of the cable feeding the receiver.

The difficulties associated with the connection between an unbalanced and a balanced system can be understood considering the coax line below a ground plane. Figure 8

Figure 8. Unbalanced line connected to a balanced line.

Figure 9. Idealized generator of the circuit shown in Fig. 3.

illustrates the connection between the system and the parallel wire line. In this figure, Z_L is the load impedance and Z_S is the impedance associated with the support structures. The resulting currents in this system are equivalent to the ones created by the ideal generator shown in Fig. 9.

The currents in lines A and B are not necessarily the same. The total current leaving point *b* in Fig. 9 flows into the line. However, the total current in *b* comes from line B and the connection with ground. The main purpose of baluns is to ensure that the currents in lines A and B (Fig. 8) are similar.

Figure 10 illustrates a device capable of introducing symmetry in the line with respect to ground. The symmetry is essential in all kinds of baluns or balanced systems. Figure 11 shows the equivalent representation of this kind of balun.

In this case $I_A = I_B$. Even so, if the length *FC* (Fig. 10) is small, the coax cable is almost short-circuited and very little power is delivered to the load. In order to achieve satisfactory operation, the length *FC* should be of the order of a quarter-wavelength ($\lambda/4$). Because of this restriction, the type of balun shown in Fig. 10 is inherently narrowband.

A possible solution to increase the bandwidth is to wind the coaxial under a coil form of length *FC*. This introduces a high impedance to the system. However, there are design limitations. One of them is in the lower frequency range. In this case, the impedance of the winding is lower in comparison to load (seen at the input of the twin-lead line). The upper limit is at the resonance point of the space between the windings. A technique used to increase the inductive effect is to wind the cable in ferrite cores, providing a high impedance level on a wider frequency band. Careful designs of structures of this type allow their operation in frequency bands ratios up to 10:1 [5].

The most commonly used baluns are those based on $\lambda/4$ short-circuited line sections. Such an arrangement is shown in Fig. 12. In this way, high impedance is obtained

Figure 10. Connection by means of a balun.

Figure 11. Equivalent circuit of the circuit shown in Fig. 5.

from point *B* toward the external side of the outer mesh of the coaxial line. This prevents the current from flowing into the outer side of the external mesh of the cable.

In practice, the characteristic impedance of the transmission line is usually real, whereas that of the antenna element is complex. It is frequently desirable to operate the balun at a length other than a quarter-wavelength, in order to take advantage of the shunt reactance presented by the balun to the load, for impedance-matching purposes.

Among many coupling matching networks that can be used to connect the transmission line to the antenna, we can introduce a quarter-wavelength transformer (see Fig. 24). If the impedance of the antenna is real, the transformer is attached directly to the load. However, if the antenna impedance is complex, the transformer is placed at a distance *l* away from the antenna. The distance *l* is chosen so that the impedance toward the load, at *l*, is real.

If the transformer is a two-wire line section, and the line is a coaxial cable, obviously the coaxial line cannot be connected directly to the two-wire line. In this case, a balun may be used to connect the transformer to the coaxial line.

3. RADIO FREQUENCY CHOKES

A radiofrequency (RF) choke coil is an inductance designed to offer a high impedance to alternating currents over the frequency range for which the coils are to be used. This result is obtained by increasing the inductance of the coil and decreasing the distributed capacitance. The result is that the inductance is in parallel resonance with the distributed capacitance somewhere in the desired operating frequency range.

A typical RF choke coil consists of one or more universal wound coils mounted on an insulating rod; it can

Figure 12. (a) Balun bazooka; (b) cross section of the balun.

also be made by a series of ferrite beads wrapped in deep narrow slots in a slotted bobbin. A long single-layer solenoid is sometimes used.

Proper use of slug-type magnetic cores improves the performance of RF chokes. These cores increase the inductance, and hence the impedance of the coil, without materially affecting the distributed capacitance.

One particular use of chokes is to minimize common-mode (CM) currents on wires and cables. The inductance is usually of the order of 5 mH. This value is achieved using high-permeability ferrites. In these cases, saturation of the choke is not an issue.

The choke behaves as a common-mode filter. The most common type of ferrite used for electromagnetic compatibility is composed of NiZn. Below 10 MHz, the ferrite behaves as an inductance. Above this value it can be seen as a frequency-dependent resistor with peak loss at about 100 MHz.

Several types of cable use ferrite chokes to prevent CM currents. The main advantage of this approach is that the choke does not filter differential-mode (DM) currents, so it will prevent (up to 100 MHz, at least) some of the electromagnetic interference effects of common-mode (CM) currents.

4. COAXIAL CABLE

Coaxial cable is used in antenna engineering to connect the transmitter to the antenna, particularly at high frequencies. This is largely because of convenient construction and practically perfect shielding between fields both inside and outside the line. The range of impedances that may be obtained most conveniently by coaxial lines is 30–100 Ω. However, since the cable is an unbalanced structure, its connection to a dipole needs a balun transformer. Figure 13 shows its configuration with the dimensions of interest; *d* is the internal conductor diameter, and *b* is the outer conductor diameter. Its characteristic impedance is given by

$$Z_0 = \frac{60}{\sqrt{\epsilon_r}} \ln \frac{b}{d} \tag{8}$$

where ϵ_r is the relative permittivity of the medium.

Figure 13. Geometry of a coaxial cable. A dielectric of relative permittivity ϵ_r fills the space between the inner and the outer conductors.

The attenuation α_c of a coaxial line due to ohmic losses in the conductor is

$$\alpha_c = \frac{4.343R_s}{Z_0\pi} \left(\frac{1}{b} + \frac{1}{d} \right) \text{ (dB/m)} \quad (9)$$

where

$$R_s = \sqrt{\frac{\pi f \mu}{\sigma}} \Omega$$

where f is measured in hertz; μ , in H/m (henries per meter); and σ is the conductivity in S/m (siemens per meter).

The attenuation α_d of the coaxial line due to losses in the dielectric is

$$\alpha_d = \frac{27.3\sigma Z_0}{\ln(b/d)} \text{ (dB/m)} \quad (10)$$

Breakdown will occur in an air-filled coaxial line at atmospheric pressure when the maximum electric field E_m reaches a value of approximately 2.9×10^6 V/m. The average power P that can be transmitted on matched coaxial lines under these conditions is

$$P = \left(\frac{E_m^2}{480} \right) b^2 \frac{\ln(b/d)}{(b/d)^2} \text{ W} \quad (11)$$

The first high-order TE (transverse electric) mode that will propagate in a coaxial cable experiences cutoff when the average circumference is about equal to wavelength, so

$$\lambda_c \approx \frac{\pi}{2(b+d)} \quad (12)$$

5. INSULATORS

A material is said to be an “insulator” if this is its most dominant characteristic. This does not mean that other electric effects, such as conductivity or magnetism, are not present; they are just less significant. From a macroscopic point of view, the constitutive relationship of the material, specifically in the case of the insulating ones (dielectrics), is given by

$$\mathbf{D} = \epsilon \mathbf{E} \quad (13)$$

where \mathbf{E} is the electric field intensity vector and \mathbf{D} is the electric flux density vector.

From the microscopic perspective, it is better to use the relationship introduced by Lorentz [6], where two terms contribute to the vector density of electric flow: the *vector electric field* by the vacuum permittivity and the *vector polarization* \mathbf{P} . Mathematically, this is

$$\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P} \quad (14)$$

$$\epsilon_0 = 8.856 \times 10^{-12} \text{ F/m}$$

Contributions of the material to the behavior of vector \mathbf{P} are different for solids, liquids, and gases. These contributions are too complicated to be summarized here (for more details, see Ref. (6)). However, for linear materials, \mathbf{P} is directly proportional to \mathbf{E} ; therefore

$$\mathbf{P} = \epsilon_0 \chi_e \mathbf{E} \quad (15)$$

where χ_e is the electric susceptibility to the medium.

Substituting Eq. (15) in Eq. (14), one returns to Eq. (13), since

$$\epsilon = \epsilon_0(1 + \chi_e) \quad (16)$$

Therefore there is no difference between this perspective and that of the constitutive relationship.

In the term that defines the loss of energy in Poynting’s theorem, the vector current density (which considers the conduction current) is in phase with the intensity of the vector electric field. In the general characterization of the dielectrics presenting losses, the complex permittivity is introduced:

$$\epsilon = \epsilon' - j\epsilon'' \quad (17)$$

This is introduced in Maxwell’s equations as the current $j\omega(\epsilon' - j\epsilon'')\mathbf{E}$, where the second term is in phase with the electric field. Both ϵ' and ϵ'' are, in general, functions of frequency. Table 1 lists values of ϵ'/ϵ_0 and ϵ''/ϵ' for some representative materials used in antenna engineering as well as the breakdown fields for some materials.

Table 1. Characteristics of Insulating Materials

6. LIGHTNING ARRESTERS

Lightning is an atmospheric phenomenon of harmful consequences. It is caused by the accumulation of electric charges in a cloud, and the consequent discharge on the terrestrial surface. This effect occurs mainly on structures that offer conditions favorable to discharge. The best protection against atmospheric discharges is the enclosure of a site with a grounded conductive structure. Even so, such protection, although not expensive, becomes impracticable.

The antennas must be immune (impervious) to atmospheric discharges, and must maintain integrity as the lightning current flows to the ground. Protection against the direct and induced effects of lightning must be designed in to avoid damage to operators, equipment, and construction. For antennas, several techniques can be used, such as

- Protective conductors on radome [7] (so as to avoid degradation of antenna performance)
- Grounded towers (positioning the antennas below the tower summit as much as possible)
- Lightning arresters [mainly in high-frequency (HF) operation, where the antennas are relatively large structures]

Common types of lightning arresters are varistors, gas discharge devices, and semiconductors. No type is suitable for all applications, and each one may be combined with another into a hybrid device. A simple lightning arrester can be assembled by maintaining a gap between the structure to be protected and the ground. These gaps are adjusted to the minimum width to prevent arcing when the transmitter is in operation.

7. PHASE SHIFTERS

A *phase shifter* is a two-port component that provides a fixed or variable change in phase of the traveling wave. The shift occurs with respect to a “reference” (the line without the component) and a “test” (the line and the component) lengths; therefore it is always understood as the phase difference between the two cases. The shift may be fixed or variable. The variable phase shift uses mechanical or electronic techniques to change the phase dynamically. The main applications of these devices are test, measurement systems, modulation devices, and phased-array antennas. The use of phase shifters in antenna systems provides controllable steering of the main beam of the radiation pattern without moving the antenna. There are several ways to implement these components for communication systems. The type of phase shifter used in this process depends on the kind of antenna being used, including its cost and power requirements.

7.1. Fixed and Variable Phase Shifters

The shifters can provide fixed or variable phase shifts. The fixed phase shifters are usually extra transmission-line

sections of certain length to shift the phase with respect to the reference line. The variable shifters use mechanical or electronic means to achieve a dynamical range of phase difference. In the case of antenna systems, the main use of variable phase shifters is beamsteering, while fixed shifters are more frequently used for beamforming (pattern synthesis).

The mechanically tuned phase shifter usually consists of variable short circuits used with hybrids or, in the case of waveguide components, a dielectric slab with variable position in the guide. Step motors move the slab across the guide (from its center toward outer walls), therefore accomplishing maximum or minimum phase shift.

Another method for obtaining the desired mechanically tuned phase shift is to combine variable short circuits and hybrid circuits. The movement of the short circuit along a transmission line results in the phase shift, therefore making it appear shorter or longer.

There are two classes of electronically tuned phase shifters depending on component cost, weight, and power-handling capability: ferrite and switching circuit shifters. The *ferrite shifter* uses slabs of this magnetic material inside waveguides. Since the electrical properties of ferrite vary with the applied bias magnetic field, this process can yield the desired phase shift. Ferrite phase shifters are essentially low-cost, bulky, high-power-handling-capability devices. The switching circuit shifters are essentially low-power pin (positive–intermediate–negative) diodes or FETs used as switching (ON–OFF states) elements. Depending on the applied bias current in these devices, these devices will work either as short or open circuits. The phase shift is the result of an extra section of transmission line added to the switching element. Therefore, depending on the bias current, the wave traveling along the transmission line will have an additional traveling path. Since these devices are binary switches, only discrete phase shifts are possible. The construction of a continuously variable shifter demands the use of several of these switching elements. The design of variable phase shifters depends on the expression of the variable shift in respect to a specific position or applied bias magnetic field or current. In all cases, the procedures depend on the topology of the device and its mathematical models.

7.2. Ferrite Phase Shifters

Ferrite phase shifters are common in power applications in waveguide technology. The ferrite phase shifter is a result of the combination of two properties of this medium: (1) dependence of the velocity of the propagating waves on the direction of propagation of the wave relative to the ferrite slab and (2) application of a bias magnetic field. Ferrite is an anisotropic medium; therefore, the propagation constant (and the velocity of propagation) is an important factor in the ferrite phase shifters, which are commonly used in power applications in waveguide technology. The anisotropic properties of ferrites are also critical factors if a magnetic field is applied. This is a macroscopic result of the microscopic interaction between the fields and the atomic nuclei.

Figure 14. PIN switching circuit phase shifter representation. Application of the bias current results in change in electrical length of the line. The resulting shift is the difference in the electrical angle between direct polarization and reverse polarization.

The phase shift in these devices is the difference between the forward and backward traveling waves. This is a nonreciprocal phase shift, which is dependent on an applied external magnetic field. Accurate design of these devices is not straightforward because of the complexity of the mathematical models of ferrites. A detailed procedure is shown by Pozar [8] and Bornemann [9].

7.3. Switching Circuit Phase Shifters

The switching circuit phase shifter uses solid-state technology (pin diodes). In these applications, pin diodes behave as ON-OFF elements. The switching circuit shifters are common to several manufacturing technologies such as microstrip, coplanar guides and lines, slotlines, waveguides, and finlines. The diodes act as binary switches along the line (Fig. 14). With the bias applied, the diode will behave as a short circuit for the incoming wave. Therefore, the phase transmitted signal has two possible states, determined by which diode is polarized. A variable phase shift results from the mounting of several diodes on the line. The returning wave enters a hybrid circuit and then the antenna.

8. PLANAR TECHNOLOGY

Planar transmission lines are the basic transmission media for microwave integrated circuits (MICs) when the hybrid or monolithic technology is used. Figure 15 shows the cross section of the three basic planar transmission lines: stripline, microstrip, and slotline. Several other configurations are possible, such as listed by Bhat and Koul [10]. All are variations of the three main types. Each one offers certain advantages, depending on the circuit type and its application. Some of these configurations are the suspended stripline, the suspended microstrip, the inverted microstrip, the coplanar guide, and the coplanar stripline. Planar designs using special substrates have been applied at frequencies up to 10.0 GHz.

A designer can perform several microwave circuits and electric functions with planar transmission lines. Therefore, this constitutes a very important technology for the

Figure 15. Basic planar transmission lines: (a) stripline, TEM (transverse electric mode); (b) microstrip line, quasi-TEM mode; (c) slotline, non-TEM mode.

development of antenna accessories in the microwave range. These components, called *distributed circuits*, are generally of the order of a wavelength or more (in the propagation medium). Thus, in the lower microwave range these circuits can have large dimensions. In this case, one uses lumped components.

However, several lumped components can be obtained starting from planar technology. These components are called *microwave integrated circuits* (MICs). Figure 16 illustrates lumped and distributed circuits in planar technology.

The most important project parameters for planar transmission lines are

- Effective dielectric constant
- Characteristic impedance
- Dispersion
- Losses
- Working frequency limitations

Figure 16. Lumped and distributed MICs: (a) spiral inductor (lumped element); (b) bandpass interdigital filter (distributed MIC). (Courtesy of the Department of Electrical Engineering, University of Brasilia.)

Antenna accessories that can be manufactured for planar technology include directional couplers, hybrid rings, power dividers, and impedance matchers [11,12]. These components are generally used in antenna feeds, for impedance matching between the antenna and transmission system, and for antenna measurement.

The effect of the electromagnetic coupling between two parallel transmission lines (sufficiently near to each other) constitutes the design framework of several microwave devices (especially for antennas). An example is the directional coupler, which has wide application in circuits and telecommunication systems. It performs several electrical functions, such as the separation and combination of signal power (received or delivered from/to antennas). It also allows the sampling of power and separation of incident and reflected waves of a system. This separation is used for power control or performance measurements.

Couplers are either conductively or electromagnetically coupled transmission line circuits with three, four, or more ports. In general, a directional coupler is a four-port device, with two of its ports mutually decoupled, with respect to the other two. Figure 17 shows the block diagram of a directional coupler. From the theoretical point of view, if port 1 receives a microwave signal, this power will be delivered to ports 2 and 3, but no power will appear in port 4. Port 4 is decoupled from port 1. On the other hand, if port 2 receives the microwave signal, then this signal will be divided between ports 1 and 4, and port 3 will be decoupled, in relation to port 2.

Figure 17. Block diagram of a directional coupler.

Figure 18. Directional couplers in $\lambda/4$ parallel lines, in the microstrip technology. (Courtesy of the Department of Electrical Engineering, University of Brasilia.)

In the special case where the power is equally divided between ports 2 and 3, the coupler is called a “hybrid” or 3-dB directional coupler. If the phase difference is 90° between ports 2 and 3, the coupler is termed to “ 90° hybrid” or “quadrature hybrid”. Another hybrid design provides 180° between the output ports.

Different topologies of directional couplers exist [11,12]. Figure 18 shows a directional coupler in the topology of parallel lines of $\lambda/4$ length. As in any directional coupler, a fraction of the incident power in the primary branch is coupled to the secondary branch. In fact, when a microwave signal is incident in port 1, port 2 receives part of its power. In this topology, another part of the power will be coupled to port 3. This coupling occurs through the gap, and practically no power will be coupled to port 4, which is terminated by the load. The load has the same value of the characteristic impedance of the coupler lines. In parallel line couplers, the smaller is the gap between branches of the coupler, the greater is the coupling. The spacing between conductors can compromise high coupling designs.

The main parameters of a directional coupler are the coupling, directivity, isolation, and transmission factors. The *coupling factor* is defined by the relationship between the power in the coupled (port 3) and input (port 1) ports; this factor is a measurement of the coupling. The *transmission factor* is defined by the relationship between the power in ports 2 and 1. The *directivity* is the relationship between the power in the isolated (port 4) and coupled (port 3) ports; this measures the undesirable coupling. The *isolation* is the relationship between powers in the isolated (port 4) and input (port 1) ports.

Figure 19a shows a coupler in branchline topology [11,12]. In this directional coupler, a larger coupling factor can be obtained. It also allows keeping DC (direct-current) continuity between the ports, which is an interesting feature for phase shifter design (as shown in Fig. 19b). It allows high power levels. The branchline coupler uses branching transmission lines to couple 3–9 dB. The length of all branches of this coupler is $\lambda/4$. However, the widths, and consequently the impedances, of these branches are

Figure 19. (a) Branchline coupler structure; (b) branchline coupler in a phase shifter circuit. (Courtesy of the Department of Electrical Engineering, University of Brasilia.)

different: Y_1, Y_2, Y_3, Y_4 . The operating principle of this coupler can be presented in the following way. When the input port (port 1) receives a signal, the energy will be divided and will propagate in clockwise and counterclockwise sense through the branches. The power in each output (ports 2–4) will depend on the phase relationships between the propagating signals. In a 3-dB coupler, the power is divided equally between the coupled (port 2) and matched (port 3) ports. Port 4 is the isolated one.

A special version of branch line coupler is the hybrid ring (Fig. 20). The ring has a 1.5λ circumference and all sections of equal impedance. It can be assembled using several technologies such as coaxial lines, stripline, microstrip lines, or even waveguides. The operating principle is the same as that of the branchline coupler. The signal injected in the input port is divided into two opposite-

Figure 20. Hybrid ring. (Courtesy of the Department of Electrical Engineering, University of Brasilia.)

Figure 21. Lange coupler.

direction propagating waves. In the coupled output port, the two signals arrive in phase and reinforce each other, providing an output signal. In the direct output port, the signal that propagates counterclockwise travels a length of 1.25λ and the signal propagating clockwise travels 0.25λ . The two signals arrive at this port in phase, providing an output signal at this port. For the same reason, there is an isolated port that has no output signal. The output signals in the direct and coupled ports are 180° out of phase.

Another topology of directional coupler is the Lange coupler (Fig. 21). The Lange coupler is well adapted to microstrip technology [13]. It is an interdigital structure with superior performance in comparison to the parallel line coupler. Its bandwidth can be greater than one octave. The Lange coupler, which is compatible with tandem topology (Fig. 22), makes it possible to obtain power coupling near 3 dB, with a combination of two inferior-order couplers, if their design dimensions are feasible.

Power dividers are used in antenna feeds and performance measurements. Directional couplers and hybrid rings can be used as power dividers. The branchline coupler output signals are in phase quadrature (90° out of phase). The hybrid rings output signals that are in opposite phases. However, in several microwave applications, such as parallel feeds for phased-array antennas, the input has to be divided into an arbitrary number of signals with equal power and in phase. A symmetric power divider of n branches provides the successive division of the input signal into n signals with the same power and phase at all frequencies. This power divider can also be used as a signal combiner by inverting the input and the output ports.

Figure 22. Lange Coupler in tandem topology. (Courtesy of the Department of Electrical Engineering, University of Brasilia.)

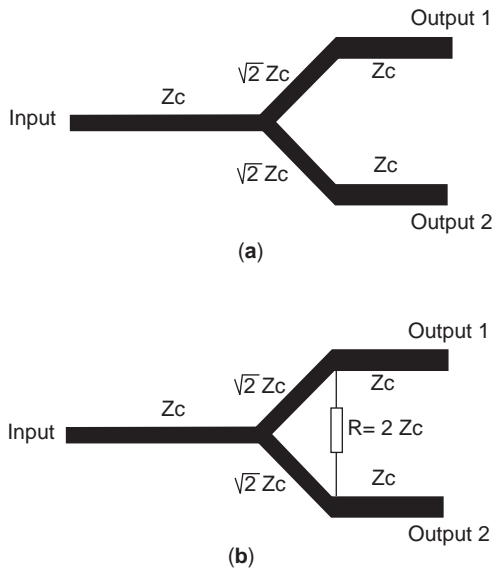

Figure 23. Unmatched and matched two-way power dividers.

There are several kinds power dividers and combiners. One of them is the two-branch power divider, shown in Fig. 23. It is also possible to obtain output signals in phase, but with different power levels.

Impedance-matching circuits are another type of antenna accessory. They are also manufactured in planar technology [2]. These circuits are commonly used in antenna feeds, avoiding power losses caused by mismatch. In most cases, the load will have an impedance different from that of the transmission line. This is the case in telecommunication systems, where the output impedance of the generator is usually different from the input impedance of the antenna. The problem is how to reduce or eliminate the resulting reflections and high voltage standing-wave ratios (VSWRs).

One method is to cascade transmission-line sections (planar structures) or lumped components with different impedances between the mismatched transmission line and its terminations (the system output and the antenna input). The antenna input impedance is then transformed. This new impedance value seen at the output point (the end of the transmission line) can be matched to the system for maximum power transfer.

Different topologies and technologies are used in impedance-matching circuits. Examples involve the use of stub association and quarter-wave transformers. Figure 24a shows a schematic of a quarter-wave impedance transformer. The impedance Z_1 can be matched to a transmission line of characteristic impedance Z_s with a section of transmission line that is a quarter-wave long based on the wavelength in the transmission line. This characteristic impedance of the matching section is shown as $Z_t = \sqrt{Z_s Z_1}$. The microstrip feed on Fig. 24b is planar, allowing the patch and the feed to be printed on a single metallization layer. The impedance of the edge-fed patch can be transformed by using a quarter-wave matching section of a microstrip transmission line, as shown in Figs. 24a and 24c. Another kind of quarter-wave

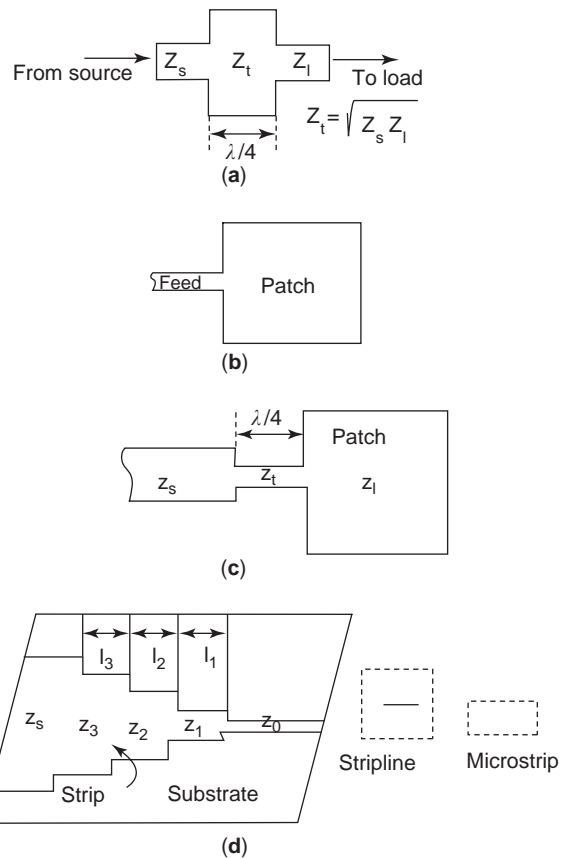

Figure 24. (a) Quarter-wave impedance transformer. (b) Top view of patch antenna. (c) Microstrip edge feed with quarter-wave transformer. (d) Multisection quarter-wave transformer.

transformer is the multisection quarter-wave transformer, as shown in Fig. 24d. This kind of transformer is commonly used in wideband systems.

9. TWIN-LEAD LINE

The bifilar (twin-lead) line is a two-wire parallel conductor line that carries the power from the generator to the antenna. Each wire carries equal and opposite currents (180° out of phase). However, since the wires are spaced by a certain distance, their radiated fields do not cancel out completely. If the two wires were located in the same place in space, there would be no radiated field. However, since this is not possible, there will be a certain amount of radiation loss. Keeping the distance between the parallel wires small (typically of the order of 1% of the wavelength of the radiowave) can reduce this loss. The spacing between conductors is a constraint of the physical limitations of the line construction. Parallel conductor lines, open-wire lines, two-wire lines, two-wire cable, and two-wire ribbon cable are also bifilar lines.

9.1. Types of Bifilar Lines

The bifilar line is usually supported a fixed distance apart. Usually insulating rods, called “spacers,” or molded

plastics such as polystyrene provide the support. The spacers have to be placed at small length intervals to prevent the wires from moving apart from each other. These lines are air-insulated, since air is the medium between them. The spacers have little effect on the impedance behavior of the line. However, flexible dielectric separation (molded) lines have several advantages over air-insulated types. In this type, a plastic coating similar to a ribbon surrounds the conductors. These lines maintain uniform spacing between conductors. They are also less bulky, weigh less, and are easier to install. One common example of the flexible dielectric bifilar line is the television receiving cable (called "ribbon cable" or two-wire cable).

9.2. Uses of Bifilar Lines

In television reception applications, polyethylene molded ribbon bifilar lines are available with spaces of 2.54 mm (1 in.) and 1.27 mm ($\frac{1}{2}$ inch) with conductor sizes of AWG (American Wire Gauge) 18 (diameter of 2.053 mm). These lines have characteristic impedances of 450 and 300 Ω , respectively. The attenuation is quite low for these receiving applications (typically under 0.03 dB/m for applications under 20 m). There is also the 75- Ω bifilar line, which has AWG 12 conductors (diameter of 1.024 mm) with close spacing between them (see Ref. 14 for a detailed description). The spacing keeps most of the fields confined to the solid dielectric instead of the surrounding air.

The bifilar line is also used in amateur radio applications and LF to VHF (low- to very-high frequency) antennas, although for higher-frequency applications, the coaxial line tends to be used more frequently because of its superior characteristics. The lines are simple to assemble. However, the designer should avoid sharp bends. These bends tend to change the characteristic impedance of the lines, which cause reflections at each bend and power mismatch.

9.3. Design Equations of Bifilar Lines

The analysis of bifilar transmission lines uses Maxwell equations subjected to the appropriate boundary conditions. The main parameters of the bifilar transmission line are

- Characteristic impedance

$$Z_0 = \frac{\eta}{\pi} \cosh^{-1} \left(\frac{d}{2r} \right) = \frac{120}{\sqrt{\epsilon_r}} \cosh^{-1} \left(\frac{d}{2r} \right) \quad (18)$$

where r is the radius of the conductors, d is the spacing between them, and ϵ_r is the relative dielectric of the surrounding medium (Fig. 25).

- Attenuation

$$A \text{ (dB/m)} = 8.686 \left(\frac{1}{\pi r} \sqrt{\frac{\omega \mu}{\sigma}} \left[\frac{d/2r}{\sqrt{(d/2r)^2 - 1}} \right] + \frac{\pi}{\lambda} \left(\frac{\epsilon''}{\epsilon'} \right) \right) \quad (19)$$

Figure 25. Geometry of the bifilar line. In the molded plastic casing, the dielectric surrounding the lines has the shape of a ribbon. Since most of the field is inside the ribbon, the line is less susceptible to external influences.

where μ is the permeability of the surrounding medium, ω is the operating frequency, σ is the loss in the conductors, and ϵ''/ϵ' is relative loss of the dielectric constant.

- Propagation constant

$$\beta = \frac{\omega}{c} \quad (20)$$

where c is the speed of light in a medium that surrounds the conductors. In the case of the ribbon transmission line, ϵ_r is 2.56 with $(\epsilon''/\epsilon') = 0.7$. If the wire is made of copper, then σ is 58 MS/m. In this case, since most of the field is inside the dielectric, the relative dielectric constant ϵ_r is approximately 2.56.

ANTENNA ANECHOIC CHAMBERS

BOON-KUAN CHUNG
Multimedia University
Cyberjaya, Malaysia

1. INTRODUCTION

Electromagnetic wave measurements involving very low signal levels are commonly performed in laboratory facilities that provide high isolation from external electromagnetic environment. Shielded enclosures with isolation performance in excess of 100 dB prevent extraneous energy from masking measurements of the intended signals. However, an electromagnetic wave generally propagates in all directions, and waves reflected by the walls, ceiling, and floor of the shielded enclosure will give rise to a complex wavefront at the test region where the test antenna is to be placed. As it is desirable to provide an environment for electromagnetic energy to propagate between the transmitter and the receiver in a simple and well-defined manner, waves propagating toward the walls, ceiling, and floor of the enclosure must be absorbed using a suitable absorbing material. The shielded enclosure with the entire inner surfaces covered with wave absorber to create a nonreflecting environment equivalent to free space is known as the *anechoic chamber*. With no echo, the anechoic chamber provides a “quiet” environment for electromagnetic wave measurements.

Anechoic chambers were initially utilized as a means to improve the accuracy of indoor radiofrequency (RF) measurements during World War II in response to the increasing need to test RF devices, antennas, and radar signature in a controlled environment, with all-weather capability and minimum electromagnetic interference. Throughout the years, many chambers have been designed with the capabilities to perform a wide variety of measurements, including antenna gain, directivity, radiation pattern, phase, polarization, impedance, radar cross section (RCS), radiation hazards, and electromagnetic compatibility (EMC) testing. Others have been designed for specific types of measurement.

Anechoic chambers are conventionally utilized in the microwave region (above 1000 MHz). In the 1990s, an increasing number of low-frequency (30–1000-MHz) electromagnetic anechoic and semianechoic test chambers were manufactured in response to the rapid growth in electronic and telecommunication industries. Products must meet both emission and immunity requirements of EMC regulations before they can be marketed. A full anechoic chamber is commonly used to determine the immunity of

products to an impinging electromagnetic field. As for the emission limit, interference emissions from electronic products are referenced to measurements performed on an ideal open-area test site (OATS) having a perfectly conducting infinite ground-plane. A semi-anechoic chamber in which the conductive floor is not covered with wave absorbing material can be used as the alternative test site for this measurement. International standards are being developed to qualify full anechoic chamber for use in both immunity and emission EMC measurements.

2. SHAPES OF ANECHOIC CHAMBER

The most common geometric shapes for anechoic chamber design are those of rectangular shape, due to the simplicity of constructing the chamber structure and ease of lining the absorbers. One deficiency of this simple geometry, however, is that the absorbers on the sidewalls, ceiling, and floor scatter a considerable amount of waves that are approaching at large angle of incidence with respect to the normal direction of the absorbers (as illustrated in Fig. 1). These wide-angle reflections are especially crucial at lower frequencies, where the absorbers are less effective in absorbing incident waves. As a result, the reflected waves add with the direct path signal at the test region and form an interference field (with sharp peaks and nulls), giving rise to errors in various wave propagation measurements.

In the 1960s, the tapered-shape chamber was invented to overcome the limitation of rectangular chambers at low frequencies (below 1 GHz) [1]. The diverging geometry of the tapered chamber (see Fig. 2) greatly reduces the wide-angle reflection problem. As a result, less expensive absorbers can be used at the tapered section. Additional cost saving is attained because a smaller surface area in the chamber and thus fewer wave absorbers are required. The tapered chamber has been designed, tested, and used at frequencies as low as 30 MHz. However, these improvements are not achieved without tradeoff. For example, only a single-source antenna can be placed at the taper apex, which limits the measurements involving multiple sources, moving sources, and bistatic radar cross section. The path loss is different from that of free space, making the chamber unsuitable for measurements involving

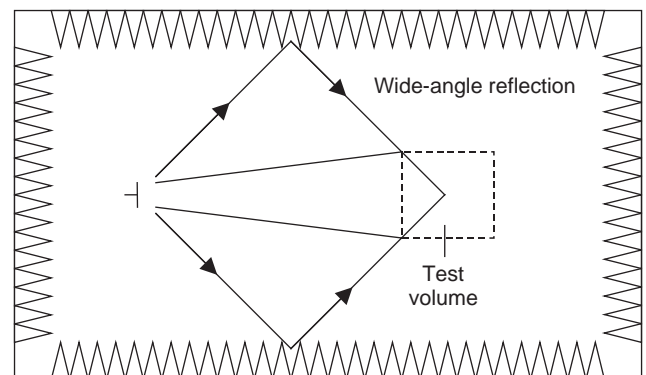

Figure 1. Plan view of a simple rectangular anechoic chamber.

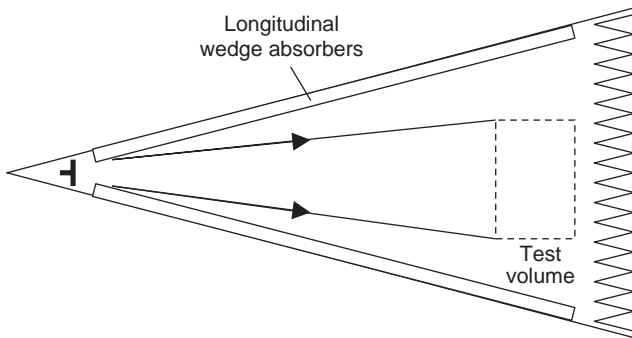

Figure 2. Diverging geometry of a tapered chamber.

absolute field strength. At higher frequencies, the rectangular chamber is preferred since the antenna can be configured in a highly directional radiation pattern and the level of wide-angle reflection can be controlled. In addition, absorbers with good absorbing properties at these frequencies can easily be manufactured at low cost.

A quasitapered chamber has been designed and evaluated from 100 MHz to 93 GHz [2]. It consists of a small rectangular room, connected to a tapered section, and then followed by a larger rectangular room where the test region is located. This design incorporates the performance advantages of a fully tapered chamber at low frequencies and provides some flexibility of a rectangular chamber at high frequencies.

Microwave antenna and RCS measurements usually require that the target under test be illuminated by a uniform plane wave. This is achieved only in the far-field region and often dictates a very large distance. To reduce the room area required, the compact-range anechoic chamber uses large offset parabolic reflector to produce an approximate plane wave at a much shorter range. The parabolic reflector is illuminated by a broadband horn antenna feed placed at the focal point of the reflector (as shown in Fig. 3). The diverging spherical wavefront is converted into a plane wave with very flat phase front and small amplitude taper over the test zone, making the compact range equivalent to a much larger conventional antenna test range. The offset focal point eliminates scattering and shadowing from the feed and feed support. However, limited cross-polarization isolation can be achieved.

Figure 3. Compact range anechoic chamber configuration.

Figure 4. Dome-shaped anechoic chamber for monostatic and bistatic RCS measurements.

A few dome-shaped chambers have been designed and built [3,4] to facilitate a variety of monostatic as well as bistatic RCS measurements at a constant range. A number of antennas are mounted on the dome surface (see Fig. 4) inside the chamber as receivers to detect the electromagnetic waves scattered from radar targets placed at the center of the spherical space.

Anechoic chambers that are built specifically for EMC tests are usually not suitable for microwave RCS and antenna measurements. Similarly a microwave anechoic chamber is seldom suitable for EMC tests, due to differences in the measurement techniques and test-site validation criteria. Nevertheless, a major limitation has been the availability of ultrawideband wave absorber that can provide adequate reflectivity performance covering the frequency bands of EMC test requirements and microwave frequencies.

3. ELECTROMAGNETIC WAVE ABSORBERS

Much research has focused on developing absorbers with superior absorbing properties such as low normal incidence reflection, low forwardscatter and backscatter at wide-angle incidence, lower usable frequency, wide bandwidth, and reduced absorber thickness in the course of improving the “quietness” of anechoic chambers, cost-efficiency, and required room size. The idea of using material that provides wave impedance near that of free space at the front surface gradually tapers to that of a lossy medium at the back surface has dominated this area of development. One implementation of such idea is to shape the absorbing material into a wedge or pyramid shape (see Fig. 5) in contrast to a flat front surface.

An extremely broadband absorber can be made with pyramidal shaped urethane foam impregnated with carbon black. The height of the pyramid must be greater than quarter wavelength to function efficiently. A 60-cm-thick pyramidal foam absorber may offer a reflectivity level below -40 dB over the frequency range 1–40 GHz at normal incidence. Optimum performance of the electrically thick foam absorber is obtained by adjusting the percentage carbon loading of the foam material. For frequencies as low as 30 MHz, 2.5-m-thick absorbers were used for con-

Figure 5. Pyramid (a), wedge (b), and twisted pyramid (c).

struction of anechoic chambers during the 1970s. The bulky size gives rise to high cost of material, difficulty of installation, and large room space requirement, thus limiting its use at the lower frequency range of the spectrum.

The wedge-shaped absorber gives better absorbing characteristics compared to the pyramidal-shaped absorber for wave directions nearly parallel to the ridge of the wedge. It can be used at the tapered section of chamber with diverging geometry.

The twisted pyramid structure has been used in the fabrication of thick absorbers because of its improved mechanical strength. The pyramid is “twisted” by 45° with respect to the base as shown in Fig. 5. The droop with age will be less for the twisted pyramid tips compared to the standard pyramid tips. However, its reflectivity performance is generally not as good as the standard pyramid.

Microscopic particles of metal can be dispersed in a nonconducting matrix to adjust the effective conductivity of the material. The resistive material can be coated onto a hollow pyramid-shaped substrate with a height of quarter-wavelength to realize a wideband absorber. A large absorber has been constructed with adequate mechanical strength and light weight for construction of EMC test chamber.

Wide band absorption can also be achieved by increasing the material loss tangent with respect to depth from a flat outer surface. A variation of this approach is to use multiple layers of carbon-impregnated foam. The layers have an increasing loss tangent from the front layer toward the bottom layer, hence achieve an electrical taper that yield a material with good reflectivity level over a wide frequency range.

To achieve low reflectivity using taper length less than a quarter-wavelength, a different carbon loading for the foam pyramids must be used. If the carbon loading is too high, the impedance taper will be too abrupt, causing the incident wave to be reflected from the region near the pyramid tips instead of penetrating into the absorber medium. On the other hand, if the carbon loading is too low, the incident wave that penetrates the absorber medium will not be sufficiently absorbed. With a carbon loading that gives optimum reflectivity of -20 dB for the 200–1000 MHz range, the performance of the pyramids may not be adequate at higher frequencies where the required reflectivity is below -40 dB for the typical applications in designing antenna and radar cross-section measurement chamber.

Ferrite tile is a new generation of low-frequency wideband absorber that has been widely used in many EMC

Figure 6. Geometry of a ferrite grid.

test chambers. The ferrite tile (NiZn) with a thickness of 6.3 mm may offer a reflectivity level below -15 dB over the frequency range of 30–600 MHz, but the reflectivity deteriorates rapidly as the frequency increases [5]. The ferrite grid (see Fig. 6) is a variant of ferrite tile. Because of the square air section, the ferrite material can be considered as having an equivalent permittivity and an equivalent permeability. The filling factor or fraction of space occupied by ferrite can be selected in order to place a reflectivity null at a desired frequency. Ferrite grid with a thickness of 19 mm can be used to cover the frequency range of 30–1000 MHz. An exponentially tapered ferrite grid is also investigated in an effort to widen the bandwidth to 2400 MHz.

A method to improve the reflectivity of ferrite tiles and grids is by simply adding a dielectric layer between the ferrite and the metal wall of the screened room [5]. The dielectric layer can be commercial plywood with dielectric constant of ~ 2.0 . However, the thickness of the dielectric must be properly chosen in order to give an optimum performance over a wider bandwidth. A multi-layer approach with different types of ferrite and/or magnetic composite materials separated by air space is under investigation.

Electrically thin urethane foam pyramids that are optimized to operate at 200–1000 MHz have been combined with ferrite tiles that are effective at 30–600 MHz. This hybrid absorber provides the required performance to cover the frequency range of 30–1000 MHz. The carbon loading of the pyramids must not be too high; otherwise the low-frequency performance of the ferrite tiles will be degraded.

The weight of ferrite and hybrid absorbers (> 30 kg/m²) are generally heavier than foam absorbers. The strength of the room must be strong enough to support the weight of the absorbers. A special room structure will be necessary in constructing the large anechoic chamber. On the other hand, the use of 2.5-m-thick pyramid absorbers requires a screened room size larger than $20 \times 10 \times 9$ m height in order to construct a 10-m-range anechoic chamber. The required cost and space are substantial. Hence, there is much interest in trying to reduce the required investment while still maintaining adequate performance.

Small and medium-size foam absorbers are conventionally glued onto the chamber wall using rubber-based contact adhesive. Pyramids longer than 1 m are usually supplied with metal baseplate to be installed onto a rail-and-clip mounting system on the chamber wall in order to ensure installation reliability. Ferrite tiles can be installed using glue. However, because of weight and sharp edges of the tile, overhead net must be installed as safety measure to prevent fallen tile from injuring the personnel who enter the room. A more secure method is to install a plywood panel onto the wall and then fasten the ferrite tile through a centre hole onto the plywood panel using self-tapping screws. The gap between adjacent tiles can then be precisely controlled to give better reflectivity performance, in contrast to using adhesive in which some glue may be trapped between the tiles. The plywood panel also acts as the dielectric backing to improve the performance of the ferrite tile.

In addition to electrical and mechanical specifications of the absorber, the fire retardant property of the absorber must also be considered in order to comply with building safety codes. Lifespan and maintenance needs of the absorber may also be an aspect to consider in the absorber selection criteria.

4. SIZE OF ANECHOIC CHAMBER

Wave measurements are usually performed at far field so that uniform field distribution can be obtained. The measurement facility must be sufficiently large to accommodate the source and the receiver at a separation defined by the Rayleigh range criterion. For an antenna aperture D of 1 m diameter, the separation distance must be greater than $2D^2/\lambda$, which is 67 m at 10 GHz and 6.7 m at 1 GHz. At lower frequencies, the separation must be longer than $\lambda_{\max}/2\pi$ (where λ_{\max} is the maximum wavelength to be measured) so that the coupling between the transmitter and receiver antennas is radiative rather than reactive.

Absorber reflectivity is a function of the wave impedance. The wave impedance near a dipole-type source is higher than intrinsic wave impedance of free space, while the wave impedance near a current loop source is lower than the intrinsic wave impedance. For RF absorber to work efficiently, the distance between the radiation source and the absorber must be greater than $\lambda_{\max}/2\pi$. In general, the thickness of a pyramidal foam absorber must be greater than $\lambda_{\max}/4$ to be effective. However, in order to provide absorber reflectivity better than -40 dB, the height of pyramid shall be several wavelengths. For antenna aperture of 1 m diameter operating at 1 GHz, the size of the screened room may have to be larger than $8 \times 2 \times 10$ GHz, the Rayleigh range criterion can be met for antenna aperture smaller than 0.3 m diameter. For larger antenna, near-field measurement techniques may be used.

5. SCREENED ROOM

The ideal environment for taking RF wave measurements should be free from electromagnetic energy not directly associated with the measurements. The isolation require-

ment is necessary to prevent extraneous energy from masking measurements of electromagnetic field of interest and to protect nearby systems from interference caused by the energy generated by radiation source used in the measurement setup.

RF-shielded enclosures are widely used for various types of RF measurements in the increasingly crowded electromagnetic environment. A volume of space completely enclosed by metal plates will be shielded against electromagnetic radiation. However, ventilation holes and access doors to the screened room, as well as cables penetrating the shielding walls for signal-power interconnection purposes, will cause leakage of electromagnetic waves. Different construction methods will give rise to varying degrees of imperfection that determine the shielding effectiveness. The required shielding design is a function of the purpose of the shield, type of equipment involved, the measurement distance, and the sensitivity of the information being processed.

The geometry of the anechoic chamber must not be too complex so that the screened room can easily be constructed, the shielding effectiveness can be under controlled, and the RF absorbers can properly be lined on the chamber walls, ceiling and floor.

The screened room is commonly fabricated from sheet copper, aluminum, or steel. The most common material is 24-gauge galvanized/zinc-plated steel sheet laminated to wooden board. Sheetmetal offers more than 120 dB shielding effectiveness. However, the total shielding effectiveness of screened room is usually limited by the presence of holes and/or seams, high-impedance discontinuities, and wires/cables passing through holes in the shield. In all practical cases, shielding effectiveness in excess of 120 dB can rarely be achieved [6]. Doors, vents, filters, and piping must be carefully designed and constructed to maintain the shielding integrity. On the other hand, standing waves due to resonance effects may cause certain areas within a screened enclosure to exhibit poorer performance.

A smaller screened enclosure is commonly constructed as a modular clampup structure using prefabricated wooden panels laminated with sheetmetal. The panels are tied together to form the six-sided freestanding room by a framework made of plated steel. A metal-to-metal seal between the panels is provided by the clamping unit, which consists of two metal straps brought together by a number of screws. The shielding performance is dependent on the degree of electrical continuity between the panels and the absence of cracks or breaks between the panels. Installation workmanship is critical. Cleanliness is required around the edges of the panels. Painting of the shielding panels is not recommended because the paint may capillarize under the clamping straps, thus negating the shielding properties of the system. A few problems of the modular construction are the floor panels tend to become loose under varying loads and constant stresses caused by people moving about the room. Expensive maintenance and recertification are required. Water will cause contamination and corrosion of the clamped seams and degrade the shielding effectiveness. The wooden core will swell with moisture and damage the shielding integrity. Hence, modular screened enclosure is not suitable for climate that

has continuous high humidity unless marine-grade plywood is used.

When the required room size exceeds 20 m^2 , welded construction must be considered. A large modular system may not be cost-effective because of the required steel support structure to carry the weight of the screened room ceiling panels. Welded enclosure is structurally reliable and provides long-term high-performance shielding. Low-carbon steel is commonly used because of its relatively low materials cost. However, it has the tendency to rust when exposed to moisture. The corrosion can be protected with paints containing a large amount of zinc. Galvanized steel is not suitable because it produces toxic gas in the welding process.

Architectural shielding system is a method where metal foil or sheet metal is built into the walls, floor, and ceiling of existing or new construction. It is used for application requiring moderate shielding performance. Soldering and shielding tapes are used to join together the metal shields to form a continuous barrier.

A standing wave will be reinforced by reflections between the opposing walls, and between the ceiling and the floor, causing cavity resonance to be established in the screened room. The absorber must provide sufficient damping of Q factors of the resonant modes. Hence, an RF absorber must be applied over the entire inner surfaces of the enclosure to create an anechoic environment. The strength of the shielding structure must be strong enough to support the weight of the RF absorber.

The appearance, physical layout, lighting, HVAC properties, and environmental requirements will depend on the operational purpose of the anechoic chamber. Air conditioning and controlled humidity are generally required to ensure the lifespan of RF absorber in an anechoic chamber.

6. PERFORMANCE CRITERIA

The performance of the antenna anechoic chamber is defined by the uniformity of the illuminating field over a given region known as the “quiet zone”, the region in which

the test antenna is to be placed. The illuminating field across the quiet zone may have small amplitude ripple due to interference of the direct signal with reflections from various mounting structures, cables, turntable, obstacles on or near the range surface, and irregularities in the range surface. The “quietness” of the zone is then defined as the average ratio of reflected energy to that of the direct signal. However, there is no standardized figure of merit for an anechoic chamber. The “free-space voltage standing-wave ratio” field probe technique is recommended by IEEE Standard 149-1979 to evaluate the quietness level. An antenna with stated directivity is used as the probe. The probe carriage is oriented perpendicular to the axis of the chamber to enable the probe to move continuously along a transverse line. The interference pattern of the field is recorded along with the linear motion of the probe. A typical result is shown in Fig. 7. Measurements are made for horizontal and vertical transverse directions with both horizontal and vertical polarizations. A standard-gain horn antenna is generally used as the probe. The directivity of the probe antenna will affect the results obtained.

The radiation pattern of antenna is conventionally measured at far-field distance between the transmitter and the receiver antennas. In an anechoic chamber, the size of the quiet zone is dictated by the Rayleigh range criterion to ensure that the phase variation of the direct wave from the center to the edge of the quiet zone is less than 22.5° (equivalent to $\lambda/16$). Larger phase variation may cause the measured antenna pattern to depart appreciably from the true far-field pattern. For a fixed range distance $R = 10 \text{ m}$, the width of the quiet zone decreases with frequency from 1.22 m at 1 GHz to 0.39 m at 10 GHz.

There must be minimum amplitude variation of the field within the quiet zone. If the antenna under test (AUT) is configured as the receiver antenna, the effect of wide-angle reflection (from the walls, ceiling, and floor of the anechoic chamber) may be reduced by the use of directional transmitting antenna. Hence, the acceptable tolerance for the level of reflected wave below the direct wave amplitude depends on the radiation pattern of the

Figure 7. Amplitude variations within the quiet zone. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

AUT and the source antenna. The directivity of the source antenna must not be too high, to ensure that the amplitude taper from the center to the edge of the quiet zone will not adversely affect the measurement accuracy. For antenna polarization measurement, cross-polarization isolation of the source antenna and the anechoic chamber must be better than that for the AUT.

The performance criteria employed to evaluate an anechoic chamber depend on the type of measurements to be made in the chamber. For RCS measurements, the performance criterion of the chamber is its apparent radar cross section measured in the absence of the scatterer. This is, in effect, the total system sensitivity of the measurement system. It determines the smallest RCS that can be reliably measured. The accuracy, however, is not specified because it does not depend on just a few parameters but on a complex combination of a number of factors. These include the calibration technique, data processing algorithm, signal-to-noise ratio, as well as the nature of the target in terms of the scattering mechanism involved in the wave-target interaction such as edge diffraction, creeping wave, traveling wave, and coupling between constituents in a dense medium.

For EMC-radiated emission measurements, the site validation requirements are defined in international standard CISPR 16 (and ANSI C63.4 in the United States; EN50147-2 in the Europe). The measurement site shall be validated with a method involving a series of normalized site attenuation (NSA) measurements for 30–1000 MHz frequencies. The *site attenuation* is defined as the ratio of the voltage input to a matched and balanced lossless tuned dipole radiator, to that at the output of a similarly matched balanced lossless tuned dipole receiver antenna. The NSA measurements are carried out for the given transmitter-receiver separation and heights above a flat conductive surface for both horizontal and vertical polarizations. The measured NSA data shall be compared to that calculated for an ideal site.

7. ABSORBER AND CHAMBER MODELING

The calculations of the interference field in an anechoic chamber are often inaccurate because of the lack of a proper model to characterize the scattering behavior of absorbers when they are lined up on the chamber walls. With the transmitter located at one end of the chamber and the receiver located at the other end, the reflected waves in magnitude and phase must be known in order to calculate the total field due to the sum of the direct wave and the reflected waves. Absorber manufacturers usually specify only the reflectivity at normal incidence due to the limitation of the large waveguide or large coaxial line used to carry out the measurement. In fact, the reflectivity at oblique incidence may deteriorate rapidly with increasing incident angle. An engineering model that describes the behaviors of the absorber as a function of incident angle, frequency, and polarization, in magnitude and phase, is required for calculation of the sum of waves propagating directly toward the receiver and those reflected from the chamber walls and ceilings.

Theoretical models for pyramidal and wedge absorbers have been developed to calculate absorber reflectivity using the known complex permittivity and permeability, as well as the conductivity, of the bulk material [7]. However, multiple samples extracted from several places of a real absorber may show large differences in the bulk parameters. The calculated absorber reflectivity based on the bulk parameters may not be accurate. Furthermore, the final use of the absorber is not as a small isolated absorber element. The great variation of bulk parameters as well as gaps in lining the absorber material over the area illuminated by a plane wave may result in large error of the actual reflection coefficient compared to the calculated value. The mounting methods used in the absorber installation (thickness of adhesive, mounting bracket, etc.) may also contribute to additional errors. In some situations, the RF absorber is illuminated at near field by a spherical wave rather than a plane wave. Therefore, the assumption of plane wave illumination in the calculation will be invalid.

On the other hand, wave energy incident on the absorber will be scattered in virtually all directions in much the same way as on a rough surface. A geometric optic modeling method that traces the rays of electromagnetic waves propagating from the transmitter to the receiver assumes specular reflection at the walls, ceiling, and floor. The calculated field quantities may not compare well with the measurement data. The only reliable method to give a good prediction of the performance is to perform a complete 3D solution of Maxwell's equations over the entire interior of the chamber. This method is very laborious in terms of specifying the exact dimensions of the chamber structure and fixtures and absorber material properties, and it involves extremely long computation time. In all practical cases, it is very difficult to characterize the chamber fixtures (antenna mast, turntable, lighting, CCTV camera, "honeycomb" waveguide vents, penetration panels, etc.) and imperfection in lining the absorbers for an exact computer simulation. Hence, the use of ray-tracing method together with a suitable model for the absorber-lined surfaces will suffice for prediction of the chamber performance as a first approximation prior to the chamber construction.

An anechoic chamber usually represents a substantial investment both financially and in building space. Hence, there is much interest in trying to reduce the required investment while still maintaining adequate performance. With a suitable computer simulation tool, together with a reasonable absorber model, the anechoic chamber geometry may be optimized to achieve the cost-effectiveness target.

Wireless cellular networks are growing rapidly around the world, and this trend is likely to continue for several years. The progress in radio technology enables new and improved services. Current wireless services include transmission of voice, fax, and low-speed data. More bandwidth-consuming interactive multimedia services such as

video-on-demand and Internet access will be supported in the future. Wireless networks must provide these services in a wide range of environments, spanning dense urban, suburban, and rural areas. Varying mobility needs must also be addressed. Wireless local loop networks serve fixed subscribers. Microcellular networks serve pedestrians and other slow-moving users, and macrocellular networks serve high-speed vehicle-borne users. Several competing standards have been developed for terrestrial networks. AMPS (advanced mobile phone system) is an example of a first-generation frequency-division multiple-access analog cellular system. Second-generation standards include GSM (global system for mobile) and IS-136, using time-division multiple access (TDMA); and IS-95, using code-division multiple access (CDMA). IMT-2000 is proposed to be the third-generation standard and will use mostly a wideband CDMA technology.

Increased services and lower costs have resulted in an increased airtime usage and number of subscribers. Since the radio (spectral) resources are limited, system capacity is a primary challenge for current wireless network designers. Other major challenges include (1) an unfriendly transmission medium, with multipath transmission, noise, interference, and time variations; (2) the limited battery life of the user's handheld terminal; and (3) efficient radio resource management to offer high quality of service.

Current wireless modems use signal processing in the time dimension alone through advanced coding, modulation, and equalization techniques. The primary goal of smart antennas in wireless communications is to integrate and exploit efficiently the extra dimension offered by multiple antennas at the transceiver in order to enhance the overall performance of the network. Smart antenna systems use modems that combine the signals of multi-element antennas in both space and time. Smart antennas can be used for both receive and transmit, both at the base station and at the user terminal. The use of smart antennas at the base alone is more typical, since practical constraints usually limit the use of multiple antennas at the terminal. See Fig. 1 for an illustration.

Spacetime processing offers various advantages. The first is array gain; multiple antennas capture more signal energy, which can be combined to improve the signal-to-noise ratio (SNR). Next, spatial diversity obtained from multiple antennas can be used to combat channel fading. Finally, spacetime processing can help mitigate intersymbol interference (ISI) and cochannel interference (CCI). These leverages can be traded for improvements in

- Coverage: square miles per base station
- Quality: bit error rate (BER); outage probability
- Capacity: erlangs per hertz per base station
- Data rates: bits per second per hertz per base station

1. EARLY FORMS OF SPATIAL PROCESSING

1.1. Adaptive Antennas

The use of adaptive antennas dates back to the 1950s with their applications to radar and antijam problems. The

Figure 1. The user signal experiences multipath propagation and impinges on a two-element array on a building rooftop.

primary goal of adaptive antennas is the automatic generation of beams (beamforming) that track a desired signal and possibly reject (or *null*) interfering sources through linear combining of the signals captured by the different antennas. An early contribution in the field of beamforming was made in 1956 by Altman and Sichak, who proposed a combining device based on a phase-locked loop. This work was later refined in order to incorporate the adjustment of antenna signals in both phase and gain, allowing improved performance of the receiver in the presence of strong jammers. Howells proposed the sidelobe canceler for adaptive nulling. Optimal combining schemes were also introduced in order to minimize different criteria at the beamformer output. These include the minimum mean-squared error (MMSE) criterion, as in the LMS algorithm proposed by Widrow; the signal-to-interference-and-noise ratio (SINR) criterion proposed by Applebaum, and the minimum-variance beamformer distortionless response (MVDR) beamformer proposed by Capon. Further advances in the field were made by Frost, Griffiths, and Jim among several others. A list of references in beamforming can be found in Refs. 1 and 13.

Besides beamforming, another application of antenna arrays is direction-of-arrival (DoA) estimation for source or target localization purposes. The leading DoA estimation methods are the MUSIC and ESPRIT algorithms [2]. In many of the beamforming techniques (e.g., in Capon's method), estimation of the source direction is an essential step. DoA estimation is still an area of active research.

Antenna arrays for beamforming and source localization are, of course, of great interest in military applications. However, their use in civilian cellular communication networks is now gaining increasing attention. By enabling the transmission and reception of signal energy from selected directions, beamformers play an important role in improving the performance of both the base-to-mobile (forward) and mobile-to-base (reverse) links.

1.2. Antenna Diversity

Antenna diversity can alleviate the effects of channel fading, and is used extensively in wireless networks. The basic idea of space diversity is as follows. If several replicas of the same information-carrying signal are received over multiple branches with comparable strengths and exhibit independent fading, then there is a high probability that at least one branch will not be in a fade at any given instant of time. When a receiver is equipped with two or more antennas that are sufficiently separated (typically several wavelengths), they offer useful diversity branches. Diversity branches tend to fade independently; therefore, a proper selection or combining of the branches increases link reliability. Without diversity, protection against deep channel fades requires higher transmit power to ensure the link margins. Therefore, diversity at the base can be traded for reduced power consumption and longer battery life at the user terminal. Also, lower transmit power decreases the amount of cochannel user interference and increases the system capacity.

Independent fading across antennas is achievable when radiowaves impinge on the antenna array with sufficient angle spread. Paths coming from different arriving directions will add differently (constructive or destructive manner) at each antenna. This requires the presence of significant scatterers in the propagation medium, such as in urban or hilly terrain.

Diversity also helps to combat large-scale fading effects caused by shadowing from large obstacles (e.g., buildings or terrain features). However, antennas located in the same base station experience the same shadowing. Instead, antennas from different base stations can be combined to offer a protection against such fading (*macro diversity*).

Antenna diversity can be complemented by other forms of diversity. Polarization, time, frequency, and path diversity are some examples. These are particularly useful when physical constraints prevent the use of multiple antennas (e.g., at the handheld terminal). See Ref. 3 for more details.

Combining the different diversity branches is an important issue. The main options used in current systems are briefly described below. In all cases, independent branch fading and equal mean branch powers are assumed. However, in nonideal situations, branch correlation and unequal powers will result in a loss of diversity gain. A correlation coefficient as high as 0.7 between instantaneous branch envelope levels is considered acceptable.

1.2.1. Selection Diversity. Selection diversity is one of the simplest forms of diversity combining. Given several branches with varying carrier-to-noise ratios (C/N), selection diversity consists in choosing the branch having the highest instantaneous C/N . The performance improvement from selection diversity is evaluated as follows: Let us suppose that M branches experience independent fading but have the same mean C/N , denoted by Γ . Let us now denote by Γ_s the mean C/N of the selected branch. Then it

can be shown that [4]

$$\Gamma_s = \Gamma \sum_{j=1}^M \frac{1}{j}$$

For instance, selection over two branches increases the mean C/N by a factor of 1.5. More importantly, the statistics of the instantaneous C/N is improved. Note that selection diversity requires a receiver behind each antenna.

Switching diversity is a variant of selection diversity. In this method, a selected branch is held until it falls below a threshold T , at which point the receiver switches to another branch, regardless of its level. The threshold can be fixed or adaptive. This strategy performs almost as well as the selection method described above, and it reduces the system cost, since only one receiver is required.

1.2.2. Maximum-Ratio Combining. Maximum-ratio combining (MRC) is an optimal combining approach to combat fading. The signals from M branches are first cophased to mutual coherence and then summed after weighting. The weights are chosen to be proportional to the signal level to maximize the combined C/N . It can be shown that the gain from MRC in mean C/N is directly proportional to the number of branches:

$$\Gamma_s = M\Gamma$$

1.2.3. Equal-Gain Combining. Although optimal, MRC is expensive to implement. Also, MRC requires accurate tracking of the complex fading, which is difficult to achieve in practice. A simpler alternative is given by equal-gain combining, which consists in summing the cophased signals using unit weights. The performance of equal-gain combining is found to be very close to that of MRC. The SNR of the combined signals using equal gain is only 1 dB below the SNR provided by MRC [4].

2. EMERGING APPLICATION OF SPACETIME PROCESSING

While the use of beamforming and space diversity proves useful in radiocommunication applications, an inherent limitation of these techniques lies in the fact that they exploit signal combining in the space dimension only. Directional beamforming, in particular, heavily relies on the exploitation of the spatial signatures of the incoming signals but does not consider their temporal structure. The techniques that combine the signals in both time and space can bring new advantages, and their importance in the area of mobile communications is now recognized [5].

The main reason for using spacetime processing is that it can exploit the rich temporal structure of digital communication signals. In addition, multipath propagation environments introduce signal delay spread, making techniques that exploit the complete spacetime structure more natural.

The typical structure of a spacetime processing device consists of a bank of linear filters, each located behind a branch, followed by a summing network. The received

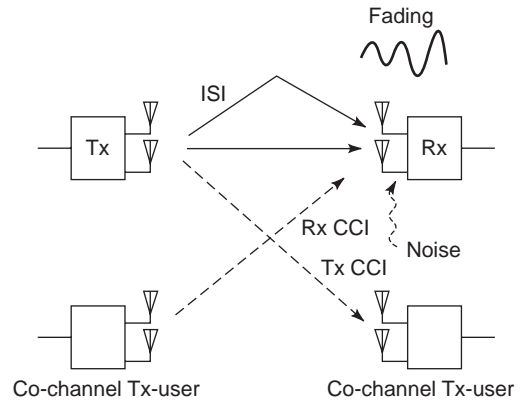

Figure 2. Smart antennas help mitigate the effects of cellular radio propagation.

spacetime signals can also be processed using nonlinear schemes, for example, maximum-likelihood sequence detection. The spacetime receivers can be optimized to maximize array and diversity gains, and to minimize

1. Intersymbol interference (ISI), induced by the delay spread in the propagation channel. ISI can be suppressed by selecting a spacetime filter that equalizes the channel or by using a maximum-likelihood sequence detector.
2. Cochannel (user) interference (CCI), coming from neighboring cells operating at the same frequency. CCI is suppressed by using a spacetime filter that is orthogonal to the interference's channel. The key point is that CCI that cannot be rejected by space-only filtering may be handled more effectively using spacetime filtering.

Smart antennas can also be used at the transmitter to maximize array gain and/or diversity and to mitigate ISI and CCI. In the transmit case, however, the efficiency of spacetime processing schemes is usually limited by the lack of accurate channel information.

The major effects induced by radio propagation in a cellular environment, are pictured in Fig. 2. The advantages offered by spacetime processing for receive and transmit are summarized in Table 1.

In the following sections, we describe channel models and algorithms used in spacetime processing. Both simple and advanced solutions are presented, and tradeoffs

Table 1. Advantages of Spacetime Processing

For transmit (Tx)	Reduces Tx CCI Maximizes Tx diversity Reduces ISI Increases Tx EIRP
For receive (Rx)	Reduces Rx CCI Maximizes Rx diversity Eliminates ISI Increases C/N

highlighted. Finally, we describe current applications of smart antennas.

3. CHANNEL MODELS

Channel models capture radio propagation effects and are useful for simulation studies and performance prediction. Channel models also help in motivating appropriate signal-processing algorithms. The effects of radio propagation on the transmitted signal can be broadly categorized into two main classes: fading and spreading.

Fading refers to the propagation losses experienced by the radio signal (on both the forward and reverse links). One type of fading, called *selective fading*, causes the received signal level to vary around the average level in some regions of space, frequency, or time. *Channel spreading* refers to the spreading of the information-carrying signal energy in space, and on the time or frequency axis. Selective fading and spreading are complementary phenomena.

3.1. Channel Fading

3.1.1. Mean Path Loss. The mean path loss describes the attenuation of a radio signal in free-space propagation, due to isotropic power spreading, and is given by the well-known inverse square law:

$$P_r = P_t \left(\frac{\lambda}{4\pi d} \right)^2 G_t G_r$$

where P_r and P_t are the received and transmitted powers, λ is the radio wavelength, d is the range, and G_t , G_r are the gains of the transmit and receive one-element antennas, respectively. In cellular environments, the main path is often accompanied by a surface-reflected path that may interfere destructively with the primary path. Specific models have been developed that consider this effect. The path loss model becomes [4]

$$P_r = P_t \left(\frac{h_t h_r}{d^2} \right)^2 G_t G_r$$

where h_t, h_r are the effective heights of the transmit and receive antennas, respectively. Note that this particular path loss model follows an inverse fourth-power law. In fact, depending on the environment, the path loss exponent may vary from 2.5 to 5.

3.1.2. Slow Fading. Slow fading is caused by long-term shadowing effects of buildings or natural features in the terrain. It can also be described as the local mean of a fast fading signal (see below). The statistical distribution of the local mean has been studied experimentally and shown to be influenced by the antenna height, the operating frequency, and the type of environment. It is therefore difficult to predict. However, it has been observed that when all the abovementioned parameters are fixed, then the received signal fluctuation approaches a normal distribution when plotted on a logarithmic scale (i.e., in decibels) [4].

Figure 3. The radio channel induces spreading in several dimensions. These spreads strongly affect the design of the space-time receiver.

Such a distribution is called lognormal. A typical value for the standard deviation of shadowing distribution is 8 dB.

3.1.3. Fast Fading. The multipath propagation of the radio signal causes path signals to add up with random phases, constructively or destructively, at the receiver. These phases are determined by the pathlength and the carrier frequency, and can vary extremely rapidly along with the receiver location. This gives rise to *fast fading*: large, rapid fluctuations of the received signal level in space. If we assume that a large number of scattered wavefronts with random amplitudes and angles of arrival arrive at the receiver with phases uniformly distributed in $(0, 2\pi)$, then the in-phase and quadrature phase components of the vertical electrical field E_z can be shown to be Gaussian processes [4]. In turn, the envelope of the signal can be well approximated by a Rayleigh process. If there is a direct path present, then it will no longer be a Rayleigh distribution but becomes a Rician distributed instead.

3.2. Channel Spreading

Propagation to or from a mobile user, in a multipath channel, causes the received signal energy to spread in the frequency, time, and space dimensions (see Fig. 3, and also Table 2 for typical values). The characteristics of the spreading [that is to say, the particular dimension(s) in which the signal is spread] affects the design of the receiver.

3.2.1. Doppler Spread. When the mobile user is in motion, the radio signal at the receiver experiences a shift in the frequency domain (called the *Doppler shift*), the amplitude of which depends on the path direction of arrival. In the presence of surrounding scatterers with multiple directions, a pure tone is *spread* over a finite spectral bandwidth. In this case, the Doppler power spectrum is defined as the Fourier transform of the time autocorrelation of the

Table 2. Typical Delay, Angle, and Doppler Spreads in Cellular Radio Systems

Environment	Delay Spread (μs)	Angle Spread (deg)	Doppler Spread (Hz)
Flat rural (macro)	0.5	1	190
Urban (macro)	5	20	120
Hilly (macro)	20	30	190
Microcell (mall)	0.3	120	10
Picocell (indoors)	0.1	360	5

received signal, and the Doppler spread is the support of the Doppler power spectrum. Assuming scatterers uniformly distributed in angle, the Doppler power spectrum is given by the so-called classical spectrum:

$$S(f) = \frac{3\sigma^2}{2\pi f_m} \left[1 - \left(\frac{f - f_c}{f_m} \right)^2 \right]^{-1/2},$$

$$f_c - f_m < f < f_c + f_m$$

where $f_m = v/\lambda$ is the maximum Doppler shift, v is the mobile velocity, f_c is the carrier frequency, and σ^2 is the signal variance. When there is a dominant source of energy coming from a particular direction (as in line-of-sight situations), the expression for the spectrum needs to be corrected according to the Doppler shift of the dominant path f_D

$$S(f) + B\delta(f - f_D)$$

where B denotes the ratio of direct to scattered path energy.

The Doppler spread causes the channel characteristics to change rapidly in time, giving rise to the so-called *time selectivity*. The coherence time, during which the fading channel can be considered as constant, is inversely proportional to the Doppler spread. A typical value of the Doppler spread in a macrocell environment is about 200 Hz at 30 m/s (65 mi/h) in the 1900-MHz band. A large Doppler spread makes good channel tracking an essential feature of the receiver design.

3.2.2. Delay Spread. Multipath propagation is often characterized by several versions of the transmitted signal arriving at the receiver with different attenuation factors and delays. The spreading in the time domain is called *delay spread* and is responsible for the selectivity of the channel in the frequency domain (different spectral components of the signal carry different powers). The coherence bandwidth, which is the maximum range of frequencies over which the channel response can be viewed as constant, is inversely proportional to the delay spread. Significant delay spread may cause strong intersymbol interference, which makes necessary the use of a channel equalizer.

3.2.3. Angle Spread. *Angle spread at the receiver* refers to the spread of directions of arrival of the incoming paths. Likewise, *angle spread at the transmitter* refers to the spread of departure angles of the paths. As mentioned earlier, a large angle spread will cause the paths to add up in a random manner at the receiver as the location of the receive antenna varies; hence it will be a source of *space-selective fading*. The range of space for which the fading remains constant is called the coherence distance and is inversely related to the angle spread. As a result, two antennas spaced by more than the coherence distance tend to experience uncorrelated fading. When the angle spread is large, which is usually the case in dense urban environments, a significant gain can be obtained from space

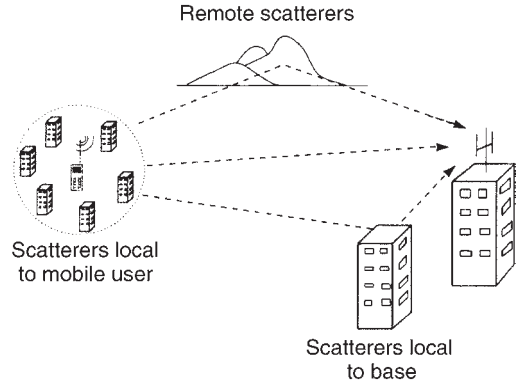

Figure 4. Each type of scatterer introduces specific channel spreading characteristics.

diversity. Note that this usually conflicts with the possibility of using directional beamforming, which typically requires well-defined and dominant signal directions, that is, a low angle spread.

3.3. Multipath Propagation

3.3.1. Macrocells. A macrocell is characterized by a large cell radius (up to a few tens of kilometers) and a base station located above the rooftops. In macrocell environments, the signal energy received at the base station comes from three main scattering sources: scatterers local to the mobile, remote dominant scatterers, and scatterers local to the base (see Fig. 4 for an illustration). The following description refers to the reverse link but applies to the forward link as well.

The scatterers local to the mobile user are those located a few tens of meters from the handheld terminal. When the terminal is in motion, these scatterers give rise to a Doppler spread, which causes time-selective fading. Because of the small scattering radius, the paths that emerge from the vicinity of the mobile user and reach the base station show a small delay spread and a small angle spread.

Of the paths emerging from the local-to-mobile scatterers, some reach remote dominant scatterers, such as hills or high-rise buildings, before eventually traveling to the base station. These paths will typically reach the base with medium to large angle and delay spreads (depending, of course, on the number and locations of these remote scatterers).

Once these multiple wavefronts reach the vicinity of the base station, they usually are further scattered by local structures such as buildings or other structures that are close to the base. These scatterers local to the base can cause large angle spread; therefore they can cause severe space-selective fading.

3.3.2. Microcells. Microcells are characterized by highly dense built-up areas, and by the user’s terminal and base being relatively close (a few hundred meters). The base antenna has a low elevation and is typically below the rooftops, causing significant scattering in the vicinity of the base. Microcell situations make the propagation

difficult to analyze, and the macrocell model described earlier no longer can be expected to hold. Very high angle spreads along with small delay spreads are likely to occur in this situation. The Doppler spread can be as high as in macrocells, although the mobility of the user is expected to be limited, due to the presence of mobile scatterers.

3.4. Parametric Channel Model

A complete and accurate understanding of propagation effects in the radio channel requires a detailed description of the physical environment. The *specular model*, to be presented below, provides only a simplified description of the physical reality. However, it is useful, as it describes the main channel effects and provides the means for a simple and efficient mathematical treatment. In this model, the multiple elementary paths are grouped according to a (typically small) number L of main path clusters, each of which contains paths that have roughly the same mean angle and delay. Since the paths in these clusters originate from different scatterers, the clusters typically have near-independent fading. Based on this model, the continuous-time channel response from a single transmit antenna to the i th antenna of the receiver can be written as

$$f_i(t) = \sum_{l=1}^L \alpha_i(\theta_l) \alpha_l^R(t) \delta(t - \tau_l) \quad (1)$$

where $\alpha_l^R(t)$, θ_l , and τ_l are respectively the fading (including mean path loss and slow and fast fading), the angle, and the delay of the l th receive path cluster. Note that this model also includes the response of the i th antenna to a path from direction θ_l , denoted by $\alpha_i(\theta_l)$. In the following we make use of the specular model to describe the structure of the signals in space and time. Note that in the situation where the path cluster assumption is not acceptable, other channel models, called *diffuse* channel models, are more appropriate [6].

4. DATA MODELS

This section focuses on developing signal models for spacetime processing algorithms. The transmitted information signal is assumed to be linearly modulated. In the case of a nonlinear modulation scheme, such as the Gaussian minimum shift keying (GMSK) used in the GSM system, linear approximations are assumed to hold. The baseband equivalent of the transmitted signal can be written [7]

$$u(t) = \sum_k g(t - kT) s(k) + n(t) \quad (2)$$

where $s(k)$ is the symbol stream, with rate $1/T$, $g(t)$ is the pulse shaping filter, and $n(t)$ is an additive thermal noise. Four configurations for the received signal (two for the reverse link and two for the forward link) are described below. These are also depicted in Fig. 5. In each case, one assumes $M > 1$ antennas at the base station and a single antenna at the mobile user.

Figure 5. Several configurations are possible for antenna arrays, in transmit (T) and in receive (R).

4.1. Reverse Link

We consider the signal received at the base station. Since the receiver is equipped with M antennas, the received signal can be written as a vector $\mathbf{x}(t)$ with M entries.

4.1.1. Single-User Case. Let us assume a single user transmitting towards the base (no CCI). Using the specular channel model in Eq. (1), the received signal can be written as follows:

$$\mathbf{x}(t) = \sum_{l=1}^L \mathbf{a}(\theta_l) \alpha_l^R(t) u(t - \tau_l) + \mathbf{n}(t) \quad (3)$$

where $\mathbf{a}(\theta_l) = (a_1(\theta_l), \dots, a_M(\theta_l))^T$ is the vector array response to a path of direction θ_l , and where T refers to the transposition operator.

4.1.2. Multiuser Case. We now have Q users transmitting toward the base. The received signal is the following sum of contributions from the Q users, each of them carries a different set of fading, delays, and angles:

$$\mathbf{x}(t) = \sum_{q=1}^Q \sum_{l=1}^{L_q} \mathbf{a}(\theta_{lq}) \alpha_{lq}^R(t) u_q(t - \tau_{lq}) + \mathbf{n}(t) \quad (4)$$

where the subscript q refers to the user index.

4.2. Forward Link

4.2.1. Single-User Case. In this case, the base station uses a transmitter equipped with M antennas to send an information signal to a unique user. Therefore, spacetime processing must be performed *before* the signal is launched into the channel. As will be emphasized later,

this is a challenging situation, as the transmitter typically lacks reliable information on the channel.

For the sake of simplicity, we will assume here that a space-only beamforming weight vector \mathbf{w} is used, as the extension to spacetime beamforming is straightforward. The baseband signal received at the mobile station is scalar and is given by

$$x(t) = \sum_{l=1}^L \mathbf{w}^H \mathbf{a}(\theta_l) \alpha_l^F(t) u(t - \tau_l) + n(t) \quad (5)$$

where $\alpha_l^F(t)$ is the fading coefficient of the l th transmit path in the forward link. Superscript H denotes the transpose conjugation operator. Note that path angles and delays remain theoretically unchanged in the forward and reverse links. This is in contrast with the fading coefficients, which depend on the carrier frequency. Frequency-division duplex (FDD) systems use different carriers for the forward and reverse links, which result in $\alpha_l^F(t)$ and $\alpha_l^R(t)$ being nearly uncorrelated. In contrast, time-division duplex (TDD) systems will experience almost identical forward and reverse fading coefficients in the forward and reverse links. Assuming, however, that the transmitter knows the forward fading and delay parameters, transmit beamforming can offer array gain, ISI suppression, and CCI suppression.

4.2.2. Multiuser Case. In the multiuser case, the base station wishes to communicate with Q users, simultaneously and in the same frequency band. This can be done by superposing, on each of the transmit antennas, the signals given by Q beamformers $\mathbf{w}_1, \dots, \mathbf{w}_Q$. At the m th user, the received signal waveform contains the signal sent to that user, plus an interference from signals intended for all other users. This gives

$$x_m(t) = \sum_{q=1}^Q \sum_{l=1}^{L_q} \mathbf{w}_q^H \mathbf{a}(\theta_{lm}) \alpha_{lm}^F(t) u_q(t - \tau_{lm}) + n_m(t) \quad (6)$$

Note that each information signal $u_q(t)$ couples into the L_m paths of the m th user through the corresponding weight vector \mathbf{w}_q , for all q .

4.3. A Nonparametric Model

The data models above build on the parametric channel model developed earlier. However, there is also interest in considering the end-to-end channel impulse response of the system to a transmitted symbol rather than the physical path parameters. The channel impulse response includes the pulseshaping filter response, the propagation phenomena, and the antenna response as well. One advantage of looking at the impulse response is that the effects of ISI and CCI can be described in a better and more compact way. A second advantage is that the nonparametric channel relies only on the channel linearity assumption.

We look at the reverse-link and single-user case only. Since a single scalar signal is transmitted and received over several branches, this corresponds to a single-input multiple-output (SIMO) system, depicted in Fig. 6. The model below is also easily extended to multiuser channels. Let $\mathbf{h}(t)$ denote the $M \times 1$ global channel impulse response.

Figure 6. The source signal $s(n)$ can be seen as driving a single-input multiple-output filter with M outputs, where M is the number of receive antennas.

The received vector signal is given by the result of a (noisy) convolution operation:

$$\mathbf{x}(t) = \sum_k \mathbf{h}(t - kT) s(k) + \mathbf{n}(t) \quad (7)$$

From Eqs. (2) and (3), the channel response may also be expressed in terms of the specular model parameters through

$$\mathbf{h}(t) = \sum_{l=1}^L \mathbf{a}(\theta_l) \alpha_l^R(t) g(t - \tau_l) \quad (8)$$

4.3.1. Signal Sampling. Consider sampling the received signal at the baud (symbol) rate, that is, at $t_k = t_0 + kT$, where t_0 is an arbitrary phase. Let N be the maximum length of the channel response in symbol periods. Assuming that the channel is invariant for some finite period of time [i.e., $\alpha_l^R(t) = \alpha_l^R(t_0 + jT - \tau_l)$], the received vector sample at time t_k can be written as

$$\mathbf{x}(k) = \mathbf{H} \mathbf{s}(k) + \mathbf{n}(k) \quad (9)$$

where \mathbf{H} is the sampled channel matrix, with size $M \times N$, whose (i, j) term is given by

$$[\mathbf{H}]_{ij} = \sum_{l=1}^L a_i(\theta_l) \alpha_l^R g(t_0 + jT - \tau_l)$$

and where $\mathbf{s}(k)$ is the vector of N ISI symbols at the time of the measurement:

$$\mathbf{s}(k) = (s(k), s(k-1), \dots, s(k-N+1))^T$$

To allow for the presence of CCI, Eq. (9) can be generalized to

$$\mathbf{x}(k) = \sum_{q=1}^Q \mathbf{H}_q \mathbf{s}_q(k) + \mathbf{n}(k) \quad (10)$$

where Q denotes the number of users and q the user index. Most digital modems use sampling of the signal at a rate higher than the symbol rate (typically up to 4 times). Oversampling only increases the number of scalar observations per transmitted symbol, which can be regarded

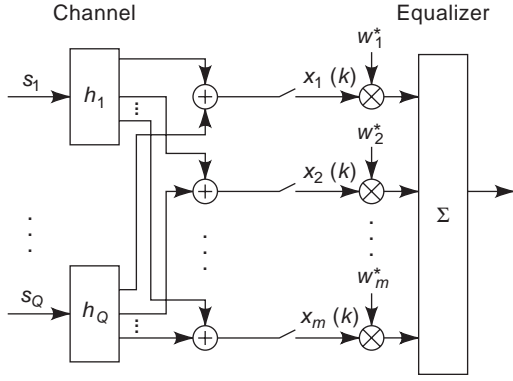

Figure 7. Structure of the spatial beamformer. The spacetime beamformer is a direct generalization that combines in time the outputs of several spatial beamformers.

mathematically as increasing the number of channel components, in a way similar to increasing the number of antennas. Hence the model above also holds true when sampling at $T/2$, $T/3$, and so on. However, although mathematically equivalent, spatial oversampling and temporal oversampling lead to different signal properties.

4.4. Structure of the Linear Spacetime Beamformer

Space combining is now considered at the receive antenna array. Let \mathbf{w} be an $M \times 1$ space-only weight vector (a single complex weight is assigned to each antenna). The output of the combiner, denoted by $y(k)$ is as follows:

$$y(k) = \mathbf{w}^H \mathbf{x}(k)$$

The resulting beamforming operation is depicted in Fig. 7. The generalization to spacetime combining is straightforward. Let the combiner have m time taps. Each tap, denoted by $\mathbf{w}(i)$, $i = 0, \dots, m-1$, is an $M \times 1$ space weight vector defined as above. The output of the spacetime beamformer is now written as

$$y(k) = \sum_{i=0}^{m-1} \mathbf{w}(i)^H \mathbf{x}(k-i) \quad (11)$$

which can be reformulated as

$$y(k) = \mathbf{W}^H \mathbf{X}(k) \quad (12)$$

where $\mathbf{W} = (\mathbf{w}(0)^H, \dots, \mathbf{w}(m-1)^H)^H$ and $\mathbf{X}(k)$ is the data vector compactly defined as $\mathbf{X}(k) = (\mathbf{x}(k)^H, \dots, \mathbf{x}(k-m+1)^H)^H$.

4.5. ISI and CCI Suppression

The formulation above gives insight into the algebraic structure of the spacetime received data vector. It also allows us to identify the conditions under which the suppression of ISI and/or CCI is possible. Recalling the signal model in Eq. (9), the spacetime vector $\mathbf{X}(k)$ can be in turn written as

$$\mathbf{X}(k) = \mathcal{H} \mathbf{S}(k) + \mathbf{N}(k) \quad (13)$$

where $\mathbf{S}(k) = (s(k), s(k-1), \dots, s(k-m+N+2))^T$ and where

$$\mathcal{H} = \begin{pmatrix} \mathbf{H} & 0 & \dots & 0 \\ 0 & \mathbf{H} & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \dots & 0 & \mathbf{H} \end{pmatrix} \quad (14)$$

is an $mM \times (m+N-1)$ -channel matrix. The block Toeplitz structure in \mathcal{H} stems from the linear time-invariant convolution operation with the symbol sequence.

Let us temporarily assume a noise-free scenario. Then the output of a linear spacetime combiner can be described by the following equation:

$$y(k) = \mathbf{W}^H \mathcal{H} \mathbf{S}(k) \quad (15)$$

In the presence of Q users transmitting towards the base station, the output of the spacetime receiver is generalized to

$$y(k) = \sum_{q=1}^Q \mathbf{W}^H \mathcal{H}_q \mathbf{S}_q(k) \quad (16)$$

4.5.1. ISI Suppression. The purpose of equalization is to compensate for the effects of ISI induced by the user's channel in the absence of CCI. Tutorial information on equalization can be found in Refs. 7 and 8. In general, a linear filter \mathbf{W}_q is an equalizer for the channel of the q th user if the convolution product between \mathbf{W}_q and the channel responses yields a Dirac function, that is, if \mathbf{W}_q satisfies the following so-called zero-forcing condition:

$$\mathbf{W}_q^H \mathcal{H}_q = (0, \dots, 0, 1, 0, \dots, 0) \quad (17)$$

Here, the location of the 1 element represents the delay of the combined channel–equalizer impulse response. Note that from an algebraic point of view, the channel matrix \mathcal{H}_q should have more rows than columns for such solutions to exist: $mM \geq m+N-1$. Therefore, it is essential to have enough degrees of freedom (number of taps in the filter) to allow for ISI suppression. Note that zero-forcing solutions can be obtained using temporal oversampling at the receive antenna only, since oversampling by a factor of M provides us theoretically with M baud rate branches. However, having multiple antennas at the receiver plays an important role in improving the conditioning of the matrix \mathcal{H} , which in turn will improve the robustness of the resulting equalizer in the presence of noise. It can be shown that the condition number of the matrix \mathcal{H}_q is related to some measure of the correlation between the entries of $\mathbf{h}(t)$. Hence, a significant antenna spacing is required to provide the receiver with sufficiently decorrelated branches.

4.5.2. CCI Suppression. The purpose of CCI suppression in a multiple-access network is to isolate the contribution of one desired user by rejecting that of others. One way to achieve this goal is to enforce *orthogonality*

between the response of the spacetime beamformer and the response of the channel of the users to be rejected. In other words, in order to isolate the signal of user q using \mathbf{W}_q , the following conditions must be satisfied (possibly approximately):

$$\mathbf{W}_q^H \mathcal{H}_f = 0 \quad \text{for all } f \neq q \in [1, \dots, Q] \quad (18)$$

If we assume that all the channels have the same maximum order N , Eq. (18) provides as many as $(Q-1)(m+N-1)$ scalar equations. The number of unknowns is again given by mM (the size of \mathbf{W}_q). Hence a receiver equipped with multiple antennas is able to provide the number of degrees of freedom necessary for signal separation. This requires $mM \geq (Q-1)(m+N-1)$. At the same time, it is desirable that the receiver capture a significant amount of energy from the desired user; hence an extra condition on \mathbf{W}_q should be $\mathbf{W}_q^H \mathcal{H}_q \neq 0$. From an algebraic perspective, this last condition requires that \mathcal{H}_q and $\{\mathcal{H}_f\}_{f \neq q}$ should not have the same column subspaces. The required subspace misalignment between the desired user and the interferers in spacetime processing is a generalization of the condition that signal and interference should not have the same direction, needed for interference nulling using beamforming.

4.5.3. Joint ISI and CCI Suppression. The complete recovery of the signal transmitted by one desired user in the presence of ISI and CCI requires both channel equalization and separation. A spacetime beamformer is an exact solution to this problem if it satisfies both Eq. (17) and Eq. (18), which can be further written as

$$\begin{aligned} \mathbf{W}_q^H (\mathcal{H}_1, \dots, \mathcal{H}_{q-1}, \mathcal{H}_q, \mathcal{H}_{q+1}, \dots, \mathcal{H}_Q) \\ = (0, \dots, 0, 1, 0, \dots, 0) \end{aligned} \quad (19)$$

where the location of the 1 element designates both the index of the user of reference and the reconstruction delay. The existence of solutions to this problem requires the multiuser channel matrix $\mathcal{H}_* \stackrel{\text{def}}{=} (\mathcal{H}_1, \dots, \mathcal{H}_Q)$ to have more rows than columns: $mM \leq Q(m+N-1)$. Here again, smart antennas play a critical role in offering a sufficient number of degrees of freedom. If, in addition, the global channel matrix \mathcal{H}_* has full column rank, then we are able to recover any particular user using spacetime beamforming. In practice, though, the performance of an ISI-CCI reduction scheme is limited by the SNR and the condition number \mathcal{H}_* .

5. SPACETIME ALGORITHMS FOR THE REVERSE LINK

5.1. General Principles of Receive Spacetime Processing

Space processing offers several important opportunities to enhance the performance of the radiolink. First, smart antennas offer more resistance to channel fast fading through maximization of *space diversity*. Then, space combining increases the received SNR through array gain, and allows for the suppression of interference when the user of reference and the cochannel users have different DoAs.

Time processing addresses two important goals. First, it exploits the gain offered by path diversity in delay-spread channels. As the channel time taps generally carry independent fading, the receiver can resolve channel taps and combine them to maximize the signal level. Second, time processing can combat the effects of ISI through equalization. Linear zero-forcing equalizers address the ISI problem but do not fully exploit path diversity. Hence, for these equalizers, ISI suppression and diversity maximization may be conflicting goals. This is not the case, however, for maximum-likelihood sequence detectors.

Spacetime processing allows us to exploit the advantage of both the time and space dimensions. Spacetime (linear) filters allow us to maximize space and path diversity. Also, spacetime filters can be used for better ISI and CCI reduction. However, as mentioned above, these goals may still conflict. In contrast, spacetime maximum-likelihood sequence detectors (see below) can handle harmoniously both diversity maximization and interference minimization.

5.2. Channel Estimation

Channel estimation forms an essential part of most wireless digital modems. Channel estimation in the reverse link extracts the information that is necessary for a proper design of the receiver, including linear (spacetime beamformer) and nonlinear (decision feedback or maximum-likelihood detection) receivers. For this task, most existing systems rely on the periodic transmission of training sequences, which are known to both the transmitter and receiver and are used to identify the channel characteristics. The estimation of \mathcal{H} is usually performed using the nonparametric FIR model in Eq. (9), in a least-squares manner or by correlating the observed signals against decorrelated training sequences (as in GSM). A different strategy consists in addressing the estimation of the physical parameters (path angle and delays) of the channel using the model developed in Eq. (8). This strategy proves useful when the number of significant paths is much smaller than the number of channel coefficients.

Channel tracking is also an important issue, necessary whenever the propagation characteristics vary (significantly) within the user slot. Several approaches can be used to update the channel estimate. The *decision-directed method* uses symbol decisions as training symbols to update the channel response estimate. Joint data-channel techniques constitute another alternative, in which symbol estimates and channel information are recursively updated according to the minimization of a likelihood metric: $\|\mathbf{X} - \mathcal{H}\mathbf{S}\|^2$.

5.3. Signal Estimation

5.3.1. Maximum-Likelihood Sequence Detection (Single User). Maximum-likelihood sequence detection (MLSD) is a popular nonlinear detection scheme that, given the received signal, seeks the sequence of symbols of one particular user that is most likely to have been transmitted. Assuming temporally and spatially white Gaussian noise,

maximizing the likelihood reduces to finding the vector \mathbf{S} of symbols in a given alphabet that minimizes the following metric:

$$\min_{\mathbf{S}} \|\mathbf{X} - \mathcal{H}\mathbf{S}\|^2 \quad (20)$$

where the channel matrix \mathcal{H} has been previously estimated. Here, $\|\cdot\|$ denotes the conventional euclidean norm. Since \mathbf{X} contains measurements in time and space, the criterion above can be considered as a direct extension of the conventional ML sequence detector, which is implemented recursively using the well-known Viterbi algorithm [7].

MLSD offers the lowest BER in a Gaussian noise environment, but is no longer optimal in the presence of co-channel users. In the presence of CCI, a solution to the MLSD problem consists in incorporating in the likelihood metric the information on the statistics of the interferers. This, however, assumes that the interferers do not undergo significant delay spread. In general, though, the optimal solution is given by a multiuser MLSD detection scheme (see below).

5.3.2. Maximum-Likelihood Sequence Detection (Multi-user). The multiuser MLSD scheme has been proposed for symbol detection in CCI-dominated channels. The idea consists in treating CCI as other desired users and detecting all signals simultaneously. This time, the Q symbol sequences $\mathbf{S}_1, \mathbf{S}_2, \dots, \mathbf{S}_Q$ are found as the solutions to the following problem

$$\min_{\{\mathbf{S}_q\}} \left\| \mathbf{X} - \sum_{q=1}^Q \mathcal{H}_q \mathbf{S}_q \right\|^2 \quad (21)$$

where again all symbols should belong to the modulation alphabet. The resolution of this problem can be carried out theoretically by a multiuser Viterbi algorithm. However, the complexity of such a scheme grows exponentially with the number of users and the channel length, which limits its applicability. Also, the channels of all the users are assumed to be accurately known. In current systems, such information is very difficult to obtain. In addition, the complexity of the multiuser MLSD detector falls beyond current implementation limits. Suboptimal solutions are therefore necessary. One possible strategy, known as *onion peeling*, consists in first decoding the user having the largest power and then subtracting it out from the received data. The procedure is repeated on the residual signal, until all users are decoded. Linear receivers, described below, constitute another form of suboptimal but simple approach to signal detection. Minimum mean square error detection is described below.

5.3.3. Minimum Mean-Squared Error Detection. The spacetime minimum mean-squared error (STMMSE) beamformer is a spacetime linear filter whose weights are chosen to minimize the error between the transmitted symbols of a user of reference and the output of the beamformer defined as $y(k) = \mathbf{W}_q^H \mathbf{X}(k)$. Consider a situation with Q users. Let q be the index of the user of reference.

\mathbf{W}_q is found by

$$\min_{\mathbf{W}_q} E|y(k) - s_q(k-d)|^2 \quad (22)$$

where d is the chosen reconstruction delay. E here denotes the expectation operator. The solution to this problem follows from the classical normal equations:

$$\mathbf{W}_q = E[\mathbf{X}(k)\mathbf{X}(k)^H]^{-1} E[\mathbf{X}(k)s_q(k-d)^*] \quad (23)$$

The solution to this equation can be tracked in various manners, for instance, using pilot symbols. Also, it can be shown that the intercorrelation term in the right-hand side of Eq. (23) corresponds to the vector of channel coefficients of the decoded user, when the symbols are uncorrelated. Hence Eq. (23) can also be solved using a channel estimate.

STMMSE combines the strengths of time-only and space-only combining, hence is able to suppress both ISI and CCI. In the noise-free case, when the number of branches is large enough, \mathbf{W}_q is found to be a solution of Eq. (19). In the presence of additive noise, the MMSE solution provides a useful tradeoff between the so-called zero-forcing solution of Eq. (19) and the maximum-SNR solution. Finally the computational load of the MMSE is well below that of the MLSD. However, MLSD outperforms the MMSE solution when ISI is the dominant source of interference.

5.3.4. Combined MMSE-MLSD. The purpose of the combined MMSE-MLSD spacetime receiver is to be able to deal with both ISI and CCI using a reasonable amount of computation. The idea is to use a STMMSE in a first stage to combat CCI. This leaves us with a signal that is dominated by ISI. After channel estimation, a single-user MLSD algorithm is applied to detect the symbols of the user of interest. Note that the channel seen by the MLSD receiver corresponds to the convolution of the original SIMO channel with the equalizer response.

5.3.5. Spacetime Decision Feedback Equalization. The *decision feedback equalizer* is a nonlinear structure that consists of a spacetime linear feedforward filter (FFF) followed by a nonlinear feedback filter. The FFF is used for precursor ISI and CCI suppression. The nonlinear part contains a decision device that produces symbol estimates. An approximation of the postcursor ISI is formed using these estimates and is subtracted from the FFF output to produce new symbol estimates. This technique avoids the noise enhancement problem of the pure linear receiver and has a much lower computational cost than MLSD techniques.

5.4. Blind Spacetime Processing Methods

The goal of blind spacetime processing methods is to recover the signal transmitted by one or more users, given only the observation of the channel output and minimal information on the symbol statistics and/or the channel structure. Basic available information may include the type of modulation alphabet used by the system. Also, the fact that

channel is quasi-invariant in time (during a given data-frame) is an essential assumption. Blind methods do not, by definition, resort to the transmission of training sequences. This advantage can be directly traded for an increased information bit rate. It also helps to cope with the situations where the length of the training sequence is not sufficient to acquire an accurate channel estimate. Tutorial information on blind estimation can be found in Ref. 9.

Blind methods in digital communications have been the subject of active research since the late 1970s. It was only recently recognized, however, that blind techniques can benefit from utilization of the spatial dimension. The main reason is that oversampling the signal in space using multiple antennas, together with the exploitation of the signal channel structure, allows for efficient channel and beamformer estimation techniques.

5.4.1. Blind Channel Estimation. A significant amount of research work has been focused lately on identifying blindly the impulse response of the transmission channel. The resulting techniques can be broadly categorized into three main classes: higher-order statistics (HOS) methods, second-order statistics (SOS) methods, and maximum-likelihood (ML) methods.

HOS methods look at third- and fourth-order moments of the received data and exploit simple relationships between those moments and the channel coefficients (assuming the knowledge of the input moments) in order to identify the channel. In contrast, the SOS of the output of a scalar (single input–single output) channel do not convey sufficient information for channel estimation, since the second-order moments are phase-blind.

In SIMO systems, SOS does provide the necessary phase information. Hence, one important advantage of multiantenna systems lies in the fact that they can be identified using second-order moments of the observations only. From an algebraic point of view, the use of antenna arrays creates a low-rank model for the vector signal given by the channel output. Specifically, the channel matrix \mathcal{H} in Eq. (14) can be made tall and full-column-rank under mild assumption on the channels. The low-rank property allows one to identify the column span of \mathcal{H} from the observed data. Along with the Toeplitz structure of \mathcal{H} , this information can be exploited to identify the channel.

5.4.2. Direct Estimation. Direct methods bypass the channel estimation stage and concentrate on the estimation of the spacetime filter. The use of antenna arrays (or oversampling in time or space in general) offers important advantages in this context, too. The most important one is perhaps the fact that, as was shown in Eq. (17), the SIMO system can be inverted exactly using a spacetime filter with finite time taps, in contrast with the single-output case.

HOS methods for direct receiver estimation are typically designed to optimize a nonlinear cost function of the receiver output. Possible cost functions include Busgang cost functions [Sato, decision-directed, and constant modulus (CM) algorithms] and kurtosis-based cost functions. The most popular criterion is perhaps the CM criterion, in which the coefficients of the beamformer \mathbf{W} are updated

according to the minimization (through gradient-descent algorithms) of

$$J(\mathbf{W}) = E[|y(k)|^2 - 1]^2$$

where $y(k)$ is the beamformer output.

SOS techniques (sometimes also referred to as “algebraic techniques”) look at the problem of factorizing, at least implicitly, the received data matrix \mathbf{X} into the product of a block-Toeplitz channel matrix \mathcal{H} and a Hankel symbol matrix \mathbf{S}

$$\mathbf{X} \approx \mathcal{H} \mathbf{S} \quad (24)$$

A possible strategy is as follows. Because \mathcal{H} is a tall matrix, the row span of \mathbf{S} coincides with the row span of \mathbf{X} . Along with the Hankel structure of \mathbf{S} , the row span of \mathbf{S} can be exploited to uniquely identify \mathbf{S} .

6. MULTIUSER RECEIVER

The extension of blind estimation methods to a multiuser scenario poses important theoretical and practical challenges. These challenges include an increased number of unknown parameters, more ambiguities caused by the problem of user mixing, and a higher complexity. Furthermore, situations where the users are not fully synchronized may result in an abruptly time-varying environment that makes the tracking of the channel or receiver coefficients difficult.

As in the nonblind context, multiuser reception can be regarded as a two-stage signal equalization plus separation. Blind equalization of multiuser signals can be addressed using extensions of the aforementioned single-user techniques (HOS, CM, SOS, or subspace techniques). Blind separation of the multiuser signals needs new approaches, since subspace methods alone are not sufficient to solve the separation problem. In CDMA systems, the use of different user spreading codes makes this possible. In TDMA systems, a possible approach to signal separation consists in exploiting side information such as the finite-alphabet property of the modulated signals. The factorization Eq. (24) can then be carried out using alternate projections (see Ref. 10 for a survey). Other schemes include adjusting a spacetime filter in order to restore the CM property of the signals.

6.1. Spacetime Processing for Direct-Sequence Code-Division Multiple Access

Direct-sequence CDMA (DSCDMA) systems are expected to gain a significant share of the cellular market. In CDMA, the symbol stream is spread by a *unique* spreading code before transmission. The codes are designed to be orthogonal or quasi-orthogonal to each other, making it possible for the users to be separated at the receiver. See Ref. 11 for details. As in TDMA, the use of smart antennas in CDMA systems improves the network performance.

We first introduce the DSCDMA model; then we briefly describe spacetime CDMA signal processing.

6.1.1. Signal Model. Assume $M > 1$ antennas. The received signal is a vector with M components and can be

written as

$$\mathbf{x}(t) = \sum_{q=1}^Q \sum_{k=-\infty}^{\infty} s_q(k) \mathbf{p}_q(t - kT) + \mathbf{n}(t)$$

where $s_q(k)$ is the information bitstream for user q and $\mathbf{p}_q(t)$ is the composite channel for user q that embeds both the physical channel $\mathbf{h}_q(t)$ (defined as in the TDMA case) and the spreading code $c_q(p)$ of length P :

$$\mathbf{p}_q(t) = \sum_{p=0}^{P-1} c_q(p) \mathbf{h}_q\left(t - \frac{pT}{P}\right)$$

6.1.2. Spacetime Receiver Design. A popular single-user CDMA receiver is the rake combiner. The rake receiver exploits the (quasi)orthogonal codes to resolve and coherently combine the paths. It uses one correlator for each path and then combines the outputs to maximize the SNR. The weights of the combiner are selected using diversity combining principles. The rake receiver is a matched filter to the spreading code plus multipath channel.

The spacetime rake is an extension of the above. It consists of a beamformer for each path followed by a rake combiner (see Fig. 8). The beamformer reduces the CCI at the rake input and thus improves the system capacity.

7. SPACETIME ALGORITHMS FOR THE FORWARD LINK

7.1. General Principles of Transmit Spacetime Processing

In transmit spacetime processing, the signal to be transmitted is combined in time and space before it is radiated by the antennas to encounter the channel. The goal of this operation is to enhance the signal received by the desired user, while minimizing the energy sent toward cochannel users. Spacetime processing makes use of the spatial and temporal signature of the users to differentiate them. It may also be used to pre-equalize the channel, that is, to reduce ISI in the received signal. Multiple antennas can also be used to offer transmit diversity against channel fading.

7.2. Channel Estimation

The major challenge in transmit spacetime processing is the estimation of the forward link channel. Further, for

Figure 8. The spacetime rake receiver for CDMA uses a beamformer to spatially separate the signals, followed by a conventional rake.

CCI suppression, we need to estimate the channels of all cochannel users.

7.2.1. Time-Division Duplex Systems. TDD systems use the same frequency for the forward link and the reverse link. Given the reciprocity principle, the forward and reverse link channels should be identical. However, transmit and receive take place in different time slots; hence the channels may differ, depending on the ping-pong period (time duration between receive and transmit phases) and the coherence time of the channel.

7.2.2. Frequency-Division Duplex Systems. In frequency-division duplex (FDD) systems, reverse and forward links operate on different frequencies. In a multipath environment, this can cause the reverse and forward link channels to differ significantly.

Essentially, in a specular channel, the forward and reverse DoAs and times of arrival (ToAs) are the same, but not the path complex amplitudes. A typical strategy consists in identifying the DoAs of the dominant incoming path, then using spatial beamforming in transmit in order to focus energy in these directions while reducing the radiated power in other directions. Adaptive nulls may also be formed in the directions of interfering users. However, this requires the DoAs for the cochannel users to be known.

A direct approach for transmit channel estimation is based on feedback. This approach involves the user estimating the channel from the downlink signal and sending this information back to the transmitter. In the sequel, we assume that the forward channel information is available at the transmitter.

7.2.3. Single-User Minimum Mean-Squared Error. The goal of spacetime processing in transmit is to maximize the signal level received by the desired user from the base station, while minimizing the ISI and CCI to other users. The spacetime beamformer \mathbf{W} is chosen so as to minimize the following MMSE expression

$$\begin{aligned} & \min_{\mathbf{W}} \left(E \|\mathbf{W}^H \mathcal{H}_q^F \mathbf{S}_q(k) - s_q(k-d)\|_2^2 \right. \\ & \left. + \alpha \sum_{k=1, k \neq q}^Q \mathbf{W}^H \mathcal{H}_k^F \mathcal{H}_k^{FH} \mathbf{W} \right) \end{aligned} \quad (25)$$

where α is a parameter that balances the ISI reduction at the reference mobile and the CCI reduction at other mobiles. d is the chosen reconstruction delay. \mathcal{H}_q^F is the block Toeplitz matrix [defined as in Eq. (14)] containing the coefficients of the forward link channel for the desired user. $\mathcal{H}_k^F, k \neq q$, denotes the forward channel matrix for the other users.

7.3. Multiuser Minimum Mean-Squared Error

Assume that Q cochannel users, operating within a given cell, communicate with the same base station. The multiuser MMSE problem involves adjusting Q spacetime beamformers so as to maximize the signal level and minimize the ISI and CCI at each mobile. Note that CCI that

originates from other cells is ignored here. The base communicates with user q through a beamformer \mathbf{W}_q . All beamformers \mathbf{W}_q , $q = 1, \dots, Q$, are jointly estimated by the optimization of the following cost function:

$$\min_{\mathbf{W}_q, q=1, \dots, Q} \sum_{q=1}^Q \left(E \|\mathbf{W}_q^H \mathcal{H}_q^F \mathbf{S}_q(k) - s_q(k-d)\|_2^2 \right. \\ \left. + \alpha \sum_{k=1, k \neq q}^Q \mathbf{W}_k^H \mathcal{H}_q^F \mathcal{H}_q^{FH} \mathbf{W}_k \right) \quad (26)$$

It turns out that the problem above decouples into Q independent quadratic problems, each having the form shown in Eq. (25). The multiuser MMSE problem can therefore be solved without difficulty.

7.4. Spacetime Coding

When the forward channel is unknown or only partially known (in FDD systems), transmit diversity cannot be implemented directly as in TDD systems, even if we have multiple transmit antennas that exhibit low fade correlation. There is an emerging class of techniques that offer transmit diversity in FDD systems by using spacetime channel coding. The diversity gain can then be translated into significant improvements in data rates or BER performance.

The basic approach in spacetime coding is to split the encoded data into multiple datastreams, each of which is modulated and simultaneously transmitted from a different antenna. Different choices of data-to-antenna mapping can be used. All antennas can use the same modulation and carrier frequency. Alternatively, different modulation (symbol waveforms) or symbol delays can be used. Other approaches include use of different carriers (multicarrier techniques) or spreading codes. The received signal is a superposition of the multiple transmitted signals. Channel decoding can be used to recover the data sequence. Since the encoded data arrive over uncorrelated faded branches, diversity gain can be realized.

8. APPLICATIONS OF SPACETIME PROCESSING

We now briefly review existing and emerging applications of spacetime processing that are currently deployed in base stations of cellular networks.

8.1. Switched-Beam Systems

Switched-beam systems (SBSs) are nonadaptive beamforming systems that involve the use of four to eight antennas per sector at the base station. Here the system is presented for receive beamforming, but a similar concept can be used for transmit. The cell usually consists of three sectors that cover a 120° angle each. In each sector, the outputs of the antennas are combined to form a number of beams with predesigned patterns. These fixed beams are obtained through the use of a Butler matrix. In most current cellular standards (including analog FDMA and digital FDMA-TDMA), a sector and a channel-timeslot pair

are assigned to one user only. In order to enhance the communication with this user, the base station examines, through an electronic *sniffer*, the best beam output and switches to it. In some systems, two beams may be picked up and their outputs forwarded to a selection diversity device. Since the base also receives signals from mobile users in surrounding cells, the sniffer should be able to detect the desired signal in the presence of interferers. To minimize the probability of incorrect beam selection, the beam output is validated by a color code that identifies the user. In digital systems, beam selection is performed at baseband, after channel equalization and synchronization.

SBSs provide array gain, which can be traded for an extended cell coverage. The gain brought by SBS is given by $10 \log m$, where m is the number of antennas. SBSs also help combat CCI. However, since the beams have a fixed width, interference suppression can occur only when the desired signal and the interferer fall into different beams. As a result, the performance of such a system is highly dependent on propagation environments and cell loading conditions. The SBS also experiences several losses, such as cusping losses (since there is a 2–3 dB cusp between beams), beam selection loss, mismatch loss in the presence of nonplanar wave fronts, and loss of path diversity.

8.2. Reuse within Cell

Since cellular communication systems are (increasingly) interference-limited, the gain in CCI reduction brought by the use of smart antennas can be traded for an increase in the number of users supported by the network for a given quality of service. In current TDMA standards, this capacity improvement can be obtained through the use of a smaller frequency reuse factor. Hence, the available frequency band is reused more often, and consequently a larger number of carriers are available in each cell.

Assuming a more drastic modification of the system design, the network will support several users in a given frequency channel in the same cell. This is called “reuse within cell” (RWC). RWC assumes these users have sufficiently different spacetime signatures so that the receiver can achieve sufficient signal separation. When the users become too closely aligned in their signatures, spacetime processing can no longer achieve signal recovery, and the users should be handed off to different frequencies or timeslots. As another limitation of RWC, the spacetime signatures (channel coefficients) of each user needs to be acquired with good accuracy. This can be a difficult task when the powers of the different users are not well balanced. Also, the propagation environment plays a major role in determining the complexity of the channel structure. Finally, angle spread, delay spread, and Doppler spread strongly affect the quality of channel estimation. As an additional difficulty, the channel estimation required in forward link spacetime processing is made difficult in FDD systems.

9. SUMMARY

Smart antennas constitute a promising but still emerging technology. Spacetime processing algorithms provide

powerful tools to enhance the overall performance of wireless cellular networks. Improvements, typically by a factor of 2 in cell coverage or capacity, are shown to be possible according to results from field deployments using simple beamforming. Greater improvements can be obtained from some of the more advanced spacetime processing solutions described in this article. The successful integration of spacetime processing techniques will, however, also require a substantial evolution of the current air interfaces. Also, the design of spacetime algorithms must also be application- and environment-specific.

ANTENNA COMPACT RANGE

W. NEILL KEFAUVER
Lockheed Martin
Denver, Colorado

1. INTRODUCTION

Bringing large antenna measurements indoors has been a very necessary technology since antennas measurement began, and the antenna compact range is one solution.

The father of the compact range is R. C. Johnson, who patented (U.S. 3,302,205) the concept of compact ranges for the measurement in 1967 based on his research at the Air Force's Rome Laboratories [1]. His research centered on testing for radar cross section (RCS), but he also used the technique to evaluate high-gain antennas as well. Compact ranges were further improved in the following decades to solve two major problems in the world of microwave testing: security and environmental control. Generically, the measurements in a specific range are made on an "article," a term used throughout this text. An article can be an antenna, a model including one or more antennas for interactions, or just a model in the case of RCS measurements.

Direct characterization of electrically large articles requires immense outdoor facilities that have high maintenance costs and limited operational time due to weather conditions. The primary types of large articles needing extensive evaluation during the design-and-build stage are antennas for space and structures designed to have low RCS. Neither of these items should be moved outside until it is ready for use. Space antennas are very lightweight and fragile in conventional environments and are often integrated into sophisticated electronics that are very sensitive to contamination and electromagnetic interference. While these antennas can handle the rigors of outer space, the outdoor measurement method simply introduces too high a risk, and case of very high frequencies, has unacceptable propagation variations. The security issues with RCS measurement, along with the cost of building a full-scale operational test article with each design change, would never have allowed outdoor testing as the primary research tool. RCS is mentioned here only because compact ranges for measuring antennas probably would never have been developed without the need to measure the radar cross section.

By 1980 there a fully validated technique with superior accuracy had been developed to measure antennas that eliminated all the problems found in outdoor ranges and in compact ranges: near-field measurements. The primary reason for growth of compact ranges in the 1980s was the absolutely essential need for the compact range in the RCS community, and the gradual acceptance of near-field measurement technology as the compact range could provide direct measurements instantaneously. In this article we will discuss the capabilities that compact ranges provide for the user attempting to perform evaluations of antennas and satellite systems.

2. BASIC PHYSICS

An antenna compact range is designed to do one thing very well, namely, to deliver a collimated wave of microwave fields to a test article. The collimated wave will simulate the far field that the article will see in its final application. The basics of the process are also straightforward, taking a point source antenna with a fairly broad beamwidth and placing it at the focus of an offset reflector, which, due to the surface—usually a section of a paraboloid—will cause all the rays projecting from the focus to cross the plane of the test article simultaneously (see Fig. 1).

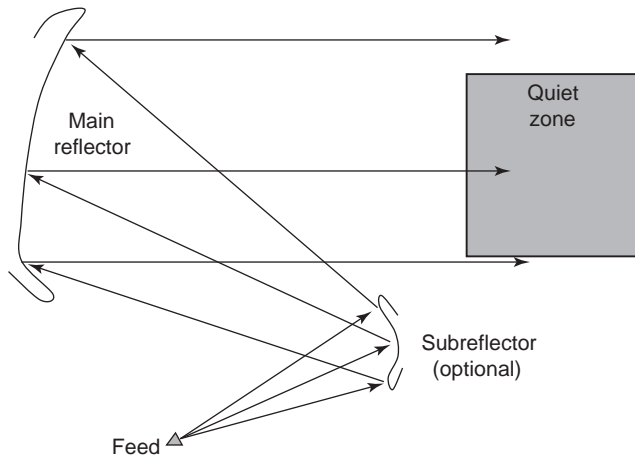

Figure 1. Basic antenna compact range schematic.

In a conventional far-field range this collimation is caused by sheer distance; the standard engineering term for minimum far field distance is $2D^2/\lambda$. This relationship of the diameter enclosing the article to wavelength will result in a phase curvature of 22.5° on an article of diameter D centered in the range between the outside edge and center of the article. Ideally, both the edge and the center on the same plane will see a phase difference of zero. This property arises because a plane wave has no phase curvature, only direction. The obvious advantage of a compact range is that testing at higher frequencies does not require a longer range—a conventional far-field requirement becomes inverse linearly with wavelength. If one wishes to build and test a 4-m aperture at 3 GHz, one would need a 320 m (1050 ft) range; at 36 GHz this distance would increase to 3.84 km (2.4 mi). In contrast, the compact range size for the same measurement is fixed or even slightly smaller because of reduction in edge diffraction for electrically large reflectors. More importantly, this requirement is the minimum to ensure reasonable prediction of pattern, which for many challenging telecommunication requirements utilizing frequency reuse and multiple beams, the standard distance requirement will not yield the high accuracy needed to ensure successful system operation.

2.1. Advantages

Antenna compact ranges have a huge size advantage over conventional outdoor ranges and are impervious to weather conditions. They also have an important advantage over near-field ranges. Compact ranges are significantly larger physically for the same testing requirements—typically 3 times the largest expected test article versus $1\frac{1}{2}$ times for a near-field range. However, the compact range performs a direct measurement that needs little additional processing for comparison of performance requirements, and the near-field range will require extensive data processing. The operator who is trained to take measurements in a far field will see results in an antenna compact range that look very similar to those that would have been obtained from measurements in a conventional range. The tricky

issues arise in separating the range interaction with the measurement. Seemingly endless papers on the design of a compact range to minimize the range interactions have been written [2–6]. For satellite system measurements, the antenna compact range does truly shine because the direct measurement of special system requirements as well as conventional antenna pattern characterization can be performed.

The special system measurements are discussed below and can often have millions of dollars associated with values of less than a decibel. Effective isotropic radiated power (EIRP) is a direct measurement of the satellite's capacity to deliver the required power to the coverage of the antenna pattern. Although each component in the system may have been evaluated to high accuracy in its benchtest, the integrated spacecraft test providing integrated system results is where the engineer can finally know whether the unit will perform as designed. G/T is the reciprocal measurement of spacecraft performance—whether the receiver will deliver the designed sensitivity. The primary concern to be evaluated in the antenna compact range for this measurement is that the noise measurement be accurate; if the noise temperature of the room is not true blackbody-ambient, the final number may be meaningless. Errors can arise from several noise sources, including fluorescent lights and computers. However, for both these measurements, because the full gain of the antenna system is in the link, high accuracies can be obtained with very few measurements.

2.2. Disadvantages

Compact ranges are expensive relative to indoor far-field ranges of similar physical size because the reflector will probably double the cost. This author would say that this is not a disadvantage of the antenna compact range, for several reasons:

1. A compact range should be considered only when the tests to be performed are sufficiently extensive to generate a capital investment and the requirements will not be satisfied by alternative methods. The cost of an equivalent outdoor far-field range of several miles is similar for the infrastructure, but the property maintenance cost will continually increase. The cost for a near-field scanner will be lower, but the throughput can be much lower, depending on the test requirements, and iterative troubleshooting of system problems will typically take much longer because of staff training.
2. Although the compact range can do a wonderful job of testing small articles and low-cost antennas, the engineering requirements will never direct the designer to build such a range. This would be equivalent to using an electron scanning microscope to examine a thumbprint. Yes, the system can do the task, but why would you buy one?
3. Once one has established that the antennas you are testing are too complicated and the requirements too tight to be done using a conventional far-field method, then the antenna compact range is justified.

Having made the decision to build the antenna compact range will solve many of your future problems and has minimal maintenance costs as the most expensive piece of equipment—the reflector—never moves and is far away from any operation activities. One item that is difficult to estimate is the impact of the need to rotate a spacecraft or even an antenna in the gravity field found on Earth. For spacecraft antennas designed for zero gravity, the Earth's gravity field can cause significant deflections that will dynamically change as the article rotates. For some designs the cost would be astronomical—particularly unfurlable (deployable) antennas that cannot support their weight to eliminate this deflection. Some structures, because of the surface tolerances required for proper performance, may not be stable enough even for rigid reflectors to test in an antenna compact range. Additionally, some accommodation must be made in the positioning system to offset any imbalance the test article may put on the positioning structure. This problem does not occur in planar near-field scanners, making them very popular for these special testing issues where only minimal movement of the test article is allowed.

3. APPLICATIONS

The primary applications of compact ranges are to evaluate the microwave performance parameters of full or scaled models of antennas, spacecrafts, and airplanes. The compact range does a very good job of simulating the microwave operational environment to facilitate the measurement of the radar cross section, antenna patterns, and spacecraft radiation parameters.

3.1. Radar Cross Section

The compact range became very popular in the 1970s as an efficient method to measure radar cross section—the microwave signal reflected from an object illuminated by a radar pulse (primarily in the direction of the radar). The compact range brought this testing inside and allowed small-scale models to be tested without weatherization. In addition, the designer now had physical security to develop new designs in order to lower the cross section if desired. As these techniques continued to improve, the ease of performing antenna measurements in the same facilities using the same equipment popularized the use of compact ranges for measuring antennas as well. Ultimately the needs for antenna measurements to be more accurate caused changes in the reflector designs, resulting in some very specialized reflector designs for difficult antenna measurements. Two obvious differences between antenna measurements and RCS measurements are that the antenna (1) receives a signal having only a single path loss (targets have a two path loss) and (2) may cause a very high degree of reflection in the range while working perfectly (very few targets have high-level reflections). Difference 1 would mean that the range should require much less power to perform an accurate measurement; differ-

ence 2 would require the user to check data routinely for range interaction. The primary method is to perform a “range walk.” Range walks are achieved by measurement of many frequencies to reconstruct the time response of the range over several times its physical length or using the hardware gating to remove responses not due to the antenna in the collimated wave.

3.2. Antenna Measurements

The major difference in measuring RCS and antenna patterns from the test setup is that the receiver detector is moved from the feed to the antenna under test. Because of the need to pass signals from the antenna to the receiver, a second model tower may also be required so that a coaxial cable can be run back through the range (RCS towers are usually microwave-“transparent”—cables are not). Additionally, particularly if an entire spacecraft is tested, the tower must have sufficient strength to support a large load. The quiet zone must have much higher performance than a RCS measurement because often the antennas will have shaped patterns with low sidelobes. Erroneously low sidelobes can be measured on an antenna in a range due to taper of the quiet-zone amplitude since the amplitude taper of the antenna aperture is how sidelobes are reduced. The compact range can also cause increased sidelobes due to range interactions. To evaluate these two scenarios, the range operator has three available methods: field probing of the quiet zone using a less directive source, measuring the antenna oriented differently in the quiet zone, or performing a “range walk” where the time-domain response of the range is imaged using a frequency chirp (the Fast Fourier transform (FFT) of the frequency chirp will produce the time-domain response). “Range walk” can also be implemented directly in the time domain at a fixed frequency using hardware gating to determine where in the range the pulses are being generated by reflections delaying the signal.

3.2.1. Compensation From Field Probing. The best approach to minimize risk of pattern measurement error from quiet-zone anomalies is to gather an extensive set of field probe data during certification of the range as a required baseline for operation of the range. If this set of data is not established as an initial requirement, it will be very difficult to convince any user of the need for the data since the contributions will often be hidden below the measurement envelope. Ideally these data will be complex phasor measurements of the field over the entire plane with sufficient density to facilitate a reasonable prediction of the fields on the test article. Ultimately these data can be applied to the antenna pattern to show the level of purity of the quiet zone relative to the antenna pattern.

The method employed for this compensation is to use quiet-zone data as near-field data. If the envelope of the two-dimensional FFT of the field probe exceeds the expected envelope of the antenna pattern, the measurement will be flawed. The transform of the field probe gives the wavenumber distribution of the quiet-zone fields; the wavenumber converts to angular information using the

direct relationships $k_x/k_0 = \cos \phi \sin \theta$, $k_y/k_0 = \sin \phi \sin \theta$, and $k_z/k_0 = \cos \theta$. The contribution of compact range errors to the first sidelobe measurement is more subtle. Because a perfect plane-wave circular aperture will transform to a -17 -dB sidelobe, the envelope test is not sufficient. What needs to be evaluated is the convolution response of the two patterns. A first-order approach is to apply the measured amplitude and phase-taper to the predicted antenna aperture and bound the contribution. Alternately, the pattern from integrating the quiet-zone measurements directly should be the ideal constant aperture mentioned above with a -17 -dB first sidelobe. The discrepancy of the first sidelobe from theoretical can be used to predict the threshold of the first sidelobe measurement error. If the sidelobe is off by 1 dB, then the quiet-zone error is -37 dB for the first sidelobe due to amplitude taper. The quiet zone integrated in this case should be the size of the antenna aperture being tested, not the nominal size of the range quiet zone. This type of error evaluation obviously requires very detailed and accurate knowledge of the quiet zone and will also require gathering at least two planes of data to fully encompass the test article.

3.2.2. Compensation for Polarization. The other measurement best performed immediately prior to measuring the test article is an evaluation of the range polarization symmetry using a purely polarized source. Since compact ranges are of an inherently asymmetric geometry, there should be no expectation of the vertical and horizontal polarization would be identical. If a circularly polarized source antenna is used in the compact range, the issue becomes even more complicated: (1) the beam off the reflector will be squinted by the geometry, (2) the cross-polarized horn will be squinted in the opposite direction, and (3) the normalization factor between the two measurements must be determined, which may be complicated by drift for the time it takes to reconfigure the feed. An alternative method is to measure the complete polarization matrix to allow use of lower polarization purity with post-processing of the measured data. This technique allows for accurate measurement of wideband antennas using simple source; if a dual-polarized source horn is used, then the pattern can be collected and compensated by a simple inversion of the 2×2 polarization matrix (P^{-1}) and the measured two-element vector E_{aut}^m .

$$E_{\text{aut}} = P^{-1} * E_{\text{aut}}^m$$

The polarization matrix is typically measured by using a linearly polarized gain standard that must have the same response in both orientations and is expected to be an almost pure polarization device. If the gain standard is clocked 90° in the chamber, the resulting responses should be identical. The measured response then can be normalized by inverting the matrix, so that the antenna can be rotated to any polarization orientation in the chamber and the same maximum field response will be measured using the P -matrix compensation if the orthogonal polarizations define an ellipse.

Obviously, even this compensation method will not eliminate the polarization errors, but it is good for establishing a lower bound for the range accuracy. If measurement of the range as described is performed, gathering at least the diagonal points, then the limit on measuring the axial ratio of an antenna or equivalently the cross-polarization of a linear antenna can be established. If the test article is significantly larger than the gain standard, this bound still applies, but the error will probably be greater because data for an increasing quiet-zone area are being gathered. The quiet-zone data mentioned above help in determining how significant the additional contributions are off axis. The compensation method described above is still valid on axis for validating measurement accuracy because fundamentally the fields of an antenna are independent of its rotation around the z axis of the range. Using the field probe data and the technique described by Rose et al. [9], additional improvement of the measurements can be achieved.

3.3. System Integration

In system integration, a compact range often is more useful than other types of ranges. The test article can effectively be flown through its operational environment with all the systems integrated, and direct evaluation of performance parameters can be evaluated instantaneously. The instantaneous evaluation can sometimes significantly reduce total test duration and, if the accuracy is acceptable, greatly reduce the amount of postprocessing analysis required to certify performance of a system. One measurement requirement in which this capability is advantageous is in measuring active arrays. One can program the array to track the positioner on a peak or a null and get a continuous response, whereas a near-field range would have to do this measurement by interpolation and require full collections instead of single-point checks.

4. REFLECTOR TYPES

Design of reflectors have become more sophisticated over the years as modeling tools have improved, but the basic principle is unchanged—how to get the maximum performance in a quiet zone for a sufficiently large reflector. This section addresses the solutions; the more complicated the design, the more specialized the application—as is the case for most test tools, the more the performance is optimized for one attribute, the less capable the design will be for general use. A range optimized for testing low cross-polarization will have problems measuring low frequency, a range optimized for measuring radar cross section will not perform antenna measurements nearly as well, and a range optimized for testing satellite systems will not facilitate testing of antenna components or radar cross section.

4.1. Prime Focus

Prime focus reflectors as shown in Fig. 2 are the most common compact range reflectors and can be ordered from several vendors with small variations in design. The major

Figure 2. Example of a prime focus reflector. (Courtesy of Lockheed Martin, Sunnyvale, CA operations.)

problem with a prime focus reflector is the cross-polarization created by the reflection of the feed pattern off the reflector. Many antenna requirements in the telecommunications industry require quiet-zone cross-polarization (XPOL) to be limited to less than -40 dB to accurately measure the ability of the test antenna to perform polarization reuse. *Polarization reuse* is where the antenna can receive and separate two signals whose only distinguishing characteristic is polarization. The minimal XPOL level needed to maintain acceptable bit error rates is typically 30 dB. For a prime focus reflector the geometry will generate XPOL for even a pure linearly polarized feed, due to the polarization rotation from reflecting off the doubly curved surface. While the cross-polarization is symmetric across the reflector's axis of symmetry and will tend to cancel out for applications where the test article is similarly aligned [3], for a complex multibeam spacecraft antenna this situation is seldom the case. Cross-polarization of the quiet zone can be decreased by increasing the focal length of the reflector—unfortunately the directivity of the feed horn will also have to increase until eventually the designers will find that they need a second reflector to collimate the feed sufficiently to obtain the needed focal length of the main reflector. This limit in the prime focus design is the starting point for a dual-reflector design. Once a second reflector is introduced into the system, the two reflectors can be designed with intentional cross-polarization cancellation [7].

4.2. Dual Reflector

The photo in Fig. 3 shows a typical dual-reflector compact range (although extremely large, 20 m in diameter). In the foreground is the pylon where the antenna or RCS target can be mounted, at the bottom of the photo is the back of the subreflector, and in front of the subreflector is an array of feeds to cover various frequency bands. The center of the photo is the large rolled edge main reflector constructed from many panels.

The first obvious reason for a dual-reflector system is the reduction in overall range size to meet a requirement within a minimal physical footprint [8]. While the cross-polarization of a range can be reduced by increasing the focal length, the feed will ultimately end up on the other side of the test article—an unacceptable geometry,

Figure 3. Example of a dual-reflector system. (Courtesy of Composite Optics Incorporated.)

resulting in increasing the size of the chamber, resulting in higher costs to maintain the facility. The alternative is to introduce a subreflector, which would move the feed back toward the main reflector, and if several additional design constraints are imposed, the primary sources of compact range cross-polarization will also be reduced dramatically. The subreflector can be Cassegrain or Gregorian; ranges have been created using both geometries. The initial advantage of the Gregorian configuration is that the subreflector is beyond the focal point of the main reflector and can be designed to be further out of the quiet zone. Classical examples of this design are the DASA (now the European Aeronautic Defense and Space Company) compact ranges built for several companies, such as Loral, SPAR Canada, Astrium, and RCA. In the DASA range the geometry is set horizontally rather than vertically, allowing the overall range height to be only slightly greater than that of the main reflector. In most compact ranges the subreflector and feed are located below the main reflector, resulting in a much taller facility for the same-size reflector.

4.3. Other Reflector Types

Other types of systems have been developed for specialized measurement applications, including multiple subreflector systems and modified single-cylindrical-reflector designs; these alternate designs arise from various needs. MI-Technologies produces a cylindrical reflector because it maximizes the quiet-zone area with minimal installation and manufacturing difficulty, while XPOL contamination is reduced by postprocessing [9]. The original compact range design by Scientific Atlanta combined a parabolic cylinder with a rolled edge parabolic dish, these can be found at all facilities in the United States. Ultimately, the end user has to determine whether the design needs to be customized for the article testing requirements or whether a general-purpose system is sufficient. With the advent of modern processing capabilities, many sources of measurement errors can be removed in the processing without

designing them out of the original range. With compact ranges in particular, this problem always arises because a range that did a splendid job of testing one article may be inadequate for the next article because of changes in size, frequency, pattern type, and other variables that cannot be anticipated in the original design. The problem is simple, the compact range is ultimately an antenna, and if the antenna you are testing is optimized for performance to specific requirements, quite often the compact range is not. That said, the compact range will give you very acceptable results on a broad range of designs without any additional data analysis; this feature alone can drastically reduce the time from prototype to final design. The final design can then be carefully evaluated at an alternative range to verify that the range does not affect the measured performance requirements.

4.4. Edge Treatments

The edge treatments for compact ranges are used to ease the boundary conditions of conventional reflector designs; for the purposes of packaging and weight, the conventional reflector designer may not have to worry about sharp edge transitions that represent less than 0.01% of the total aperture power. In a compact range these discontinuities are deliberately reduced with edge treatments because they can cause elevated sidelobes. The three common solutions in order of preference in common use are serrated, blended, and absorber [2,4]. Serrated is the most popular because of the ease of implementation; a technician can easily stamp out a series of triangles to place about the reflector edge in a day with a brief description of the desired sizes. The blended edge treatment is difficult because you are trying to force a doubly curved surface to be continuous as you change it from concave to convex without causing significant discontinuities through at least two derivatives. Performing this operation accurately requires elaborate sheetmetal forming capabilities with only marginal improvements over serrations in many test applications—if the compact range aperture is always going to be larger than 10 wavelengths, the extra work cannot be justified. The absorber treatment requires consistent control of the reflectivity of the dielectric materials that you are using and may result in failure if the materials used are not tightly controlled. Realistically, most absorber manufacturers have problems in maintaining precise controls on the material's dielectric properties. Also, lossy materials do not have effectively frequency-independent behavior as does metal, which render the designs even less stable. In addition, absorber materials are often fragile, which means that the range may require frequent repair with materials that may not be equivalent to the originals.

5. ERROR SOURCES

Error sources in the compact range arise from several areas. There is an emerging method utilizing the generic ANSI Z-540/ISO25 standard that is gaining acceptance for quantification of these areas for RCS. One can safely assume that if the range is acceptable for RCS using this

methodology, it will also be able to test antennas of similar size to a normal accuracy. The major issue in determining the accuracy of the compact range relative to other measurement methods is the need to know the limits of the reflector's collimation ability. The basic tool for evaluating this quantity is the field probe (which is also used in far field range certification). The field probe simply introduces a low-gain antenna, although still having a good front:back ratio, in the "quiet" zone where the test article is to be placed after range evaluation. For a conventional far-field range, the ripples in the "quiet" zone are typically due to wall reflections for indoor ranges or ground reflections for outdoor ranges. In a compact range these ripples will typically be caused by the reflector edge diffraction; the radiation from the feedpoint and the subreflector, if used, will also cause ripples. Ripples from the feed and subreflector can usually be time-gated with modern instrumentation. However, the reflector diffraction cannot be gated and usually serves as the lower limit frequency for a particular reflector.

5.1. Reflector Surface

The limit for the ultimate high frequency of a reflector is typically the precision of the reflector surface. Present-day manufacturers will certify surface tolerances to 0.1 mm (0.004 in.) RMS (root mean squared) or less for reflectors up to 10 m (30 feet)—this surface corresponds to a loss of 0.1 dB at 36 GHz. The more important issue is how these errors will manifest themselves in the pattern of a high-performance antenna. The RMS valuation is supposed to be coupled to a Gaussian distribution of surface errors. If the reflector is built from multiple panels (all large reflectors are due to transportation and manufacturing issues), the quiet zone may have a significant systematic error due to the alignment of the panels. The misalignment will cause errors in the pointing of the antenna and feed orientation. The techniques of photogrammetry and automated triangulation by theodolites are used to minimize this contribution to range errors. Likewise, a correlated machining error could cause a false sidelobe in the antenna pattern; even a properly built reflector will produce sidelobes due to the edge transitions. In most instances these sidelobes can be pinpointed by using a secondary test position in the compact range. Range induced sidelobes will move as a result of change in the chamber orientation, whereas the true antenna pattern should be independent of the chamber orientation. Many of the processing techniques developed for RCS analysis and near-field measurements have applications in isolating quiet-zone errors in the antenna measurements, and with a proper understanding of the source can sometimes allow the measurements to be accurately compensated.

5.2. Feed Pattern

The feed pattern will significantly affect the measurement of several antenna parameters: polarization, gain, and sidelobe envelope. The feed controls the taper of the quiet-zone fields, and the designer has to choose between range ripple due to edge illumination and edge taper due to feed directivity. This problem is equivalent to Gibb's

phenomenon in communication theory. The dangerous part of this problem is that it can deceptively make an antenna look better than it really is by reducing the edge illumination of the test article. Additionally, because it is a first-order effect, it can be isolated only by large lateral displacement. Typically, if the error is significant, the article cannot be moved a large amount laterally because it will then be outside the defined quiet zone. Location of the feed can also be problematic, as most feeds are corrugated waveguide horns used to minimize cross-polarization and will not maintain a stable phase center over the full frequency band of operation. All these effects are easily isolated by field probing, but depending on the test article, the pattern may be much more severely affected than obvious from first glance at the quiet-zone data. The issue is that the observed range response is the convolution of the quiet zone with the antenna's pattern. For a low-gain antenna, this problem is negligible because the quiet zone is almost a Dirac function relative to the pattern variation of the test article. The range collimates virtually all the power in one direction, yielding a spatial impulse response, and the test article has an insufficient beamwidth to be affected by the angular width of the spatial impulse versus that of a Dirac function. Once the test article approaches the size of the range, the correlated function will no longer be swamped by the beamwidth of the test article and the pattern will begin to show errors due to the process of integrating the compact range fields by the large-aperture antenna. The obvious result is that the higher the performance the antenna, the higher the quality of the compact range that is needed to measure it. This problem is to determine what the various multiple reflector compact ranges were designed to solve. For example, by changing from a point source to an additional source aperture, the polarization and taper of the quiet zone could be improved. The trade off when this solution is implemented is that the subreflector size now becomes the fundamental limit to the lowest usable frequency for the compact range.

5.3. Multipath

Most compact range multipath arises from three sources: chamber wall reflections, direct-feed radiation, and reflector diffraction. Chamber wall reflections are minimized by anechoic material. Since the reflector collimates the signal, the sidewalls are treated uniformly, unlike the case for a rectangular range, where the sidewall absorber is thicker in the area of specular reflection. The backwall is treated just like a conventional range, where the thickness of the absorber is about a wavelength at the lowest test frequency. The direct-feed radiation can typically be time-gated by either hardware or software because of the significant lead in arrival time. The diffraction of the reflector is usually the limiter on range operation because the arrival time is almost simultaneous with the plane wave from the reflector, and it contaminates the quiet-zone polarization and causes amplitude and phase ripple; hence the emphasis area of modeling the diffraction and synthesizing of reflector designs to reduce this effect.

5.4. Test Article Interaction

One of the most important measurement issues to verify when using an antenna compact range for measurements is the interaction with the test article. When calibrating a range with a gain standard, the article is often not in the facility or is oriented away from the direction in which it will be characterized. In a conventional far field the interaction level will be minimal as a result of the path loss associated with secondary bounces. In a compact range, however, the path loss is minimal so that a highly directive test article can reflect a significant signal level into the feed system, leading to a very rapidly varying standing wave in the chamber due to the error signal traversing the range 3 times to once for the calibrated signal. The behavior is similar to the interaction between the feed and the subreflector commonly addressed by a scattering cone or similar device to eliminate the standing wave. Several solutions can be taken to avoid this problem, such as absorber baffles about the feed, gating by software or hardware, and repeating measurements at multiple locations in the chamber. The most troubling issue with this error is that it appears only when the test article is being measured and is highly sensitive to the orientation of the article. If the test article has flat surfaces, such as those of a phased array or a spacecraft, or if the article is a large reflector, the issue must be evaluated. Typically, the expected level of the contaminant can be found through the classical "range walk" as the interaction impulse is beyond the length of the facility.

6. SPECIALIZED TESTING REQUIREMENTS

Particular test articles require specific facility equipment; in particular, antenna compact ranges are often pulsed systems employed to minimize the chamber multipath. The receivers used with antenna compact ranges must usually be frequency-agile to facilitate rapid data acquisition and also enhance or replace the hardware pulsing capability. Depending on the type of data results desired, extensive processing of the data may sometimes need to be performed, and depending on the type of system and engineering needs, the facility may require a high degree of shielding.

6.1. Pulsed Systems

Pulsed systems arise from the radar world, where the operator, when operating a monostatic radar, transmits a pulse and then switches to the receiver front end to observe reflections downrange from objects. The antenna compact range can be operated the same way and quickly eliminates signals significantly delayed in time in the range such as the backlobe of the feed or diffraction from the subreflector, as these signals will arrive significantly ahead of the main reflector's collimated wave. In a typical compact range this delay will be many nanoseconds whereas the risetime of the antenna under test will be almost instantaneous. There are two obvious drawbacks to a pulsed system: (1) the lower the duty cycle, the lower the system dynamic range; and (2) for large test articles, it is

possible to have a pulse smaller than the risetime on the article because of the limited bandwidth. Overall, although pulsing is an excellent tool to help minimize range errors in measurements, especially if the range is already configured to perform RCS measurements as well, there are other ways to accomplish the same result without these tradeoffs.

6.2. Frequency-Agile Receivers

With the advent of the Agilent 8510/8530, MI-Technologies 1797 and similar receivers using frequency-agile sources, the user now has the capability to take a virtually unlimited number of frequencies at each position as the unit is rotated in the range with virtually no additional time overhead for testing. The advantage to these receivers is that the dynamic range limitation of a pulsed system is eliminated and instead, the data can be carefully evaluated postacquisition for range/antenna-generated time-domain pulses. The major problem with these systems is the tendency to accumulate large blocks of data that can be processed only by extensive computational tools. As the computers continue to improve, this problem has been increasingly eliminated—for instance, in 1985, when this type of processing was required, one often would need a dedicated mainframe, whereas in 2003 the same processing activity using general application software was reduced from hours to minutes, and the asset cost is now negligible. The advantage of this type of system is that one can achieve high-quality and high-quantity measurements using a PC, an HPIB (Hewlett-Packard interface bus) card, a network analyzer, and a commercial positioner system in an existing range. The increased capabilities have had two impacts on antenna measurements—engineers routinely asking for more data and less investment in new infrastructure other than compact ranges and near-field ranges. The outdoor direct measurement has been abandoned because of cost and the limited quality of the measurement and this work has moved indoors.

6.3. Extensive Postprocessing

Antenna compact ranges are fundamentally limited in their polarization symmetry, which has led to postprocessing techniques of varying degrees of sophistication. Since the reflector is offset by design and therefore asymmetric relative to the feed, regardless of the F/D ratio, there will be some residual imbalance in the quiet zone, whether it lies in the cross-polarization or the amplitude taper as the unit or feed polarization is rotated. With sufficient knowledge of the quiet zone, these errors can be corrected to the first order in much the same way as the imperfections of the network analyzer testset are calibrated out.

The simplest level of calibration is to take the quasi-static approach to the quiet zone and assume that measurement at a given point represents the response of the quiet zone. The operator can create a 2×2 matrix of points to establish whether the measured response was using a pure polarization source such as a standard-gain horn, with matrix components of HH , HV , VH , and VV

responses, where H is horizontal and V is vertical orientations of the polarization standard. Even if one were not to compensate the data, this measurement should be taken to establish error bounds. If the matrix is inverted, then the bias can be removed from the data. Obviously, this technique can be expanded to include higher-order terms in the quiet zone with additional measurements increasing the accuracy of the compensation method. The standard-gain horn can also be replaced with a more symmetric probe to increase the accuracy of matrix measurements. Ultimately, the limit to this approach is similar to the near-field probe compensation—you can consistently measure the quiet zone to only a finite accuracy, and the higher the order of compensation, the less stable.

6.4. Shielding

Shielding of the range can be particularly important if the testing is done using spacecraft receivers, which are very sensitive and may even be damaged by ground-based signals. Typically there risk is greater involved in getting stray signals in the measurement that complicate the analysis of data. Shielding is accomplished using the standard techniques from the electromagnetic compatibility community of placing the test article in a Faraday cage (welded steel enclosure) to isolate it from external sources and then additionally lining the range with absorber material to reduce reflections. Using this technique, the stray signal levels can be reduced by 100 dB, although quite often the test instrumentation will also need to be removed from the cage to achieve these levels.

7. CONCLUSIONS

The antenna compact range is a very useful tool in the science of evaluating antenna performance. Careful development of this technology has virtually eliminated the need for outdoor testing and lowered the cost and risk of testing fragile spacecraft antennas. The capabilities of range reflectors rapidly matured in the late 1980s to facilitate very clean direct measurements of antennas with minimal effort in compensating the range errors. The chief technology competitor to the antenna compact range is the near-field scanner, which requires much more data processing as well as a much more detailed working knowledge of antenna theory since the measured data do not correspond directly to the needed far-field pattern. The antenna compact range is a very cost-effective tool to evaluate antennas with modest performance requirements. For antennas with extremely low cross-polarization and sidelobe performance requirements, the technology becomes limited since the test antenna may outperform the range.

1. INTRODUCTION

1.1. Definition and General Description

According to the *Macquarie Dictionary*, a “Feed” is a “Feeding mechanism.” The term “antenna feeds” describes many types of antennas in common use. Feeds are a means of supplying energy to (or receiving energy from) a “secondary antenna,” such as a reflector, lens, or beam waveguide, via a transmission line or waveguide. Hence, an antenna feed is often referred to as a “primary feed.” Everyday applications of antennas with feeds include satellite communications, radar, radio telescopes, deep-space probes, and terrestrial microwave and millimeter-wave radiolinks. Some examples are shown in Figs. 1 and 2. Depending on the application, secondary antennas can be designed to produce beams that are highly directional to minimize the effects of interference and noise or shaped to cover a specific region or angular segment. For example, shaped beams allow reuse of the frequency spectrum in another region as in the case of satellite coverage on the Earth’s surface. In other applications, such as broadcasting, secondary antennas and feeds can be used to produce beams tailored to suit the demographics around the

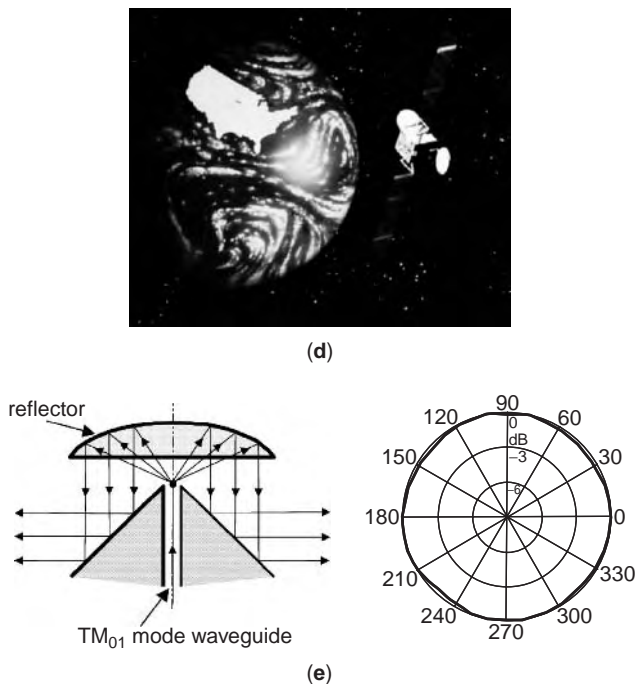

Figure 1. (Continued).

transmitter. The secondary antenna can be used to illuminate another device such as in a beam waveguide system for a reflector or a particle accelerator.

Feed antennas come in many different shapes and sizes, ranging from simple dipoles and waveguides to horns and printed antennas such as microstrip patches, arrays, and traveling-wave antennas. The choice of feed in any given situation is often a complex decision and depends on the type of application and secondary antenna. Factors to be considered when selecting a feed antenna include the frequency of operation, bandwidth, polarization requirements, impedance properties, the transmission line connecting to the feed, and mechanical aspects such as the size, volume and weight, available materials, and cost.

Secondary antennas are typically capable of extremely wide bandwidth performance and are, in practice, severely restricted by the bandwidth limitations of the feed antenna and its associated network, the feed system. There have been significant advances in improving the performance of feed systems, especially in regard to wideband and multiband operation.

The most common type of secondary antenna is the parabolic reflector (Fig. 2a). This has a point focus and, when illuminated by a feed emitting a spherical wave, it produces a narrow pencil beam. Other secondary antennas are cylindrical or spherical reflectors (Fig. 2b), which require a line-source feed to produce a pencil beam, lenses (Figs. 1c and 2c), and reflectarrays (Fig. 2d). Reflectarrays combine the techniques of reflectors and printed circuit antennas. A standard reflectarray consists of an array of microstrip patches or dipoles printed on a thin dielectric substrate. The elements of the printed array are suitably phased to convert a spherical wave from a conventional

feed into a plane wave. The advantage is that the antenna is planar, has low volume, and is potentially lightweight. Phasing of the printed array is achieved with patches that have different size, different length delay lines, or varying angles of rotation.

In some applications, the aim is to shape the secondary radiation pattern and the role of the antenna feed is simply to give the correct illumination. For example, an array feed or a corrugated horn can be used to illuminate a shaped reflector system for a satellite system that will produce a shaped secondary pattern to cover selected Earth coverage regions (see Fig. 1d). Another application is a mobile base station antenna that requires an omnidirectional pattern. A suitable feed antenna and a shaped reflector are able to produce a 360° coverage as shown in Fig. 1e. Secondary antennas with elliptical beamshapes can be used to maximize the radiated field intensity within an angular region that has different beamwidths in two orthogonal planes. Such antennas are used in radar, Earth stations, and satellite applications to provide an elliptical footprint on Earth.

1.2. Historical Perspective

The first feed antennas date back to the pioneering work of Heinrich Hertz during his demonstration of the consequences of James Clerk Maxwell's equations, which were published a decade earlier. In 1888, Hertz employed a half-wavelength dipole in front of a cylindrical parabolic reflector to demonstrate the opticslike properties of electromagnetic waves at about 60 cm [1]. Other feeds and antennas now used as basic feeds were discovered prior to 1900 by Lodge (circular waveguide), Bose (dielectric rod and pyramidal horn), and Rayleigh [2]. From the early 1900s to the 1930s, little work on feeds appears to have occurred, mainly because of the outstanding success of long-range low-frequency communications where directly radiating antennas were the natural choice.

The rising interest in microwave techniques in the 1930s resulted in major developments in antenna feeds. The then new applications using ultrahigh frequencies and microwaves, such as radar and point-to-point communications, required many new antennas, and reflectors, in particular, became extremely important because of their versatility, effectiveness, and practicability. In short, feeds became an area of significant interest and research. The MIT Radiation Laboratory series of books published in the late 1940s, and especially the volume edited by Silver [3], did much to establish the basis of reflector and feed antenna design. It is significant that Silver's book was the primary reference for a generation of feed designers and is still a great source of information. With radar, and the deployment of terrestrial microwave systems for communications, reflectors came into common use. These used simple waveguides or horns, rear-radiating feeds [4] or arrays such as the Yagi-Uda or logperiodic arrays [5]. The creation of new applications in the 1950s, such as radio astronomy and satellite communications, added new dimensions to feed design with requirements for low noise and low cross-polarization. These demands resulted in new feed antennas, including the dual-mode Potter horn

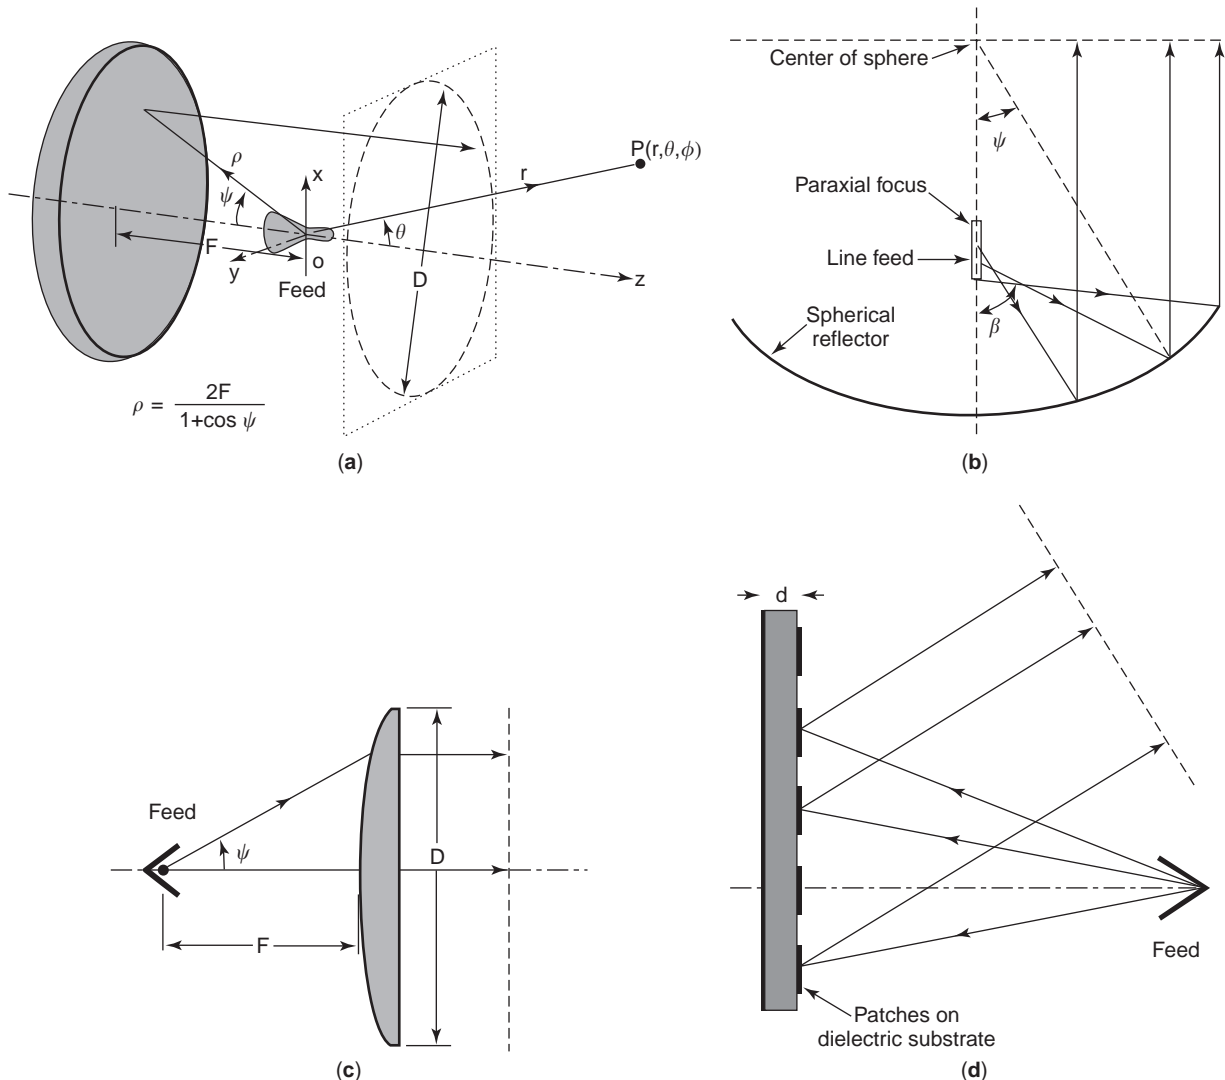

Figure 2. Examples of secondary antennas: (a) parabolic reflector; (b) spherical reflector; (c) two-dimensional lens; (d) reflectarray.

[6], the corrugated horn (see Thomas [7] for an historical summary of this important feed), multimode horns [8], stepped horns, and dielectric-lined feeds. Many of the most influential papers on horns written prior to 1976 have been collected by Love [9], and a more recent survey is given by Olver et al. [10]. Array feeds were investigated first in the early 1960s [11] and over the next two decades were adopted in radar and satellite communications for producing scanned and shaped beams with reflectors. In the 1980s and early 1990s, compact corrugated horns covering octave bandwidths were developed, while easy to manufacture, high-performance feeds, such as axially corrugated horns, were widely adopted. Major advances in electromagnetic modeling have allowed the development of horns whose performance can be tailored by computer optimization. In more recent years, improvements in the theoretical understanding of printed antennas has resulted in microstrip and printed slot or Vivaldi arrays being used as feeds.

1.3. Design of Feeds

A feed antenna should be designed to suit the secondary antenna to obtain the best overall performance. This is usually expressed in terms of the signal level, whether received or transmitted, immunity to noise or interference, and frequency of operation. There are essentially two ways of designing the overall antenna. The first way, called the *transmit mode of operation*, specifies the combined radiation pattern of the feed and the secondary antenna that meets the system requirements when both are transmitting signals. Figure 2a depicts a parabolic¹ reflector operating in the transmit mode. The electromagnetic field radiated by the feed is called the *primary field* and the radiation pattern, the *primary pattern*. The

¹This refers to a paraboloid or part of a paraboloidal surface as for an offset-fed parabolic reflector.

illuminated antenna is the secondary antenna and the associated radiated field is the secondary field.

In the second approach, called the *receive mode of operation*, the antenna feed is designed to match the fields produced in the secondary antenna due to a specific illumination; for example, plane-wave illumination is used for a directive beam. In most common situations the two approaches are equivalent (due to the principle of reciprocity [5]) and are often used interchangeably. If the fields are matched in the focal region of a reflector or lens, this is called focal plane matching. Optimum antenna gain and minimum cross-polarization are achieved simultaneously if the feed aperture field (represented by the complex vector \mathbf{E}_a) is conjugate matched to the focal field of the reflector or lens (\mathbf{E}_f). This is expressed approximately by

$$\mathbf{E}_{\text{acp}} \approx \mathbf{E}_{\text{fcp}}^*, \quad \mathbf{E}_{\text{axp}} \approx -\mathbf{E}_{\text{fxp}}^* \quad (1)$$

where the subscripts cp and xp denote the copolar and cross-polar components of the fields and the asterisk indicates the complex conjugate. This approach is applicable to single feeds or arrays in the focal region.

The design of the feed antenna's primary or aperture field depends on the geometry of the secondary antenna. For example, the geometry of a symmetric parabolic reflector is defined simply by its diameter D and its focal length F (see Fig. 2a). However, in the symmetric case there is usually some blockage by the feed and the supporting struts close to where the energy is strongest. The offset parabolic reflector geometry is slightly more complex, but the advantage is the ability to design the antenna to avoid blockage by the feed or to move this blockage toward a region on the aperture where the field is weak. For a given F/D ratio, the half-subtended angle at the feed is given by

$$\theta_c = \arctan\left(\frac{8F/D}{16(F/D)^2 - 1}\right) \quad (2)$$

In typical reflectors, F/D has a value from 0.6 to 0.3, which corresponds to half-subtended angles from $\sim 45^\circ$ to 80° . Particular applications require specific feed illuminations and the choice of illumination for the secondary antenna is a compromise between gain, sidelobes, beamwidth, and spillover, which are determined by the characteristics of the primary feed antenna. We return to this compromise at the end of the next section.

1.4. Characteristics of Primary Feed Antennas

It is usual to describe the performance of an antenna in terms of its far-field radiation characteristics and its terminal impedance or reflection coefficient into a specified transmission line. Some important terms used to describe feed antennas are

1. Radiation pattern
2. Gain
3. Phase center

Figure 3. Geometry for radiated fields from feeds.

4. Polarization
5. Input match
6. Bandwidth
7. Spillover
8. Edge illumination and edge taper

These terms are defined below.

1.4.1. Radiation pattern. In the far field of an antenna, the amplitude of the electromagnetic fields radiated is proportional to $1/r$, where r is the distance from the antenna (see Fig. 3). Plots of the magnitude of the radiated power at a constant distance r are called *radiation power patterns*. The power pattern P in a given direction (θ, ϕ) is

$$P(\theta, \phi) = 4\pi r^2 P_r(r, \theta, \phi) \quad (3)$$

where P is the power density per unit solid angle, P_r is the power density (in W/m^2), and r, θ, ϕ are the spherical polar coordinates (see Fig. 3). The power density is the radial component of the Poynting vector given by

$$P_r(r, \theta, \phi) = \frac{1}{2\eta} |\mathbf{E}|^2 \quad (4)$$

where \mathbf{E} is the electric field intensity (V/m) transverse to the direction of wave propagation. The quantity $\eta = \sqrt{\mu_0/\epsilon_0}$ is the wave impedance in free space (μ_0 and ϵ_0 are the permeability and permittivity of free space) and is approximately $120\pi\Omega$.

The power pattern of a feed usually consists of a maximum beam in the main direction and a series of subsidiary maxima called *sidelobes*. These are numbered consecutively from the mainbeam. Usually, the power pattern (3) is normalized to the maximum value and graphs are constructed of this function as contours or intensity plots in two dimensions, or in one-dimensional pattern cuts. The magnitude of the pattern is usually expressed in decibels (dB). The most common type of pattern cut for feeds is a plot of P at a constant angle ϕ , the so-called azimuth cut.

The half-power beamwidth (HPBW) is the angle subtended at the half-power or -3 dB points of the

normalized power pattern. The beamwidth between first nulls (BWFN) and the -12 dB power beamwidth are also used.

1.4.2. Gain. The power gain of an antenna in a given direction (θ, ϕ) is defined as the ratio of the power intercepted by a large sphere enclosing the antenna when that same power density at (θ, ϕ) is radiated in all directions (i.e., isotropically) and the total power input to the antenna.² The power density at (θ, ϕ) is given by (4). If this power were radiated isotropically, the power that would be radiated on a large sphere of radius r would be given by (3). Therefore, if P_{in} is the power incident on the antenna, the power gain function G is

$$G(\theta, \phi) = \frac{P(\theta, \phi)}{P_{\text{in}}} \quad (5)$$

The maximum value of (5) is the maximum power gain and is often used to describe the performance of an antenna. Usually when the term *gain* is used, maximum power gain is being referred to.

Directivity is similar to gain except that the reference power is in the radiated field. Thus the directivity function D is defined as

$$D(\theta, \phi) = \frac{P(\theta, \phi)}{P_{\text{T}}} \quad (6)$$

where P_{T} is the total radiated power and is obtained by integrating the power density P_{r} over a surface enclosing the antenna. For aperture antennas, it is common to integrate the power density over the aperture, rather than the far-field sphere, as this is easier to do. A special case of (6) is where the antenna is excited by sources with uniform amplitude and phase distribution (or illumination) over its aperture area A . The maximum directivity in this case is $D_0 = 4\pi A/\lambda^2$.

The aperture efficiency η_{a} is the ratio of the maximum directivity D_{max} given by (6), and the directivity of a uniformly illuminated aperture

$$\eta_{\text{a}} = \frac{D_{\text{max}}}{D_0} \quad (7)$$

Most practical feeds have aperture efficiencies in excess of 60%, and in excess of 90% can be achieved over limited bandwidths.

Gain and directivity are related through the antenna efficiency, which is the ratio of gain and directivity or equivalently the ratio of total radiated power and the power incident at the antenna input. Antenna efficiency (η_{ae}) is equal to the product of the mismatch efficiency (η_{m}), conversion efficiency (η_{c}), and the aperture efficiency η_{a} . In a lossless, matched feed, the antenna efficiency equals the aperture efficiency.

²This compares with the IEEE definition (Std. 145–1993 §2.165) for gain, which uses the power *accepted* by the antenna. The present definition is more convenient for feeds and differs from the IEEE definition by the factor $1/(1 - |\Gamma_{\text{in}}|^2)$ for single mode excitation where Γ_{in} is the input reflection coefficient.

1.4.3. Phase Center. The phase center is the apparent origin of the spherical wave radiating from an antenna. Because phase varies significantly over the full sphere, this center is not unique for all applications because it depends on the solid angle over which the radiated field is incident on the secondary antenna. The phase center is obtained experimentally by rotating the antenna about its axis and determining the position on the axis where the measured phase function variation is minimized over the desired angle for illuminating the secondary antenna. This can be time-consuming as the phase center is usually different for each pattern cut. An alternative approach is to calculate the phase center from measured or numerically obtained data. One approach is to average the phase center from locations d_n of N pattern cuts. Thus, the phase center d_{pc} is given by

$$d_{\text{pc}} = \frac{1}{N} \sum_{n=1}^N d_n \quad (8)$$

The phase center in the n th azimuth plane is given by [12]

$$kd_n = \frac{(A_0 B_1 - A_1 B_0)}{(A_0 A_2 - A_1^2)} \quad (9)$$

where $k = 2\pi/\lambda$, $A_0 = \sum_{i=1}^M \theta_i$, where M is the number of data points of the phase function $\Phi(\theta_i, \phi_n)$, θ_i is the i th angle of the n th pattern cut ϕ_n , $A_1 = \sum_{i=1}^M \cos \theta_i$, $A_2 = \sum_{i=1}^M \cos^2 \theta_i$, $B_0 = \sum_{i=1}^M \Phi(\theta_i, \phi_n)$, and $B_1 = \sum_{i=1}^M \Phi(\theta_i, \phi_n) \cos \theta_i$. The simplest case of (8) corresponds to a single cut ($N=1$). A better estimate is to average the phase centers of the two principal plane patterns ($N=2$). With circularly symmetric feeds, an average of the two principal planes plus the intercardinal plane (45° and 135°) phase centers ($N=4$) is usually sufficiently accurate for most purposes.

1.4.4. Polarization. Although the fields radiated by feed antennas are usually complicated, they can be resolved into two components on any chosen surface, such as the far-field sphere (see Fig. 3) or on the secondary antenna. Without loss of generality, we will consider here only the former. The two components are the desired polarization or the copolarized component (denoted by the vector $\hat{\mathbf{p}}$) and the usually undesired cross-polarized component (given by $\hat{\mathbf{q}}$). Further, there are two main types of polarization, linear and circular. There is no unique way of defining the components of these polarizations. For feeds, the common method is to define co- and cross-polarization in the manner in which they are measured in practice. In the case of predominantly linearly polarized feeds, the copolar component is obtained as for conventional far-field measurement, by aligning the test antenna on boresight with the polarization of the distant source antenna. Maintaining this alignment, the test antenna is then rotated about the phase center. The signal received at the test antenna is the copolar pattern. If the polarization of the distant antenna is now rotated through $\pm 90^\circ$ and the radiation pattern remeasured, the received signal is the cross-polar pattern of the test antenna. If the test antenna is rotated in the plane of the principal electric field com-

ponent, the pattern cut is called the *E-plane* (see Fig. 3). The orthogonal plane is called the *H-plane cut*. For feed antennas it is common also to measure the pattern in the 45° and 135° planes. The co- and cross-polarized field components are obtained from the spherical field components by means of

$$\begin{bmatrix} E_p \\ E_q \end{bmatrix} = \begin{bmatrix} \cos(\phi - \alpha) & -\sin(\phi - \alpha) \\ -\sin(\phi - \alpha) & -\cos(\phi - \alpha) \end{bmatrix} \cdot \begin{bmatrix} E_\theta \\ E_\phi \end{bmatrix} \quad (10)$$

where E_θ and E_ϕ are the spherical components in the θ and ϕ directions, ϕ is the azimuth angle, and α is the polarization angle referenced to the x axis of the coordinate system (Fig. 3).

Cross-polarization becomes important in antenna design when two orthogonal polarizations are used to transmit two separate channels. Frequency reuse by dual polarization effectively doubles the available system bandwidth. The antenna, and the feed in particular, is the means by which isolation is maintained between the channels. Signals may be sent or received in either linearly polarized vertical and horizontal components or circularly polarized where the signals rotate in space and time in a right- or left-hand sense.

1.4.5. Input Match. This is the input reflection coefficient of the feed antenna when it is excited at its input. Usually this is measured with the feed alone; however, care must be taken to ensure that reflection from the secondary antenna does not significantly affect the match. If this occurs, a matching vertex plate can be added to the reflector or lens to reduce the reflection.

1.4.6. Bandwidth. The bandwidth of the feed antenna is the continuous frequency range over which the feed performance is acceptable. The parameter measured is often the input reflection coefficient, and the acceptable level depends on the application. In satellite ground stations and radio astronomy, a commonly used maximum level is -17.7 dB (VSWR = 1.3). The percentage bandwidth is used to compare the performance of different feeds. This is calculated from the minimum and maximum frequencies, f_{\min} and f_{\max} over which the parameter meets the criterion, thus

$$\% \text{ bandwidth} = 200 \frac{(f_{\max} - f_{\min})}{(f_{\max} + f_{\min})}$$

1.4.7. Spillover. In transmit mode, the energy from a feed antenna that is not incident on the secondary antenna is called *spillover*. In receive mode, received spillover is an important contributor to the overall antenna noise temperature. Considerable effort goes into minimizing the amount of spillover in systems requiring low antenna noise temperatures such as radio astronomy and deep-space probes. Spillover efficiency η_{spill} is the ratio of the power intercepted by the secondary antenna to the total power radiated by the feed.

1.4.8. Edge Illumination and Edge Taper. *Edge illumination* is the ratio of the field strength radiated by the feed in

the direction of the edge of the secondary antenna and its level at the center of the secondary antenna, where field strength is measured on a sphere of radius equal to the distance to the center of the secondary antenna. *Edge taper* is a related quantity, and gives the ratio of the feed field strength at the center of the secondary antenna relative to the level at the edge. The difference between edge illumination and edge taper (apart from the sign) is the free-space loss between the sphere and the edge. In a symmetric reflector antenna, the edge is the reflector rim and the intersection point is the vertex. For a paraboloid with focal length F and diameter D

$$\begin{aligned} \text{Edge taper (dB)} &= 20 \log_{10} \left(1 + \frac{1}{4(F/D)^2} \right) \\ &- \text{edge illumination (dB)} \end{aligned} \quad (11)$$

The choice of primary feed illumination for a secondary antenna (e.g., reflector F/D) is often a compromise between spillover efficiency (η_{spill}) and the secondary antenna aperture efficiency (η_{sae}). As the feed beamwidth is increased, the edge taper decreases and η_{sae} increases. At the same time, the spillover loss increases (η_{spill} decreases), causing the overall antenna efficiency to decrease. Consequently, there is an optimum edge taper that maximizes the overall antenna efficiency and, therefore, gain for a given secondary antenna. A -12 dB edge illumination is recommended for a paraboloid as a compromise between gain, sidelobes, and spillover (noise). With this edge illumination, a paraboloid with $F/D = 0.4$ has an edge taper of 14.9 dB. Further increase in edge taper results in lower sidelobes and wider beamwidth in the secondary pattern. A similar argument applies for a lens, except that a lower edge taper can be used in receive-only applications because the feed spillover radiation contributes to the sidelobes close to the mainbeam rather than the rear lobes of the antenna.

1.5. Types of Feed Antennas

Antenna feeds can be grouped into four basic categories as shown in Table 1. The class of aperture antennas is the most extensive and has the property that the area normal to the direction of propagation of the radiation from the antenna determines the gain and beamwidth. Linear antennas are distinguished by their physical appearance and how the dominant currents are supported on line elements. Traveling-wave antennas derive essentially from fields or currents that propagate along the antenna and radiate in the endfire direction with gain that is approximately proportional to the length of the antenna. Most

Table 1. Types of Antenna Feeds

Aperture	Linear	Traveling-Wave	Compound
Waveguides	Dipole	Dielectric rod	Arrays
Horns	Yagi-Uda	Profiled slot	Beam waveguide
Microstrip patch	Logperiodic	Vivaldi	Splash plate
Slots	Zigzag	Linefeeds	Dichroic reflector
Rear-radiating			
Short backfire			

linear arrays belong to this category also. Compound feeds are made up of several antenna types including aperture or traveling antennas with reflectors, lenses, or grids. In the following sections, different feed types will be described according to this classification.

2. APERTURE FEED ANTENNAS

Aperture antennas radiate from a surface that serves as the interface between the circuit attached to the transmitter or receiver and the radiation field. Actual or equivalent electric and magnetic currents flow on this surface, and the radiated fields and impedance properties can be derived from these currents. The equivalence principle says there is no unique surface but, for horns,

the aperture is commonly taken as the opening and the external walls. For slot antennas, the aperture is usually the opening and the surrounding metallic surface, while for rectangular microstrip antennas the aperture is sometimes taken as a pair of rectangular “slots” formed between the edges of the patch and the ground plane. Examples of some aperture antennas are shown in Fig. 4.

Some of the simplest and most commonly used aperture feeds are based on smooth metallic waveguides and their extension by flaring into horns. The main types of waveguide and horn feed have rectangular or circular cross sections. In feed applications, the radiation in the forward direction is the fundamental concern and, to a reasonable approximation, these functions are given by the radiation of the first waveguide mode.

(a)

(b)

(c)

(d)

(e)

(f)

Figure 4. Examples of aperture antennas: (a) waveguide feeds—left to right, rectangular, circular, and coaxial; (b) pyramidal horn; (c) circular waveguide with choke ring; (d) corrugated horn; (e) cup feed; (f) profiled superelliptical corrugated horn.

A commonly used model for radiation from aperture feeds is the E -field model. It is so called because the field is derived from the electric fields in the aperture and corresponds physically to an aperture opening out into an infinite ground plane. The model is useful for predicting the field in the forward direction and, of course, it predicts zero fields behind the conductor. The fields radiated by simple waveguide and horn feeds are a spherical wave of the form

$$\mathbf{E} = jk \frac{\exp(-jkr)}{2\pi r} (\hat{\theta} F(\theta, \phi) \cos \phi - \hat{\phi} \cos \theta G(\theta, \phi) \sin \phi); \quad |\theta| \leq 90^\circ \quad (12a)$$

$$\mathbf{H} = \frac{1}{\eta} \hat{\mathbf{r}} \times \mathbf{E} \quad (12b)$$

where $k = 2\pi/\lambda$, λ is the free-space wavelength, and the functions $F(\theta, \phi)$ and $G(\theta, \phi)$ depend on the aperture geometry. The radial field components are small in the far field and are neglected in (12), although they are important when the secondary antenna is in the near field of the feed. Assuming that the waveguide aperture is in a ground plane or the waveguide wall is thick, F and G are approximately given by the E -field model and are listed in Table 2 for rectangular, circular, coaxial, and corrugated waveguides. Other waveguide cross sections, such as the elliptic and polygonal shapes, have the same form as (12), although the functions are not expressible in terms of simple functions and must be computed by other methods. The effect of a finite-size ground plane or flange can be included in the E -field model simply by the method of geometrical or physical theory of diffraction

[5,13]. The main effect on the mainbeam of the finite ground plane is to change the multipliers (known as *Huygens factors*) in (12), respectively 1 and $\cos \theta$ of the $\hat{\theta}$ and $\hat{\phi}$ vector components.

When $F(\theta, \phi)$ and $H(\theta, \phi) = \cos \theta G(\theta, \phi)$ are independent of ϕ , the radiation pattern is axisymmetric; furthermore, if F and H are identical, the cross-polarized field is zero. Ideal corrugated horns have these properties if the “balanced hybrid condition” is satisfied. For smooth-wall circular horns, F and H are generally different, although the phase of these functions may be almost the same. Equation (12) shows that, for feeds with axisymmetric patterns, the peak cross-polarization is in the intercardinal planes and equals $|F(\theta) - H(\theta)|/2$; thus the cross-polarization depends on the difference between the E - and H -plane pattern functions. The copolar pattern in the intercardinal planes is $|F(\theta) + H(\theta)|/2$, that is, the average of the E - and H -plane pattern functions.

2.1. Feeds with Circular and Related Cross Section

Circular aperture antennas find wide application as feeds because of their geometric symmetry, low cross-polarization, and ease of manufacture. Examples of this type of feed are illustrated in Fig. 5.

A circular waveguide (Fig. 5a) is an efficient feed for moderately deep reflectors or lenses where the half-cone angle is around 60° . It has an almost equal E - and H -plane pattern (pattern symmetry) for pipe diameters in the range of 0.7–1.2 wavelengths depending on the size of the flange at the aperture. Higher efficiencies may be obtained by the addition of parasitic rings as shown in Fig. 5b. A coaxial waveguide (Fig. 5c) operating in

Table 2. Simple Waveguide Feeds

Type of Feed	$F(\theta, \phi)$	$G(\theta, \phi)$	Notes
Aperture			
TE ₀₁ -mode rectangular waveguide	$\frac{2ab}{\pi} S\left(U \frac{b}{2}\right) C\left(V \frac{a}{2}\right)$	$F(\theta, \phi)$	a and b are the width and height of the waveguide
TE ₁₁ -mode circular waveguide	$2\pi a J_1(k_c a) \frac{J_1(wa)}{k_c wa}$	$2\pi a J_1(k_c a) \frac{k_c J_1'(wa)}{k_c^2 - w^2}$	a is the waveguide radius; $k_c a = 1.8412$
TE ₁₁ -mode coaxial waveguide	$\frac{2\pi a [Z_1(k_c a, k_c b) J_1(wa) - Z_1(k_c b, k_c b) J_1(wb)]}{k_c wa}$	$\frac{2\pi a k_c [Z_1(k_c a, k_c b) J_1'(wa) - \frac{b}{a} Z_1(k_c b, k_c b) J_1'(wb)]}{k_c^2 - w^2}$	a and b are outer and inner conductor radii; $k_c a \approx 2/(1 + (b/a))$ and is the first root of $J_1'(k_c a) Y_1'(k_c b) - J_1'(k_c b) Y_1'(k_c a) = 0$

Key: $U = w \cos \phi$, $V = w \sin \phi$, $w = k \sin \theta$, J_p is a Bessel function of order p , and J_p' is its first derivative; Y_1 is a Bessel function of second kind and Y_1' is its first derivative:

$$S(x) = \frac{\sin x}{x}, \quad C(x) = \frac{\cos x}{1 - \left(\frac{2x}{\pi}\right)^2}, \quad Z_1(x, y) = J_1(x) - \frac{J_1'(y)}{Y_1'(y)} Y_1(x)$$

Figure 5. Circular waveguides and horn antennas: (a) circular waveguide; (b) circular waveguide with parasitic rings; (c) coaxial waveguide; (d) rear-radiating coaxial waveguide; (e) conical horn; (f) corrugated horn. (Parts (b)–(d) from Bird [14], courtesy of IEEE.)

predominantly the TE_{11} mode has potentially greater flexibility of available radiation patterns because of the extra degree of freedom given by the internal conductor. Figure 5d shows a self-supporting radiating coaxial waveguide (sometimes called a “tomato can”) feed for a reflector. Here the inner conductor extends all the way to the vertex of the reflector, allowing the feed to be driven from a transmission line or waveguide inside this conductor.

Flaring the circular or coaxial waveguide produces a conical horn (Fig. 5e) that has a more directive radiation pattern. The quality of the pattern depends on many factors, including the size of the output aperture, the internal structure of the flare, and the means of exciting the flared section. As an example, a horn with transverse internal corrugations (Fig. 5f), the so-called corrugated horn, is very commonly used in satellite communications and radio astronomy because of its low cross-polarization. When the depth of the corrugations is about a quarter-

wavelength, almost pure polarized radiation patterns result. Several other types of feeds with circular or elliptical cross section are discussed in the following sections.

2.1.1. Circular and Coaxial Waveguide. Smooth-wall circular or coaxial waveguide and horns are most frequently excited in the first waveguide mode, the TE_{11} mode (see Fig. 6a). The transverse field components of this mode in circular waveguide are

$$\mathbf{E}_t = A_0 \left[\hat{\rho} \frac{J_1(k_c \rho)}{k_c \rho} \cos \phi - \hat{\phi} J_1(k_c \rho) \sin \phi \right] e^{-j\beta z} \quad (13a)$$

and

$$\mathbf{H}_t = Y_W \hat{z} \times \mathbf{E}_t, \quad (13b)$$

where $k_c = 1.8412/a$ is the cutoff wavenumber, a is the waveguide radius, $Y_W = \beta/k\eta$ and $\beta = \sqrt{k^2 - k_c^2}$, J_1 is the

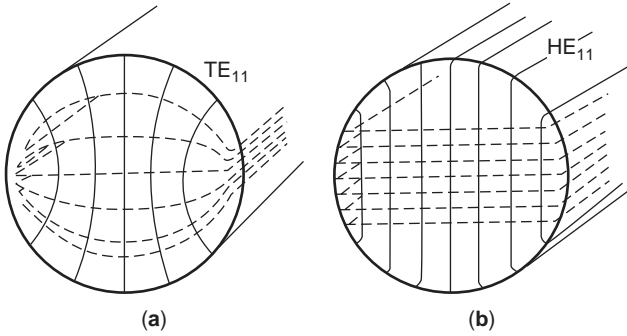

Figure 6. Electric and magnetic fields in (a) smooth-wall circular waveguide and (b) corrugated waveguide (— electric; - - - magnetic).

Bessel function of first order, A_0 is a constant, and (ρ, ϕ, z) are the cylindrical polar coordinates.

When the TE_{11} mode is incident on the open end as in Fig. 6a, an external field is produced and the TE_{1n} and TM_{1n} ($n = 1, 2, \dots$) modes are excited in order to satisfy the boundary conditions. These modes radiate and also propagate back into the waveguide; the dominant component is due to the reflected TE_{11} mode. This coupling to other modes is often ignored as a first approximation, but it should be included for accurate design. To first order, the aperture fields [$z = 0$ in (13)] expressed in terms of rectangular components are

$$\mathbf{E}_a = \hat{x} \frac{A_0}{2} [J_0(k_c \rho) + J_2(k_c \rho) \cos 2\phi] + \hat{y} \frac{A_0}{2} J_2(k_c \rho) \sin 2\phi \tag{14a}$$

$$\mathbf{H}_a = Y_w \hat{z} \times \mathbf{E}_a \tag{14b}$$

These equations show that the TE_{11} mode has both x - and y -field components and, therefore, so does the radiated fields. The principal aperture field polarization is maximum on axis and the cross-polarized component is maximum in the intercardinal (45° and 135°) planes. When a center conductor of radius b is introduced into circular waveguide, as in Fig. 5c, the basic properties of a TE_{11} -mode excited coaxial waveguide are similar, but there are significant differences as shown in Figs. 7–9. The fields radiated by circular and coaxial waveguide are given in Table 2. The -12 dB semiangle of the principal radiation patterns for circular ($b = 0$) and coaxial waveguides ($b > 0$) is shown in Fig. 7, and the maximum cross-polar level is given in Fig. 8. The E - and H -plane patterns of circular waveguide are approximately the same when $ka \sim 3.4$ ($a \sim 0.55\lambda$), and this results in a cross-polar minimum for the same ka value (Fig. 8). Coaxial waveguide also has a cross-polar minimum, (as shown in Fig. 8), which depends on the inner–outer conductor ratio (b/a).

The reflection coefficient S_{11} of the TE_{11} mode in circular waveguide due to the aperture mismatch is

Figure 7. The 12 dB semiangle of far-field radiation pattern of a coaxial waveguide, (— E plane; - - - H plane; parameter is b/a). (From Bird [14], courtesy of IEEE.)

approximately

$$S_{11} = \left(\frac{1 - y_{11}}{1 + y_{11}} \right) \tag{15}$$

where the admittance of the TE_{11} mode in circular waveguide is given by

$$y_{11} = 9.617 \frac{k}{\beta} \int_0^\infty \left(\frac{w\sqrt{1-w^2}}{(ka)^2} \frac{J_1^2(kaw)}{(w^2 - (1.84118/ka)^2)^2} + 0.087 \frac{J_1^2(kaw)}{w\sqrt{1-w^2}} \right) dw \tag{16}$$

As shown in Fig. 9, Eq. (15) has a minimum when $ka \sim 3.4$ ($a \sim 0.55\lambda$), which is coincident with the condition for minimum cross-polarization. Providing $a > \lambda$, the TE_{11} mode reflection coefficient is < -30 dB. Coaxial waveguide has a large mismatch, as Fig. 9 shows, when the inner–outer conductor diameter ratio exceeds ~ 0.3 . By means of a pair of capacitive and inductive coaxial irises, it

Figure 8. Maximum cross-polar level relative to peak copolar level within a 75° semiangle versus normalized frequency ka (parameter is b/a). (From Bird [14], courtesy of IEEE.)

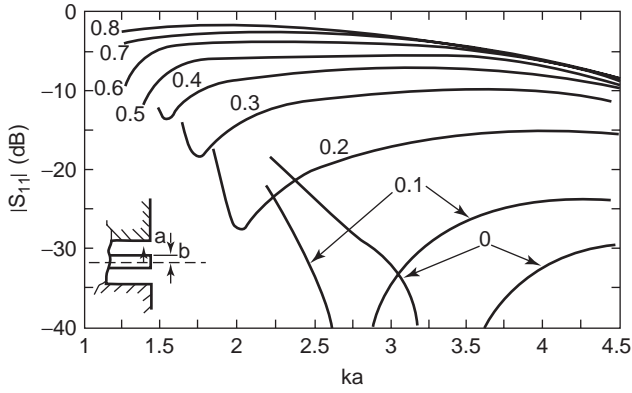

Figure 9. Reflection coefficient at the aperture of coaxial waveguide (parameter is b/a). (From Bird et al. [15], courtesy of IEEE.)

is possible to match coaxial feeds with inner-outer conductor ratios of ≤ 0.6 over $>17\%$ bandwidth. This is achieved by stepping down to an inner-to-outer conductor diameter of 0.3 and matching into this guide using the technique described by Bird et al. [15].

The maximum gain predicted by the E -field model for circular waveguide is

$$G_{\max} = 0.209(ka)^2 \frac{k}{\beta} \left(1 + \frac{\beta}{k}\right)^2 \left(\frac{|1 + S_{11}|^2}{1 - |S_{11}|^2}\right) \quad (17)$$

where the mode is above cutoff. For frequencies well above cutoff ($\beta \approx k$), $G_{\max} \approx 0.837 (ka)^2$ and the maximum aperture efficiency is 83.7%.

Circular horns are desirable for dual-polarized applications because of their geometric symmetry. However, this does not ensure low cross-polarization and thereby high polarization isolation. We have seen that the TE_{11} mode of circular waveguide has a radial directed electric field at the wall and, therefore, cross-polarized fields arise to satisfy the boundary conditions. Cross-polarization is transferred from the aperture to the radiation field, but this can be reduced in some situations by exciting other modes.

Cross-polar patterns of rationally symmetric feeds have a characteristic null on axis. If the symmetry is broken and other modes excited, it is possible to have cross-polarization on axis. Equality of the E - and H -plane patterns may be difficult or impossible to achieve in practice over any reasonable bandwidth. In feed applications, reasonably low cross-polarization can be achieved in the secondary pattern by selecting the geometry so that the E - and H -plane patterns cross over at around the -10 to -14 dB level. Choke rings either inside the horn or at the aperture (Fig. 5b) are useful for tailoring the radiation pattern of small horns to minimize cross-polarization over a moderate bandwidth [16]. Figure 7 shows that up to a certain ka value, the E -plane beamwidth is wider than the H -plane beamwidth. By placing a 0.2 – 0.26λ deep choke ring concentric with the aperture, the E -plane beamwidth can be reduced to almost the same as the H -plane beamwidth.

2.1.2. Conical Horn. If a circular aperture is flared into a conical horn as shown in Fig. 5e, the field at the aperture has a spherical wavefront. In simple terms, when the TE_{11} mode reaches the flare, it expands outward in order to satisfy the wall conditions and forms a spherical wave that propagates to the aperture. Therefore, the distance between a planar and a spherical wavefront is approximately given by [5]

$$\delta \approx \frac{1}{2} \frac{\rho'^2}{L} \quad (18)$$

where ρ' is the radial distance from the axis to the field point on the aperture and L is the distance from the horn apex to the aperture. The result is that (14) is modified by the application of the phase factor $\exp(-jk\delta)$ and the radiated fields are now given approximately by the functions

$$\begin{aligned} F(\theta, \phi) &= L_0(\theta) - L_2(\theta) \quad \text{and} \\ G(\theta, \phi) &= L_0(\theta) + L_2(\theta) \end{aligned} \quad (19)$$

where

$$\begin{aligned} L_m(\theta) &= 2\pi \int_0^a J_m(k_c \rho') J_m(k \sin \theta \rho') \\ &\quad \times \exp(-jk\rho'^2/2L) \rho' d\rho' \end{aligned} \quad (20)$$

Equation (19) gives reasonable results providing the semicone angle $\theta_0 = \arctan(a/L)$ is less than $\sim 30^\circ$.

The radiation pattern of the conical horn is strongly dependent on the flare angle. In Fig. 10 the E - and H -plane patterns are plotted as a function $\Delta = (a/\lambda)\tan(\theta_0/2)$, which is the distance in wavelengths between the spherical wavefront and the aperture (see Fig. 5e). As the angle is increased, the patterns broaden and lose distinctive sidelobes. The phase center in these two principal planes has been calculated from (8) over the angular range defined by the -12 dB semiangles. The results given in Fig. 11 show when Δ is small, the phase center is near the aperture. However, as Δ increases, the phase centers in the two planes move toward the apex at a different rate. When $\Delta > 0.8$, the phase center is almost at the apex.

The radiation performance of the conical horn can be improved by changing the surface of the horn, with corrugations, for example, or by introducing discontinuities to excite high-order modes, particularly the TM_{11} mode. The Potter horn discussed in Section 2.1.6 uses steps placed near the throat to produce such improvements.

2.1.3. Corrugated Horns. The corrugated horn is widely used as a feed antenna for reflector antennas and lenses because it can radiate fields with a high degree of axial symmetry. Smooth-wall circular waveguides and horns have, in general, different E - and H -plane patterns because the electric and magnetic field components in the pipe satisfy different types of boundary conditions on the walls (see Fig. 6). In simple terms, the tangential electric field of the TE_{11} mode experiences a short circuit at the wall while the tangential magnetic field experiences an open circuit.

Figure 10. Normalized radiation patterns of conical horn where $\Delta = (a/\lambda) \tan(\theta_0/2)$ is the parameter: (a) *E* plane; (b) *H* plane.

The end result is that the field lines in the waveguide are curved. By modifying the wall surface conditions, such as corrugating the surface, covering it with dielectric or inserting strips, the wall impedance experienced by the mode can be altered and the field lines made almost unidirectional, which results in low cross-polarization.

The corrugated surface was one of the first used to create alternative wall impedances and has proved most successful in circular waveguide and horns. When there are many corrugations per waveguide (typically greater than about five per wavelength) and the corrugation depth is approximately $\lambda/4$ (where λ is the free-space wavelength), the radial transmission line formed by the

Figure 11. Phase center location for the principal planes of conical, corrugated, and rectangular horns.

slots transforms the short circuit for the electric field into an open circuit while having only a second-order effect on the transverse magnetic field. This creates a nonzero axial electric field at the corrugated surface, allowing a zero circumferential component. Consequently, the modes in the corrugated waveguide or horn are no longer TE or TM to the longitudinal (propagation) direction and, because both axial field components are generally nonzero, they are called “hybrid modes.” The principal mode used for feed horns is the HE_{11} mode, shown in Fig. 6b. An axisymmetric radiation pattern is produced if the HE_{11} mode operates at the “balanced hybrid condition,” which is achieved when the corrugations are approximately $\lambda/4$ deep. Under this condition, the horn has low cross-polarization, pattern symmetry, and low sidelobes, which are almost ideal for many applications and gives rise to the popularity of these hybrid-mode feed horns [17,18].

At the balanced hybrid condition, the aperture electric field of the HE_{11} mode is approximately

$$\mathbf{E}_a = \hat{x}A_0J_0(k_\rho\rho) \tag{21}$$

and the magnetic field is as given by (14b); J_0 is the zero-order Bessel function, A_0 is a constant, and $k_\rho a = 2.4048$. The far zone field radiated by the HE_{11} mode is provided in Table 2. The maximum gain of the corrugated waveguide under these conditions is $G_{\max} \approx 0.692(ka)^2$ and the maximum aperture efficiency of 69.2%.

The conical corrugated horn may be modeled by the same method described above for smooth-wall conical horn. The radiated fields are given approximately by (12), where

$$F(\theta, \phi) = L_0(\theta) = G(\theta, \phi) \tag{22}$$

where $L_0(\theta)$ is as given by (20), wherein $m = 0$ and k_c is replaced by k_ρ .

The radiation pattern of a corrugated horn operating in the balanced HE_{11} mode is given by the set of universal

Figure 12. Normalized radiation pattern of corrugated horn with balanced hybrid mode, where Δ is the parameter.

curves shown in Fig. 12 plotted as a function of $\Delta = (a/\lambda) \tan(\theta_0/2)$. When $\Delta > 0.4$, the shape of the horn's pattern changes very little with Δ , indicating that the pattern and gain become virtually independent of aperture size. This is called “gain-saturated” and means that the horn is suitable for wideband operation. For $\Delta < 0.4$, the horn is said to be narrowband.

By virtue of the high pattern symmetry, the phase center for the corrugated conical horn is the same in all planes. Figure 11 gives the phase center location as a function of Δ based on the pattern over the -12 dB beamwidth.

The reflection coefficient of the HE_{11} balanced hybrid mode at the aperture is relatively low in most practical cases. If required, it can be calculated from (14) and the self-admittance

$$y_{11} = \frac{5.783k}{(ka)^2 \beta} \int_0^\infty \frac{w(2-w^2)}{\sqrt{1-w^2}} \frac{J_0^2(kaw)}{(w^2 - (2.4048/ka)^2)^2} dw \quad (23)$$

This equation predicts that when $a > 1.1\lambda$, the HE_{11} -mode reflection from the aperture is < -30 dB.

The corrugated horn equations given in Table 2 and Eq. (22) are useful only for narrowband feed design near the balanced hybrid condition. In a typical conical corrugated horn, there are 5–10 slots per wavelength, the slot width-to-pitch ratio (w/p) is > 0.75 , and the slot depth is approximately [19]

$$d_n \approx \frac{\lambda}{4} \exp\left(\frac{2}{5ka_n}\right) \quad (24)$$

where a_n is the radius of the corrugated surface at the n th slot (see Fig. 5f). Wideband feed design requires more accurate design methods and to achieve optimal performance, the input throat region, the flare from the input, and the profile to the aperture must be considered. The corrugated horn is limited to a continuous bandwidth performance of about 2:1. Thomas et al. [20] discuss

matching of corrugated horns and wideband design in detail.

The standard design of a corrugated horn starts from the smooth-wall input circular waveguide with a section of about a wavelength long where the depth of the corrugations are gradually decreased from a half-wavelength to a quarter-wavelength deep as the horn is widened. Following this input transition, a linear taper can be used for the horn profile, although some other profiles, such as “hour-glass” (sine-squared), have been found more effective. To achieve the widest bandwidth operation, the first four or five slots of the input section may need to terminate in a short-circuited coaxial waveguide—known as “ring-loaded slots.” These slots present a capacitive reactance over a bandwidth considerably wider than that of the conventional constant-width slot. The design of ring-loaded slots is described by James and Thomas [19]. The final part of the design is tapering the profile from the initial transition to the final output diameter. Corrugated horns with a profiled corrugated internal surface [21] produce a more compact design while maintaining high performance. A number of different profiles have been attempted in order to achieve low sidelobes and cross-polarization. The hyperbolic [10], or the identical Gaussian [22], profile has been found very effective overall for designing compact horns. Thus, if a_i is the radius of the input section, a_o is the output or aperture radius, and L is the length of the profile section, the horn profile as a function of axial distance (z) is given by

$$a(z) = a_i \sqrt{1 + \left(\frac{z}{L}\right)^2 \left(\left(\frac{a_o}{a_i}\right)^2 - 1\right)} \quad (25)$$

2.1.4. Horns with Axial Corrugations. Horns with internal axial corrugations (or internal short-circuited ring slots) are widely used as feeds for direct broadcast by satellite applications. As well as having good performance, they are relatively inexpensive to manufacture, especially by die casting. There are several different types of axially corrugated horn. One particular configuration is the choked aperture feed shown in Fig. 13a. It has choke rings in the aperture plane and also internal ring slots [23]. Although a simple prime-focus feed, it has an excellent performance over nearly an octave bandwidth.

Through the selection of a number of internal axial corrugations, a combination of TE_{11} , TM_{11} , and TE_{12} modes are produced in the aperture. These modes are maintained by a compensating action of the TE_{11} mode in the coaxial corrugations, which vary in length from about 0.37λ at the throat to about 0.25λ at the aperture. At least two corrugations are needed to achieve reasonable performance, but little is gained from using more than four corrugations.

2.1.5. Scrimp Horn. Originally devised by Wolf [24], the scrimp horn (Fig. 13b) is a compact and lightweight feed element for satellite antenna feed arrays. The scrimp horn has high aperture efficiency (typically $> 80\%$), operating bandwidth of about 20%, low cross-polarization, and better sidelobes than do most similar sized horns. The scrimp horn has three main sections: a conical horn input section,

Figure 13. Circular horn feeds: (a) circular horn with axial corrugations; (b) scrimp horn; (c) Potter horn; (d) stepped horn.

a short-circuited coaxial waveguide section, and a cylindrical output waveguide section that terminates in the aperture. A TE_{11} mode in a circular waveguide of between 0.75λ and 0.95λ is input to the conical horn section, and this generates a standing wave in the coaxial waveguide section, which is dominated by a TE_{11} mode. The semian- gular of the flare (θ_0 in Fig. 13b) of the conical horn is typically $15\text{--}25^\circ$, and the length of the coaxial waveguide is about 0.25λ . This input TE_{11} mode in the conical horn oscillates in odd phase to the TE_{11} mode in the output section and to ensure continuity of the fields, additional higher-order modes, mainly TM_{11} and TE_{12} , are generated. These modes are superimposed with the fundamental TE_{11} mode to produce a field distribution in the aperture that is low in cross-polarized components. The aperture diameter can be from about $\sim 1.2\lambda$ to $\sim 1.8\lambda$ depending on the required edge taper.

2.1.6. Multimode and Stepped Circular Horns. The basic idea of multimode and stepped horns is to excite modes in addition to the fundamental mode in such a way as to improve the aperture efficiency, shape the radiation pattern or reduce cross-polarization. An early feed antenna that was designed for low cross-polarization characteristics is the dual-mode horn (Fig. 13c) described by Potter [6]. In this horn, a combination of TE_{11} and TM_{11} modes that are approximately in the ratio 1:0.3 in the aperture modes are excited in a smooth-wall horn. The modes are brought into the correct phase relationship over the length of the horn. This concept has been extended by several workers, including Takabayashi et al. [25], where a double-band dual-mode conical horn design is described. The band separation is not given and, as is typical with this type of design, the individual bandwidths are quite narrow ($\sim <5\%$).

Another approach [26] uses a thin dielectric ring in the flare of the horn, producing a rotationally symmetric beam and low sidelobe levels over a bandwidth greater than 25%.

Figure 14. The 13-element multibeam feed system for the Parkes (Australia) radio telescope.

Instead of inserting discontinuities inside the horn to generate higher-order modes, the horn profile can also be stepped. A horn of this type, which is useful for closely packed arrays, is the one-wavelength diameter dual-mode stepped horn in Fig. 13d [27]. This feed is excited by a traveling TE_{11} mode and an evanescent TM_{11} , which is produced at the step, is brought into phase over a $\sim 0.7\lambda$ uniform section to the aperture.

An example of multisteped circular horns are the elements of the multibeam array feed for the Parkes radio telescope [28], which has been in operation since early 1997 (the horns and receiver cryogenics are shown in Fig. 14). Bandwidths of about 20% can be achieved with these types of horns.

Aperture efficiencies in excess of 90% can be obtained with circular horns by exciting the right combination of modes using steps. For example, Bhattacharyya and Goyette [29] achieved both high aperture efficiency and low cross-polarization by exciting only TE-type modes in appropriate amplitudes and suppressing undesired TM modes.

Excitation of two or more hybrid modes in corrugated horns can also be used to improve aperture efficiency over a narrow band. For example, Thomas [30] showed that if the HE_{11} and HE_{12} hybrid modes were excited, the feed gave an increased efficiency of 12% over a single-mode design. Thomas and Bathkar [31] were able to achieve very low sidelobes with a multimode corrugated horn.

2.1.7. Profiled and Optimized Circular Horns. The profile of smooth-wall or corrugated horns can be optimized to achieve a desired performance. This is done either by using known information on the effect of conventional pro-

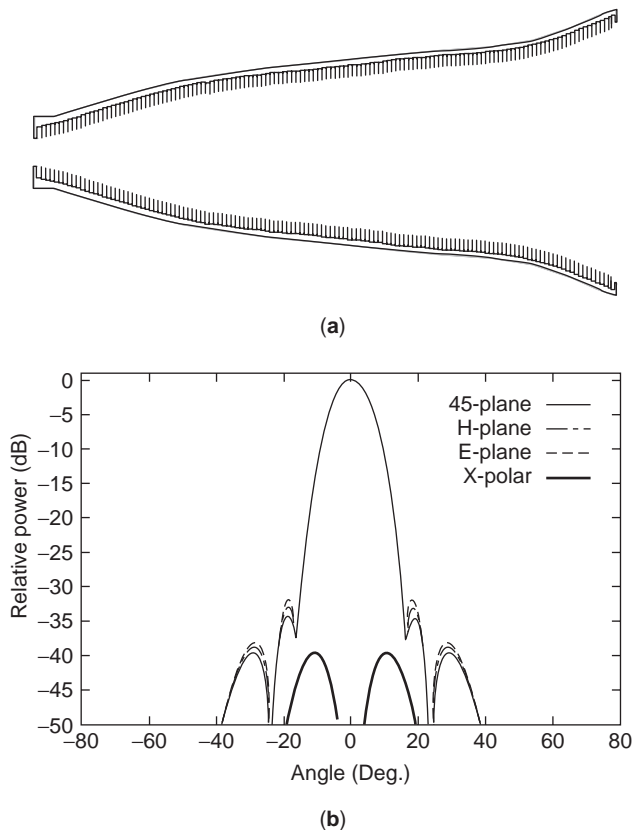

Figure 15. Profiled corrugated horn: (a) geometry; (b) radiation pattern at 11.7 GHz [33].

files, by combining some of these profiles [22,32], or through direct optimization [33]. The former approach is illustrated by the use of Gaussian/hyperbolic profiles (25), which produce a beam with low cross-polarization over very wide bandwidths. Direct optimization is achieved using the profile and/or slot depths of each corrugation as parameters. An alternative approach that is more efficient is to fix the slot width-to-pitch ratio and optimize the profile by defining splines. An example of a horn designed by this method for a Ku-band transmit/receive feed application is shown in Fig. 15 [33]. Through these means, excellent performance can be realized with very compact structures.

2.1.8. Dual- and Multiband Feeds. Some applications require feeds that operate in two or more frequency bands simultaneously. Two basic ways to achieve this are to multiband the feed or to use dichroic reflectors (see Section 5.4). A common dual-band feed is a coaxial horn structure where the high-frequency band is diverted into an inner (usually) circular horn and the low-frequency band is handled by an outer coaxial waveguide. The two bands often share a tapered section that leads to the aperture. The match of the outer coaxial horn is strongly affected by the diameter of the inner pipe, and, to keep this at an acceptable level, this waveguide is sometimes loaded with dielectric or has an aperture choke ring. To improve the match and the pattern, the dielectric loading some-

Figure 16. Dual-band coaxial horn for S- and X-band operation [34].

times protrudes into the common horn. The concentric coaxial feed concept can be extended to three or more bands with increasing difficulty for matching and inputting signals.

Multiple-step Potter-type horn designs can be used for coaxial structures, as demonstrated by James et al. [34] in providing a simultaneous dual-band/dual circularly polarized feed for a Cassegrain reflector antenna. Figure 16 shows a cross-sectional view of the complete feed design to provide S/X-band operation and satellite tracking. The inner section is a Potter horn for X-band (including provision of tracking) operation, and the outer S-band system has a coaxial waveguide geometry. In both horns, multiple steps are used in the throat region of the horn to provide a symmetrical low cross-polarization radiation pattern over the $\sim 5\%$ bandwidth of each band. The input to the dual-polarized coaxial horn is through four orthogonal probes (two excited in anti-phase to couple the TE_{11} -mode) and the X-band horn is input through a compound band-pass/band-stop filter in circular waveguide where both irises and ring-loaded slots were utilized in the design to achieve the required performance. Another example of a coaxial feed is the compact dual-band feed of Henderson and Richards [35] suitable for small front-fed parabolic reflectors. This feed is integrated with a diplexer and septum polarizer to provide dual-circular polarization in both bands.

An alternative approach to multiband horn design is shown in Fig. 17 [36]. This dual-depth corrugated horn (see inset to Fig. 17) operates in three relatively narrow frequency bands to provide transmit and receive in X-band and receive-only in Ka-band. The X-band receive signal is obtained from a junction of four waveguides that are arranged radially at 90° . A similar junction is used to inject the transmit signal at X-band. Ka-band is extracted from the rear of the corrugated horn. Another example is given by Green and Smith [37] for a dual-band corrugated horn design where operation is required in Ku/Ka-bands separated by a ratio of 1.5:1.

2.1.9. Elliptical Horns. Horns with elliptical cross section are used to feed reflectors or lenses that are noncircularly symmetric, particularly when low cross-polarization or circular polarization is required. The field in the aperture of an elliptical horn is tapered in the two

Figure 17. A triband X/X/Ka horn. (From Chen et al. [36], courtesy of IEEE.)

principal planes, resulting in lower sidelobes in the E plane than for a rectangular horn. The dominant modes of the air-filled horn are the TE_{c11} (even) and TE_{s11} (odd) modes, corresponding to the electric field maximum aligned with the minor and the major axes, respectively.

In an elliptical waveguide or horn (Fig. 18), the fields are expressed in terms of Mathieu functions, which are readily calculated via a computer but that, unlike circular geometries, preclude closed-form expressions for the F and G functions in (12). For an elliptical aperture radiating in the TE_{c11} mode, the fields are obtained from

$$F(\theta, \phi) = N_x + N_y \tan \phi \text{ and } G(\theta, \phi) = N_x - N_y \cot \phi \quad (26)$$

Figure 18. Geometry of elliptical horn.

where

$$N_x = \int_0^{\xi_0} \int_0^{2\pi} [Ce_1(\xi)ce'_1(\eta) \sinh \xi \cos \eta + Ce'_1(\xi)ce_1(\eta) \cosh \xi \sin \eta] \times \exp(jkae \sin \theta(\cosh \xi \cos \eta \cos \phi + \sinh \xi \sin \eta \sin \phi)) d\eta d\xi \quad (27a)$$

$$N_y = \int_0^{\xi_0} \int_0^{2\pi} [Ce_1(\xi)ce'_1(\eta) \cosh \xi \sin \eta - Ce'_1(\xi)ce_1(\eta) \sinh \xi \cos \eta] \times \exp(jkae \sin \theta(\cosh \xi \cos \eta \cos \phi + \sinh \xi \sin \eta \sin \phi)) d\eta d\xi \quad (27b)$$

where a is the length of the semi-major axis, $ce_1(\eta, q)$ and $Ce_1(\xi, q)$ are the ordinary and modified even Mathieu functions of order 1 respectively, a prime on the Mathieu functions denotes the first derivative, q is the first zero of $Ce'_1(\xi, q) = 0$ and is implied in (27), e is the eccentricity of the aperture, and $\cosh \xi_0 = 1/e$. The aperture mismatch for the TE_{c11} mode is < -30 dB for $a > \lambda$ providing $e < 0.9$.

The patterns in the two principal planes are generally different, although for some geometries it can be shown that the beam can be highly symmetric for some eccentricities. For example, a horn of length 5.09λ that is fed

Figure 19. Dielectric-lined horns: (a) cone-loaded; (b) profiled ultrawideband.

from an elliptical waveguide with semi-major axis 0.42λ and eccentricity 0.422, gives good beam symmetry for an aperture with semi-major axis 2.65λ when $e \approx 0.67$ [38].

Elliptical corrugated horns have been designed and used in some applications [39,40], although the bandwidth is somewhat limited ($\sim 10\%$), probably because of the excitation of high-order modes.

2.1.10. Dielectric-Loaded Horns. Horns that are partially loaded with a central dielectric cone or core are capable of very wideband operation (Fig. 19). Between the core of permittivity ϵ_{r2} and the metal wall is a material of thickness t with a permittivity ϵ_{r1} close to 1. An estimate of the optimum gap thickness for circular, dielectric-lined horns, which is valid for large apertures, is [41]

$$t \approx \frac{\lambda}{4\pi\sqrt{\epsilon_{r2} - \epsilon_{r1}}} \ln \left(\frac{\sqrt{\epsilon_{r2} + \epsilon_{r1}}}{\sqrt{\epsilon_{r2} - \epsilon_{r1}}} \right) \quad (28)$$

However, the horn performance is not sensitive to the gap thickness. Dielectric-lined horns support a hybrid mode similar to a corrugated horn [42], but which is not band-limited by the slot depth of the corrugations. The potential of the dielectric-loaded horn has been made possible by the advent of accurate design software and also high-quality low-loss dielectric materials. For example, Clark and James [43] showed that a partially filled circular dielectric-loaded horn (Fig. 19b) could have high performance with respect to return loss, cross-polarization, pattern symmetry, and phase center stability over a bandwidth ratio of $> 30:1$. However, as frequency increases, the main frequency dependency is in the general reduction in beamwidth.

Many different types of dielectric-loaded horns have been developed. Some use a solid dielectric with permittivity of ~ 2.5 , and others use foam materials with permittivity close to 1. The wider bandwidth horns use a dielectric permittivity of between 1.1 and 1.2 for the inner core and also a thin airgap.

Other types of dielectric-lined horns have been shown to give excellent performance [44]. An estimate for gap thickness is given by (28), but is often profiled to suit the horn profile. In a rectangular dielectric-lined horn, if the airgap is small, the field in the horn appears approximately uniform in the principal direction, compared with an air-filled guide that has a cosine dependence. The result is a radiation pattern in both principal planes with a sinc-function dependence. The elliptical dielectric-lined horn has lower sidelobes compared to the rectangular horn for the same beamwidth, indicating that the latter has a slightly lower efficiency when used as a feed.

A practical difficulty with the dielectric-loaded horn is obtaining suitable dielectric materials with a permittivity of ~ 1.2 with an acceptable low loss (loss tangent $< 5 \times 10^{-4}$). One approach is to simulate the required dielectric by forming alternate layers of low-loss materials such as PTFE and low-loss, low-density, expanded polystyrene foam in a sandwich construction. With several layers of foam and PTFE per wavelength, and adjusting the relative thickness of the two materials or cutting holes in the material, a simulated material of the required permittivity with low loss can be achieved [45].

2.2. Rectangular Feeds

Rectangular horns that operate predominantly in the fundamental TE_{10} mode³ radiate fields where the E - and H -plane patterns are significantly different. Equation (12) and Table 2 give the radiated field. The quantity a is the aperture width in the H plane, and b is the height in the E plane. The different patterns can be advantageous in some array feed applications or where the secondary structure is not axisymmetric, as in a pillbox reflector. The reason for this difference is seen through the TE_{10} -mode aperture fields. The E plane of this mode's field is almost uniform, while in the H plane the field is cosine-tapered. The radiation by single-mode rectangular and pyramidal horns is detailed in many texts on antennas and is not repeated here [5,10]. In addition, a design procedure for so-called standard-gain horns is provided in these references. We note, however, that although the standard-gain horn design maximizes gain for given aperture dimensions, this is usually not a good design strategy for feed antennas because the pattern shape is often unsuitable, and high sidelobes occur in the E plane, causing significant spillover loss.

The radiation pattern of a rectangular horn radiating in the TE_{10} mode is given by the set of universal curves shown in Fig. 20 as a function of $\Delta = (w/\lambda) \tan(\theta_0/2)$, where $w = b$ in the E plane and $w = a$ in the H plane. An open-ended rectangular waveguide or small flare-angle horn is an effective feed antenna if the aperture dimensions are suitably chosen. For a symmetric reflector or lens, the aperture dimensions are usually chosen to equalize the E - and H -plane patterns across the mainbeam, although the cross-polar level in the intercardinal planes remains high. The rectangular horn dimensions for maximum gain with a given reflector F/D has been determined by Truman and Balanis [46]. The dimensions are shown in Fig. 21 for various horn slant lengths (where infinity corresponds to uniform waveguide).

The phase center in the two principal planes of a flared rectangular horn is given in Fig. 11, which was obtained from the patterns over the angular range defined by the -12 dB semiangles in the E and H planes. In this figure, L is the distance from the apex to the aperture in each plane. Similar to the conical horn, the phase centers are significantly different in the two planes, except when the aperture size is large and they are close to the horn apex.

³The TE_{10} and TE_{01} modes are fundamental modes of rectangular waveguide with the electric field aligned in the y and x directions, respectively. The latter is obtained from the former by rotating the waveguide clockwise by 90° .

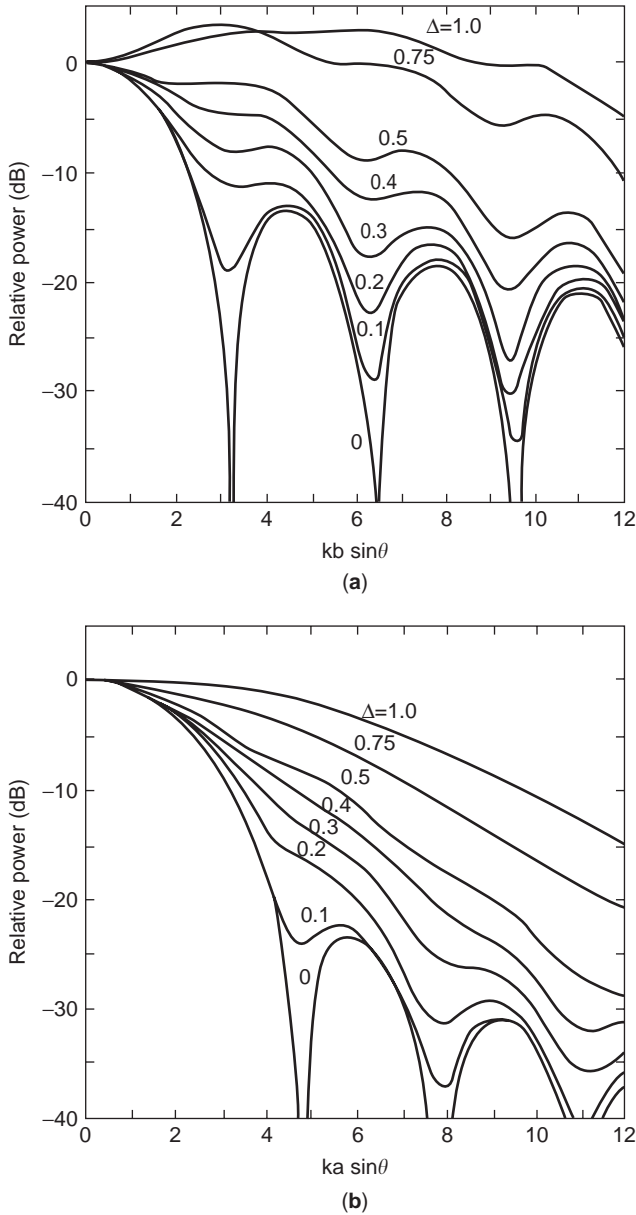

Figure 20. Normalized pattern of rectangular horn: (a) E plane; (b) H plane.

The reflection coefficient of the TE_{10} mode at the aperture is given by (15) and the mode self-admittance

$$\begin{aligned}
 y_{11} = & \frac{2jk^2}{\pi ab\beta} \left(\int_0^{z_0} d\alpha \int_0^{a \sec \alpha} dx + \int_{z_0}^{\pi/2} d\alpha \int_0^{b \csc \alpha} dx \right) \\
 & \times \exp(-jkx)(b - x \sin \alpha) \\
 & \times \left(\frac{1}{k_c} \left(1 + \left(\frac{k_c}{k} \right)^2 \right) \sin(k_c x \cos \alpha) \right. \\
 & \left. + \left(1 - \left(\frac{k_c}{k} \right)^2 \right) (a - x \cos \alpha) \cos(k_c x \cos \alpha) \right)
 \end{aligned} \quad (29)$$

Figure 21. Optimum horn dimensions versus reflector F/D ratio for various rectangular horn lengths. (From Truman and Balanis [46], courtesy of IEEE.)

where $k_c = \pi/a$ and $\alpha_0 = a \tan(b/a)$. The aperture mismatch is -30 dB for $a > 2\lambda$ and $a < b < 2a$. When the height (b) is small compared with the width (a), as with some sectoral horns, the aperture mismatch can be significant (~ -20 dB).

2.2.1. Multimode Feeds. A way to improve the pattern of rectangular horns is to excite one or more additional modes to the TE_{10} mode to make the patterns in the two planes more identical or to reduce sidelobes. Beamshaping in rectangular horns can be achieved in the same way as with circular horns. As described by Cohn [8], changes of flare angle introduced along the length of the horn can be used to excite the required mixture of high-order modes, which must be brought into correct phase at the aperture. In particular, flare-angle changes can generate the TE_{12}/TM_{12} mode pair, and relative to the TE_{10} mode, the amplitude of the TE_{12}/TM_{12} modes is

$$A_{TE_{12}-TM_{12}} \approx \frac{2}{3} j \frac{(\theta_1 - \theta_2)s}{\lambda} \quad (30)$$

provided the flare angle change $|\theta_1 - \theta_2|$ is small ($< 25^\circ$), where s is the width of waveguide at the transition. Since the mixture of the TE_{12}/TM_{12} modes leads the phase of the TE_{10} -mode by 90° , this phase must be removed with a length of waveguide that gives 270° phase shift. Despite this complication, especially in designing the several flares to avoid breaking the condition described above, good pattern symmetry can be achieved over moderate bandwidths ($\sim 30\%$).

Figure 22. Width a_2 in the H plane required to produce a TE_{30} mode with amplitude $\frac{1}{3}$ of the TE_{10} mode in the aperture of a dual-mode rectangular horn, which is excited from a square waveguide with side length a_1 .

Rectangular horns are often used as feed elements in arrays to produce shaped beams from secondary reflectors for satellite communications. In such cases, the efficient illumination of the reflector is crucial, and this can be achieved with multimode horns. Multimode rectangular horns employ TE_{m0} ($m = 1, 3, 5, \dots$) modes with approximate amplitude of $1/m$ to improve the aperture field uniformity. This results in higher aperture efficiencies than horns with the fundamental mode alone, typically $>90\%$. The aperture dimension in the H plane of these horns needs to be at least $m\lambda/2$ for efficient excitation and for these modes to propagate. However, significant improvement in performance is achieved by exciting the TE_{30} mode in addition to the fundamental TE_{10} mode [3]. The TE_{30} mode is produced with an H -plane step, and Fig. 22 shows the dimension of the step in a square waveguide needed to produce a TE_{30} mode with an amplitude one-third that of the TE_{10} mode in the output waveguide [47]. This step excites the TE_{30} mode approximately 180° out of phase with the transmitted TE_{10} mode, and a length of waveguide s is required to equalize the mode phases at the aperture.

2.2.2. Diagonal Horn. Another type of dual-mode horn is the diagonal horn due to Love [48, 49]. Two spatially orthogonal modes TE_{10} and TE_{01} are excited with equal amplitude and phase in a square waveguide. This waveguide is then flared into the required aperture dimensions. The principal electric field of the diagonal horn is along one of the diagonals. While principal plane patterns are the same, in the intercardinal plane the copolar pattern is different and the cross-polarization is unacceptably high for most dual-polarized applications. The horn has optimal performance when the aperture size is relatively large

Figure 23. Dielectric-lined rectangular horn.

and, therefore, is suitable mainly for long-focal-length or dual-reflector applications.

2.2.3. Dielectric-Loaded Rectangular Horns. Another form of dielectric-loaded rectangular horn has a dielectric lining the wall parallel to the E plane. Dielectric loading of feed arrays of rectangular waveguides and pyramidal horns provides an extra degree of freedom in the design of shaped beams for satellite antennas. It improves the illumination efficiency of the array and can be applied to both small- and large-aperture horns. Usually the dielectric is placed on the walls that are parallel to the principal electric field, as in Fig. 23. The aperture field is almost uniform in the H plane if the dielectric thickness t is chosen to be approximately [50]

$$t \approx \frac{\lambda}{4\sqrt{\epsilon_{r1} - \epsilon_{r2}}} \quad (31)$$

where λ is the free-space wavelength and ϵ_{r1} and ϵ_{r2} are the dielectric constants in regions shown in Fig. 23. At the center frequency when t is given by (31), the radiation pattern of the dielectric-loaded horn is obtained from (12), where $F = G$ and F is given by

$$F(\theta, \phi) = 2bdS \left(U \frac{b}{2} \right) \left[S(Vd) + \frac{2t \cos\left(\frac{V\alpha}{2}\right) + \frac{2t}{\pi} V \sin(Vd)}{1 - \left(\frac{2t}{\pi} V\right)^2} \right] \quad (32)$$

where S , U , and V are defined in Table 2 while a , b , and d are defined in Fig. 23. The factor in the square brackets determines the H -plane pattern and the first term predominates if t/d is small. Consequently, for thin dielectric layers, the E - and H -plane radiation patterns have almost the same shape.

Another property of dielectric-loaded horns is that their gain can be greater than the corresponding unloaded

horn. For a uniform waveguide satisfying (31), with $\epsilon_{r2} = 1$ the relative aperture efficiency is

$$\frac{\eta_{\text{load}}}{\eta_{\text{unload}}} = \frac{\pi^2 d^2}{2a(a-t)} \left(1 + \frac{2t}{\pi d}\right)^2 \sqrt{1 - \left(\frac{\lambda}{2a}\right)^2} \quad (33)$$

where the subscripts “load” and “unload” refer to loaded and unloaded waveguide cases. Equation (33) shows, that for most commonly available dielectrics, an increase occurs only if $a > \lambda$. With dielectric loading, the H -plane beamwidth is usually less than in the unloaded case. This is important in array feed applications for satellites because the reflector edge is often overilluminated and, therefore, dielectric loading should help improve antenna efficiency. However, ohmic loss in the dielectric decreases the gain, but the thinner the dielectric layer, the lower the loss.

2.3. Rear-Radiating Feeds

In prime-focus-fed symmetric reflectors, blockage by the feed and feed support struts causes reduced gain and increased sidelobe levels. The loss of performance due to strut blockage can be eliminated by employing a self-supporting or axial feed antenna. Mechanical support is provided in this case by the transmission line, which extends from the reflector vertex to the feed. Such feeds have a long history, and many different types have been reported. Some examples are shown in Fig. 24.

All rear-radiating feeds depend for their operation on the efficient transition from the feeder line in the axial conductor to the radiator. Usually, it is this feature that limits the usable bandwidth to only a few percent of the operating frequency. For example, the match from the resonant dipole disk feed [3] shown in Fig. 24a is narrowband, and this is even worse for the feed in Fig. 24b, which incorporates a resonant ring to improve the radiation pattern [51]. In the Cutler feed [4] (Fig. 24c), two radiating slots are excited by a cavity driven from the waveguide transmission line. A tuning screw in the cavity improves the match, although the design remains essentially narrowband. The cup feed (an example is shown in Fig. 24d [52]) is distinguished by its axial symmetry, and a number of designs have been tried in order to achieve an effective transition from the circular waveguide to the cup region. An example of a cup feed design is a circular waveguide version of the Cutler feed using an annular slot; another design [53] uses coaxial waveguide sections at the end of the cup to improve the match. Both of these designs are relatively narrowband (approximately 5%). However, Schwerdtfeger [54] was able to achieve up to 20% bandwidth by exciting dipoles within the cup with a thin TEM transmission line.

The cup feed developed by Poulton and Bird [52] shown in Fig 24d uses a simple transition from circular waveguide to excite the cup. This produces a bandwidth of about 20%, and its symmetry allows dual polarization to be used. The waveguide to cup transition is most effective when the inner–outer conductor radius ratio (b/a) is ~ 0.5 . Radiation from the cup is due predominantly to the TE_{11} coaxial waveguide mode in the cup. This radiates in the

Figure 24. Rear-radiating feed antennas: (a) dipole and disk fed by transmission line (after Silver [3]); (b) the same as (a) with ring; (c) rectangular waveguide with radiating slots (after Cutler [4]); (d) cup feed (Poulton and Bird [52], Bird [55], courtesy of IEEE); (e) hat feed (after Kildal and Yang [57]).

presence of the supporting central conductor, which has a significant effect when the central conductor diameter is even moderately large. To keep cross-polar levels below -20 dB, the central conductor radius should be kept relatively small, typically $b/a < 0.3$ and $ka > 2.5$. A cup feed excited with an air-filled circular waveguide has a relatively poor performance with poor pattern symmetry and, as a result, has high levels of cross-polarization. Significantly improved performance is obtained by dielectric-loading the central conductor and this also provides mechanical support for the cup. The main disadvantage

of dielectric loading is matching into the feeder waveguide. Further improvement in the pattern is possible by adjusting the size of the flange surrounding the aperture and by inclusion of a concentric ring slot. The ring slot flange considerably improves the radiation performance over a narrow band (typically 5–10%) [55].

The “hat” feed of Kildal [56] and Kildal and Yang [57] shown in Fig. 24e uses a circular waveguide transmission line, a circumferential slot, and a corrugated reflecting brim. An iris-matching network is used in the waveguide to give a good match over a $\sim 15\%$ bandwidth. The feed is excited by a propagating TE_{11} mode in the waveguide, and this excites radial waveguide modes in the dielectric aperture. The $\lambda/4$ -deep corrugations ensure that the radiation pattern is symmetric with little spillover radiation. The beamwidth is relatively broad for a flat brim, but this can be reduced by angling the brim as shown in Fig. 24e.

2.4. Microstrip Feeds

Microstrip patch antennas are a possible alternative to horns in feed applications or as a feeder for a horn. The advantages of microstrip as a feed are its ease of integration with the system electronics, compact size, reduced weight, and lower volume compared with a horn. Multi-layer patch antennas can provide a return loss of 10 dB or better over a $\geq 50\%$ bandwidth. Microstrip feed antennas are used singly or in arrays and can be incorporated in a cavity or a horn to improve the radiation performance for feed applications where low noise temperature is required [58,59].

Microstrip antennas are suitably shaped printed circuits that are designed to radiate at discontinuities [60,61]. The most common types are rectangular and circular patches. Two simple models are used to describe these antennas. These are the cavity and transmission-line models. In the cavity model, the antenna, which is excited by a probe or a slot in the ground plane, sets up resonances in the cavity formed between the patch and the ground plane. The antenna radiates through currents set up around the edge of the patch. To take a circular patch, for example, the radius of the patch a is determined by the desired mode and its resonance frequency. The TM_{11} mode has suitable characteristics for feed antennas, and its resonance occurs at the first root of $J_1(k\sqrt{\epsilon_r}a) = 0$, where J_1 is the first-order Bessel function and ϵ_r is the dielectric constant of the substrate, which gives $a \approx 0.61\lambda/\sqrt{\epsilon_r}$. In the transmission-line model of a rectangular microstrip patch antenna, the radiation appears to occur at two rectangular apertures on either side of the patch, and these apertures are connected by a parallel-plate transmission line, which is the length ℓ of the patch. Now assume a patch of width w lies in the y - z plane on a substrate of thickness h . The radiated fields are given by (12), where F is approximately

$$F(\theta, \phi) = whS\left(\frac{kw}{2} \sin \theta \sin \phi\right) \cos\left(\frac{k\sqrt{\epsilon_r}\ell}{2} \cos \theta\right) \quad (34)$$

where the function $S(x)$ is defined in Table 2 and $G(\theta, \phi) = F(\theta, \phi)$. The first factor in (34) is due to the radiation

Figure 25. Two-layer circular microstrip antenna in a cavity with a choke ring.

pattern of the $w \times h$ apertures at the ends of the patch, while the second factor is a consequence of the pathlength between these apertures. In this geometry, the E plane is the $\phi = 0$ plane and the H plane corresponds to $\theta = 90^\circ$. Further discussion of the design of microstrip antennas is beyond the scope of this review; for further information, the reader should consult specialized texts [60,61].

The patterns given by (12) and (34) are asymmetric and produce high cross-polarization. By designing the ground-plane size (typically a diameter of $\sim 0.8\lambda$) and incorporating a choke at the edge of the ground plane, the pattern symmetry, and hence cross-polar performance, can be considerably improved over a ~ 5 – 10% bandwidth. The chokes also assist to reduce the spillover energy and rear lobes, which is important in low-noise applications. An example of a two-layer microstrip patch feed is shown in Fig. 25 [58,59].

2.5. Short-Backfire Antenna

A useful narrowband feed is the short-backfire antenna, particularly in low-frequency applications when compactness and light weight are important [62]. It has a relatively directive pattern, low sidelobes, and low rear lobes. The short-backfire antenna consists of two parallel-plate reflectors, spaced about $\lambda/2$ apart, and a driven element, a $\sim \lambda/2$ dipole shown in Fig. 26, placed about midway between the reflectors. In this arrangement the backfire antenna is basically a modified endfire array. One of the

Figure 26. Geometry of a circular short backfire antenna fed by a folded dipole.

reflectors is small, and the energy concentrated between the reflectors radiates through this reflector. The larger rear reflector has a skirt of about $\lambda/4$ to reduce the side-lobes. Due to the resonant structure, the antenna has only about a 3% bandwidth. Rectangular waveguide versions of this antenna have also been proved useful.

3. LINEAR ANTENNA FEEDS

Historically, one of the earliest feeds for a reflector was a half-wave dipole, which was fed from a transmission line via a balun. The dipole is backed by a circular disk set about $\lambda/4$ away to produce a unidirectional radiation pattern (see Fig. 24a) [3, Chap. 8]. The disk diameter is $0.5-1\lambda$, depending on the required edge taper. Alternative to the circular disk, one or more parasitic elements can achieve a similar effect. This type of feed is relatively narrowband.

The extension of the parasitic array is the Yagi-Uda array and the logperiodic antennas (Fig. 27) [5,49,63,64]. These are often used as feeds, especially at low frequencies for practical considerations, such as low weight, and also because the latter can operate over relatively wide bandwidths. Other practical advantages are that they are low-profile, which minimizes blockage, and have relatively simple input requirements. A major disadvantage in wide-

band applications is the defocusing caused by axial phase center movement with frequency. The optimum feed design for maximum antenna gain changes with the angle subtended by the secondary antenna (e.g., F/D for a paraboloid). In narrowband applications, the Yagi-Uda or log-periodic array is placed at the focal point of the secondary antenna and defocusing loss is negligible.

The Yagi-Uda array consists of a center-driven dipole element with a number of parasitic elements arranged in the same plane. These parasitic elements increase the gain of the antenna over that of a single dipole. A longer parasitic element is a reflector and is opposite the main radiation direction. The shorter elements lying in the direction of the main radiation are called *directors*. Varying the length and spacing of the elements relative to the driven element optimizes the radiation pattern. The input match is sensitive to the first reflector element, and usually only one or possibly two reflectors are needed to control the rear radiation and hence the pattern front-to-back ratio. The typical dimensions of a Yagi-Uda feed for a reflector with $F/D = 0.4$ are given in Fig. 27a. The classical Yagi-Uda array has a limited bandwidth of $\sim 2\%$ and the directivity increases approximately with the number of directors.

The bandwidth of a linear antenna may be increased significantly by means of a logperiodic geometry that feeds all elements in the array instead of a single dipole (Fig. 27b). The logperiodic antenna consists of dipole elements arranged in a plane that have a constant ratio (τ) between the element's distance from the apex (x_n) and the dipole lengths (l_n). Successive dipole elements are excited by reversing the phase. The pattern depends on the apex angle (α) and element spacing (d_n) (Fig. 27b), usually expressed in terms of the parameter $\sigma = d_n/(2l_n)$. Higher gains occur with large τ and σ and small α . For broadband designs, logperiodic antennas with large α are favored, as the phase center is closer to the apex and suffers less from defocusing loss. Details of the optimum design of log periodic feeds are given by Imbriale [65].

The tapered zigzag antenna (Fig. 27c) has properties similar to those of the classical linear logperiodic array and can be more convenient to fabricate. It has found use as a wideband feed for a reflector with F/D ratios from ~ 0.4 to 0.5 . To ensure that correct scaling is achieved, the wire is replaced with a plane metal sheet that tapers along the antenna. As well as the parameter τ , the design of the logperiodic zigzag antenna depends on the two angles α and β shown in Fig. 27c as described by Lo and Lee [64, Chap. 9]. Of importance in feed design is that the E - and H -plane half-power beamwidths are similar when $\gamma = 2\alpha$.

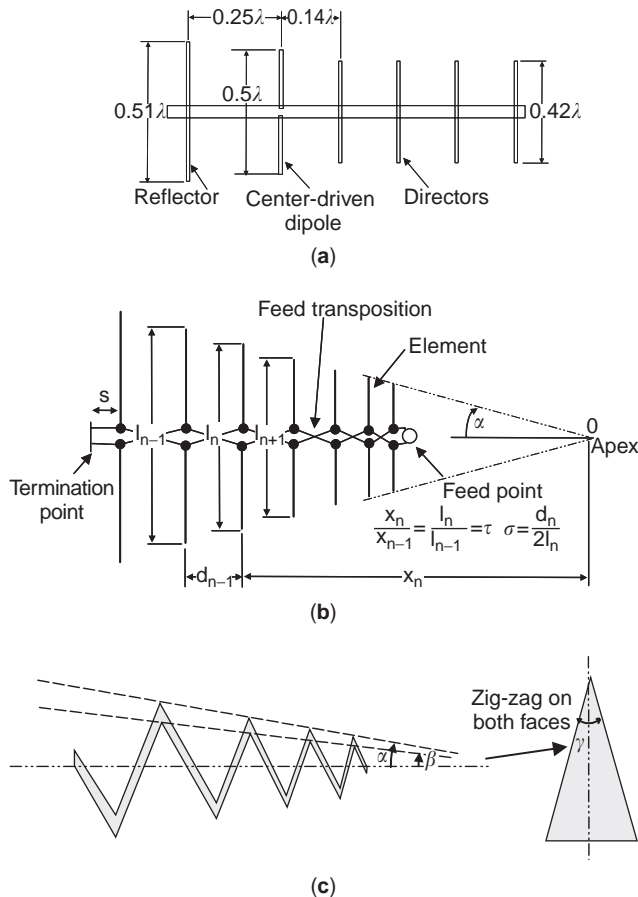

Figure 27. Linear feed antennas: (a) Yagi-Uda; (b) logperiodic; (c) zigzag.

4. TRAVELING-WAVE FEEDS

Traveling-wave antennas of the surface-wave type support a wave propagating along the antenna structure with a phase velocity $v < c$, producing an endfire beam. The distinctive feature of this type of antenna is that their directivity is proportional to their length. With traveling-wave antennas, the maximum directivity is achieved by meeting the Hansen-Woodyard condition [5], which requires that the phase difference between the surface wave and

the free-space wave be 180° at the termination of the antenna. Under this condition, the gain is $10 \log(10L/\lambda)$ dB and the beamwidth is $55\sqrt{\lambda/L}$ degrees, where L is the length.

Other excitation conditions give lower gain and side-lobe levels that are often more suitable for antenna feeds.

4.1. Dielectric Rod

The dielectric rod antenna is usually excited by an open-ended waveguide and has the property of a single lobe along the axis of the antenna. The wave traveling along the rod consists of hybrid modes whose fields exist inside and outside the dielectric. The radiation from a waveguide-fed dielectric rod has three main contributions: radiation from the waveguide-rod interface, radiation along the rod, and radiation at the end of the rod. To improve the match and prevent the occurrence of standing waves, the rod is often tapered either along its length or near its end. The choice of rod material is usually a compromise between size, directivity, and bandwidth. Both circular and rectangular dielectric-rod antennas are used [66,67]. Rods can be used in arrays and for ease of integration with electronics printed launchers have proved effective over a modest bandwidth (Fig. 28a) [68].

4.2. Traveling-Wave Slot

This type of antenna consists of a tapered slotline cut in a thin layer of metal, which is usually supported by a thin dielectric substrate on one side (Fig. 28b) [69,70]. The slotline is narrowed at one end to efficiently couple to the

feeding network and is tapered outward at the other end to improve radiation effectiveness. A traveling wave excited by the feed network propagates in the slot and radiates in an endfire direction at the tapered end. The energy in the traveling wave is tightly bound to the slotline when the separation distance is small compared to the free-space wavelength. An electric field is created across the slot, which produces a linearly polarized beam in the plane of the antenna (E plane). As the slotline width increases, radiation occurs most efficiently when the slotline width is about a half-wavelength. Tapered slot antennas have been found to have very wide bandwidths and the ability to generate a symmetric beam pattern despite their planar geometry.

The Vivaldi antenna (Fig. 28b) is one of a class of slot traveling-wave antennas and is characterized by an exponential curve for the taper in the slotline [71]. The antenna belongs to the class of aperiodic continuously scaled antenna structures, giving it the property of a theoretically infinite bandwidth. The Vivaldi antenna can produce a symmetric endfire beam (in both the E and H planes) with moderately high gain and low sidelobes. Figure 28b shows the basic geometry of the Vivaldi antenna and how the exponential taper is defined. Vivaldi antennas lend themselves well to being integrated with different types of circuits because of their planar construction. The radiating portion of the antenna is well separated and isolated from the nonradiating portion, allowing circuits to be integrated onto the dielectric at the nontapered end of the slot. It is common for the tapered slot to continue into a slotline circuit, which can then be fed by a microstrip/stripline to slotline transition or a finline. There are many variations of the Vivaldi antenna, including antipodal [72] and balanced configurations [73], which have, respectively, advantages of better feeding and lower cross-polarization than does the conventional Vivaldi. Arrays of Vivaldi antennas are used also as feeds for reflectors and lenses (Fig. 29).

4.3. Line-Source Feeds

Some secondary antennas, unlike the parabolic reflector, do not have a unique focus. Examples of such antennas are

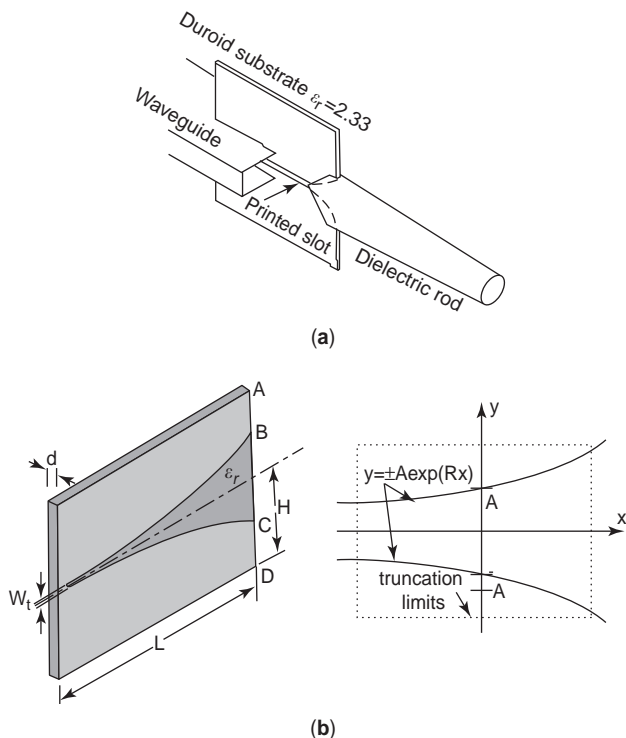

Figure 28. Traveling-wave feed antennas: (a) dielectric rod (From Qassim and McEwan [68], courtesy of IEE); (b) Vivaldi antenna.

Figure 29. Dense-packed array of Vivaldi antenna elements for a focal plane array (courtesy of ASTRON).

spherical and cylindrical reflectors. In a spherical reflector (Fig. 2b), only the axial ray has a unique point focus on the axis and the remainder suffer from spherical aberration. There are several ways to correct for spherical aberration; one approach is to use a phased linefeed, which adds the incident radiation in correct phase at a single point. Rumsey [74] has detailed the condition for exciting a spherical reflector for maximum gain. This is a conjugate field match condition (1) where the feed produces a tangential electric field at the surface of a mathematical cylinder that just encloses it, equal to the conjugate of the field that would be produced by the reflector currents if the reflector were illuminated by a plane wave.

Linefeeds can be divided into two main types: those that use waveguides and those that use cables for phasing. A waveguide can support phase velocities higher than the velocity of light, and this gives the required aberration correction. Examples include channel waveguide, dielectric rod antennas, a combination of the previous two antennas as described by Love [75], and a slotted waveguide. In the latter, varying the slot length while maintaining a fixed slot width and constant slot spacing throughout controls the rate of radiation. Using the TE_{10} mode in a waveguide of rectangular cross section enables the phase velocity to be controlled by varying the cutoff wavelength, which depends on the wide dimension of the waveguide. The second approach is to use a linear array of radiating elements such as dipoles, microstrip patches, or Vivaldi elements, and achieve the correct phasing by adjusting the transmission-line lengths between the elements. The main limitation is that aberration correction can be maintained only over a very narrow bandwidth with conventional transmission lines. When the frequency is varied, phase errors arise and the gain of the antenna is reduced. This problem may be overcome by means of a correcting subreflector and a point feed in which the spherical aberration is corrected by introducing a correcting pathlength in air.

An example of a circularly polarized linefeed was a feed developed for the 300-m-diameter spherical reflector antenna at Arecibo [76,77]. This feed used slotted circular cylinders (Fig. 30a) with circumferential fins between each slot that acted as radial waveguides to provide the correct phasing between the two orthogonal fields within the fins. The slots and fins provided also a radiation pattern with the correct azimuthal dependence. To improve the illumination, a few of the upper feed elements of the azimuthally-directed slot fields were closed off to compensate for the finite length, and the spacing between the upper elements was reduced to lower spillover.

Another feed for spherical reflectors is the sectoral hoghorn shown in Fig. 30b [78]. This consists of a primary feed and a section of subreflector surface enclosed between parallel plates spaced $< \lambda/2$ apart. The aperture of the hoghorn is placed parallel to the incident rays in the receiving case. Energy from the spherical reflector is incident on the aperture of the hoghorn, and an appropriate pathlength is included in the parallel-plate region to produce in-phase addition of the incident energy at the primary feed.

A parabolic cylinder reflector antenna, which is a cylindrical reflector with a parabolic cross section, has a

Figure 30. Line-source feeds: (a) slotted cylinder (From Love and Gustincic [76], courtesy of IEEE); (b) sectoral hoghorn (From Pratt and Shearman [78], courtesy of IEE).

linefeed along the focal line of the reflector. An example of a feed for this antenna is a linear array of crossed dipoles. The dipoles are located parallel and normal to the focal line, specifically, longitudinal and transverse polarizations. The two polarizations are fed separately through two completely branched transmission-line systems, exciting each dipole with identical amplitude and phase. The beam may be steered by adjusting the phasing of the elements. Another suitable feed for a parabolic cylinder is a pillbox horn [3]. These are usually single-polarization, although two polarizations can be obtained by stacking two orthogonally-polarized horns.

5. COMPOUND FEED ANTENNAS

Feeds for secondary antennas are sometimes made from a combination of the other types of feeds, reflectors, or resonant structures. The most common types of compound feeds are the array, beam waveguide, splash-plate (feed), and dichroic reflector.

5.1. Array Feeds

Single antenna feeds can be combined in arrays to create properties that are unattainable with more elementary antennas. Arrays of feeds are used for a variety of applications, including the creation of shaped beams, multiple pencil beams, beam scanning over a limited region of space, or correction of deficiencies in the reflector system arising from surface errors or misalignments. Single feeds or clusters are used to excite multiple beams. Overlapping

Figure 31. Array feed and beamforming network for the Galaxy IV satellite. (Courtesy of Hughes Aircraft Co.).

clusters can produce beams closer together than can arrays of single feeds. In pencil-beam applications where the array essentially compensates for the field distortion through the reflector, a natural design technique is conjugate-field matching (1). In this approach, the network connected to the array input excites the feeds so that the field in the aperture is the complex conjugate of the fields in the focal region that would be produced by a beam from the required direction. If there is more than one beam, then the array excitation is the conjugate of the superposition of focal fields of these beams.

The most common elements of feed arrays are waveguide horns, typically circular or rectangular cross section (see Figs. 14 and 31). The circular geometry is convenient for hexagonal array arrangements, while rectangular elements have advantages for producing shaped beams from satellites. Other types of array elements used for array feeds are tapered slot, dielectric rod, and microstrip patches.

Array feeds can also be phased to allow beam scanning over a limited angular range. If the spacing between elements is s , the maximum angular range the beam can be scanned before grating lobes appear is given by $\sin\theta_{\max} = \lambda/(2s)$. In typical practical arrays, $s \sim \lambda$ because of the physical size of the elements, and therefore the scan range of the feed is less than 30° . Grating lobes are not deleterious in some feed applications, except for lost power, provided these lobes do not illuminate the secondary antenna or a noisy source. The Vivaldi element allows greater close packing and therefore greater scan capability. Coaxial waveguides can also be used in arrays to achieve closer packing than with circular horns in applications requiring moderate bandwidths ($<20\%$) [79].

Another concern is the design of the individual elements in the array. For example, Amitay and Gans [80] showed that blindspots could exist as a result of forced aperture resonances in arrays of tapered rectangular horn elements with oversized (overmoded) apertures. The dominant contributor to these blindspots is the resonance of the equivalent transverse magnetic waveguide mode (TM_{12}). By appropriate design of the taper, these resonances can be avoided.

Another important effect to include in feed array design is the mutual coupling between the elements. Mutual

coupling affects both the input match and the radiated fields, particularly cross-polarization. Mutual coupling in finite arrays has been studied in detail for many different horn types, including rectangular [47,81], circular [82], and coaxial [83] apertures and also tapered-slot arrays [84]. The effect can be represented by a scattering matrix that is combined with the scattering matrices of the different elements constituting the array. The results obtained from a multimode analysis of mutual coupling are very accurate, and computer programs based on mode-matching methods have been widely used in satellite antenna and radio telescope feed array design [47,79]. In large arrays, prediction of the element patterns and array performance can be obtained using the Floquet periodic boundary conditions in combination with finite-element or finite-difference time-domain numerical methods (see Section 7).

5.2. Beam Waveguide

A beam waveguide feed uses a sequence of focusing elements to translate a beam pattern from a conventional feed horn to the secondary antenna. An example is shown in Fig. 32 for the NASA Deep Space Network [85]. The focusing elements may be reflectors or lenses, and sometimes polarizing grids are used to combine or separate two beams with orthogonal polarizations. The design technique commonly used is based on Gaussian beam propagation [86,87]. In this approach, the field radiated by the feed horn, usually a transversely corrugated horn, is represented by a sum of Gaussian beam modes. These modes have the characteristic that the amplitude has a Gaussian function variation with distance from the axis of propagation. The distance from the axis to the point where the Gaussian beam has decayed to $1/e$ of its value is called the beam waist (w), and this is a function of distance (z) along

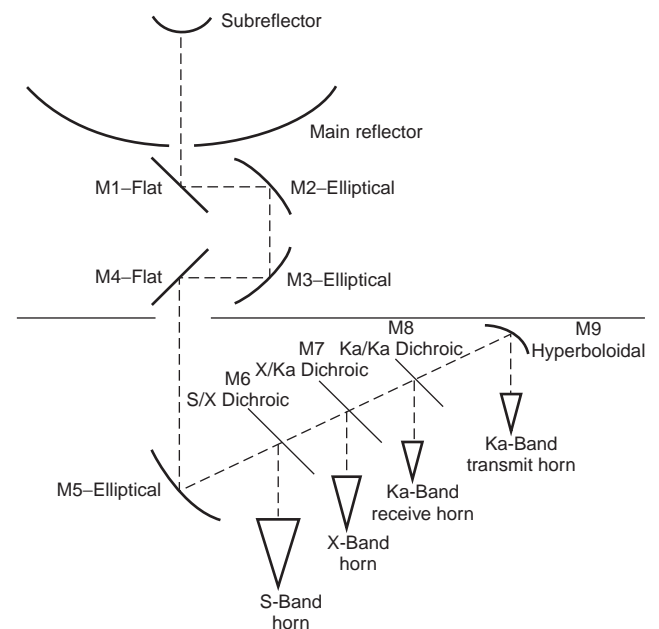

Figure 32. Geometry of beam waveguide system for the NASA Deep Space Network antenna DSS-25. (From Imbriale [85], courtesy of Wiley.)

the beam. Thus

$$w = w_0 \sqrt{1 + \left(\frac{\lambda z}{\pi w_0^2}\right)^2} \quad (35)$$

where w_0 is the minimum beam waist radius, which occurs where the radius of curvature of the wavefront is infinite, corresponding to a plane wave. The path through the sequence of reflectors, lenses, and grids can be represented step by step as a series of spreading transverse Gaussian beams. Each transformation from input to output beam through the focusing element can be represented by a 2×2 *ABCD* matrix, and the complete system can be found by concatenating these matrices. The *ABCD* matrices of different focusing elements is described by Kitsuregawa [86] and also Goldsmith [87], who also give many more details than there is space to record here. Ultimately, the method leads to output Gaussian beams that can be summed to give the field emanating from the beam waveguide. Kitsuregawa [86] provides a design procedure from feed horn to output reflector and design equations. If the focusing elements are moderate in size (say, >10 wavelengths, the minimum size for a beam waveguide element, but <50 wavelengths), it is prudent to calculate the effect of diffraction through the system using a more rigorous analysis method than Gaussian beams before completing the system design.

5.3. Splash-Plate Feeds

A splash-plate feed is a version of a self-supporting feed (Fig. 33). An open-ended waveguide irradiates a small reflector, the “splash-plate,” that is usually located a short distance s away. The splash plate then illuminates the

Figure 33. Splash-plate feeds: (a) vertex plate with matching cone; (b) periscope; (c) step-cut Vlasov mode converter.

secondary antenna, commonly a parabolic reflector. From image theory, the radiation pattern is approximately equal to that of the waveguide situated a distance s behind the plate and directed at the reflector, plus the edge diffraction field due to the rim of the splash plate [88]. Struts or a dielectric insert in the waveguide are often used to support the plate, which is usually about a wavelength in diameter and fitted with a cone or knob at the center to minimize the reflections back in the feed. The reflection coefficient in the waveguide is approximately given by [12]

$$\Gamma \approx \Gamma_{wg} + \frac{G_{wg}\lambda}{8\pi s} \left[\frac{R_1 R_2}{(R_1 + s)(R_2 + s)} \right]^{1/2} e^{-j(2ks + \theta_{wg})} \quad (36)$$

where Γ_{wg} is the reflection coefficient of the waveguide alone, s is the distance from the waveguide phase center to the splash plate, R_1 and R_2 respectively are the principal radii of curvature at the center of the splash plate, G_{wg} is the maximum gain of the waveguide, and θ_{wg} is a phase constant that depends on the reference plane in the waveguide; $\theta_{wg} = 0$ at the waveguide aperture.

The periscope feed in Fig. 33b is used to convert the beamshape to provide a more appropriate edge illumination for a secondary antenna. A third type of splash plate, the Vlasov mode converter shown in Fig. 33c, converts zero-azimuth index modes from high-power microwave and millimeter-wave sources into TE_{11} or HE_{11} modes for use in plasma heating and conventional antenna systems.

5.4. Dichroic Reflector

In the usual arrangement, a dichroic reflector (or frequency-selective surface) consists of an array of resonant slots or patches on a surface that is illuminated by signals in two frequency bands (see Fig. 34). The resonant elements are designed to reflect the fields of one feed in one frequency band and to transmit the fields of the second feed in the second band. In this way, a dual-band feed can be designed for a secondary reflector. The resonant patch approach uses a grid of crossed dipoles, resonant rings, concentric loops, or dumbbell-shaped patches printed on a dielectric surface that has the profile of the desired sub-reflector for the primary reflector [87]. These patches resonate at the frequency of the feed at the secondary focus of the surface, usually the higher of the two bands. The second feed is placed in the prime focus of the primary

Figure 34. Dichroic reflector.

reflector, and at low frequencies the grid of patches and the dielectric is almost transparent. The complementary approach to resonant patches is to use a metallic reflector with resonant slots or perforations. Here the reflector reflects the signals at frequencies below the cutoff frequency of the slots and is transparent above this cutoff frequency. More frequency bands can be accommodated using more than one dichroic reflector as shown in Fig. 32.

6. FEED SYSTEMS

Following the feed antenna is usually a circuit consisting of waveguide, printed circuits, finline, or coaxial cables, and the design of these is a separate topic in itself. However, an overview of feed antennas would be incomplete without some mention of the circuit following the feed, which is commonly called the *feed system*. There are several major types of feed systems, depending on the application. Three types of feed system will be briefly mentioned, namely, diplexers, beamforming networks, and comparator networks for monopulse tracking.

6.1. Diplexing

After the feed antenna, the orthomode transducer (OMT) and (for circular polarization) a polarizer are basic components of the feed system. Uher et al. [89] detail design techniques for waveguide components used in feed systems. To date, the maximum continuous bandwidth achieved by both polarizers and OMTs is about 50%, and this limits the feed system configurations possible when considering multiband operation over wide frequency ranges. The means of diplexing several frequency bands can considerably complicate the feed system design. One of the “simpler” diplexing techniques is to use a series of dichroic plates to deflect selectively a given band to an appropriate feed system (Fig. 32). This type of diplexing can be designed using Gaussian beam optics analysis [87].

For dual-frequency operation, a number of feed system configurations are possible. If the individual bandwidths are small (typically less than 10%) and the overall bandwidth ratio to cover the two bands is less than $\sim 40\%$, then diplexing can take place at the OMT ports before the signals are combined through the OMT into a common waveguide and through the polarizer. In that case we need consider only a single polarized signal in the diplexer and associated filters. These are usually built in rectangular waveguide to maintain polarization purity. A feed system for reception of dual linear and circularized polarized signals is shown in Fig. 35.

Figure 35. Schematic of a feed system for a dual linear/circular receive-only antenna.

For larger bandwidth requirements, it has been necessary to develop more sophisticated feed configuration schemes. An example of a dual-band, dual-polarized feed system for both circular and linear polarization is shown in Fig. 36 and has a very wideband dielectric-loaded horn. The lower-frequency band has a bandwidth of 24%, while the upper band has a bandwidth of 19%, with an interband separation ratio of $\sim 3.7:1$ [90]. The bands of this feed system are separated in a coaxial orthomode-junction diplexer where the center core of the coaxial waveguide is a loaded circular waveguide, which uses a low-loss dielectric with a permittivity of 2.4. This coaxial junction is matched to the horn with a dielectric of 1.15 permittivity by a dielguide section. The horn, dielguide section through to the coaxial junction, and beyond the highband rejection filter in the coaxial waveguide were completely analyzed by mode-matching methods, which was essential to obtain a workable design.

6.2. Beamforming Networks

A beamforming network (BFN) is required for an array feed to produce either a fixed illumination, as for the case of a shaped beam for a satellite, or variable illumination, if the feed is phased for radar systems. In satellite applications, the standard approach for producing contoured beams is with a parabolic reflector and an array feed of which the amplitude and phase at the input of each feed is supplied by a BFN, which must be low loss, low volume and light weight [91]. Typically, for Ku⁺ and Ka⁺ band these networks are realized in waveguide technology and for C band and lower frequencies, in TEM line. The BFN may need to be reconfigured into a number of fixed beams for different satellite orbital locations. The main components are power dividers, often 1-to-2-way, 1-to-4-way, or 1-to-8-way, fixed or variable, lengths of waveguide for phasing, variable phase shifters, and microwave switches. To achieve the best performance, the power divider couplers need to be accurately known and made. Accurate computer-aided design (CAD) software is used for this purpose and, with software based on methods such as mode matching, BFNs can be designed and built for flight without any trimming. An example of a beamforming network for a reflector providing a beam covering continental United States, Puerto Rico, Alaska, and Hawaii is shown in Fig. 37 [92]. The array itself is shown in Fig. 31. When the beam is scanned, rather than fixed, variable phase shifters are usually required. There are several ways of doing this, including uniform amplitude illumination over the array with variable phasing to steer the beam and use of Butler matrices with intervening phase shifters to

Figure 36. Dielectric cone-loaded feed system for dual-band applications. (From James et al. [90], courtesy of IEEE.)

produce multiple simultaneous beams. More details are given by Lo and Lee [64] and Mailloux [93].

6.3. Monopulse Feeds

A monopulse feed for a reflector or lens allows searching and tracking in radar and communications. The aim of such a feed is to produce sum, azimuth difference, and elevation difference signals from which tracking information can be obtained [94]. Among the available designs that use a secondary antenna there are three main types:

1. The first type uses four or five feeds arranged orthogonally in the focal plane of the secondary antenna. One arrangement uses four multimode rectangular feed horns and a suitable feed network to balance the efficiency of the sum and difference beams. A practical implementation of this design is given by Lee and Chu [95] (see Fig. 38a). These multimode horn designs suffer from different phase centers and different beamwidths between the sum and difference beams, which results in poor

efficiency for the sum beam and high spillover for the difference beam.

2. The second method uses a single circular waveguide input to a corrugated horn from a beamforming network, which produces appropriate modes to give the three tracking signals. In one implementation of this, due to Watson et al. [96], the beamforming network produces a combination of TM_{01} and TE_{21} modes.

3. The third method employs a single multimode horn and four input waveguides that control the modes excited in the horn by means of a comparator network (see Figs. 38b and 39). As shown in Fig. 40, a corrugated horn can be used in this case where the HE_{11} mode provides the sum beam while combinations of orthogonal HE_{21} modes with H_{01} and E_{02} modes of corrugated waveguide provide azimuth and elevation difference beams [97,98]. The challenge in this type of monopulse feed design is balancing the diameter of the horn at the junction, which gives the correct mode excitation, with the size of the input waveguides and also phasing the modes at the aperture.

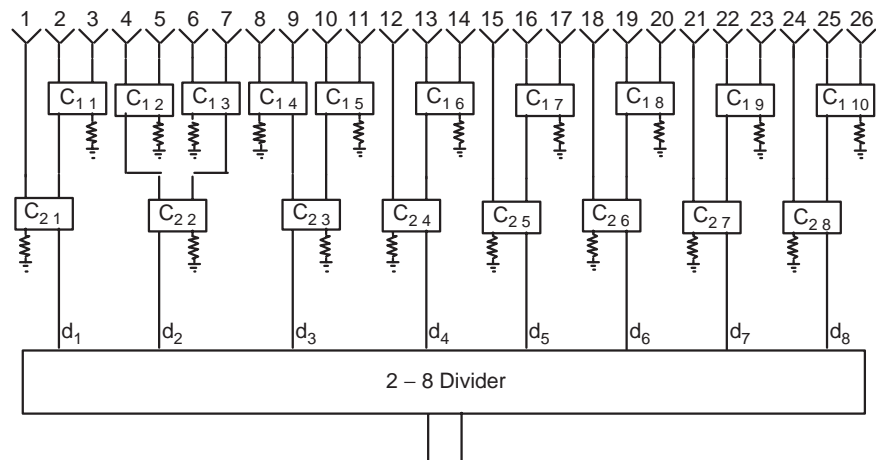

Figure 37. Beamforming network layout for the vertical transmit beam, where C_{mn} is the coupling value. (From Bird and Sroka [92].)

Figure 38. Monopulse tracking feeds: (a) multifeed array (From Lee and Chu [95], courtesy of IEEE); (b) multimode monopulse feed.

Rectangular waveguide can be used, but square waveguide allows better performance. While greater beam efficiency is obtained for all beams at the center frequency, the bandwidth for best performance is typically narrow (~2%) and the match is often poor for the difference beam (reflection coefficient ~ -10 dB).

7. DESIGN METHODS

A feature of modern antenna feed design is the extent to which accurate computer software is now used. Electromagnetic software is used to analyze both the antenna and

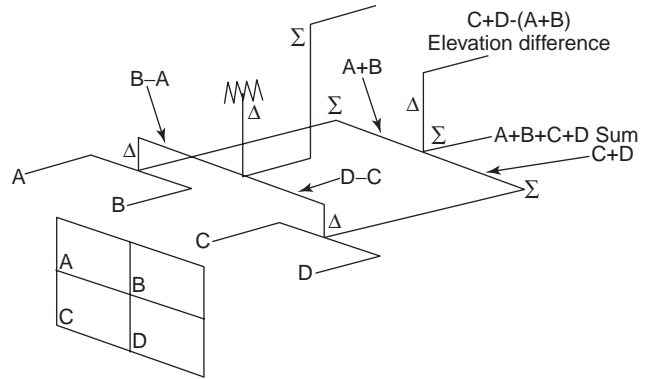

Figure 39. Schematic of a monopulse comparator (Σ and Δ respectively indicate sum and difference ports of four-port magic-T junctions). (After Zhang et al. [98], courtesy of Wiley.)

the feed system. While many analysis methods are available, the main software packages are based on five principal analysis methods: the finite-difference time-domain (FDTD), the finite-element method (FEM), mode matching (MM), method of moments (MoM), and the transmission-line matrix (TLM) method [99]. In the past, the most widely used were MoM and the MM technique because radiation is easily and accurately incorporated. However, with improvements in artificial boundary conditions, the accuracy of the more general finite methods such as FDTD and FEM is approaching that of the traditional methods. Hybrid methods are also used, and these can give additional flexibility. Methods used to design components

Signal	Aperture distribution	Modes
Sum		
Azimuth difference		
Elevation difference

relevant to antenna feeds are reviewed in articles by Steer et al. [100] and Arndt et al. [101].

The most accurate method currently available for aperture-type feeds employs a combination of MM and MoM. The former is used to analyze the internal structure and MoM, the outer structure. To analyze a device by the mode-matching method, the scattering matrix solution of the transverse modal coefficients is required at each discrete boundary surface that describes the geometry of the structure. By cascading these matrices, we can completely characterize the device [10,101]. This technique has been used with great success in analyzing numerous waveguide horns, arrays, and components. While a common elemental or building-block solution required to analyze complex structures in circular waveguide components is the junction between two circular waveguides, other scattering matrix solutions are available for junctions between coaxial waveguides, partially filled circular waveguides, rectangular waveguides, elliptical waveguides, and ridged waveguides as well as junctions between rectangular and circular waveguides. In all cases, however, the basic procedure remains the same. Radiation from the outer structure is expressed as a summation of elementary radiating current sources, called a *Green function integral equation*. The currents are approximated by many simple functions, called *shape functions*, such as triangular functions for line currents [99] and the “rooftop tiles” of Rao et al. [102] for surface currents. The mode matching and integral equations are solved together to give the mode amplitudes in the aperture and the external currents. Once these are known, the radiated field is found by summing the contributions from all modes and sources. It is important to include all high-order terms in the radiation calculation, especially when the feed and reflector are within the Fresnel (near-field) zone, as ignoring these terms can lead to significant errors in predicting cross-polarization and phase center. This particular approach can predict the performance of horn antennas very accurately down to the -60 dB level of the radiation pattern.

Proprietary electromagnetics software, such as Ansoft’s HFSS [103] and CST Microwave Studio [104], is now achieving impressive results that more specialized software achieved in the past. As an example, Fig. 41 shows the three-dimensional drawing of a quad-band feed system that has been analysed with Microwave Studio. The results for the input reflection coefficient for all bands show excellent agreement with accurate mode-matching software and measurement.

Another aspect of design is optimization of performance and, until only relatively recently, computer speed limited the degree this was possible. Now, for example, horns are regularly designed by MM to suit particular performance criteria by optimizing the profile [33]. Optimizers are also employed in many electromagnetics software packages to adjust the geometry to peak the performance [100].

8. FUTURE OUTLOOK

The developments in antenna feeds go in parallel with new applications and improvements in software, materials, devices, and manufacturing methods. The inexorable

Figure 41. Cutaway drawing of a quad-band feed system analyzed completely with computer software. (© CSIRO.)

push for higher levels of integration in future systems should see active devices, both receivers and transmitters, fully integrated with the feed antenna. At the moment, lower bandwidth capability and higher initial cost of these units is limiting wider use of integrated feeds. The ability to manufacture a feed antenna has, in the past, limited some of the antennas that are used. With further improvements in software, materials, and computer-aided manufacture, some of these limitations should reduce. Of the feed antennas themselves, we expect to see more multi-band and wideband feeds, which will allow system designers to provide greater flexibility and functionality. Some examples of these wideband feeds that will be more widely used are dielectric-lined horns and arrays of traveling-wave slots. The means of extracting the different frequency bands or wideband signals from these antennas remains a challenging problem.

Antenna feeds are by definition used in conjunction with other antennas forming a system. In the past, these antennas were designed separately, and the effect of the interactions between them was ignored as insignificant or calculated approximately. Effects such as scattering from reflectors, feeds, struts, or the supporting structure itself can be important contributors to cross-channel interference in communication systems. It is expected that future computers and software will allow the design and optimization of complete antenna systems as a matter of course. Encouraging steps have been made in this direction in recent years. While these developments depend heavily on improvements in computers, software, and display technology, the search continues for the most accurate and fastest electromagnetics methods for analysis and optimization of antenna feeds.

ANTENNA PARAMETERS

CONSTANTINE A. BALANIS
Arizona State University
Tempe, Arizona

1. INTRODUCTION

An antenna is a communication system component that is designed to radiate or receive electromagnetic waves. In other words, the antenna is the electromagnetic transducer that is used to convert, in the receiving mode, free-space waves to guided waves, and in the transmitting mode, guided waves to free-space waves, as shown in Fig. 1. The Thevenin equivalent of the antenna in the transmission-line mode is shown in Fig. 2. In a modern RF–microwave system, the antenna must also act as a directional device to optimize or accentuate the transmitted or received energy in some directions while suppressing it in the others. The antenna serves to an RF and microwave system the same purpose that eyes and eyeglasses serve for a human.

Figure 1. Antenna as a transitional device.

The history of antennas dates back to James Clerk Maxwell, who unified the theories of electricity and magnetism, and eloquently represented their relations through a set of profound equations best known as *Maxwell's equations*. His work was first published in 1873. He also showed that light was electromagnetic, and that both light and electromagnetic waves travel by wave disturbances of the same speed. In 1886, Professor Heinrich Rudolph Hertz demonstrated the first wireless electromagnetic system. In his laboratory, he was able to produce at a wavelength of 4 m a spark in the gap of a transmitting $\lambda/2$ dipole, which was then detected as a spark in the gap of a nearby loop. It was not until 1901 that Guglielmo Marconi was able to send signals over long distances. He performed, in 1901, the first transatlantic transmission from Poldhu in Cornwall, England, to St. John's in Newfoundland [1].

From Marconi's inception through the 1940s, antenna technology was centered primarily on wire-related radiating elements and frequencies up to about UHF. It was not until World War II that modern antenna technology was launched and new elements (waveguide apertures, horns, reflectors, etc.) were introduced, especially for RF and

Figure 2. Thevenin equivalent in transmission mode.

microwave frequencies. A contributing factor to this new era was the invention of microwave sources (such as the klystron and magnetron) with frequencies of 1 GHz and above.

While a new era in antennas was launched, during World War II, the advances made in computer architecture and wireless communications technology during the 1960s–1990s have had a major impact on the advances of modern antenna technology, and they are expected to have an even greater influence on antenna engineering in this new millennium. Beginning primarily in the early 1960s, advanced numerical and computational methods were introduced that allowed previously intractable complex antenna system configurations to be analyzed and designed very accurately. Antenna design plays a critical role in overall system design since the success of a system relies strongly on the performance of the antenna. Detailed analysis, design, and measurements of antennas can be found in Ref. 2. A tutorial on antennas is described in Ref. 3.

2. ANTENNA ELEMENTS

Prior to World War II most antenna elements were of the wire type (long wires, dipoles, helices, rhombuses, fans, etc.), and they were used either as single elements or in arrays. During and after World War II, many other radiators, some of which may have been known for some time and others of which were relatively new, were put into service. This created a need for better understanding and optimization of their radiation characteristics. Many of these antennas were of the aperture type (such as open-ended waveguides, slots, horns, reflectors, lenses), and they have been used for communication, radar, remote sensing, and deep-space applications on both airborne and Earth-based platforms. Many of these operate at RF and microwave frequencies.

Prior to the 1950s, antennas with broadband pattern and impedance characteristics had bandwidths not much greater than about 2:1. In the 1950s, a breakthrough in antenna evolution was created that extended the maximum bandwidth to as great as 40:1 or more. Because the geometries of these antennas are specified by angles instead of linear dimensions, they have ideally an infinite bandwidth. Therefore, they are referred to as *frequency-independent* [2]. These antennas are used primarily in the 10–10,000 MHz region in many applications, including TV, point-to-point communications, and feeds for reflectors and lenses.

It was not until almost 20 years later that a fundamental new radiating element, which has received a lot of attention and many applications since its inception, was introduced. This occurred in the early 1970s when the *microstrip* or *patch* antenna was reported [2]. This element is simple, lightweight, inexpensive, low-profile, and conformal to the surface. Microstrip antennas and arrays can be flush-mounted to metallic and other existing surfaces. Operational disadvantages of microstrip antennas include low efficiency, narrow bandwidth, and low power-handling capabilities. Major advances in millimeter-wave antennas have been made in recent years, including integrated antennas where

active and passive circuits are combined with radiating elements in one compact unit (monolithic form).

The unparalleled advances in telecommunications have brought a dramatically increased interest and activity in antenna design. This has resulted in many new elements and design concepts [4], including increased interest in adaptive arrays and “smart” antennas [5–7]. A short description on the analysis and modeling of antennas can also be found in Ref. 8.

3. FUNDAMENTAL PARAMETERS AND FIGURES-OF-MERIT

To describe the performance of an antenna, definitions of various parameters are necessary. Some of the parameters are interrelated, and not all of them need to be specified for complete description of the antenna performance. Parameter definitions will be given in this article. Many of the definitions in quotation marks are from the *IEEE Standard Definitions of Terms for Antennas* (IEEE Standard 145-1983) [9]. This is a revision of the IEEE Standard 145-1973. Many of these definitions relating to parameters and figures-of-merit (including directivity, gain, input impedance, effective area, polarization, etc.) that characterize the performance of the antenna system can also be found in the literature [2,3,8].

The space surrounding an antenna is usually subdivided into three regions: the reactive near-field region, the radiating near-field (Fresnel) region, and the far-field (Fraunhofer) region, as shown in Fig. 3. These regions are so designated to identify the field structure in each. Although no abrupt changes in the field configurations are noted as the boundaries are crossed, there are distinct differences among them. The boundaries separating these regions are not unique, although various criteria have been established and are commonly used to identify the regions [2]. The following definitions in quotation marks are from Ref. 9.

The *reactive near-field region* is defined as “that region of the field immediately surrounding the antenna wherein the reactive field predominates.” For most antennas, the outer boundary of this region is commonly taken to exist at a distance $R < 0.62\sqrt{D^3/\lambda}$ from the antenna, where λ is the wavelength and D is the largest dimension of the antenna.

The *radiating near-field (Fresnel) region* is defined as “that region of the field of an antenna between the reactive near-field region and the far-field region wherein radiation fields predominate and wherein the angular field distribution is dependent upon the distance from the antenna.” The radial distance R over which this region exists is $0.62\sqrt{D^3/\lambda} \leq R < 2D^2/\lambda$ (provided D is large compared to the wavelength). This criterion is based on the maximum phase error of $\pi/8$ radians (22.5°). In this region the field pattern is, in general, a function of the radial distance and the radial field component may be appreciable.

The *far-field (Fraunhofer) region* is defined as “that region of the field of an antenna where the angular field distribution is essentially independent of the distance from the antenna.” In this region, the real part of the power density is dominant. The radial distance defining the far-field region is $R \geq 2D^2/\lambda$ (provided D is large compared to

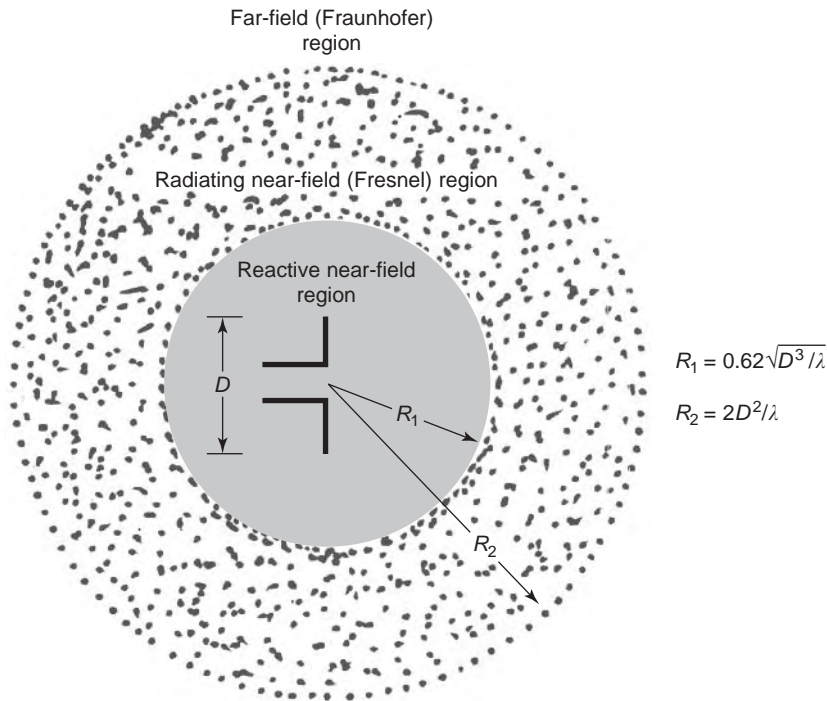

Figure 3. Field regions surrounding an antenna.

the wavelength). The outer boundary is ideally at infinity. The criterion is also based on the maximum phase error of $\pi/8$ radians (22.5°). In this region, the field components are essentially transverse to the radial direction, and the angular distribution is independent of the radial distance.

An *antenna pattern* is defined as a graphical representation, usually in the far-field region, of one of the antenna's parameters. For a complete description, the parameters of interest are usually plotted as a function of the spherical angles θ , ϕ . Parameters of interest include amplitude, phase, polarization, and directivity. An amplitude pattern usually consists of a number of lobes, as shown in Fig. 4, where the first quadrant has been deleted to visualize the directional part of the pattern.

Figure 4. Three-dimensional pattern of $l = 1.25\lambda$ dipole.

A *main- (major) lobe* is defined as “the radiation lobe containing the direction of maximum radiation. In certain antennas, such as multi-lobed or split-beam antennas, there may exist more than one major lobe.”

A *sidelobe* is defined as “a radiation lobe in any direction other than that of the major lobe.” The amplitude level of a sidelobe relative to the mainlobe (usually expressed in decibels) is referred to as *sidelobe level*.

The antennas, based on their amplitude radiation pattern, can be classified into three categories: isotropic, directional, and omnidirectional. An *isotropic* antenna/radiator is defined as “a hypothetical lossless antenna having equal radiation in all directions.” Although it is ideal and not physically realizable, it is often taken as a reference for expressing the directive properties of actual antennas. A *directional* antenna is one “having the property of radiating or receiving electromagnetic waves more effectively in some directions than in others. This term is usually applied to an antenna whose maximum directivity is significantly greater than that of a half-wavelength dipole.” A special case of a directional radiator is the *omnidirectional* antenna, which is defined as one “having an essentially nondirectional pattern in a given plane and a directional pattern in any orthogonal plane.” An example of an omnidirectional pattern is shown in Fig. 4 that is the pattern of a symmetric linear dipole of length $l = 1.25\lambda$. That pattern is nondirectional in the azimuth plane [$f(\phi)$, $\theta = 90^\circ$] and directional in the elevation plane [$g(\theta)$, $\phi = \text{constant}$].

For a linearly polarized antenna, performance is often described in terms of the principal *E*-plane and *H*-plane amplitude patterns. The *E plane* is defined as “the plane containing the electric-field vector and the direction of maximum radiation,” while the *H plane* is “the plane containing the magnetic-field vector and the direction of maximum radiation.” Although it is very difficult to illustrate

the principal planes without considering a specific example, it is the usual practice to orient most antennas so that at least one of the principal plane patterns coincides with one of the geometric principal planes. Figure 4 illustrates the omnidirectional pattern of a linear dipole of length $l = 1.25\lambda$. For this example, any elevation plane pattern ($\phi = \text{constant}$, $0^\circ \leq \theta \leq 180^\circ$) represents the principal E plane while the azimuth x - y plane pattern ($\theta = 90^\circ$, $0^\circ \leq \phi \leq 360^\circ$) is the principal H plane. The E -plane pattern follows the vector of the electric field while the H -plane follows the vector of the magnetic field. For this example, because of the symmetry of the dipole antenna and its omnidirectional amplitude pattern, we have an infinite number of principal E -plane patterns and only one principal H plane. For most other directional antennas, there is usually only one principal E plane and only one principal H plane.

An antenna is often represented by an equivalent circuit with antenna impedance Z_A , as shown in Fig. 2. The antenna impedance Z_A consists of the *radiation resistance* R_r , the *loss resistance* R_L , and an imaginary part X_A [$Z_A = R_A + jX_A = (R_r + R_L) + jX_A$]. The radiation resistance is the resistance that accounts for antenna radiation or scattering. The loss resistance is the element that accounts for the conductive and dielectric losses of the antenna. Expressions for R_r and R_L for dipoles and small circular loops can be found, respectively, in Chapters 4 and 5 of Ref. 2.

Input impedance is defined as “the impedance presented by an antenna at its terminals.” It is expressed at the terminals as the ratio of the voltage to current or the ratio of the appropriate components of the electric to magnetic fields, and it is usually complex. When the antenna impedance Z_A is referred to the input terminals of the antenna, it reduces to the input impedance.

Radiation efficiency is defined as “the ratio of the total power radiated by an antenna to the net power accepted by an antenna from the connected transmitter.” Using the equivalent circuit representation of an antenna of Fig. 2, the radiation efficiency of the antenna can be expressed as

$$e_r = \frac{R_r}{R_r + R_L} \quad (1)$$

Power density S is defined as the power density (W/m²) of the fields radiated by the antenna. In general, the power density is complex. In the reactive near field, the imaginary component is dominant. In the far field, the real part is dominant. In equation form, the power density \mathbf{S} is expressed as

$$\mathbf{S} = \frac{1}{2} \mathbf{E} \times \mathbf{H}^* = \mathbf{S}_r + j\mathbf{S}_i \quad (2)$$

where \mathbf{E} and \mathbf{H} are the fields radiated by the antenna (* indicates complex conjugate). The real part of (2) is usually referred to as *radiation density*.

Radiation intensity U is defined as “the power radiated from an antenna per unit solid angle (steradian).” The radiation intensity is usually defined in the far field and is related to the real part of the power density by

$$U = r^2 S_r \quad (3)$$

where r is the spherical radial distance.

Beamwidth is defined as the angular separation between two directions in which the radiation intensity is identical, with no other intermediate points of the same value. When the intensity is one-half of the maximum, it is referred to as *half-power beamwidth*.

An *isotropic radiator* is defined as “a hypothetical, lossless antenna having equal radiation intensity in all directions.” Although such an antenna is an idealization, it is often used as a convenient reference to express the directive properties of actual antennas. The radiation density S_{r0} of an isotropic radiator and corresponding intensity U_0 are defined, respectively, as

$$S_{r0} = \frac{P_r}{4\pi r^2} \quad (4a)$$

$$U_0 = \frac{P_r}{4\pi} \quad (4b)$$

where P_r represents the power radiated by the antenna.

Directivity is one of the most important figures-of-merit that describes the performance of an antenna. It is defined as “the ratio of the radiation intensity in a given direction from the antenna to the radiation intensity averaged over all direction.” Using Eq. (4b), it can be written as

$$D = \frac{U(\theta, \phi)}{U_0} = \frac{4\pi U(\theta, \phi)}{P_r} \quad (5)$$

where $U(\theta, \phi)$ is the radiation intensity in the direction θ, ϕ and P_r is the radiated power. For antennas radiating both electric field components (E_θ and E_ϕ), partial directivities D_θ and D_ϕ associated, respectively, with E_θ and E_ϕ (and their corresponding radiation intensities U_θ and U_ϕ), can be defined as [2]

$$D_\theta = \frac{4\pi U_\theta}{(P_{\text{rad}})_\theta + (P_{\text{rad}})_\phi} \quad (6a)$$

$$D_\phi = \frac{4\pi U_\phi}{(P_{\text{rad}})_\theta + (P_{\text{rad}})_\phi} \quad (6b)$$

where the total directivity D is then the sum of the two, or

$$D = D_\theta + D_\phi \quad (6c)$$

If the direction of observation is not specified, directivity in general implies the direction of maximum radiation intensity (maximum directivity) expressed as

$$D_0 = \frac{U_m(\theta, \phi)}{U_0} = \frac{4\pi U_m(\theta, \phi)}{P_r} \quad (7)$$

The directivity is an indicator of the relative directional properties of the antenna. As defined by Eqs. (5)–(7), the directional properties of the antenna in question are compared to those of an isotropic radiator. Figure 5 displays the three-dimensional directivity pattern of a $\lambda/2$ dipole and an isotropic source. In each angular direction, only the greater directivity between the two radiators is shown. As can be seen, the directivity of the $\lambda/2$ dipole is

Figure 5. Three-dimensional directivity pattern of $\lambda/2$ dipole.

greater than that of an isotropic source for angles of $57.44^\circ < \theta < 122.56^\circ$ with a maximum value of 1.67 (or 2.23 dB) at $\theta = 90^\circ$. In the other angular region ($0^\circ \leq \theta < 57.44^\circ$ and $180^\circ \geq \theta > 122.56^\circ$), the directivity of the isotropic source ($D = 1$ or 0 dB) is greater than that of the $\lambda/2$ dipole. This allows us to relate the directivity of the element in question to that of an isotropic radiator by simply adding (if expressed in decibels) the relative directivities of one element to another. This procedure is analogous to that used to determine the overall gain of cascaded amplifiers.

Gain is probably the most important figure-of-merit of an antenna. It is defined as “the ratio of the radiation intensity in a given direction, to the radiation intensity that would be obtained if the power accepted by the antenna were radiated isotropically.” Antenna gain is expressed as

$$G = \frac{4\pi U(\theta, \phi)}{P_a} \quad (8)$$

where P_a is the accepted (input) power of the antenna. If the direction is not specified, it implies the direction of maximum radiation (maximum gain). In simplest terms, the main difference between the definitions of directivity and gain is that the directivity is based on the radiated power (assuming that all input power is radiated) while the gain is based on the accepted (input) power. Since all of the accepted (input) power is not radiated (because of losses), the two are related by

$$P_r = e_{cd} P_a \quad (9)$$

where e_{cd} is the radiation efficiency of the antenna as defined by (1). By using (5), (8) and (9), the gain can be expressed as

$$G = e_{cd} \frac{4\pi U(\theta, \phi)}{P_r} = e_{cd} D \quad (10)$$

For a lossless antenna, its gain is equal to its directivity. As with the directivity, there can be partial gains G_θ and

G_ϕ , analogous to (6a)–(6b), related to the electric field components E_θ and E_ϕ (and their corresponding intensities U_θ and U_ϕ).

For each antenna, whether it is a linear or aperture antenna, there is a parameter referred to it as *vector effective length* \mathbf{l}_e (in some places it is referred to as *vector effective height* \mathbf{h}_e), which is used to determine the voltage induced on the open-circuit terminals of the antenna when a wave impinges on it, as shown in Fig. 6. The vector effective length \mathbf{l}_e for an antenna is usually a complex vector quantity represented by

$$\mathbf{l}_e(\theta, \phi) = \hat{\mathbf{a}}_\theta \ell_\theta(\theta, \phi) + \hat{\mathbf{a}}_\phi \ell_\phi(\theta, \phi) \quad (11)$$

The vector effective length is a far-field quantity, and it is related to the far-field \mathbf{E}_a radiated by the antenna, with equivalent current I_{in} in its terminals, by [2]

$$\mathbf{E}_a = \hat{\mathbf{a}}_\theta E_\theta + \hat{\mathbf{a}}_\phi E_\phi = -j\eta \frac{k I_{in}}{4\pi r} \mathbf{l}_e e^{-jkr} \quad (11a)$$

The effective length represents the antenna in its transmitting and receiving modes, and it is particularly useful in relating the open-circuit voltage V_{oc} of receiving antennas, as shown in Fig. 6. This relation can be expressed as

$$V_{oc} = \mathbf{E}^i \cdot \mathbf{l}_e \quad (12)$$

where V_{oc} is the open-circuit voltage at antenna terminals, \mathbf{E}^i is the incident electric field, and \mathbf{l}_e is vector effective length.

Polarization of a radiated wave is defined as “the figure traced as a function of time by the extremity of the vector (electric or magnetic field) at a fixed location in space, and the sense in which it is traced, as observed along the direction of propagation.” Based on the definition of

Figure 6. Geometry for vector effective height.

the polarization of a radiated wave, we can now state that the *antenna polarization* in a given direction is determined by the polarization of the fields radiated by the antenna. In general, the polarization of an antenna is classified as *linear*, *circular*, or *elliptical*. Although linear and circular polarizations are special cases of elliptical, in practice they are usually treated separately. Circular and elliptical polarizations also are classified according to the rotation of the transmitted field vectors; the rotation can be either *clockwise (right-hand)* or *counterclockwise (left-hand)* as viewed in the direction of propagation. For more details about polarization of electromagnetic fields and that of antennas, the reader is referred to Refs. 2 and 10.

Polarization efficiency (polarization mismatch or polarization loss factor) is defined as “the ratio of the power received by an antenna from a given plane wave of arbitrary polarization to the power that would be received by the same antenna from a plane wave of the same power flux density and direction of propagation, whose state of polarization has been adjusted for a maximum received power” and is represented by

$$p_e = \frac{|\mathbf{l}_e \cdot \mathbf{E}^i|^2}{|\mathbf{l}_e|^2 |\mathbf{E}^i|^2} \quad (13a)$$

where \mathbf{l}_e is the vector effective length of Eq. (11). The polarization mismatch between the antenna and the incident wave can also be represented by a polarization loss factor (PLF) [2], represented here also by p_f , which is defined by referring to Fig. 7 as

$$p_f = \text{PLF} = |\hat{\rho}_w \cdot \hat{\rho}_a|^2 = |\cos(\psi_p)|^2 \quad (13b)$$

In (13a) $\hat{\rho}_w$ and $\hat{\rho}_a$ are unit vectors representing, respectively, the polarizations of the incident wave and of the

Figure 7. Polarization vector for antenna and impinging wave.

antenna [2]. The polarization efficiency of (13a) or the polarization loss factor of (13b), which represent the same polarization mismatch, is an important factor that must be included in the power budget of communications systems but is sometimes neglected.

When an incident wave impinges on an antenna, as shown in Fig. 8, the amount of power received by the antenna and transferred to the load/receiver can be determined using what is referred to as the *effective area*, which is an *equivalent area* representing the antenna, whether it is a wire, aperture, reflector, or other components. In a given direction, the *effective area* is defined as “the ratio of the available power at the terminals of a receiving antenna to the power flux density of a plane wave incident on the antenna from that direction, *the wave being polarization matched to the antenna*. If the direction is not specified, the direction of maximum radiation intensity is implied.” The maximum effective area is related to the antenna gain by [2]

$$A_{em} = p_{e,f} e_r \frac{\lambda^2}{4\pi} G_0 \quad (14)$$

where $p_{e,f}$ represents either the polarization efficiency p_e of (13) or polarization loss factor p_f of (13b), G_0 is the maximum gain of the antenna, and e_r is the impedance-matching efficiency between the transmission line and the antenna defined as

$$e_r = (1 - |\Gamma_{in}|^2) \quad (15)$$

where Γ_{in} is the reflection coefficient at the input terminals of the antenna. When multiplied by the power density of the incident wave that impinges on the antenna, the maximum effective area determines the maximum power that is delivered to a matched load connected to the antenna (assuming no other losses, such as transmission-line losses between the antenna and the load/receiver).

Aperture efficiency, usually expressed in percent, is defined as the ratio of antenna’s maximum effective area to its physical area, which can also be expressed on the ratio of the maximum directivity of the aperture to the standard directivity, or

$$\varepsilon_{ap} = \frac{A_{em}}{A_p} = \frac{D_0}{D_s} \quad (16)$$

where A_p is the physical area of the antenna and D_s is standard directivity of antenna ($4\pi A_p/\lambda$ when $A_p \gg \lambda^2$ and with radiation confined to a half-space).

For a rectangular aperture mounted on an infinite ground plane and with a triangular aperture distribution, its aperture efficiency is 75%. However, for an aperture with a sinusoidal aperture distribution, its aperture efficiency is 81% [2]. Again, we see that the aperture distribution, which satisfies the wave equation and the boundary conditions of the structure, determines its aperture efficiency. If an aperture could support an ideal uniform field distribution, which is seldom physically realizable, its aperture efficiency would be 100%.

Every object with a physical temperature above zero ($0 \text{ K} = -273^\circ\text{C}$) radiates energy. The amount of energy ra-

Figure 8. Geometry for defining effective area.

diated is usually represented by an equivalent temperature T_B , better known as *brightness temperature*, and it is defined as

$$T_B(\theta, \phi) = \varepsilon(\theta, \phi)T_m = [1 - |\Gamma(\theta, \phi)|^2]T_m \quad (17)$$

where T_B is brightness temperature (K), ε is emissivity (dimensionless), T_M is molecular (physical) temperature (K), and $\Gamma(\theta, \phi)$ is the reflection coefficient of the surface for the polarization of the wave.

The brightness temperature emitted by the different energy sources is intercepted by antennas, as shown in Fig. 9, and it appears at their terminals as an antenna temperature T_A [2]. The temperature appearing at the terminals of an antenna is that given by (17), and it is

weighted by the gain pattern $G(\theta)$ of the antenna. In equation form, this is expressed as

$$T_A = \frac{\int_0^{2\pi} \int_0^\pi T_B(\theta, \phi)G(\theta, \phi) \sin \theta d\theta d\phi}{\int_0^{2\pi} \int_0^\pi G(\theta, \phi) \sin \theta d\theta d\phi} \quad (17a)$$

where T_A is antenna temperature [effective noise temperature of antenna radiation resistance (K)] and $G(\theta, \phi)$ is gain (power) pattern of the antenna.

Assuming no losses or other contributions between the antenna and the receiver, the noise power transferred to the receiver is given by [2]

$$P_r = kT_A\Delta f \quad (18)$$

where

- P_r = antenna noise power (W)
- k = Boltzmann's constant (1.38×10^{-23} J/K)
- T_A = antenna temperature (K)
- Δf = bandwidth (Hz).

To account for other noise contributions to the receiver, such as those from the transmission line, the reader is referred to Ref. 2.

Specific amplitude radiation pattern requirements usually cannot be achieved by a single antenna element, because single elements usually have relatively wide radiation patterns and low directivities. To design antennas with very large directivities, it is usually necessary to increase the electrical size of the antenna. This can be accomplished by enlarging the electrical dimensions of the chosen single element. However, mechanical problems are usually associated with very large elements.

An alternative way to achieve large directivities and control the amplitude pattern, without increasing the size

Figure 9. Geometry for antenna and brightness temperatures.

of the individual elements, is to use multiple single elements to form an *array*. An *array* is really a sampled version of a very large single element. In an array, the mechanical problems of large single elements are traded for the electrical problems associated with the feed networks of arrays. However, with today's solid-state technology, very efficient and low-cost feed networks can be designed.

Arrays are the most versatile antenna systems. They find wide applications not only in many spaceborne systems but in many Earth-bound missions as well. In most cases, the elements of an array are identical; this is not necessary, but it is often more convenient, simpler and more practical. In general, the radiation characteristics of an array depend on many factors, including

1. The geometric configuration of the overall array (linear, circular, rectangular, spherical, etc.)
2. The relative displacement between the elements
3. The excitation amplitude of the individual elements
4. The excitation phase of the individual elements
5. The relative pattern of the individual elements

Therefore the designer has many controls or degrees of freedom that can exercise in order to make the antenna very versatile and meet the specifications of the design.

With arrays, it is practical to not only *synthesize* almost any desired amplitude radiation pattern, but the mainlobe can be scanned, resulting in a *scanning* array, by controlling the relative phase excitation between the elements. This is most convenient for applications where the antenna system is not readily accessible, especially for spaceborne missions. The beamwidth of the mainlobe along with the sidelobe level can be controlled by the relative amplitude excitation (distribution) between the elements of the array. In fact, there is a tradeoff between the beamwidth and the sidelobe level based on the amplitude distribution of the elements [2]. The spacing between the elements can be used to control many characteristics of an array, including the pattern, beamwidth, bandwidth, input impedance, and sidelobe level.

There are a plethora of array designs. Two classic array configurations include the Yagi-Uda and log-periodic arrays [2]. The Yagi-Uda is a popular antenna used by amateur radio enthusiasts and for TV. The log-periodic array, because of its large and attractive bandwidth, is probably the most widely used home TV antenna. Arrays of waveguides, horns, reflectors and microstrips are also very popular [11]. Microstrip arrays will play a key role in the realization of unique designs of adaptive and smart antennas for wireless communications.

Designs of uniform distribution arrays include the broadside, endfire, and scanning arrays. Classic non-uniform distribution arrays include the binomial, Dolph-Tschebyscheff, Woodward-Lawson, Fourier transform, and Taylor (Tschebyscheff error and line source) [2]. There are many other array designs, too numerous to name here. However there are two prominent types of arrays that are outstanding candidates for wireless communications: adaptive arrays and smart antennas [5-7].

In *adaptive antenna arrays* [12,13], the amplitude and phase distribution between the elements are adaptively chosen to improve signal reception or transmission in certain directions and reduce noise and interference in all other directions. Adaptive signal processing algorithms are often used in conjunction with the array architecture to obtain an optimum set of weights that maximizes *signal-to-noise ratio* (SNR) and minimizes *mean-square error* (MSE). In this context, such adaptive arrays are commonly referred to as "smart antennas" [5-7]. In *code-division multiple-access* (CDMA) applications, such as cellular and mobile communications, smart antennas at the base station can form a mainbeam toward the subscriber and low-level sidelobes or ideally nulls toward interfering signals. Through adaptive beamforming, smart antennas can penetrate through buildings and cover areas that are otherwise unattainable by a single-element antenna at the base station. In addition, smart antennas can more effectively alleviate problems due to multipath, fading, and time dispersion. This results in an improved system performance compared to an isotropic antenna. Also, dynamic beamforming in smart antennas enhances antenna gain in the direction of the subscriber, thus extending signal coverage. Coverage enhancement can reduce manufacturing cost in cellular and mobile communications by requiring a smaller number of base stations within a given area.

4. CONCLUSIONS

Antenna engineering has enjoyed a very successful period since the 1940s. Responsible for its success have been the introduction and technological advances of some new elements of radiation, such as aperture antennas, horns, reflectors, frequency-independent antennas, and microstrip/patch antennas. Excitement has been created by the advancement of numerical methods that have been instrumental in analyzing many previously intractable problems. Another major factor in the success of antenna technology has been the advances in the computer architecture and wireless communications. Today antenna engineering is considered a truly fine engineering science.

Although a certain level of maturity has been attained, there are many challenging opportunities and problems to be solved. Unique and innovative adaptive and smart antenna designs for wireless communication are creating new enthusiasm and interest in the exploding wireless communication technology. Phased-array architecture integrating monolithic MIC technology is still a challenging problem. Integration of new materials into antenna technology offers many advantages, and numerical methods will play key roles in their incorporation and system performance. Computational efficiency in numerical methods will allow modeling, design, and optimization of antennas on complex platforms without the need of supercomputing capabilities. Innovating antenna designs to perform complex and demanding system functions always remain a challenge. New basic elements are always welcomed and offer refreshing opportunities.

1. ANTENNAS AND FUNDAMENTAL PARAMETERS

An antenna is used to either transmit or receive electromagnetic waves. It serves as a transducer converting guided waves into free-space waves in the transmitting mode or vice versa in the receiving mode. Antennas or aeri- als can take many forms according to the radiation mechanism involved and can be divided in different categories. Some common types are wire antennas, aperture antennas, reflector antennas, lens antennas, traveling-wave antennas, frequency-independent antennas, horn antennas,

and printed and conformal antennas, [1, pp. 563–572]. When applications require radiation characteristics that cannot be met by a single radiating element, multiple elements are employed. Various configurations are utilized by suitably spacing the elements in one or two dimensions. These configurations, known as *array antennas*, can produce the desired radiation characteristics by appropriately feeding each individual element with different amplitudes and phases that allows a mechanism for increasing the electric size of the antenna. Furthermore, antenna arrays combined with signal processing lead to smart antennas (switched-beam or adaptive antennas) that offer more degrees of freedom in the wireless system design [2]. Moreover, active antenna elements or arrays incorporate solid-state components producing effective integrated antenna transmitters or receivers with many applications [1, pp. 190–209; 2].

Regardless of the antenna considered, certain fundamental figures of merit describe the performance of an antenna. The response of an antenna as a function of direction is given by the antenna pattern. This pattern commonly consists of a number of lobes, where the largest one is called the *mainlobe* and the others are referred to as *sidelobes*, *minorlobes*, or *backlobes*. If the pattern is measured sufficiently far from the antenna so there is no change in the pattern with distance, the pattern is the so called '*far-field pattern*'. Measurements at shorter distances yield '*near-field patterns*', which are a function of both angle and distance. The pattern may be expressed in terms of the field intensity, called *field pattern*, or in terms of the Poynting vector or radiation intensity, which are known as *power patterns*. If the pattern is symmetric, a simple pattern is sufficient to completely specify the variation of the radiation with the angle. Otherwise, a three-dimensional diagram or a contour map is required to show the pattern in its entirety. However, in practice, two patterns perpendicular to each other and perpendicular to the mainlobe axis may suffice. These are called the '*principal-plane*' patterns, the *E* plane and the *H* plane, containing the *E* and *H* field vectors, respectively. Having established the radiation patterns of an antenna, some important parameters can now be considered such as radiated power, radiation efficiency, directivity, gain, and antenna polarization. All of them are considered in detail in this article.

Here, scalar quantities are presented in italics, while vector quantities are in boldface, for example, electric field ***E*** (vector) of $E(=|\mathbf{E}|)$ (scalar). Unit vectors are boldface with a circumflex over the letter; $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, $\hat{\mathbf{z}}$, and $\hat{\mathbf{r}}$ are the unit vectors in *x*, *y*, *z*, and *r* directions, respectively. A dot over the symbol means that the quantity is harmonically time-varying or a phasor. For example, taking the electric field, $\dot{\mathbf{E}}$ represents a space vector and time phasor, but \dot{E}_x is a scalar phasor. The relations between them are $\dot{\mathbf{E}} = \hat{\mathbf{x}}\dot{E}_x$ where $\dot{E}_x = E_1 e^{j\omega t}$.

The first section of this article introduces several antenna patterns, giving the necessary definitions and presenting the common types. The field regions of an antenna are also pointed out. The most common reference antennas are the ideal isotropic radiator and the very short dipole. Their fields are used to show the calculation

1. ANTENNAS AND FUNDAMENTAL PARAMETERS

An antenna is used to either transmit or receive electromagnetic waves. It serves as a transducer converting guided waves into free-space waves in the transmitting mode or vice versa in the receiving mode. Antennas or aerials can take many forms according to the radiation mechanism involved and can be divided in different categories. Some common types are wire antennas, aperture antennas, reflector antennas, lens antennas, traveling-wave antennas, frequency-independent antennas, horn antennas,

and printed and conformal antennas, [1, pp. 563–572]. When applications require radiation characteristics that cannot be met by a single radiating element, multiple elements are employed. Various configurations are utilized by suitably spacing the elements in one or two dimensions. These configurations, known as *array antennas*, can produce the desired radiation characteristics by appropriately feeding each individual element with different amplitudes and phases that allows a mechanism for increasing the electric size of the antenna. Furthermore, antenna arrays combined with signal processing lead to smart antennas (switched-beam or adaptive antennas) that offer more degrees of freedom in the wireless system design [2]. Moreover, active antenna elements or arrays incorporate solid-state components producing effective integrated antenna transmitters or receivers with many applications [1, pp. 190–209; 2].

Regardless of the antenna considered, certain fundamental figures of merit describe the performance of an antenna. The response of an antenna as a function of direction is given by the antenna pattern. This pattern commonly consists of a number of lobes, where the largest one is called the *mainlobe* and the others are referred to as *sidelobes*, *minorlobes*, or *backlobes*. If the pattern is measured sufficiently far from the antenna so there is no change in the pattern with distance, the pattern is the so called '*far-field pattern*'. Measurements at shorter distances yield '*near-field patterns*', which are a function of both angle and distance. The pattern may be expressed in terms of the field intensity, called *field pattern*, or in terms of the Poynting vector or radiation intensity, which are known as *power patterns*. If the pattern is symmetric, a simple pattern is sufficient to completely specify the variation of the radiation with the angle. Otherwise, a three-dimensional diagram or a contour map is required to show the pattern in its entirety. However, in practice, two patterns perpendicular to each other and perpendicular to the mainlobe axis may suffice. These are called the '*principal-plane*' patterns, the *E* plane and the *H* plane, containing the *E* and *H* field vectors, respectively. Having established the radiation patterns of an antenna, some important parameters can now be considered such as radiated power, radiation efficiency, directivity, gain, and antenna polarization. All of them are considered in detail in this article.

Here, scalar quantities are presented in italics, while vector quantities are in boldface, for example, electric field \mathbf{E} (vector) of $E (= |\mathbf{E}|)$ (scalar). Unit vectors are boldface with a circumflex over the letter; $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, $\hat{\mathbf{z}}$, and $\hat{\mathbf{r}}$ are the unit vectors in *x*, *y*, *z*, and *r* directions, respectively. A dot over the symbol means that the quantity is harmonically time-varying or a phasor. For example, taking the electric field, $\dot{\mathbf{E}}$ represents a space vector and time phasor, but \dot{E}_x is a scalar phasor. The relations between them are $\dot{\mathbf{E}} = \hat{\mathbf{x}}\dot{E}_x$ where $\dot{E}_x = E_1 e^{j\omega t}$.

The first section of this article introduces several antenna patterns, giving the necessary definitions and presenting the common types. The field regions of an antenna are also pointed out. The most common reference antennas are the ideal isotropic radiator and the very short dipole. Their fields are used to show the calculation

and meaning of the different parameters of antennas covered in this article. The second section begins with a treatment of the Poynting vector and radiation power density, starting from the general case of an electromagnetic wave and extending the definitions to a radiating antenna. After this, radiation performance measures such that the beam solid angle, directivity, and gain of an antenna are defined. In the third section the concepts of wave and antenna polarization are discussed. Finally, in the fourth section, a general case of antenna pattern calculation is considered, and numerical solutions are suggested for radiation patterns that are not available in simple closed-form expressions.

2. RADIATION FROM ANTENNAS

2.1. Radiation Patterns

The radiation pattern of an antenna is, generally, its most basic requirement since it determines the spatial distribution of the radiated energy. This is usually the first property of an antenna that is specified, once the operating frequency has been stated. An *antenna radiation pattern* or *antenna pattern* is defined as a graphical representation of the radiation properties of the antenna as a function of space coordinates. Since antennas are commonly used as parts of wireless telecommunication systems, the radiation pattern is determined in the far-field region where no change in pattern with distance occurs. Using a spherical coordinate system, shown in Fig. 1, where the antenna is at the origin, the radiation properties of the antenna depend only on the angles ϕ and θ along a path or surface of constant radius. A trace of the radiated or received power at a constant radius is called a *power pattern*, while the spatial variation of the electric or magnetic field along a constant radius is called an *amplitude field pattern*. In practice, the necessary information from the complete three-dimensional pattern of an antenna can be received by taking a few two-dimensional patterns, according to the complexity of radiation pattern of the specific antenna. Usually, for most applications, a number of plots of the pattern as a function of θ for some particular values of ϕ , plus a few plots as a function of ϕ for some particular values of θ , give the needed information.

Antennas usually behave as reciprocal devices. This is very important since it permits the characterization of the antenna as either a transmitting or receiving antenna. For example, radiation patterns are often measured with the test antenna operating in the receive mode. If the antenna is reciprocal, the measured pattern is identical when the antenna is in either a transmit or a receive mode. If non-reciprocal materials, such as ferrites and active devices, are not present in an antenna, its transmitting and receiving properties are identical.

The radiation fields from a transmitting antenna vary inversely with distance, while the variation with observation angles (ϕ , θ) depends on the antenna type. A very simple but basic configuration antenna is the ideal or very short dipole antenna. Since any linear or curved wire antenna may be regarded, as being composed of a number of short dipoles connected in series, the knowledge of this antenna is

Figure 1. Spherical coordinate system for antenna analysis purposes. A very short dipole is shown with its no-zero field component directions.

useful. So, we will use the fields radiated from an ideal antenna to define and understand the radiation pattern properties. An ideal dipole positioned symmetrically, at the origin of the coordinate system and oriented along the z axis, is shown in Fig. 1. The pattern of electromagnetic fields, with wavelength λ , around a very short wire antenna of length $L \ll \lambda$, carrying a uniform current $I_0 e^{j\omega t}$, is described by functions of distance, frequency, and angle. Table 1 summarizes the expressions for the fields from a very short dipole antenna as [3,4] $E_\phi = H_r = H_\theta = 0$ for $r \gg \lambda$ and $L \ll \lambda$. The variables shown in these relations are as follows: I_0 = amplitude (peak value in time) of current (A), assumed to be constant along the dipole; L = length of dipole (m); $\omega = 2\pi f$ = radian frequency, where f is the frequency in Hz; t = time (s); $\beta = 2\pi/\lambda$ = phase constant (rad/m); θ = azimuthal angle (dimensionless); c = velocity of light $\approx 3 \times 10^8$ m/s; λ = wavelength (m); j = complex operator = $\sqrt{-1}$; r = distance from center of dipole to observation point (m); and ϵ_0 = permittivity of free space = 8.85 pF/m.

It is to be noted that E_θ and H_ϕ are in time phase in the far field. Thus, electric and magnetic fields in the far field of the spherical wave from the dipole are related in the same manner as in a plane traveling wave. Both are also proportional to $\sin \theta$; that is, both are maximum when $\theta = 90^\circ$ and minimum when $\theta = 0^\circ$ (in the direction of the dipole axis). This variation of E_θ or H_ϕ with angle can be presented by a *field pattern* (shown in Fig. 2), where the length r of the radius vector is proportional to the value of the far field (E_θ or H_ϕ) in that direction from the dipole. The pattern in Fig. 2a is the three-dimensional far-field pattern for the ideal dipole, while the patterns in Figs. 2b and 2c are two-dimensional and represent cross sections of the three-dimensional pattern, showing the dependence of the fields with respect to angles θ and ϕ .

All far-field components of a very short dipole are functions of I_0 , the dipole current; L/λ , the dipole length in terms of wavelengths; $1/r$, the distance factor; $j e^{j(\omega t - \beta r)}$, the phase factor; and $\sin \theta$, the pattern factor that gives the variation of the field with angle. In general, the expression for the field of any antenna will involve these factors.

Table 1. Fields of an Ideal or Very Short Dipole

Component	General Expression for All regions	Far Field Only
E_r	$\frac{I_0 L e^{j(\omega t - \beta r)} \cos \theta}{j\omega\epsilon_0 4\pi r} \left(\frac{2j\beta}{r} + \frac{2}{r^2} \right)$	0
E_θ	$-\frac{I_0 L e^{j(\omega t - \beta r)} \sin \theta}{j\omega\epsilon_0 4\pi r} \left(\beta^2 - \frac{j\beta}{r} - \frac{1}{r^2} \right)$	$\frac{j(L/\lambda) I_0 e^{j(\omega t - \beta r)} \sin \theta}{2\epsilon_0 c r}$
H_ϕ	$\frac{I_0 L e^{j(\omega t - \beta r)} \sin \theta}{4\pi r} \left(j\beta + \frac{1}{r} \right)$	$\frac{j(L/\lambda) I_0 e^{j(\omega t - \beta r)} \sin \theta}{2r}$

For longer antennas with complicated current distribution, the field components generally are functions of the terms defined above, which are grouped and designated as the *element factor* and the *space factor*. The element factor includes everything except the current distribution along the source, which is the space factor of the antenna. If, for example, we consider the case of a finite dipole antenna, we can produce the field expressions by dividing the antenna into a number of very short dipoles and summing all the contributions. The element factor is equal to the field of the very short dipole located at a reference point, while the space factor is a function of the current distribution along the source, the latter usually described by an integral. The total field of the antenna is taken by the product of the element and space factors. This procedure is known as *pattern multiplication*.

A similar procedure is used in array antennas, which are used when it is necessary to design antennas with directive characteristics. The increased electrical size of an array antenna due to the use of more than one radiating

elements gives better directivity and special radiation patterns. The total field of an array is determined by the product of *the field of a single element* and *the array factor* of the array antenna. If we use isotropic radiating elements, the pattern of the array is simply the pattern of the array factor. The array factor is a function of the geometry of the array and the excitation phase. Thus, changing the number of elements, their geometric arrangement, their relative magnitudes, their relative phases, and their spacing, we take different patterns. Figure 3 shows some cases of characteristic patterns of an array antenna with two isotropic point sources as radiating elements, by using different values of the above mentioned quantities, which produce different array factors.

2.2. Common Types of Radiation Patterns

An *isotropic source* or *radiator* is an ideal antenna that radiates uniformly in all directions in space. Although no practical source has this property, the concept of the iso-

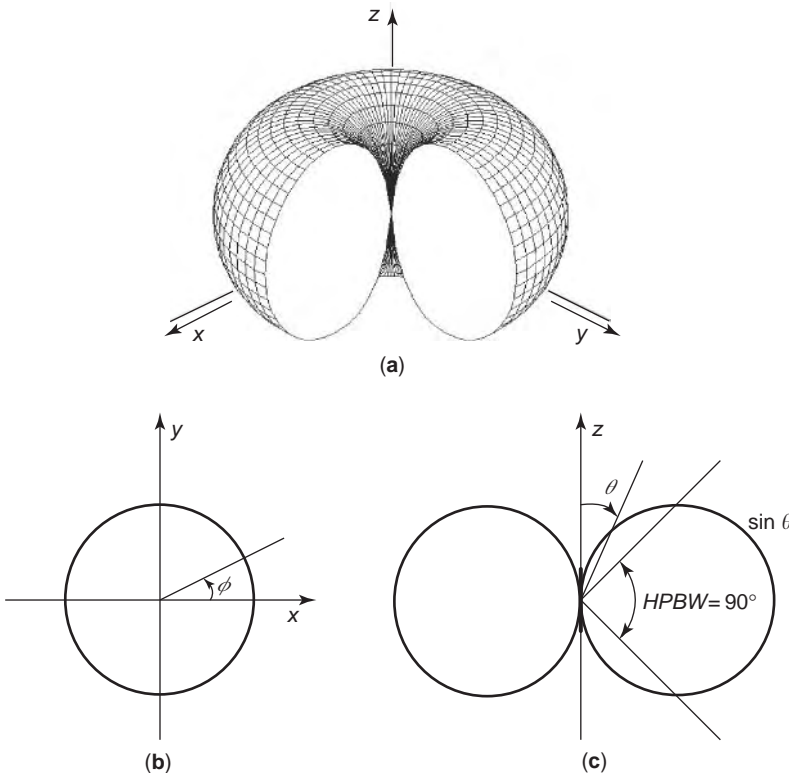

Figure 2. Radiation field pattern of far field from an ideal or very short dipole: (a) three-dimensional pattern plot; (b) E -plane radiation pattern polar plot; (c) H -plane radiation pattern polar plot.

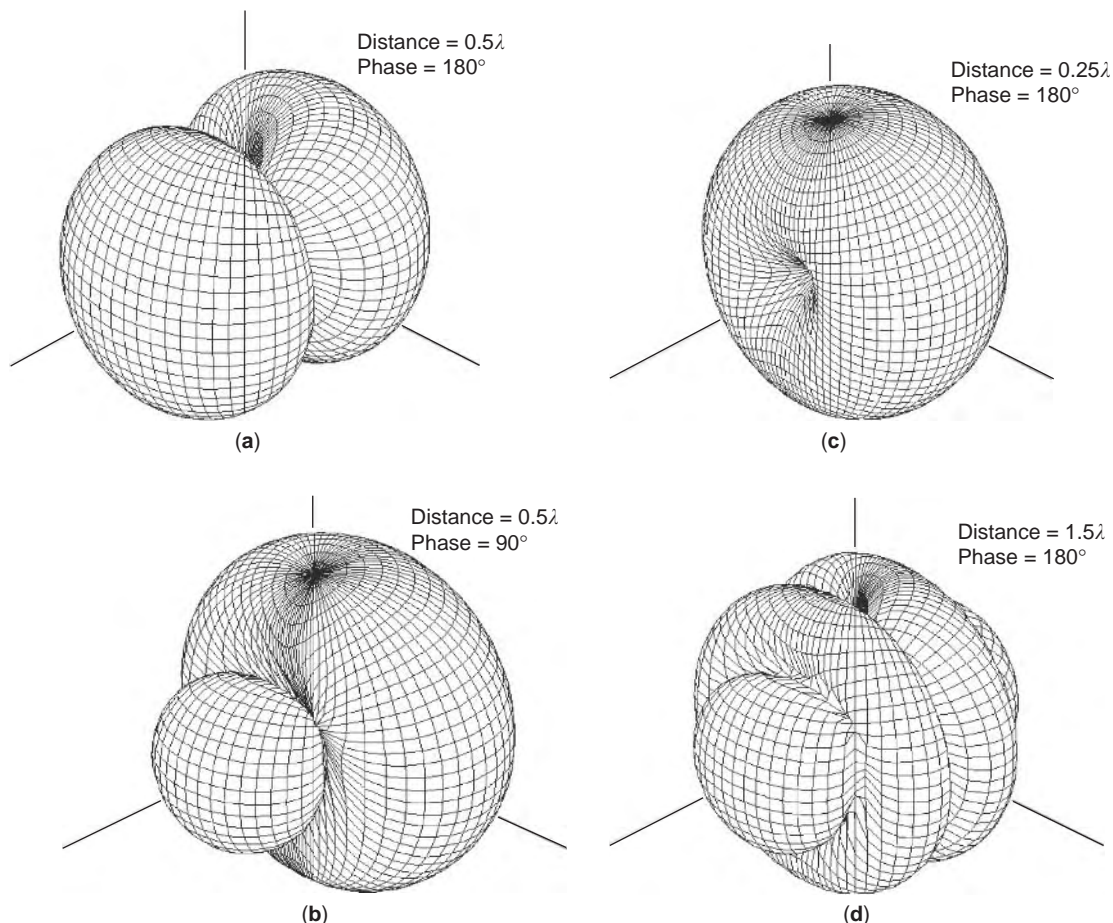

Figure 3. Three-dimensional graphs of power radiation patterns for an array of two isotropic elements of the same amplitude and (a) opposite phase, spaced 0.5λ apart; (b) phase quadrature, spaced 0.5λ apart; (c) opposite phase, spaced 0.25λ apart; and (d) opposite phase, spaced 1.5λ , apart.

tropic radiator is very useful and is often used as a reference for expressing the directive properties of actual antennas. It is worth recalling that the power flux density S at a distance r from an isotropic radiator is $P_t/4\pi r^2$, where P_t is the transmitted power, since all the transmitted power is evenly distributed on the surface of a spherical wavefront with radius r . The electric field intensity is calculated as $\sqrt{30P_t}/r$ (using the relation from electric circuits, power = E^2/η , where η = the characteristic impedance of free space = $377\ \Omega$).

On the contrary, a *directional* antenna is one that radiates or receives electromagnetic waves more effectively in some directions than in others. An example of an antenna with a directional radiation pattern is that of an ideal or very short dipole, shown in Fig. 2. It is seen that this pattern, which resembles a doughnut with no hole, is nondirectional in the azimuth plane, which is the xy plane characterized by the set of relations [$f(\phi)$, $\theta = \pi/2$], and directional in the elevation plane, which is any orthogonal plane containing the z axis characterized by [$g(\theta)$, $\phi = \text{constant}$]. This type of directional pattern is designated as an *omnidirectional pattern* and is defined as one having an essentially nondirectional pattern in a given plane, which for this case is the azimuth plane and a directional

pattern in any orthogonal plane, in this case the elevation plane. The omnidirectional pattern—also known as broadcast-type—is used for many broadcast or communications services where all directions are to be covered equally well. The horizontal-plane pattern is generally circular, while the vertical-plane pattern may have some directivity in order to increase the gain.

Other forms of directional patterns are pencil-beam, fan-beam, and shaped-beam patterns. The *pencil-beam pattern* is a highly directional pattern that is used to obtain maximum gain and when the radiation pattern is to be concentrated in as narrow an angular sector as possible. The beamwidths in the two principal planes are essentially equal. The *fan-beam pattern* is similar to the pencil-beam pattern except that the beam cross section is elliptical in shape rather than circular. The beamwidth in one plane may be considerably broader than the beamwidth in the other plane. As with the pencil-beam pattern, the fan-beam pattern generally implies a rather substantial amount of gain. The *shaped-beam pattern* is used when the pattern in one of the principal planes must preferably have a specified type of coverage. A typical example is the cosecant type of pattern, which is used to provide a constant radar return over a range of angles in the

Figure 4. Polar plots of a linear uniform amplitude array of five isotropic sources with 0.5λ spacing between the sources: (a) broadside radiation pattern (0° phase shift between successive elements); (b) endfire radiation pattern (180° phase shift).

vertical plane. The pattern in the other principal plane is usually a pencil-beam pattern but may sometimes be a circular pattern as in certain types of beacon antennas. In addition to these pattern types, there are a number of pattern shapes used for direction finding and other purposes that do not fall under the categories already mentioned. These patterns include the well-known figure-of-eight pattern, the cardioid pattern, split-beam patterns, and multilobed patterns whose lobes are of substantially equal amplitude. For those patterns, which have particularly unusual characteristics, it is generally necessary to specify the pattern by an actual plot of its shape or by the mathematical relationship that describes its shape.

Antennas are often referred to by the type of pattern they produce. Two terms that usually characterize array antennas, are broadside and endfire. A *broadside antenna* is one for which the mainbeam maximum is in a direction normal to the plane containing the antenna. An *endfire antenna* is one for which the mainbeam is in the plane containing the antenna. For example, the short dipole antenna is a broadside antenna. Figure 4 shows the two cases of broadside and endfire radiation patterns, which are produced from a linear uniform array of isotropic sources of 0.5 wavelength spacing, between adjacent elements. The type of radiation pattern is controlled by the choice of phase shift angle between the elements. Zero phase shift produces a broadside pattern and 180° phase shift leads to an endfire pattern, while intermediate values produce radiation patterns with the mainlobes between these two cases.

2.3. Characteristics of Simple Patterns

For a linearly polarized antenna, as a very short dipole antenna, performance is often described in terms of two patterns (Figs. 2b and 2c). Any plane containing the z -axis has the same radiation pattern since there is no variation in the fields with angle ϕ (Fig. 2b). A pattern taken in one of these planes is called an *E-plane pattern* because it is parallel to the electric field vector \mathbf{E} and passes through the antenna in the direction of the beam maximum. A

Figure 5. The principal plane patterns of a microstrip antenna: (a) the xy plane or *E*-plane (azimuth plane, $\theta = \pi/2$) and (b) the xz plane or *H* plane (elevation plane, $\phi = 0$).

pattern taken in a plane orthogonal to an *E* plane and cutting through the short dipole antenna, the xy plane in this case, is called an *H-plane pattern* because it contains the magnetic field H and also passes through the antenna in the direction of the beam maximum (Fig. 2c). The *E*- and *H*-plane patterns, in general, are referred to as the *principal-plane patterns*. The pattern plots in Figs. 2b and 2c are called *polar patterns* or *polar diagrams*. For most types of antennas it is a usual practice to orient them so that at least one of the principal-plane patterns coincides with one of the geometric principal planes. This is illustrated in Fig. 5, where the principal planes of a microstrip antenna are plotted. The xy plane (azimuthal plane, $\theta = \pi/2$) is the principal *E* plane, and the xz plane (elevation plane, $\phi = 0$) is the principal *H* plane.

A typical antenna power pattern is shown in Fig. 6. In Fig. 6a depicts a polar plot in linear scale; Fig. 6b shows the same pattern in rectangular coordinates in decibels. As can be seen, the radiation pattern of the antenna consists of various parts, which are known as *lobes*. The *mainlobe* (or *mainbeam* or *major lobe*) is defined as the lobe containing the direction of maximum radiation. In Fig. 6a the mainlobe is pointing in the $\theta = 0$ direction. In some antennas there may exist more than one major lobe. A *minor lobe* is any lobe except the mainlobe. Minor lobes are composed of sidelobes and backlobes. The term *sidelobe* is sometimes reserved for those minor lobes near the mainlobe but is most often taken to be synonymous with minor lobe. A *backlobe* is a radiation lobe in, approximately, the opposite direction to the mainlobe. Minor lobes usually represent radiation in undesired directions, and they should be minimized. Sidelobes are normally the largest of the minor lobes. The level of side or minor lobes is usually expressed as a ratio of the power density in the lobe in question to that of the mainlobe. This ratio is often termed the *sidelobe ratio* or *sidelobe level*, and desired values depend on the antenna application.

For antennas with simple shape patterns, the half-power beamwidth and sidelobe level in the two principal planes specify the important characteristics of the

Figure 6. Antenna power patterns: (a) a typical polar plot in linear scale; (b) a plot in rectangular coordinates in decibel (logarithmic) scale. The associated lobes and beamwidths are also shown.

patterns. The *half-power beamwidth* (HPBW) is defined in a plane containing the major maximum beam, as the angular width within which the radiation intensity is one-half the maximum value of the beam. The *beamwidth between first nulls* (BWFN) or beamwidths 10 or 20 dB below the pattern maximum are also sometimes used. Both of them are shown in Fig. 6. However, the term *beamwidth* by itself is usually reserved to describe the 3-dB beamwidth. The beamwidth of the antenna is a very important figure of merit in the overall design of an antenna application. As the beamwidth of the radiation pattern increases, the sidelobe level decreases, and vice versa. So there is a tradeoff between sidelobe ratio and beamwidth of a pattern.

The beamwidth of the antenna is also used to describe the resolution capabilities of the antenna to distinguish between two adjacent radiating sources or radar targets. The most common resolution criterion states that the resolution capability of an antenna to distinguish between two sources is equal to half the first null beamwidth, which is generally used to approximate the half-power beamwidth. This means that two sources separated by angular distances equal to or greater than the HPBW of an antenna, with a uniform distribution, can be resolved. If the separation is smaller, then the antenna will tend to smooth the angular separation distance.

2.4. Field Regions of an Antenna

For convenience, the space surrounding a transmitting antenna is divided into several regions, although, obviously, the boundaries of the regions cannot be sharply defined. The names given to the various regions denote some pertinent prominent property of each region.

In free space there are mainly two regions surrounding a transmitting antenna: the *near-field region* and the *far-field region*. The near-field region can be subdivided into two regions, the *reactive near field* and the *radiating near field*.

The first and innermost region, which is immediately adjacent to the antenna, is called the *reactive or induction near-field region*. Of all the regions, it is the smallest in coverage and derives its name from the reactive field, which lies close to every current-carrying conductor. In this region the reactive field, which decreases with either the square or the cube of the distance, dominates over all radiated fields, the components of which decrease with the first power of distance. For most antennas, the outer boundary of this region is taken to extend to a distance $r < 0.62\sqrt{D^3/\lambda}$ from the antenna as long as $D \gg \lambda$, where D is the largest dimension of the antenna and λ is the wavelength [3]. For the case of an ideal or very short dipole, for which $D = \Delta z \ll \lambda$, this distance is approximately one-sixth of a wavelength ($\lambda/2\pi$). At this distance from the very short dipole the reactive and radiation field components are individually equal in magnitude.

Between the reactive near-field and far-field regions lies the *radiating near-field region*, where the radiation fields dominate but the angular field distribution still depends on the distance from the antenna. For an antenna focused at infinity, which means that the rays at a long distance from the transmitting antenna are parallel, the radiating near-field region is sometimes referred to as the *Fresnel region*, a term taken from the fields of optics. The boundaries of this region are taken to be between the end of the reactive near-field region, $0.62\sqrt{D^3/\lambda}$, and the starting distance of the far-field region, $r < 2D^2/\lambda$ [3].

The outer boundary of the near-field region lies where the reactive field intensity becomes negligible with respect to the radiation field intensity. This occurs at distances of either a few wavelengths or a few times the major dimension of the antenna, whichever is larger. The *far-field or radiation region* begins at the outer boundary of the near-field region and extends outward indefinitely into free

Figure 7. Field regions of an antenna and some commonly used boundaries.

space. In this region the angular field distribution of the field of the antenna is essentially independent of the distance from the antenna. For example, for the case of a very short dipole, the $\sin\theta$ pattern dependence is valid anywhere in this region. The far-field region is commonly taken to exist at distances $r > 2D^2/\lambda$ from the antenna, and for an antenna focused at infinity it is sometimes referred to as the *Fraunhofer region*. All three regions surrounding an antenna and their boundaries are illustrated in Fig. 7.

3. ANTENNA PERFORMANCE MEASURES

3.1. Poynting Vector and Radiation Power Density

In an electromagnetic wave, electric and magnetic energies are stored in equal amounts in the electric and magnetic fields, which together constitute the wave. The power flow is found by making use of the Poynting vector \mathbf{S} , defined as

$$\mathbf{S} = \mathbf{E} \times \mathbf{H} \quad (1)$$

where \mathbf{E} (V/m) and \mathbf{H} (A/m) are the field vectors. Since the Poynting vector represents a surface power density (W/m^2), the integral of its normal component over a closed surface always gives the total power through the surface

$$\oint_A \mathbf{S} \cdot d\mathbf{A} = P \quad (2)$$

where P is the total power (W) flowing out of closed surface A and $d\mathbf{A} = \hat{\mathbf{n}}dA$, where $\hat{\mathbf{n}}$ is the unit vector normal to the surface. The Poynting vector \mathbf{S} and the power P in the relations above are instantaneous values.

Normally, it is the time-averaged Poynting vector \mathbf{S}_{av} , which represents the average power density, that is of

practical interest, and is given by

$$\mathbf{S}_{\text{av}} = \frac{1}{2} \text{Re}(\dot{\mathbf{E}} \times \dot{\mathbf{H}}^*) \quad (\text{W/m}^2) \quad (3)$$

where the term Re stands for the real part of the complex number and the asterisk $*$ denotes the complex conjugate. Note that $\dot{\mathbf{E}}$ and $\dot{\mathbf{H}}$ in Eq. (3) are respectively the expressions for the electric and magnetic fields written as complex numbers to include the change with time. Thus, for a plane wave traveling in the positive z direction with electric and magnetic field components in x and y directions, respectively, the electric field is $\mathbf{E} = \hat{\mathbf{x}}E_x e^{j\omega t}$, while in Eq. (1) it is $\mathbf{E} = \hat{\mathbf{x}}E_{x0}$. The $\frac{1}{2}$ factor appears because the fields represent peak values and should be omitted for RMS (root-mean-square) values.

The average power P_{av} flowing outward through a closed surface can now be obtained by integrating Eq. (3):

$$P_{\text{av}} = \oint_A \text{Re} \dot{\mathbf{S}} \cdot d\mathbf{A} = \frac{1}{2} \oint_A \text{Re}(\dot{\mathbf{E}} \times \dot{\mathbf{H}}^*) \cdot d\mathbf{A} = P_{\text{rad}} \quad (\text{W}) \quad (4)$$

Consider the case where the electromagnetic wave is radiated by an antenna. If the closed surface is taken around the antenna within the far-field region, then this integration results in the average power radiated by the antenna. This is called *radiation power* P_{rad} , while Eq. (3) represents the *radiation power density* S_{av} of the antenna. The imaginary part of Eq. (3) represents the reactive power density stored in the near field of an antenna. Since the electromagnetic fields of an antenna in its far-field region are predominately real, Eq. (3) suffices for our purposes.

The average power density radiated by the antenna as a function of direction, taken on a large sphere of constant radius in the far-field region, results in the *power pattern*

of the antenna. As an example, for an isotropic radiator, the total radiation power is given by

$$P_{\text{rad}} = \iint_A \mathbf{S}_i \cdot d\mathbf{A} = \int_0^{2\pi} \int_0^\pi [\hat{\mathbf{r}}\mathbf{S}_i(r)] \cdot [\hat{\mathbf{r}}r^2 \sin\theta \, d\theta \, d\phi] \quad (5)$$

$$= 4\pi r^2 S_i$$

where, because of symmetry, the Poynting vector $\mathbf{S}_i = \hat{\mathbf{r}}S_i(r)$ is taken independent of the spherical coordinate angles θ and ϕ , having only a radial component.

From Eq. (5) the power density can be found:

$$\mathbf{S}_i = \hat{\mathbf{r}}S_i = \hat{\mathbf{r}} \left(\frac{P_{\text{rad}}}{4\pi r^2} \right) \quad (\text{W/m}^2) \quad (6)$$

This result can also be reached if we assume that the radiated power expands radially in all directions with the same velocity and is evenly distributed on the surface of a spherical wavefront of radius r .

As we will see later, an electromagnetic wave may have an electric field consisting of two orthogonal linear components of different amplitudes, E_{x0} and E_{y0} , respectively, and a phase angle between them δ . Thus, the total electric field vector, called an *elliptically polarized vector*, becomes

$$\dot{\mathbf{E}} = \hat{\mathbf{x}}\dot{E}_x + \hat{\mathbf{y}}\dot{E}_y = \hat{\mathbf{x}}E_{x0}e^{j(\omega t - \beta z)} + \hat{\mathbf{y}}E_{y0}e^{j(\omega t - \beta z + \delta)} \quad (7)$$

which at $z = 0$ becomes

$$\dot{\mathbf{E}} = \hat{\mathbf{x}}\dot{E}_x + \hat{\mathbf{y}}\dot{E}_y = \hat{\mathbf{x}}E_{x0}e^{j\omega t} + \hat{\mathbf{y}}E_{y0}e^{j(\omega t + \delta)} \quad (8)$$

So $\dot{\mathbf{E}}$ is a complex vector (phasor vector) that is resolvable into two components $\hat{\mathbf{x}}\dot{E}_x$ and $\hat{\mathbf{y}}\dot{E}_y$. The total $\dot{\mathbf{H}}$ field vector associated with $\dot{\mathbf{E}}$ at $z = 0$ is then

$$\dot{\mathbf{H}} = \hat{\mathbf{y}}\dot{H}_y - \hat{\mathbf{x}}\dot{H}_x = \hat{\mathbf{y}}H_{y0}e^{j(\omega t - \zeta)} - \hat{\mathbf{x}}H_{x0}e^{j(\omega t + \delta - \zeta)} \quad (9)$$

where ζ is the phase lag of \dot{H}_y with respect to \dot{E}_x . From Eq. (9) the complex conjugate magnetic field can be found changing only the sign of exponents.

Now the average Poynting vector can be calculated using the fields defined above:

$$\begin{aligned} \mathbf{S}_{\text{av}} &= \frac{1}{2} \text{Re}[(\hat{\mathbf{x}} \times \hat{\mathbf{y}})\dot{E}_x\dot{H}_y^* - (\hat{\mathbf{y}} \times \hat{\mathbf{x}})\dot{E}_y\dot{H}_x^*] \\ &= \frac{1}{2} \hat{\mathbf{z}} \text{Re}(\dot{E}_x\dot{H}_y^* + \dot{E}_y\dot{H}_x^*) \\ &= \frac{1}{2} \hat{\mathbf{z}} \text{Re}(E_{x0}H_{y0} + E_{y0}H_{x0}) \cos \zeta \end{aligned} \quad (10)$$

It should be noted that \mathbf{S}_{av} is independent of δ , the phase angle between the electric field components.

In a lossless medium, $\zeta = 0$, because electric and magnetic fields are in time phase and $E_{x0}/H_{x0} = E_{y0}/H_{y0} = \eta$, where η , is the intrinsic impedance of the medium that is real. If $\mathbf{E} = \sqrt{E_{x0}^2 + E_{y0}^2}$ and $\mathbf{H} = \sqrt{H_{x0}^2 + H_{y0}^2}$ are the amplitudes of the total \mathbf{E} and \mathbf{H} fields, respectively, then

$$\begin{aligned} \mathbf{S}_{\text{av}} &= \frac{1}{2} \hat{\mathbf{z}} \frac{E_{x0}^2 + E_{y0}^2}{\eta} = \frac{1}{2} \hat{\mathbf{z}} \frac{E^2}{\eta} \\ &= \frac{1}{2} \hat{\mathbf{z}} (H_{x0}^2 + H_{y0}^2) \eta = \frac{1}{2} \hat{\mathbf{z}} H^2 \eta \end{aligned} \quad (11)$$

These expressions are the most general form of radiation power density of an elliptically polarized wave or of an elliptically polarized antenna, respectively, and hold for all cases, including the linear and circular polarization cases, which will introduce later on.

3.2. Radiation Intensity

Radiation intensity is a far-field parameter, in terms of which any antenna radiation power pattern can be determined. Thus, the antenna power pattern, as a function of angle, can be expressed in terms of its radiation intensity as [3]:

$$\begin{aligned} U(\theta, \phi) &= S_{\text{av}} r^2 \\ &= \frac{r^2}{2\eta} |\mathbf{E}(r, \theta, \phi)|^2 \\ &= \frac{r^2}{2\eta} [|\mathbf{E}_\theta(r, \theta, \phi)|^2 + |\mathbf{E}_\phi(r, \theta, \phi)|^2] \\ &\approx \frac{1}{2\eta} [|\mathbf{E}_\theta(\theta, \phi)|^2 + |\mathbf{E}_\phi(\theta, \phi)|^2] \end{aligned} \quad (12)$$

where

$$\begin{aligned} U(\theta, \phi) &= \text{radiation intensity (W/unit solid angle)} \\ S_{\text{av}} &= \text{radiation density or radial component of Poynting vector (W/m}^2\text{)} \\ \mathbf{E}(r, \theta, \phi) &= \text{total transverse electric field (V/m)} \\ \mathbf{H}(r, \theta, \phi) &= \text{total transverse magnetic field (A/m)} \\ r &= \text{distance from antenna to point of measurement (m)} \\ \eta &= \text{intrinsic impedance of medium (\Omega per square)} \end{aligned}$$

In Eq. (12) the electric and magnetic field are expressed in terms of spherical coordinates.

What makes radiation intensity important is that it is independent of distance. This is because in the far field the Poynting vector is entirely radial, which means that the fields are entirely transverse and E and H vary as $1/r$.

Since the radiation intensity is a function of angle, it can also be defined as the power radiated from an antenna per unit solid angle. The measure of a solid angle is the steradian. One *steradian* is described as the solid angle with its vertex at the center of a sphere that has radius r , which is subtended by a spherical surface area equivalent to that of a square of size r^2 . But the area of a sphere of radius r is given by $A = 4\pi r^2$, so in a closed sphere there are $4\pi r^2/r^2 = 4\pi$ sr. For a sphere of radius r , an infinitesimal area dA on its surface can be written as

$$dA = r^2 \sin\theta \, d\theta \, d\phi \quad (\text{m}^2) \quad (13)$$

and therefore the element of solid angle $d\Omega$ of a sphere is given by

$$d\Omega = \frac{dA}{r^2} = \sin\theta \, d\theta \, d\phi \quad (\text{sr}) \quad (14)$$

Thus, the total power can be obtained by integrating the radiation intensity, as given by Eq. (12), over the entire

solid angle of 4π , as

$$P_{\text{rad}} = \oint_{\Omega} U(\theta, \phi) d\Omega = \int_0^{2\pi} \int_0^{\pi} U(\theta, \phi) \sin \theta d\theta d\phi \quad (15)$$

As an example, for the isotropic radiator ideal antenna, the radiation intensity $U(\theta, \phi)$ will be independent of the angles θ and ϕ and the total radiated power will be

$$\begin{aligned} P_{\text{rad}} &= \oint_{\Omega} U_i d\Omega = U_i \int_0^{2\pi} \int_0^{\pi} \sin \theta d\theta d\phi \\ &= U_i \oint_{\Omega} d\Omega = 4\pi U_i \end{aligned} \quad (16)$$

or $U_i = P_{\text{rad}}/4\pi$, which is the power density of Eq. (6) multiplied by r^2 .

Dividing $U(\theta, \phi)$ by its maximum value $U_{\text{max}}(\theta, \phi)$, we obtain the *normalized antenna power pattern*:

$$U_n(\theta, \phi) = \frac{U(\theta, \phi)}{U_{\text{max}}(\theta, \phi)} \quad (\text{dimensionless}) \quad (17)$$

A term associated with the normalized power pattern is the beam solid angle. The *beam solid angle* Ω_A is defined as the angle through which all the power from a radiating antenna would flow if the power per unit solid angle were constant over this angle and equal to its maximum value (Fig. 8). This means that, for typical patterns, the solid beam angle is approximately equal to the half-power beam width (HPBW):

$$\Omega_A = \int_0^{2\pi} \int_0^{\pi} U_n(\theta, \phi) \sin \theta d\theta d\phi = \oint_{4\pi} U_n(\theta, \phi) d\Omega \quad (\text{sr}) \quad (18)$$

If the integration is done over the mainlobe, the *mainlobe solid angle*, Ω_M , is defined, and the difference of $\Omega_A - \Omega_M$

Figure 8. Power pattern and beam solid angle of an antenna.

gives the *minor-lobe solid angle*. These definitions hold for patterns with clearly defined lobes. The *beam efficiency* (BE) of an antenna is defined as the ratio of Ω_M/Ω_A and is a measure of the amount of power in the major lobe compared to the total power. A high beam efficiency means that most of the power is concentrated in the major lobe and that minor lobes are minimized.

3.3. Directivity and Gain

A very important antenna parameter that indicates how well an antenna concentrates power into a limited solid angle is its *directivity* D . The *directivity* of an antenna is defined as the ratio of the maximum radiation intensity to the radiation intensity averaged over all directions. The average radiation intensity is calculated by dividing the total power radiated by 4π sr. Hence

$$\begin{aligned} D &= \frac{U_{\text{max}}(\theta, \phi)}{U_{\text{av}}} = \frac{U_{\text{max}}(\theta, \phi)}{U_i} = \frac{U_{\text{max}}(\theta, \phi)}{P_{\text{rad}}/4\pi} \\ &= \frac{4\pi U_{\text{max}}(\theta, \phi)}{P_{\text{rad}}} \quad (\text{dimensionless}) \end{aligned} \quad (19)$$

since from Eq. (16), $P_{\text{rad}}/4\pi = U_i$. So, alternatively, the directivity of an antenna can be defined as the ratio of its radiation intensity in a given direction, which usually is taken to be the direction of maximum radiation intensity, divided by the radiation intensity of an isotropic source with the same total radiation intensity. Equation (19) can also be written

$$\begin{aligned} D &= \frac{U_{\text{max}}(\theta, \phi)}{P_{\text{rad}}/4\pi} \\ &= \frac{4\pi U_{\text{max}}(\theta, \phi)}{\oint_{4\pi} U(\theta, \phi) d\Omega} \\ &= \frac{4\pi}{\oint_{4\pi} U(\theta, \phi)/U_{\text{max}}(\theta, \phi) d\Omega} \\ &= \frac{4\pi}{\oint_{4\pi} U_n(\theta, \phi) d\Omega} \\ &= \frac{4\pi}{\Omega_A} \end{aligned} \quad (20)$$

Thus, the directivity of an antenna is equal to the solid angle of a sphere, which is 4π sr, divided by the antenna beam solid angle Ω_A . We can say that by this relation the value of directivity is derived from the antenna pattern. It is obvious from this relation that the smaller the beam solid angle, the larger the directivity, or stated in a different way, an antenna that concentrates its power in a narrow mainlobe has a great value of directivity.

Obviously, the directivity of an isotropic antenna is unity. By definition, an isotropic source radiates equally in all directions. If we use Eq. (20), then $\Omega_A = 4\pi$ since $U_n(\theta, \phi) = 1$. This is the smallest directivity value that one can attain. However, if we consider the directivity in a specified direction, for example, $D(\theta, \phi)$ its value can be smaller than unity. As an example, let us calculate the

directivity of the very short dipole antenna. We can calculate its normalized radiated power using the electric or the magnetic field components, given in Table 1. Using the electric field E_θ for far-field region, from Eq. (12), we have

$$U_n(\theta, \phi) = \frac{U(\theta, \phi)}{U_{\max}(\theta, \phi)} = \frac{E_\theta^2(\theta, \phi)}{[E_\theta^2(\theta, \phi)]_{\max}} = \sin^2 \theta \quad (21)$$

and

$$D = \frac{4\pi}{\oint \int_{4\pi} U_n(\theta, \phi) d\Omega} = \frac{4\pi}{\int_0^{2\pi} \int_0^\pi \sin^3 \theta d\theta d\phi} = \frac{3}{2} = 1.5 \quad (22)$$

Alternatively, we can work using power densities instead of power intensities. The power flowing in a particular direction can be calculated using Eq. (3) and using the electric and magnetic far-field components given in Table 1:

$$S_{\text{av}} = \frac{\eta}{2} \left(\frac{I_0 L \beta}{4\pi r} \right)^2 \sin^2 \theta \quad (\text{W/m}^2) \quad (23)$$

By integrating over all angles the total power flowing outward is given by

$$P_T = \frac{\eta}{12\pi} (I_0 L \beta)^2 \quad (\text{W}) \quad (24)$$

The directivity of a very short dipole antenna can be found from the ratio of the maximum power density to the average power density. For the very short dipole antenna, the maximum power density is in the $\theta = 90^\circ$ direction (Fig. 2) and the average power density is found by averaging the total power P_T from Eq. (24) over a sphere of surface area $4\pi r^2$:

$$D = \frac{S_{\text{av}}}{P_T/4\pi r^2} = \frac{(\eta/2)(I_0 L \beta/4\pi r)^2}{(\eta/12\pi)(I_0 L \beta)^2/4\pi r^2} = \frac{3}{2} \quad (25)$$

Thus, the directivity of a very short dipole is 1.5, which means that the maximum radiation intensity is 1.5 times the power of the isotropic radiator. This is often expressed in decibels, such that

$$D = 10 \log_{10}(d) \text{ dB} = 10 \log_{10}(1.5) = 1.76 \text{ dB} \quad (26)$$

Here, we use small (lowercase) letters to indicate absolute value and capital (uppercase) letters for the logarithmic value of the directivity, which is a common symbolism in the field of antennas and propagation.

In some cases it is convenient to use simpler expressions for directivity estimation instead of the exact ones. For antennas characterized by a radiation pattern consisting of one narrow mainlobe and negligible minor lobes, the beam solid angle can be approximated by the product of the half-power beamwidths in two perpendicular planes, and the directivity can be given by the expression

$$D = \frac{4\pi}{\Omega_A} \approx \frac{4\pi}{\Theta_{1r} \Theta_{2r}} = \frac{41,253}{\Theta_{1d} \Theta_{2d}} \quad (27)$$

where Θ_{1r} , Θ_{2r} and Θ_{1d} , Θ_{2d} are the half-power beamwidths in two perpendicular planes in radians and degrees, respectively.

The gain of an antenna is another basic property in the total characterization of an antenna. Gain is closely associated with directivity, which is dependent on the radiation patterns of an antenna. The *gain* is commonly defined as the ratio of the maximum radiation intensity in a given direction to the maximum radiation intensity produced in the same direction from a reference antenna *with the same power input*. Any convenient type of antenna may be taken as a reference antenna. Often the type of the reference antenna is dictated by the application area, but the most commonly used one is the isotropic radiator, the hypothetical lossless antenna with uniform radiation intensity in all directions. So

$$G = \frac{U_{\max}(\theta, \phi)}{U_i} = \frac{U_{\max}(\theta, \phi)}{P_{\text{in}}/4\pi} \quad (\text{dimensionless}) \quad (28)$$

where the radiation intensity of the reference antenna of isotropic radiator is equal to the power in the input P_{in} of the antenna divided by 4π .

Real antennas are not lossless, which means that if they accept an input power P_{in} , the radiated power P_{rad} generally will be less than P_{in} . The *antenna efficiency* k is defined as the ratio of these two powers

$$k = \frac{P_{\text{rad}}}{P_{\text{in}}} = \frac{R_r}{R_r + R_{\text{loss}}} \quad (\text{dimensionless}) \quad (29)$$

where R_r is the *radiation resistance* of the antenna. R_r is defined as an equivalent resistance in which the same current flowing at the antenna terminals will produce power equal to that produced by the antenna. R_{loss} is the *loss resistance* that comes from any heat loss due to the finite conductivity of the materials used to construct the antenna or due to losses associated by the dielectric structure of the antenna. So, for a real antenna with losses, its radiation intensity at a given direction $U(\theta, \phi)$ will be

$$U(\theta, \phi) = k U_0(\theta, \phi) \quad (30)$$

where $U_0(\theta, \phi)$ is the radiation intensity of the same antenna with no losses.

Substituting Eq. (30) into (28) yields the definition of gain in terms of the antenna directivity:

$$G = \frac{U_{\max}(\theta, \phi)}{U_i} = \frac{k U_{\max}(\theta, \phi)}{U_i} = k D \quad (31)$$

Thus, the gain of an antenna over a lossless isotropic radiator equals its directivity if the antenna efficiency is $k = 1$ and is less than the directivity if $k < 1$.

The values of gain may lie between zero and infinity, while for directivity the values range between unity and infinity. However, while directivity can be computed from either theoretical considerations or from measured radiation patterns, the gain of an antenna is almost always

determined by a direct comparison of measurement against a reference, usually the standard gain antenna.

Gain is also expressed in decibels

$$G = 10 \log_{10}(g) \text{ dB} \quad (32)$$

where, as in Eq. (26), small and capital letters denote absolute and logarithmic values, respectively. The reference antenna used is sometimes declared as subscript; for example, dBi means decibels over isotropic.

4. POLARIZATION

4.1. Wave and Antenna Polarization

Polarization refers to the physical orientation of the radiated waves in space. It is known that the direction of oscillation of an electric field is always perpendicular to the direction of propagation. An electromagnetic wave whose electric field oscillation occurs only within a plane containing the direction of propagation is called *linearly polarized* or *plane-polarized*. This is because the locus of oscillation of the electric field vector within a plane perpendicular to the direction of propagation forms a straight line. On the other hand, when the locus of the tip of an electric field vector forms an ellipse or a circle, the electromagnetic wave is called an *elliptically polarized* or *circularly polarized wave*.

The decision to label polarization orientation according to the electric intensity is not as arbitrary as it seems; as a result, the direction of polarization is the same as the direction of the antenna. Thus, vertical antennas radiate vertically polarized waves and, similarly, horizontal antennas radiate waves whose polarization is horizontal. For some time there has been a tendency to transfer the label to the antenna itself. Thus people often refer to antennas as “vertically” or “horizontally polarized”, whereas it is actually only their radiations that are so polarized.

It is a characteristic of antennas that the radiation they emit is polarized. These *polarized waves* are deterministic, which means that the field quantities are definite functions of time and position. On the other hand, other forms of radiation, for example, light emitted by *incoherent* sources such as the sun or light globes, have a random arrangement of field vectors and is said to be *randomly polarized* or *unpolarized*. In this case the field quantities are completely random and the components of the electric field are uncorrelated. In many situations the waves may be partially polarized. In fact, this case can be seen as the most general situation of wave polarization; a wave is *partially polarized* when it may be considered to consist of two parts, one completely polarized and the other completely unpolarized. Since we are interested mainly in waves radiated from antennas, we consider only polarized waves.

4.2. Linear, Circular, and Elliptical Polarization

Consider a plane wave traveling in the positive z direction, with the electric field at all times in the x direction as shown in Fig. 9a. This wave is said to be *linearly polarized* (in the x direction) and its electric field as a function of

Figure 9. Polarization of a wave: (a) linear; (b) circular; (c) elliptical.

time and position can be described by

$$E_x = E_{x0} \sin(\omega t - \beta z) \quad (33)$$

In general, the electric field of a wave traveling in the z direction may have both an x and a y component, as shown in Figs. 9b and 9c. If the two components E_x and E_y are of equal amplitude, the total electric field at a fixed value of z rotates as a function of time with the tip of the vector forming a circular trace and the wave is said to be *circularly polarized* (Fig. 9b).

Generally, the wave consists of two electric field components, E_x and E_y , of different amplitude ratios and relative phases. Obviously, there are magnetic fields (not shown in the Fig. 9, to avoid confusion) with amplitudes proportional to and in phase with E_x and E_y , but orthogonal to the corresponding electric field vectors. In this general situation, at a fixed value of z the resultant electric vector rotates as a function of time, where the tip of the vector describes an ellipse, called the *polarization ellipse*, and the wave is said to be *elliptically polarized* (Fig. 9c). The polarization ellipse may have any orientation that is determined by its tilt angle, as suggested in Fig. 10, and the ratio of the major to minor axes of the polarization ellipse is called the *axial ratio* (AR). Since the two cases of linear and circular polarization can be seen as two particular cases of elliptical polarization, we will analyze the latter one. Thus, for a wave traveling in the positive z direction, the electric field components in the x and y directions are

$$E_x = E_{x0} \sin(\omega t - \beta z) \quad (34)$$

$$E_y = E_{y0} \sin(\omega t - \beta z + \delta) \quad (35)$$

where E_{x0} and E_{y0} are the amplitudes in x and y directions, respectively, and δ is the time-phase angle between them. The total instantaneous vector field \mathbf{E} is

$$\mathbf{E} = \hat{\mathbf{x}}E_{x0} \sin(\omega t - \beta z) + \hat{\mathbf{y}}E_{y0} \sin(\omega t - \beta z + \delta) \quad (36)$$

At $z = 0$, $E_x = E_{x0} \sin \omega t$ and $E_y = E_{y0} \sin(\omega t + \delta)$. The expansion of E_y gives

$$E_y = E_{y0}(\sin \omega t \cos \delta + \cos \omega t \sin \delta) \quad (37)$$

Using the relation for E_x , we take $\sin \omega t = E_x/E_1$ and $\cos \omega t = \sqrt{1 - (E_x/E_1)^2}$, while the introduction of these terms in Eq. (37) eliminates ωt , giving the following relation, after rearranging:

$$\frac{E_x^2}{E_1^2} - \frac{2E_x E_y \cos \delta}{E_1 E_2} + \frac{E_y^2}{E_2^2} = \sin^2 \delta \tag{38}$$

If we represent this with

$$a = \frac{1}{E_1^2 \sin^2 \delta} \quad b = \frac{2 \cos \delta}{E_1 E_2 \sin^2 \delta} \quad c = \frac{1}{E_2^2 \sin^2 \delta}$$

Eq. (38) takes the form

$$aE_x^2 - bE_x E_y + cE_y^2 = 1 \tag{39}$$

which is the equation of an ellipse, the polarization ellipse, shown in Fig. 10. The line segment OA is the semi-major axis, and the line segment OB is the semi-minor axis. The tilt angle of the ellipse is τ . The axial ratio is

$$AR = \frac{OA}{OB} \quad (1 \leq AR \leq \infty) \tag{40}$$

From this general case, the cases of linear and circular polarization can be found. Thus, if there is only E_x ($E_{y0} = 0$), the wave is linearly polarized in the x direction and if there is only E_y ($E_{x0} = 0$), the wave is linearly polarized in the y direction. When both E_x and E_y exist, for linear polarization they must be in phase or inverse to each other. In general, the necessary condition for linear polarization is that the time-phase difference between the two components must be a multiple of π . If $\delta = 0, \pi, 2\pi, \dots$ and $E_{x0} = E_{y0}$, the wave is linearly polarized but in a plane at an angle of $\pm \pi/4$ with respect to the x axis ($\tau = \pm \pi/4$). If the relation of amplitudes of E_{x0} and E_{y0} is different, then the tilt angle will be related to E_{y0}/E_{x0} ratio value.

If $E_{x0} = E_{y0}$ and $\delta = \pm \pi/2$, the wave is circularly polarized. Generally, circular polarization can be achieved only

when the magnitudes of the two components are the same and the time-phase angle between them is an odd multiple of $\pi/2$.

Consider the case that $\delta = \pi/2$. Taking $z = 0$, from Eqs. (34)–(36) at $t = 0$, it is $\mathbf{E} = \hat{\mathbf{y}}E_{y0}$, while one-quarter cycle later, at $\omega t = \pi/2$, it becomes $\mathbf{E} = \hat{\mathbf{x}}E_{x0}$. Thus, at a fixed position ($z = 0$) the electric field vector rotates as a function of time tracing a circle. The sense of rotation, also referred to as the *sense of polarization*, can be defined by the sense of rotation of the wave as it is observed toward or along the direction of propagation. Thus the above mentioned wave rotates clockwise if it is observed toward the direction of travel (viewing the wave approaching) or counterclockwise observing the wave from the direction of its source (viewing the wave moving away). Thus, unless the wave direction is specified, there is a possibility of ambiguity. The most generally accepted notation is that of the IEEE, by which the sense of rotation is always determined observing the field rotation as the wave is viewed as it travels away from the observer. If the rotation is clockwise, the wave is *right-handed or clockwise circularly polarized* (RH or CW). If the rotation is counterclockwise, the wave is *left-handed or counterclockwise circularly polarized* (LH or CCW). Yet, an alternate way to define the polarization is with the aid of helical-beam antennas. A right-handed helical-beam antenna radiates (or receives) right-handed regardless of the position from which it is viewed while a left-handed one at the opposite direction.

Although linear and circular polarizations can be seen as special cases of elliptical, usually, in practice, elliptical polarization refers to other than linear or circular. A wave is characterized as elliptically polarized if the tip of its electric vector forms an ellipse. For a wave to be elliptically polarized, its electric field must have two orthogonal linearly polarized components, E_{x0} and E_{y0} , but different magnitudes. If the two components are not of the same magnitude, the time-phase angle between them must not be 0 or multiples of π , while in the case of equal magnitude, the angle must not be an odd multiple of $\pi/2$. Thus, a wave that is not linearly or circularly polarized is elliptically polarized. The sense of its rotation is determined according to the same rule as for the circular polarization. So, a wave is *right-handed or clockwise elliptically polarized* (RH or CW) if the rotation of its electric field is clockwise and it is *left-handed or counterclockwise elliptically polarized* (LH or CCW) if the electric field vector rotates counterclockwise. In addition to the sense of rotation, elliptically polarized waves are characterized by their axial ratio AR and their tilt angle τ . The tilt angle is used to identify the spatial orientation of the ellipse and can be measured counterclockwise or clockwise from the reference direction (Fig. 10). If the electric field of an elliptically polarized wave has two components of different magnitude with a time-phase angle between them that is an odd multiple of $\pi/2$, the polarization ellipse will not be tilted. Its position will be aligned with the principal axes of the field components, so that the major axis of the ellipse will be aligned with the axis of the larger field component and the minor axis, with the smaller one.

Figure 10. Polarization ellipse at $z = 0$ of an elliptically polarized electromagnetic wave.

4.3. The Poincaré Sphere and Antenna Polarization Characteristics

The polarization of a wave can be represented and visualized with the aid of a Poincaré sphere. The polarization state is described by a point on this sphere where the longitude and latitude of the point are related to parameters of the polarization ellipse. Each point represents a unique polarization state. On the Poincaré sphere the north pole represents left circular polarization while the south pole, right circular polarization, and the points along the equator linear polarization of different tilt angles. All other points on the sphere represent elliptical polarization states. One octant of the Poincaré sphere with polarization states is shown in Fig. 11a, while the full range of polarization states is shown in Fig. 11b, which presents a rectangular projection of the Poincaré sphere.

The polarization state described by a point on the Poincaré sphere can be expressed in terms of

1. The longitude and latitude of the point, which are related to the parameters of the polarization ellipse

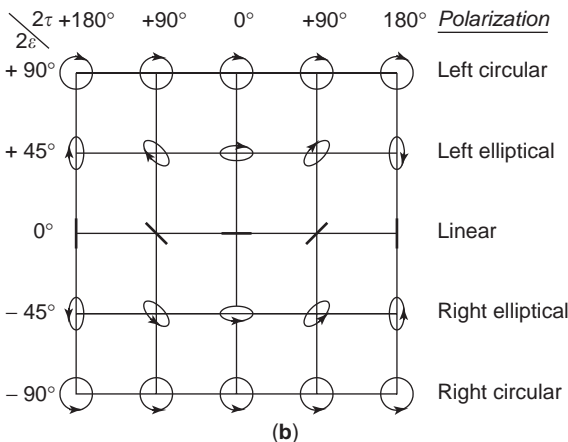

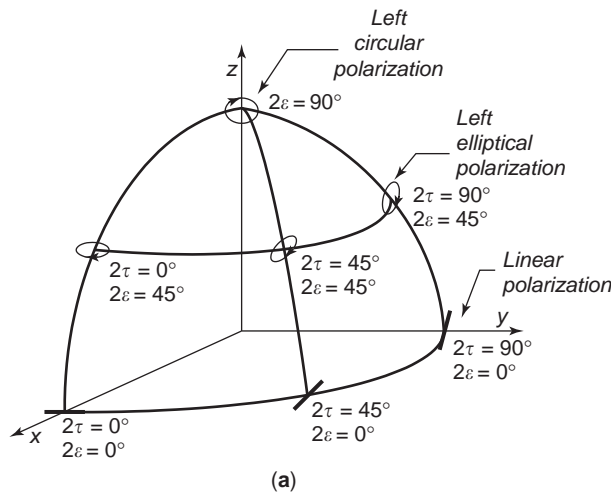

Figure 11. Polarization states of an electromagnetic wave with the aid of Poincaré sphere: (a) one octant of Poincaré sphere with polarization states; (b) the full range of polarization states in rectangular projection.

by the relations

$$L(\text{longitude}) = 2\tau \text{ and } l(\text{latitude}) = 2\varepsilon$$

where τ = tilt angle with values between $0 \leq \tau \leq \pi$ and $\varepsilon = \cot^{-1}(\mp AR)$ with values between $-\pi/4 \leq \varepsilon \leq +\pi/4$. The axial ratio (AR) is negative and positive for right- and left-handed forms of polarization, respectively.

2. The angle subtended by the great circle drawn from a reference point on the equator and the angle between the great circle and the equator:

$$\begin{aligned} \text{Great-circle angle} &= 2\gamma \text{ and equator} \\ &\text{-- great-circle angle} = \delta \end{aligned}$$

with $\gamma = \tan^{-1}(E_{y0}/E_{x0})$ with $0 \leq \gamma \leq \pi/2$ and δ = time-phase difference between the components of electric field ($-\pi \leq \delta \leq +\pi$).

All these quantities, τ , ε , γ and δ , are interrelated by trigonometric formulas [5], and the knowing of (τ, ε) can determine the (γ, δ) and vice versa. As a result, the polarization state can be described by either of the two these sets of angles. The geometric relation between these angles is shown in Fig. 12.

The polarization state of an antenna is defined as the polarization state of the wave radiated by the antenna when it is transmitting. It is characterized by the axial ratio AR, the sense of rotation and the tilt angle, which identifies the spatial orientation of the ellipse. However, care is needed in the characterization of the polarization of a receiving antenna. If the receiving antenna has a polarization that is different from that of the incident wave, a polarization mismatch occurs. In this case the amount of power extracted by the receiving antenna from the incident wave will be lower than the expected value because of the polarization loss. A figure of merit that can be used as a measure of polarization mismatch is the *polarization loss factor* (PLF), defined as the cosine raised by a power of 2 relative to the angle between the polarization states of the antenna in its transmitting mode and the incoming

Figure 12. One octant of Poincaré sphere showing the relations of angles τ , ε , γ , and δ that can be used to describe a polarization state.

wave. Alternatively, another quantity that can be used to describe the relation between the polarization characteristics of an antenna and an incoming wave is the *polarization efficiency*, also known as *loss factor* or *polarization mismatch*. It is defined as the ratio of the power received by an antenna from a given plane wave of arbitrary polarization to the power that would be received by the same antenna from a plane wave of the same power flux density and direction of propagation, whose state of polarization has been adjusted for a maximum received power.

In general, an antenna is designed for a specific polarization. This is the desired polarization and is called *copolariation* or *normal polarization*, while the undesired polarization, usually taken in the direction orthogonal to the desired one, is known as *cross-polarization* or *opposite polarization*. The latter can be due to a change of polarization characteristics, known as *polarization rotation*, during the propagation of waves. In general, an actual antenna does not completely discriminate against a cross-polarized wave because of engineering and structural restrictions. The directivity pattern obtained over the entire direction on a representative plane for cross-polarization with respect to the maximum directivity for the normal polarization, called *antenna cross-polarization discrimination*, is an important factor in determining the antenna performance.

The *polarization pattern* gives the polarization characteristics of an antenna and is the spatial distribution of the polarization of its electric field vector radiated by the antenna taken over its radiation sphere. The description of the polarizations is done by specifying reference lines, which are used to measure the tilt angles of polarization ellipses or the directions of polarization for the case of linear polarizations.

5. EVALUATION OF ANTENNA PATTERN AND DIRECTIVITY (GENERAL CASE)

5.1. Derivation of Electromagnetic Fields

As already pointed out, the radiation pattern of an antenna is generally its most basic property and it is usually the first requirement to be specified. Of course, the patterns of an antenna can be measured in the transmitting or receiving mode, selecting in most cases the receiving mode if the antenna is reciprocal. But to find the radiation patterns analytically, we have to evaluate the fields radiated from the antenna. In radiation problems, the case where the sources are known and the fields radiated from these sources are required is characterized as an analysis problem. It is a very common practice during the analysis process to introduce auxiliary functions that will aid in the solution of the problem. These functions are known as *vector potentials*, and for radiation problems the most widely used ones are the *magnetic vector potential* \mathbf{A} and the *electric vector potential* \mathbf{F} . Although it is possible to calculate the electromagnetic fields \mathbf{E} and \mathbf{H} directly from the source current densities, it is simpler to first calculate the electric current \mathbf{J} and magnetic current \mathbf{M} and then evaluate the electromagnetic fields. The vector potential \mathbf{A} is used for the evaluation of the electromagnetic field generated by a known harmonic electric current density \mathbf{J} .

The vector potential \mathbf{F} can give the fields generated by a harmonic magnetic current that, although physically unrealizable, has specific applications in some cases as in volume or surface equivalence theorems. Here, we restrict ourselves to the use of the magnetic vector potential \mathbf{A} , which is the potential that gives the fields for the most common wire antennas.

Using the appropriate equations from electromagnetic theory, the vector potential \mathbf{A} can be found as [3]

$$\mathbf{A} = \frac{\mu_0}{4\pi} \iiint \mathbf{J} \frac{e^{-j\beta r}}{r} dv \quad (41)$$

where $k^2 = \omega^2 \mu_0 \epsilon_0$, μ_0 and ϵ_0 are the magnetic permeability and electric permittivity of the air, respectively; ω is the radian frequency; and r is the distance from any point in the source to the observation point. The fields can then be given by

$$\mathbf{E} = -\nabla V - j\omega \mathbf{A} \quad (42a)$$

and

$$\mathbf{H} = \frac{1}{\mu_0} \nabla \times \mathbf{A} \quad (42b)$$

In Eq. (42a) the scalar function V represents an arbitrary electric scalar potential that is a function of position. The fields radiated by antennas with finite dimensions are spherical waves and in the far-field region, the electric and magnetic field components are orthogonal to each other and form a TEM (transverse electric mode) wave. Thus in the far-field region, Eqs. (42) simplify to

$$\mathbf{E} \approx -j\omega \mathbf{A} \Rightarrow \begin{cases} E_r \approx 0 \\ E_\theta \approx -j\omega A_\theta \\ E_\phi \approx -j\omega A_\phi \end{cases} \quad (43a)$$

and

$$\mathbf{H} \approx \frac{1}{\eta} \hat{\mathbf{r}} \times \mathbf{E} \Rightarrow \begin{cases} H_r \approx 0 \\ H_\theta \approx -\frac{E_\phi}{\eta} \\ H_\phi \approx +\frac{E_\theta}{\eta} \end{cases} \quad (43b)$$

So, the problem becomes that of evaluating the function \mathbf{A} from the specified electric current density on the antenna, first, and then, using Eqs. (43), the \mathbf{E} and \mathbf{H} fields are evaluated and the radiation pattern is extracted. For example, for the case of a very short dipole, the magnetic vector potential \mathbf{A} is given by

$$\mathbf{A} = \hat{\mathbf{z}} \frac{\mu_0 I_0}{4\pi r} e^{-jkr} \int_{-L/2}^{L/2} dz = \hat{\mathbf{z}} \frac{\mu_0 I_0 L}{4\pi r} e^{-jkr} \quad (44)$$

Using Eq. (44), the fields shown in Table 1 can be evaluated.

5.2. Numerical Calculation of Directivity

Usually, the directivity of a practical antenna is easier to evaluate from its radiation pattern using numerical methods. This is especially true when radiation patterns are so complex that closed-form mathematical expressions are

not available. Even if these expressions exist, because of their complex form, the integration necessary to find the radiated power is very difficult to perform. A numerical method of integration, like the Simpson or trapezoid rule can greatly simplify the evaluation of radiated power and give the directivity, helping in this way to provide a method of general application that necessitates only the function or a matrix with the values of the radiated field. However, in many cases the evaluation of the integral that gives the radiated power, using a series approximation, proves to be enough to give the correct value of directivity.

Consider the case where the radiation intensity of a given antenna can be written as

$$U(\theta, \phi) = Af(\theta)g(\phi) \tag{45}$$

which means that it is separable into two functions, where each is a function of one variable only and A is a constant. Then P_{rad} from Eq. (15) will be

$$P_{\text{rad}} = A \int_0^{2\pi} \left(\int_0^\pi f(\theta)g(\phi) \sin \theta d\theta \right) d\phi \tag{46}$$

If we take N uniform divisions over the π interval of variable θ and M uniform divisions over the 2π interval of variable ϕ , we can calculate the two integrals by a series approximation, respectively, as

$$\int_0^\pi f(\theta) \sin \theta d\theta = \sum_{i=1}^N [f(\theta_i) \sin \theta_i] \Delta\theta_i \tag{47a}$$

and

$$\int_0^{2\pi} g(\phi) d\phi = \sum_{j=1}^M g(\phi_j) \Delta\phi_j \tag{47b}$$

Introducing Eq. (47) in Eq. (46), we obtain

$$P_{\text{rad}} = A \left(\frac{\pi}{N} \right) \left(\frac{2\pi}{M} \right) \sum_{j=1}^M \left\{ g(\phi_j) \left[\sum_{i=1}^N f(\theta_i) \sin \theta_i \right] \right\} \tag{48}$$

A computer program can easily evaluate this equation. The directivity is then given by Eq. (19), which is repeated here:

$$D = \frac{4\pi U_{\text{max}}(\theta, \phi)}{P_{\text{rad}}}$$

In the case where θ and ϕ variations are not separable, P_{rad} can also be calculated by a computer program by a slightly different expression

$$P_{\text{rad}} = B \left(\frac{\pi}{N} \right) \left(\frac{2\pi}{M} \right) \sum_{j=1}^M \left\{ \sum_{i=1}^N F(\theta_i, \phi_j) \sin \theta_i \right\} \tag{49}$$

where we consider that in this case $U(\theta, \phi) = BF(\theta, \phi)$.

For more information on radiation patterns, in general, and radiation patterns of specific antennas the reader is encouraged to check Refs. 2–13.

1. INTRODUCTION

During the last few years there has been increasingly widespread study of the electromagnetic interference of equipment to either one of its component sections or to another apparatus operating in the close vicinity. This has been caused by the continuous development of electronic and electric systems that use the electromagnetic spectrum for information transfer purposes [1]. For this reason, there is a growing interest among scientific communities globally in the development of methods and structures that can determine and identify the electromagnetic interference phenomena. The scientific field that covers the principles of electromagnetic interference and deals with the harmonic coexistence of complex electric and electronic systems is electromagnetic compatibility (EMC). According to Williams [1], EMC is defined as the ability of a device, system, or equipment component to

satisfactorily operate in its electromagnetic environment without introducing unwanted electromagnetic disturbances in any apparatus that functions in that environment.

In order to ensure that the fundamental principles of EMC are followed, several tests have to be carried out. A piece of equipment, according to its classification, has to undergo tests related to conducted emission and conducted immunity, as well as radiated emission and radiated immunity. For every equipment unit, the corresponding EMC standards present the appropriate tests together with the proposed methods and structures. A very crucial parameter for determination of conformity of the equipment examined, within the limits and restrictions outlined in the appropriate EMC standard, is the test site that will host the measurements performed according to the standard.

The test sites that are often used and proposed by the majority of the standards are the open-area test site (OATS), the anechoic chamber, the screened room, and more recently the reverberation chamber. An OATS consists of a perfectly conducting ground plane placed on an ellipsoidal area that is free of reflecting obstacles and electromagnetic noise from the surrounding environment. It is used mostly for radiated emissions tests. The anechoic chamber is a closed structure with walls coated with a radiosorbent material in order to absorb the unwanted reflections of the propagating waves. Moreover, it provides a high-quality shielding of the test structure, ensuring that environmental electromagnetic noise is absent or under a very low level. The screened room is a test site often used for immunity tests, due to the low cost and easy constructed structure.

A form of screened room used for emission and immunity tests is the *reverberation chamber* [2], which consists of a highly conductive enclosure that provides high shielding for the electrical and electronic equipment being tested therein. The main feature that distinguishes it from the other closed cavities is the presence of one or more stirrers, which modify the internal distribution of the electromagnetic field, providing the desired electromagnetic environment for the EMC tests being carried out. It is also referred to as a mode-stirred chamber.

Reverberation chambers were first introduced for measuring the shielding effectiveness of cables, connectors, and enclosures according to specified military standards. The International Electrotechnical Commission (IEC) has established a standard (IEC 61000-4-21 [2]) that regards the test methods and procedures for using reverberation chambers for radiated immunity, radiated emissions, and shielding effectiveness measurements. It also describes the methods that have to be adopted for the proper calibration of a reverberation chamber.

The reverberation chamber (see structure shown in Fig. 1) consists of a highly conductive electrically large cavity whose smallest dimension is very large compared to the wavelength at the lowest usable frequency (LUF). The LUF [2,3] is a crucial parameter for determining the proper operation of a reverberation chamber and will be analytically discussed later in this article. As mentioned previously, the main feature of a mode-stirred chamber

Figure 1. Structure of reverberation chamber.

is the presence of a stirrer, which forms the appropriate field conditions, which will be described later. It usually appears in the shape of a paddle wheel, although several alternative methods of stirring have been proposed in the more recent literature and discussed later in this article. The choice of the kind of the stirrer as well as the position inside the chamber where it is fixed to operate are basic parameters for determining the stirrer effectiveness, as will be shown later.

The main function of a stirrer (or *tuner*, as it is also referred to) is to significantly vary the field boundary conditions in the chamber through its movement or rotation. When the stirrer has moved to a sufficient number of positions, the number of modes propagating in the closed cavity has been significantly increased (usually over 60 modes) and the field variations that are caused by its movement provide a set of fields that cover all the directions and polarizations. The cavity is then multimoded, and this is interpreted by the relative stability of the field magnitude and direction between all the chamber points within uncertainty limits. The electromagnetic environment that derives from this situation is statistically uniform and statistically isotropic when it is considered as the average value for a sufficient number of stirrer positions. However, in some cases (usually in immunity tests) the maximum value is computed for the corresponding number of stirrer positions. Thus, as will be discussed later, the choice of the number of stirrer positions during the EMC test or the calibration of the chamber forms a very critical parameter for the evaluation of the results and the proper operation of the chamber itself.

There are two basic procedures for stirrer rotation: (1) mode stirring and (2) mode tuning [4,5]. In procedure 1, the stirrer moves continuously during the test and the average field is computed or measured; in procedure 2, the stirrer (or tuner) moves at distinct positions with a predefined angle of separation to allow the field to become stable and a maximum measurement or computation is performed.

The reverberation chamber study requires the use of statistical theory to predict the field conditions inside the chamber, as the field is stochastic in nature in contrast to the anechoic chamber, where the field is deterministic. This property of the mode-stirred chamber enhances the ability of performing repeatable EMC tests, due to the

uniformity and the isotropic conditions over the working volume where the equipment under test (EUT) is positioned. This feature allows tests to be performed with a high degree of reliability without requiring the rotation of the EUT or the interchange of the antennas' polarization between horizontal and vertical as demanded when an anechoic chamber is used. Consequently, tests are performed in a quick and easy manner and are repeatable, which is usually problematic because of the long duration of the tests and the accuracy and credibility requirements of the results.

Construction of a reverberation chamber is a low-cost and easily performed procedure because of the simple and low-demand structure, as is readily seen in Fig. 1. This advantage allows for mobility in manufacture of the chamber, which can be moved and set up wherever the EUT is intended to operate (in situ measurement); thus the EUT does not have to be transferred to the laboratory for testing, which is usually inconvenient for large objects. Furthermore, the multipath propagation environment that is accomplished in a mode-stirred chamber represents the actual conditions under which the EUT is designed to routinely operate. This is a very important property, as according to EMC principles, the EUT should be tested as close as possible to its real-life operating environment [6].

The ability of a reverberating enclosure to store a high amount of energy is another significant feature. The field strengths that are generated are usually very high, corresponding to a large value for the chamber's quality factor (Q) compared to proposed EMC test sites. The Q [2] of an enclosure is another critical parameter for determining the acceptable performance of a mode-stirred chamber, and the methods of calculation and measurement of which are described analytically later in this article.

However, the use of the reverberation chamber is not a panacea for EMC tests. The statistical nature of the electromagnetic environment inside the chamber proper may have some drawbacks as it may be difficult to predict the field at a certain point. Moreover, the LUF proposes some restrictions with regard to the use of the chamber at relatively low frequencies. It then relies on the cavity dimensions, the stirrer effectiveness, and the quality factor to determine whether the chamber can be used at the desired low level of the frequency range. Additionally, when the EUT fails the test, no information is provided regarding the direction and polarization of the field due to the isotropic and randomly polarized electromagnetic environment [7].

The performance of a reverberation chamber has been tested both theoretically and experimentally as reported in the more recent literature. The theoretical approach [8–13] is based almost entirely on the use of an appropriate numerical electromagnetic method, which can compute the fields within the enclosure with high reliability and derive results for the statistics or the main reverberation chamber characteristics. The strong benefit of this chamber's realization is the ability to easily evaluate different conditions related to alternating the chamber's dimensions or shape, the stirrer shape or size, wall materials, and other parameters. Thus, an optimization of the

chamber's operation can be carried out by performing different tests with relatively tolerable time limits. The experimental procedure is based on the assessment of measurement results acquired from a manufactured mode-stirred chamber or from a screened room properly transformed to serve as a reverberating enclosure.

The use of reverberation chambers for testing various types of antennas and especially electrically small antennas used in terminal mobile or generally wireless devices is a reliable alternative compared to the widespread anechoic chamber structure. The usual small size of these antennas, combined with the relatively high-frequency spectrum in which they are designed to operate, enhances the adoption of a mode-stirred chamber for measuring the characteristics of such antennas as few restrictions based on dimensions or LUF are imposed. Moreover, the multipath environment in which these types of antennas are designed to operate is best described with the use of a reverberation chamber [14].

Many studies presented in the more recent literature suggest ways for measuring the radiation efficiency of antennas in a mode-stirred chamber [15–18]. By locating a transmitting antenna and an antenna to be tested in this kind of chamber for different chamber configurations (due to the alternating environment that the stirrers produce), the received power of the tested antenna is a stochastic variable. The radiation efficiency of the tested antenna can be assessed by computing the average value of the received power over all the different stirrer positions and comparing it with the average received power of a reference antenna with a predetermined radiation efficiency. However, the results seem to be strongly dependent on the orientation and polarization of the antenna tested, and an uncertainty of 2–3 dB is produced. This can be reduced by replacing the transmission antenna with either a helical circularly polarized antenna or three orthogonally polarized fixed antennas. In addition to the radiation efficiency, the input impedance of antennas operating near lossy materials that simulate the human tissue properties can be determined with the use of reverberation chambers [19]. These conditions are assumed to be very close to the free-space environment.

After approximately 20 years since reverberation chambers were first introduced, only now is their use in EMC tests, according to the present standards, becoming appreciable. This acceptance is predicted to become more intense in the near future as emission standards will demand that tests be carried out at frequencies greater than 1 GHz and as the tests at high frequencies of EUTs with electrically large dimensions turn out to be complicated. Reverberation chambers have also proved to be very reliable for bioelectromagnetic testing, due to their advantage of providing a uniform environment conducive to a parallel implementation in which multiple tests can be performed, resulting in an increased number of statistical samples and therefore in a more precise set of results [20].

In the following sections, we outline the basic characteristics of a mode-stirred chamber. The field uniformity, the statistical properties, the LUF, the quality factor, the alternative ways of chamber's stirring, and the numerical

methods used to simulate the reverberation performance will be presented on the basis of information acquired from the available literature.

2. FIELD UNIFORMITY

As also mentioned before, field uniformity is a basic feature of a reverberation chamber. It can be interpreted as the ability of the electromagnetic field inside the chamber to be statistically isotropic, statistically homogeneous, and randomly polarized. The term *isotropic* represents the equal statistics of the electromagnetic environment in any given direction. The homogeneous property implies that all spatial locations at a sufficient distance from any metal surfaces inside the chamber are statistically equivalent. The random phase between all waves reflects the random polarization.

After a reverberation chamber is constructed or is modified to a high degree, a calibration procedure has to be carried out to ensure that the chamber meets the requirements of adequate chamber performance. Therefore, the fields should be tested to verify that the same magnitude for all polarizations throughout the chamber is achieved, within certain limits of uncertainty. This procedure is also used to determine the LUF of the chamber, which will delineate the frequency operating range of the enclosure.

The setup for the calibration procedure is depicted in Fig. 1. The calibration is performed over a volume, including the testbench and the EUT inside the chamber, which is called the “test” or “working” volume [2]. The working volume is thought to be placed at a distance of $\lambda/4$ m at the lowest frequency of operation from any antenna, tuner, or other reflecting object. For example, for a chamber having a LUF of 100 MHz, this distance is calculated to be 0.75 m. Measurement of the field uniformity should be done in the absence of the EUT or any other support equipment and it is carried out at the eight corner points of the working volume and for the three individual axes (x, y, z) at each location. Thus, the use of isotropic probes is suggested to allow access to each axis and collecting the maximum data of the electric field at each location that will be worked out for the field uniformity assessment. The fields inside the chamber are excited with the use of an antenna that points to one of the chamber’s corners to avoid direct illumination of the working volume, which can result in degradation of the proper operation of the reverberation chamber. For that reason, a logperiodic antenna is used because of its high directivity patterns. However, as was reported in the more recent literature [21,22], the direct path between the generating antenna and the EUT, apart from not disturbing the desired electromagnetic environment inside the chamber, effectively describes the real conditions of EUT operation. A reference antenna is also employed for recording electric field measurements, which are used for the determination of certain factors of the chamber’s behavior (i.e., chamber calibration factor and chamber loading factor [2]).

The data recording is repeated while the stirrer is rotating either continuously (mode stirring) or at distinct

positions (mode tuning). For the mode-stirring technique, the use of as many samples as possible, provided these samples are independent [2], contributes to enhanced chamber operation. Moreover, the considerably shorter test time achieved compared to the mode-tuning technique is another significant advantage. However, the response of the field sensors and the EUT to the rapidly changing field is usually problematic and should be significantly considered each time this stirring method is enforced. The procedure for chamber calibration is similar to that adopted for the mode-tuning technique.

For the case of mode tuning, the number of tuner positions (i.e., number of samples) is a critical parameter for field uniformity assessment. The number of tuner steps capable of providing the required field uniformity is shown to be dependent on the frequency of operation according to the IEC specification. This approval is derived from the fact that for every chamber there is a frequency at which the overmoded condition no longer exists and the reverberation characteristics vanish. Compensation can be obtained by increasing the number of tuner steps in order to restore the optimum chamber performance. Table 1 depicts the recommended [2] number of samples (or tuner steps) required for the chamber calibration at each frequency examined and at each point of the working volume. The choice of more or fewer tuner positions (but not less than 12) will probably improve the field uniformity.

After obtaining the required data for the electric field using the procedure mentioned earlier, the field uniformity should be determined by enforcing an appropriate method. In one method presented in the literature, the acquired data are reduced by discarding 25% of the values that have the maximum variation among the eight points (i.e., $i = 1, \dots, 8$) and then requiring the variation of the remaining data to be usually within 6 dB. However, the excluded data are eliminated without regard to any “weight,” thus resulting in unknown uncertainties. For this reason the method proposed by the IEC standard [2] is widely accepted and employed in the literature.

The IEC specification utilizes the standard deviation method, which computes the standard deviation of the data among the eight points for the three polarizations and that, according to the frequency tested, should be beyond a proposed upper limit. The limits for each frequency range are depicted in Table 2 [2].

To calculate the standard deviation, the maximum value of the magnitude of the electric field over the number of the discrete tuner steps, determined according to Table 1, at each of the eight points and for each polarization is recorded and then normalized to the square root of the average input power over one tuner rotation:

$$E_{x,y,z}^i = \frac{E_{\max,x,y,z}^i}{\sqrt{P_{\text{in}}}} \quad (1)$$

where $E_{x,y,z}^i$ is the normalized value of the magnitude of the electric field for each of the three polarizations x, y, z and at each of the eight points ($i = 1, \dots, 8$), $E_{\max,x,y,z}^i$ represents the maximum, over the number of tuner steps,

Table 1. Number of Samples Required for Chamber Calibration

Frequency ^a	Number of samples
f_1-3f_1	50
$3f_1-6f_1$	18
$6f_1-10f_1$	12
$>10f_1$	12

^a(f_1 : lowest examined frequency)

recorded value at each point ($i=1,\dots,8$) and for each polarization, and P_{in} is the input power over one tuner rotation.

The average value of the normalized maximum of the electric field for each polarization obtained by Eq. (1) over the eight locations of the working volume is computed in the next step. For the x axis this is symbolized by $\langle E_x \rangle_8$ and calculated by the following equation:

$$\langle E_x \rangle_8 = \frac{\sum_{i=1}^8 E_x^i}{8} \quad (2)$$

where E_x^i is the normalized maximum magnitude of the x component of the electric field, derived by Eq. (1), at each of the eight points of the working volume.

For the y and z polarizations the equations are derived in a straightforward manner. Moreover, the average $\langle E \rangle_{24}$ of the normalized maximum values over all of the eight locations and the three polarizations is regarded as well:

$$\langle E \rangle_{24} = \frac{\sum E_{x,y,z}^i}{24} \quad (3)$$

which is interpreted as the sum of the 24 rectangular electric field maximum values divided by the number of the computed or measured values at all points and for all polarizations. The IEC specification allows the total number of values (i.e., 24) to be replaced by nine measurements or computed results if the frequency of examination is above $10f_1$, where, according to Table 1, f_1 is the lower frequency of the range in which the chamber is tested for its operation.

The standard deviation σ for each field component and for the total dataset, which will finally determine the field uniformity conditions in the reverberation chamber, is computed from the following equation:

$$\sigma = \alpha^* \sqrt{\frac{\sum (E_{x,y,z}^i - \langle E_{x,y,z} \rangle)^2}{N - 1}} \quad (4)$$

where N is the number of values in the sample examined (i.e., 8 or 24 or 9), $\langle E_{x,y,z} \rangle$ represents the average value over the eight points of the normalized maximum magnitude $E_{x,y,z}^i$ of the x, y, z component or over the total set of 24 or 9 measurements, respectively, and α is a constant equal to 1.06 for $N \leq 20$ or equal to 1 for $N > 20$. To express the standard deviation in decibels, the following equation is utilized:

$$\sigma(\text{dB}) = 20^* \log \left(\frac{\sigma + \langle E_{x,y,z} \rangle}{\langle E_{x,y,z} \rangle} \right) \quad (5)$$

Table 2. Standard Deviation Limits for Field Uniformity Determination

Frequency	Standard Deviation Limit (dB)
80–100 MHz	4
100–400 MHz	4 dB at 100 MHz with linear decrease to 3 dB at 400 MHz
> 400 MHz	3

The field uniformity criterion is thought to be satisfied if the standard deviations for each of the three polarizations and for the total dataset is under the limits specified in Table 2.

If the chamber meets the field uniformity criterion, it is regarded as calibrated in the frequency range tested, and the lowest frequency of this range is generally assumed to be its LUF. Then, the number of tuner steps required to obtain the uniformity may be reduced in order to gain valuable test time when an EUT will be introduced for testing.

The problems arise when the field uniformity criterion is not satisfied and therefore the chamber is not calibrated. The literature, as well as in the IEC specification [2], describes methods for improving the achieved field uniformity or obtaining the uniformity conditions when a chamber fails the calibration test. As mentioned in the IEC standard, increasing the number of tuner steps (or samples) by 10% or 50% could result in field uniformity.

A reduction of the size of the working volume (which should not be smaller than the size of the EUT that is intended to be tested) is another method proposed to achieve the required uniformity but only if the fail margin is relatively small. Additionally, by increasing the number of tuners or altering the size of tuners or their positions inside the chamber (e.g., by placing them on the ceiling instead of one wall [10]), the field uniformity may improve or be achieved if the criterion described above is not satisfied. As also stated in the recent literature [9], the uniformity when two stirrers in the form of the paddle wheel rotate at different speeds is improved, compared to the case in which one stirrer or two stirrers with equal speeds are utilized. This is interpreted by the observation that the alteration of boundary conditions increases with time and the modes inside the chamber are multiplied and consequently an overmoded condition is obtained. The use of a sufficient paddle ratio [10] (i.e., ratio of paddle sizes) seems to provide an increase in the effectiveness of the tuner, which subsequently improves the field conditions. Also, as illustrated by Harima [9], with a stirrer having a width greater than 3λ and positioned at a distance of over 1λ from the wall surface, the field uniformity is improved and the uncertainty of the prediction in measurements is minimized.

The properties of the chamber tested influence to a high degree the uniformity obtained. For the case of a large chamber, the field is found to be uniform at relatively low frequencies because of the overmoded condition that is observed in a chamber with large dimensions compared to the excitation wavelength. A proposed dimension of a

reverberation chamber found in the literature [8] is greater than 10λ , where λ is the excitation wavelength. The walls of a mode-stirred chamber are theoretically assumed to be perfect electric conductors, but in practical cases, the value of the reflection coefficient is less than unity. As also shown by Harima [9], as the reflection coefficient on the chamber's walls approaches unity with the appropriate choice of the constructed material, the uniformity improves. Some studies [e.g., 5] propose the use of absorbing materials (e.g., ferrite tiles) inside the chamber for improving the field uniformity, especially at low frequencies. The aim for this modification of the reverberating enclosure has been the reduction of the Q of the enclosure, which contributes in a broader resonance bandwidth that increases the field uniformity. This situation, however, results in the reduction of the available energy inside the chamber, requiring higher input power in order to compensate for the power loss. On the contrary, the use of acoustic diffusors [13] leads to better field homogeneity, due to the shifting of modes that is observed in frequency ranges where no or only a few modes are present. These structures are alternatively placed vertically or horizontally to eliminate the influence of the incident field.

An important issue that should be addressed each time a calibration of a reverberation chamber is performed is the loading effect [2,23]. After calibration is completed, the EUT should be placed inside the chamber so that the EMC test can be conducted. The introduction of the EUT in the enclosure will inevitably "load" the chamber, that is, absorb a significant amount of the energy available, which will no longer be used for generating the desired field conditions in the cavity. As a result, the input power should be increased, as mentioned previously.

No test should be carried out in a calibrated mode-stirred chamber without encountering the loading effects. For this reason, the average power received by a reference antenna injected in the chamber with the EUT in place should be recorded for a number of tuner steps equal to those used during the calibration. The eight measurements obtained from the calibration are compared to the data from this single measurement, and the chamber is not considered as loaded if the average value of the power received by the reference antenna, when the EUT is present, does not exceed the uniformity of the average field magnitude recorded during the calibration procedure. In a different case, a factor defined as the *chamber loading factor* (CLF) is introduced to compute the appropriate level of the input power capable of providing the desired amount of stored energy. The CLF is derived by calculating the ratio between (1) the measurement acquired when the EUT is placed in the chamber and (2) the mean value obtained during calibration. The chamber loading limit should also be determined by testing the field uniformity at conditions where tough loading is present.

3. STATISTICAL CHARACTERIZATION OF THE FIELD

A basic feature of a reverberating enclosure is the nature of the generated electromagnetic environment, which is purely stochastic in contrast to the alternate EMC sites

where the field is found to be deterministic. Therefore, research on the statistical properties of the field conditions inside a mode-stirred chamber turns out to be a very challenging task. In the more recent literature, the statistical behavior of a reverberation chamber has gained significant attention and an adequate number of mathematical models have been derived for the characterization of such a behavior. The received power of the antenna placed inside the chamber, which is directly related to the electric field squared, is statistically characterized with the use of theoretical prediction models. Other magnitudes that are statistically described in the literature are the maximum received power (i.e., maximum electric field squared), the rectangular component of the electric field, and the maximum value(s) of the rectangular component of the electric field. Because of the statistical nature of the electromagnetic environment in a reverberation chamber, the test conditions at the EUT can be established or monitored.

When the reverberation properties are assumed to be perfect (i.e., in an ideal mode-stirred chamber), then the spatial mean value of the field for a fixed boundary condition and the corresponding average of the field at a fixed location for variable boundary conditions (called the "ensemble average") are equivalent. The variable boundary conditions are accomplished by either rotating the stirrer or altering the configuration of the objects required for performing the EMC test in the chamber. Figure 2 demonstrates the probability density function (pdf) of the field at a location in a reverberation chamber with perfect conditions normalized by the ensemble average or the spatial mean value. It can be readily seen that as the number of the samples (i.e., different boundary conditions) is increased, the average magnitude of the field in the chamber at any location (or the "expected" value) converges to the spatial mean value. The uncertainty of this mean value is expressed by the width of the curve shown in Fig. 2, and as it can be easily derived, it shows a remarkable improvement as the number of samples grows [2].

Apart from the average value of the chamber field, the maximum magnitude, which is widely used for radiated immunity testing, also seems to be influenced by the number of the alternate boundary conditions. In Fig. 3, the pdf of the normalized by the mean value maximum magnitude of the electric field at a given location in the chamber is demonstrated. It can be noted that with the increase of the number of tuner steps (or boundary conditions), the distribution converges to a single value and the uncertainty improves as a result of the narrower width of the curve. This property, combined with the isotropic and homogeneous nature of the field in the chamber, and with the fact that the electromagnetic environment is characterized by its mean value, is used for the determination of the maximum value of all components at all locations in the working volume of the chamber by measuring or computing the mean of a specific component at a specific location. This assumption is, of course, used within some uncertainty but it is a very vigorous prediction.

When a large number of modes are present in a reverberation chamber (i.e., when the chamber is overmoded), the energy in a given mode is thought to be a random

Figure 2. Probability density function of the normalized value of the electric field at a fixed location with different number (N) of tuner steps.

variable depending on the position of the tuner [24]. The field at a given point is the sum of the contributions of the propagating modes in the chamber and is characterized by six parameters (in-phase and quadrature component in each direction). According to the central-limit theorem, each component should be normally distributed, as it is thought to be the sum of a large number of modes' amplitudes that are random variables. Also, all six components are independent and identically distributed when the distance of the point of examination and a reflecting object is large enough and, likewise, have zero means if the antenna in the chamber does not directly illuminate the location examined. That's the reason why the antenna in Fig. 1 points to the wall or to a corner opposite the EUT. According to these features, the magnitude of the total field at a location inside the mode-stirred chamber, follows the X distribution with 6 degrees of freedom, and has the following pdf [24,25]

$$f(|E_t|) = \frac{|E_t|^5}{8\sigma_t^6} \exp\left(-\frac{|E_t|^2}{2\sigma_t^2}\right) \quad (6)$$

where $|E_t|$ is the magnitude of the total field and σ_t^2 is the variance. The magnitude of any of the three electric field components (e.g., the E_x component) is again X -distributed but with only 2 degrees of freedom or in other words follows the Rayleigh distribution [24,25]

$$f(|E_x|) = \frac{|E_x|}{\sigma_x^2} \exp\left(-\frac{|E_x|^2}{2\sigma_x^2}\right) \quad (7)$$

where $|E_x|$ is the magnitude of the E_x component and σ_x^2 is the variance. The received power P_r of the antenna is proportional to the electric field squared and as a result is exponentially distributed [24,25]

$$f(P_r) = \frac{1}{2\sigma_r^2} \exp\left(-\frac{P_r}{2\sigma_r^2}\right) \quad (8)$$

where σ_r^2 is the variance.

The abovementioned statistical distributions apply for the case where the antenna, used to inject the appropriate amount of power in the chamber, does not directly

illuminate the EUT. But according to EMC requirements, the test should be done under conditions as close as possible to those under which the EUT is intended to operate. Most EUTs are designed to function in urban environments, where a direct path between the electromagnetic wave source and the EUT exists. Therefore, a model for predicting the electric field strength involving both deterministic and stochastic components has to be adopted. According to mobile communication environments, when a direct path is present, the multipath propagation phenomena are best described by the Rice distribution [21,22,26,27]

$$p_r(r) = \frac{r}{\sigma_{\text{Rice}}^2} \exp\left[-\frac{r^2 + r_s^2}{2\sigma_{\text{Rice}}^2}\right] I_0\left(\frac{rr_s}{\sigma_{\text{Rice}}^2}\right) \quad (9)$$

where r is a random variable, r_s a dominant component, σ_{Rice}^2 denotes the variance, and $I_0(\cdot)$ represents the Bessel function of the first kind and zero order. The Rician distribution is often described in terms of a parameter K defined as

$$K = 10 \log \frac{r_s^2}{2\sigma_{\text{Rice}}^2} \text{ dB} \quad (10)$$

which can be interpreted as the ratio of the dominant wave power over the power of the multipath components.

As shown in other studies [21,22], the fundamental properties of the reverberation chamber are satisfied to a high degree despite of the presence of the direct component, which is usually referred to as the "unstirred" component, due to its uninfluenced nature with regard to alteration in the chamber boundary conditions. The proposed Rice distribution [22] for the case of an unstirred component is well satisfied with the factor K lying between 1.2 and 1.5 for the majority of the frequencies examined. The uniformity tests for all the frequency ranges revealed a generated electromagnetic environment compliant with the requirements of the IEC standard [2], cited in the previous section.

The previously mentioned distributions apply to the field amplitude. The phase of the electric field component is another significant parameter to study. When the

Figure 3. Probability density function of the normalized maximum field magnitude at a fixed location with different number (N) of tuner steps.

antenna in the chamber does not directly illuminate the EUT, the magnitude of a rectangular component is Rayleigh distributed and the phase φ is uniformly distributed [28]. Therefore, it can be predicted by the following pdf:

$$f(\varphi) = \frac{1}{2\pi}, \quad -\pi < \varphi \leq \pi \quad (11)$$

The case of the presence of the unstirred component, where the electromagnetic field is partially stirred, is considered by assuming two real independent Gaussian fields, that have nonzero mean values but the same variance σ_g^2 . Consequently, the resulting field is the complex superposition of real and imaginary Gaussian fields with different means, leading to the Rice distribution for the field magnitude [Eq. (9)] and the phase distributed according to the following pdf [28]

$$f(\varphi) = \frac{1}{2\pi} \exp\left(-\frac{|E_u|^2}{2\sigma_g^2}\right) [1 + b\sqrt{\pi}e^{b^2}(1 + \operatorname{erf}(b))] \quad (12)$$

where $b = (1/\sigma_g\sqrt{2})(E_r \cos \varphi + E_i \sin \varphi)$, E_r, E_i are the means of the real and imaginary Gaussian fields, respectively, and E_u stands for the unstirred component.

There are many ways to test the behavior of a reverberation chamber and verify that it is calibrated and ready to be employed for performing EMC tests. An apparent procedure for determining the quality of the generated electromagnetic field conditions inside the chamber is to calculate the field uniformity or the statistical distribution of the field and require satisfaction of the proposed limits or distributions, respectively. Some additional ways which more or less give an indication of the proper chamber operation have been suggested in the literature.

The most widely known and commonly utilized test, apart from the field uniformity and statistical verification, is the stirring ratio test (or range test). This test determines the ability of the paddle to significantly vary the chamber boundary conditions and, consequently, the field strength at a given point. Ladbury and Goldsmith [29] defined a *stirring ratio* as the ratio of the maximum value

of the field divided by the minimum value at a fixed point. A value of 20 dB or greater proved adequate to generate the desired electromagnetic environment and revealed a significant improvement with an increase in the number of samples or tuner steps.

Similar to the stirring ratio test, the maximum : average ratio of the field strength or the received power is another indicative magnitude for determining the chamber's operation. Typical measurements [29] have shown a range of 6–8 dB to be adequate, and this improved again with the increase in the number of samples. This range is predicted by the nature of the chi-square (χ^2) distribution and appears to be important for immunity tests where the maximum values are most commonly used.

4. LOWEST USABLE FREQUENCY

The frequency above which the chamber operates according to the fundamental properties described in Sections 2 and 3 is assumed to be the lowest usable frequency. The LUF is generally determined by the effectiveness of the stirrer and the quality factor of the chamber. Its scope is about 3–5 times the first chamber resonance. In the IEC 61000-4-21 standard [2], it is assumed to be the lowest frequency above which the field uniformity requirements are achieved.

With another approach [3], the LUF is considered to be the frequency at which the chamber, due to the variable environment that is created by the movement of the tuners, hosts an electromagnetic environment with 60 modes. For a rectangular enclosure the LUF can be determined by the following equation [2]

$$N = \frac{8\pi}{3}abd \frac{f^3}{c^3} - (a+b+d) \frac{f}{c} + \frac{1}{2} \quad (13)$$

where N is number of modes, f is the frequency of propagation, c is the wave speed of propagation, and a, b, d are the dimensions of the rectangular enclosure. Equation (13), however, is a theoretical approach for determination of LUF, and an experimental verification should be per-

formed each time a chamber calibration is done. As derived by Eq. (13), the LUF depends primarily on the chamber's dimensions as they define the modal structure as a function of frequency. A commonly accepted guideline sets the LUF border at the frequency where the minimum tuner dimension is $\lambda/2$. However, the use of larger tuners, apart from improving the field uniformity, may result in lower LUF.

The dependence of the LUF on the chamber's dimensions, quality factor, and stirrer effectiveness can be conversely used, as for a given value of the LUF the minimum chamber requirements with regard to the later characteristics, can be specified. Arnaut [30] gives a theoretical expression for determination of LUF, depending on the chamber mode density and the number of available cavity modes. The use of wave diffractors shows that an increase or a decrease on the average mode density depends on their shape or position in the chamber. Additionally, as depicted by Petirsch and Schwab [13], the use of diffusors seems to increase the density of resonances at lower frequencies, which results in reduction of the minimum operating frequency of the reverberation chamber.

5. QUALITY FACTOR

An important parameter for determination of satisfactory reverberation chamber performance is the quality factor (often referred to as Q). As mentioned previously, the ability of a mode-stirred chamber to store high-intensity fields is a very important feature that distinguishes this kind of chamber from the other types of screened rooms. This ability is expressed through the quality factor, which is defined as the ratio of the energy stored in the chamber to the losses that occur in the enclosure and is depicted in the following equation [31]

$$Q = \frac{\omega U}{W_L} \quad (14)$$

where $\omega = 2\pi f$ is the angular frequency of operation, U is the energy stored in the chamber, and W_L stands for the losses.

One dominant factor of losses in a reverberation chamber is related to losses in the walls. These losses depend on the material that is used for the construction of the chamber and apparently are on low level when a highly conductive material is employed, such as copper and aluminum sheets or galvanized steel. On the contrary, copper and aluminum screen and flame spray give a low value for the quality factor of the chamber [2]. Apart from the walls' losses, some other types of losses that result in decrease in the Q value are the number of absorbing objects in the chamber, which "load" the chamber as shown before for the case of the EUT, the leakage through apertures and losses due to the dissipated power in the loads of receiving antennas. However, when a comparison is needed between different chambers with regard to the quality factor obtained, only wall losses are taken into account [31].

An expression for the determination of the chamber Q is given in the IEC 61000-4-21 standard [2]

$$Q = \frac{16\pi^2 V}{n_{Tx} n_{Rx} \lambda^3} \left\langle \frac{P_{avrec}}{P_{input}} \right\rangle \quad (15)$$

where V is the chamber volume (m^3), λ is the wavelength (m), $\langle P_{avrec}/P_{input} \rangle$ stands for the ratio of the average received power to the input power for one complete tuner rotation, and n_{Tx} , n_{Rx} are the efficiency factors of the transmit and receive antennas, respectively. These latter factors are set to 0.75 in the case of logperiodic antennas or 0.9 for horn antennas, if manufacturer's data are not available.

In the literature, a theoretical expression for the quality factor of a rectangular reverberation chamber has been derived [32]. For a chamber with dimensions a , b , c , this expression is

$$Q = \frac{3}{2} \frac{V}{S\delta_w} \frac{1}{1 + \frac{3\pi}{8k} \left(\frac{1}{a} + \frac{1}{b} + \frac{1}{c} \right)} \quad (16)$$

where V is the volume of the chamber, S is the sum of the areas of the chamber's walls, k stands for the wavenumber in free space, and δ_w is the wall skin depth, which is expressed by [33]

$$\delta_w = \frac{1}{\sqrt{\pi f \mu \sigma}} \quad (17)$$

where f is the frequency of propagation and μ, σ are the wall's permeability and conductivity, respectively.

In order to produce Eq. (16), the field inside the chamber was expressed through a series of cavity modes and then the average was taken over the ensemble of all these modes. It was additionally assumed that an equal amount of energy was in each mode, which is typical for random fields. Dunn [32] adopted a method, based on local plane waves, for the derivation of the Q of the chamber, which had the advantage of being applicable to nonseparable geometries (e.g., to a chamber with curved walls). The assumptions made were the random nature of the field well away from the walls and the large dimension of the chamber compared to the wavelength. The final expression that was derived identically agrees with (16) except for its adaptability to other than rectangular chamber geometries.

As can be observed in Eq. (16), minimization of the sum of the areas of the chamber's walls can result in an increase of the quality factor. Consequently, a spherical chamber stores larger amounts of energy compared to a rectangular, circular, or cubical chamber but will result in poorer spatial field uniformity due to the focus of the field at the chamber's center. Therefore, the arbitrary shape of the reverberation chamber is a very challenging topic to deal with, and similar to Dunn [32], Hill [34] has investigated this topic by introducing a reflection coefficient method for the determination of the quality factor. The expression derived is applicable to general wall materials and is transformed to the approach presented in Ref. 32, with utilization of highly conducting walls with small skin depth. In the following section, an expression for the qual-

ity factor of a mode-stirred chamber with vibrating walls is presented, based on an analysis performed using cavity theory.

6. ALTERNATIVE MEANS OF MODE STIRRING

Up to this point, the traditional reverberation chamber (i.e., rectangular chamber with rotating metallic paddle wheels) was assumed, and its features and properties have been presented. However, during the last few years the EMC community has also studied alternative ways of stirring the propagating modes inside a mode-stirred chamber, instead of using the traditional method. One motive for this study has been the complex structure of a chamber operating with paddle wheels, thus limiting its flexibility and mobility for in situ measurements. Additionally, the attempt to improve the performance of a mode-stirred chamber, especially at low frequencies, has also motivated this particular issue.

Since the objective for the constitution of an overmoded electromagnetic environment is the alteration of the chamber boundary conditions, this can be achieved by performing an alternative modification in some of the chamber characteristics. One apparent means of varying the chamber boundary conditions is to modify the chamber dimensions. This can be achieved by either moving one or more walls of the chamber, resulting in a moving-wall mode-stirred chamber [22], or by providing a chamber with flexible conductive walls that vibrate during the EMC test, thus introducing the vibrating reverberation chamber [26,35,36]. In the study presented in Ref. 22, the moving-wall mode-stirred chamber depicted in Fig. 4 was examined.

Assuming that the EUT is directly illuminated by a source antenna, the fields inside the chamber were analyzed with the use of a ray-tracing method [37], which was extended to best describe the direct-path status. The field was found to be homogeneous over a range of frequencies higher than 450 MHz and also Rice distributed at a specified point (due to the presence of the direct-path signal). Consequently, a LUF of ~ 450 MHz was predicted for that specific chamber. The length of the chamber was varied in a random manner, while extended simulation results showed that field homogeneity did not depend significantly on the range of variation.

Figure 4. The moving-wall mode-stirred chamber.

Figure 5. The vibrating reverberation chamber.

Another type of chamber with variable dimensions is the vibrating reverberation chamber shown in Fig. 5. The vibrating reverberation chamber consists of flexible walls made of highly conductive material to isolate the external electromagnetic environment. By vibrating the walls of the chamber, the number of the propagating modes is increased, resulting in a uniform environment. Because of the greater resonance frequency shift [36], the operating frequency range is increased and includes the lower frequencies. Another advantage of this chamber is its flexible structure, which enables it to be used for in situ measurements and does not occupy much laboratory space (or occupies no space if it is small enough to be folded).

A theoretical examination of the field conditions inside a vibrating reverberation chamber is presented in Refs. 26 and 35, where the finite-difference time-domain (FDTD) method [38] is applied. This numerical method is commonly used for the computation of the electromagnetic fields in a specified space in the time domain and provides the value of the electric or magnetic field at any given point inside the examination volume. Thus, it is a very good selection criterion for derivation of the magnitude of the electric field in a mode-stirred chamber, as is shown in the literature [26,35].

With the use of a continuous-wave [35] or pulsed [26] excitation in a vibrating reverberation chamber with a dipole antenna, the field uniformity was examined according to the rules defined in the IEC 61000-4-21 standard [2]. The vibrating surfaces were modeled according to the procedure described in Ref. 39, and the walls were assumed to be highly conductive. When a continuous wave excitation was employed, the field values were recorded after the field has reached the steady state situation. On the other hand, when a pulsed excitation was applied to the dipole antenna, the field values were computed by applying a discrete Fourier transform to derive the desired values over a wide frequency range.

The results from these two studies [26,35] reveal that the required field uniformity is obtained for all the frequencies within the frequency ranges examined (300 MHz–1 GHz for a chamber of dimensions $1 \times 1 \times 1$ m and 100 MHz–1.9 GHz for a larger chamber with dimensions $2 \times 2 \times 2$ m). In the same bands, the field was found to satisfy the Rice distribution, which was introduced by the direct-path signal. Additionally, the number of sam-

ples required for the field uniformity to be below the specified level [2] seems to be less than that proposed by the IEC specification, while the uniformity is improved as the frequency increases. From these observations it is concluded that the vibrating reverberation chamber provides a lowest LUF and requires fewer samples for obtaining the acceptable uniformity level compared to the traditional rectangular mode-stirred chamber.

Another theoretical study [31] on vibrating reverberation chambers demonstrates the ability of this chamber to store higher amounts of energy, resulting in a higher quality factor compared to the traditional mode-stirred chamber. The quality factor was computed through the relationship depicted in Eq. (14) for a chamber with highly conducting vibrating walls of the structure shown in Fig. 5. The FDTD method adopted for the theoretical simulation and a dipole antenna was again used for the field excitation. The stored energy was computed through the triple integral of the square of the electric field magnitude over the entire chamber volume. The chamber losses were focused only on the walls (as mentioned before when comparing different reverberating chambers, only walls losses are regarded) and were calculated by applying a double integral at the square magnitude of the magnetic field at each surface, which represents the forego currents. The quality factor for the rectangular reverberation chamber was computed by applying Eqs. (16) and (17) for the case of aluminum walls. The result derived proved the ability of the vibrating reverberation chamber to provide a higher quality factor compared to the traditional reverberation chamber, especially at high frequencies, with values ranging from 47 to 65 dB, whereas the rectangular chamber yielded a quality factor range of 45–50 dB for the same frequency band (300 MHz–2 GHz).

Apart from the theoretical approaches with regard to the usefulness of the vibrating reverberation chamber, some interesting experimental studies have appeared in the more recent literature. In Ref. 40, a screened room with walls made of conductive cloth was transformed in a vibrating mode-stirred chamber with the use of a fan placed outside the enclosure but close to the walls. The electromagnetic environment inside the chamber was found uniform for frequencies higher than ~ 450 MHz, and the field was found to be Rice distributed as a monopole antenna directly illuminated the examined area of the chamber. Leferink et al. [36] investigated a vibrating reverberation chamber with walls made of flexible conducting material and hanging in strings for several parameters: resonance frequency variation, voltage standing-wave ratio, stirring ratio, probability density function, and cumulative density function. The results derived showed adequate operation performance of the chamber, especially at low frequencies, where a high stirring ratio was observed.

Apart from the two alternative ways for mode stirring described earlier in this article, some others have been suggested in the literature. More specifically, frequency stirring [41], shows that field uniformity can be obtained by altering the bandwidth of the frequency modulation of the source, where a smaller bandwidth is required at high frequencies and vice versa, leading to a reduced effective-

ness of this technique at this late range. The intrinsic reverberation chamber [42], which uses nonparallel walls, where the ceiling is not parallel to the floor and at most two walls are placed perpendicular and fixed field diffusers, is another more recently proposed alternate structure of reverberation chamber. The use of a set of wires [43] or corrugated walls [44] inside the reverberating enclosure reveals that the field uniformity and the general operational conditions of a mode-stirred chamber are improved to a significant degree. One study [16] proved that for the case of radiation efficiency measurement of terminal antennas, the rotation of the EUT (i.e., the antenna) results in an improved accuracy for this measurement; and this stirring method is referred to as “platform stirring.”

7. CONCLUSION

An EMC test site, the reverberation chamber, was studied in this article. By describing its main features, the advantages that arise with the use of such a structure were outlined. Although not widespread, the reverberation chamber has been adopted at a standard level for EMC tests and is commonly used for antenna measurements, due to its compact size and uniform electromagnetic environment. In conjunction with the different ways of altering the mode distribution, measurements are performed with reliable accuracy and repeatability. Thus, when used for measurements not requiring a large test site or a very low operating frequency range (e.g., for mobile or wireless antenna measurements), the mode-stirred chamber is the best solution for performing the appropriate tests for each case. Research on reverberation chambers is being conducted continuously, with intense interest throughout the scientific community, because of the different operating conditions and structures that it provides. As expected, its characteristics will continue to be investigated and optimized in the near future, by fully utilizing the accoutrements provided by the current technology.

ANTENNA SCANNING ARRAYS

ROBERT J. MAILLOUX
AFRL/SNH
Hanscom Air Force Base,
Massachusetts

1. INTRODUCTION

There is a growing need for electronically scanned antenna arrays for both commercial and military applications. In the past the technology was driven by the need for military radars to find and track a multitude of fast-moving targets, and that led to the technology of large ground-based scanning arrays with narrow beamwidths, high gain, and thousands of control elements. More recent military trends have included the development of lightweight airborne arrays that now include solid-state transmit/receive (TR) modules at every element. The signal processing aspect of array systems has been exploited for the purpose of suppressing external noise in both commercial and military systems, and for providing simultaneous multiple functions or communication links. Research studies for wireless base station technology now include angle diversity, polarization diversity, and adaptive optimization algorithms in addition to the traditional space diversity. There is no limit to the demand for additional functions that would be useful if array technology could eventually lead to the idealized but cost-effective blackbox with huge bandwidth or multiple frequency bands and multiple beams. Unfortunately there is a limit to the rate of advances in the technology, but it is clear that these new applications will drive scanning array development for many years. This article describes some of the traditional and new features that can be incorporated into scanning arrays to meet these challenging new requirements.

The most fundamental requirement of a scanning array is to provide more gain and a narrower beamwidth than possible with a single-antenna element, and to move that beam to various observation angles. Array gain and beamwidth for broadside radiation are basically the same as for any equal-size aperture antenna, except for dissipative losses. The gain, as defined below, includes dissipative losses, but not mismatch losses, which are accounted separately. The maximum array gain when the array is scanned to some angle θ , is given as

$$G = \frac{4\pi A}{\lambda^2} \epsilon_a \epsilon_t \cos \theta \tag{1}$$

where A is the antenna area, λ is the wavelength, ϵ_a is the aperture efficiency that normalizes the directivity to that of a uniformly illuminated aperture ($\epsilon_a = 1$ for uniform), ϵ_t

accounts for loss in the feed network and antenna, and $\cos \theta$ is the array projector factor.

For a linear array of length L , the 3dB beamwidth (in radius) is given as

$$\theta_3 = \frac{B(0.886) \cos \theta}{(L/\lambda)} \tag{2}$$

where B is the beam broadening factor. It is unity for uniform illumination across the array and larger for array illuminations that produce lower sidelobes. For a rectangular arm, with sides L_1 and L_2 , the beamwidths θ_3 and θ_3 are written as above with L_1 and L_2 substituted for L and using the appropriate broadening factors in each plane.

Figure 1a illustrates how scanning is implemented in an array that scans in one dimension. Each antenna element is fed by an RF signal that is time-delayed by the sequence Δ , 2Δ , and so on across the array, where $\Delta = d_x \sin \theta_0/c$, and c is the velocity of light. This sequence of

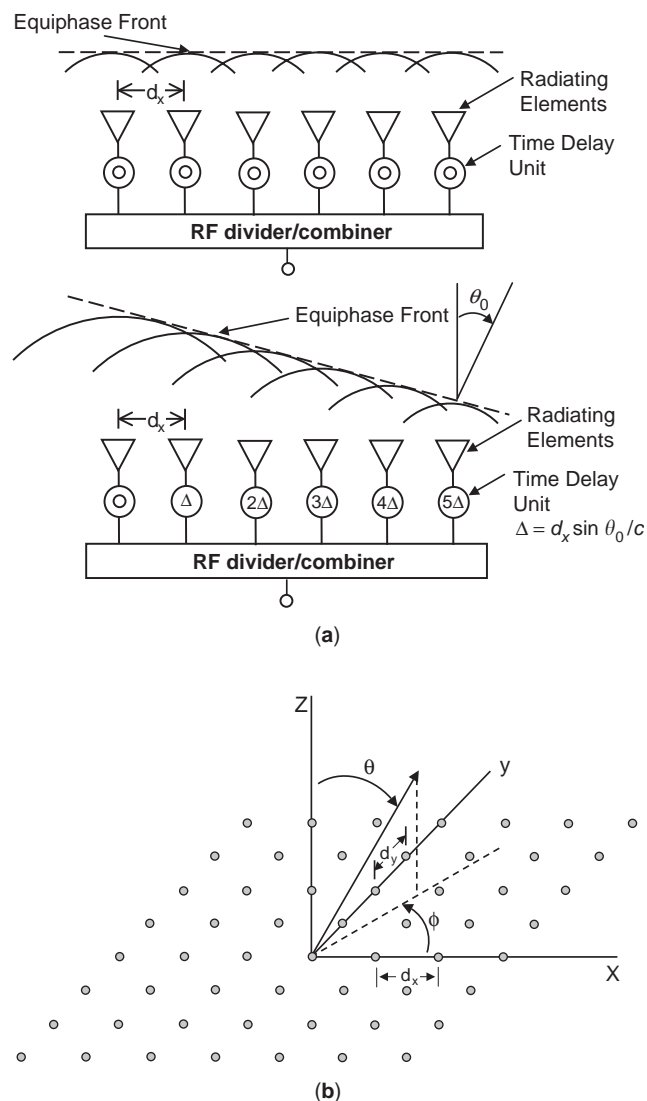

Figure 1. (a) Radiation from a linear antenna array; (b) two-dimensional scanning array.

time delays causes the radiation from the various antenna elements to add and form a coherent phase front (shown dashed) at some chosen angle θ_0 . The array beamwidth and gain are dependent on array size in ways that are described in the following section.

2. ARRAY SCANNING AND ITS CONSTRAINTS

Figures 1a and 1b show the array element grid locations and spatial angles. In the plane $\phi = 0$, the far-field pattern of a linear array of N elements located in a plane at $x_n = nd_x$ is written

$$E(\theta, \phi) = \sum_{n=1}^N a_n f_n(\theta, \phi) e^{jkn d_x u} \tag{3}$$

where $u = \sin \theta$ and $k = 2\pi/\lambda$ and $f_n(\theta, \phi)$ is the far-field element pattern of the n th element in the array environment. In general, the element patterns $f_n(\theta, \phi)$ are different for each array element even though all the elements are the same. These differences occur because each element pattern includes the scattered radiation from all other elements, from the array edges, and any scattering from the mounting structure. For most simple elements, like dipoles and slots, the currents or fields on the antennas differ by only a constant, and one can adjust the feed weights to compensate for these interaction effects.

For the purpose of illustration, we assume that all the element patterns $f_n(\theta, \phi)$ are the same [and given by $f(\theta, \phi)$]. The expression (3) becomes

$$E(\theta, \phi) = f(\theta, \phi) \sum_{n=1}^N a_n e^{jkn d_x u} \tag{4}$$

When this separation can be made, the pattern is expressed as the product of an element pattern $f(\theta, \phi)$ and an array factor (the indicated summation).

The coefficients a_n are chosen to move the array’s peak radiation to some desired angle θ_0 and to produce a specified sidelobe level. In principle, one would choose to steer the beam using time-delay devices, using the coefficients defined as

$$a_n = |a_n| e^{-jkn d_x u_0} \tag{5}$$

for $k = 2\pi/\lambda$ and $u_0 = \sin \theta_0$. In this expression the wave-number k is the same as that used in Eq. (3), and it varies linearly with frequency. The expression (3) thus has the frequency-dependent form of a signal that has passed through a length $n d_x u_0$ of coaxial line, and so is time-delayed by $n\Delta = n d_x u_0/c$. With this excitation the far-field radiation will always peak at u_0 for all frequencies, and the array bandwidth is limited only by device operation. This is immediately evident since inserting (5) into (4) leads to an expression with the exponent equal to zero at $u = u_0$. This state is highly desirable, but time-delay devices are costly and lossy and can constitute a major architectural issue in the design of array systems. This is one of the constraints that will be discussed later.

2.1. Array “Squint”

In lieu of using time delays at every element, it is more common to use phase shifters to control arrays. In this case, to move a principal maximum to some θ_0 at a single frequency ($\lambda = \lambda_0, k = k_0$), the required phased element excitations are given by

$$a_n = |a_n| e^{-jk_0 n d_x u_0} \tag{6}$$

Substituting Eq. (6) into Eq. (4) results in

$$E(\theta, \phi) = f(\theta, \phi) \sum_{n=1}^N a_n e^{j2\pi((u/\lambda) - (u_0/\lambda_0))n d_x} \tag{7}$$

The pattern has a maximum value at $u = u_0(\theta_0, \phi_0)$ when $\lambda = \lambda_0$. However, for a signal at some other frequency, since phase shifters produce a phase change that is nearly independent of frequency, Eq. (7) shows a peak at the angle θ whose sine is

$$\sin \theta = \left(\frac{\lambda}{\lambda_0} \right) \sin \theta_0 \tag{8}$$

This beam angle moves, or squints, as a function of frequency as indicated in Fig. 2, with the beam peak farthest from broadside at the lowest frequency and nearest to broadside for the highest frequency. This is called *array squint*.

This squint angle change can be interpreted in terms of a fractional bandwidth by assuming an array beamwidth of Δu and assuming that the beam is placed exactly at the angle θ_0 at center frequency f_0 . Then defining the upper and lower usable frequencies to be those at which the gain is reduced to half of the angle θ_0 results in the fractional bandwidth

$$\frac{\Delta f}{f_0} = \frac{\Delta u}{\sin \theta_0} \sim \frac{1}{(L/\lambda) \sin \theta_0} \tag{9}$$

where L is the array length. Arrays with narrow beamwidths Δu thus have less bandwidth and inverse proportionally less bandwidth as the scan angle is increased. Since the beamwidth is inversely proportional to array length, larger arrays suffer more severe squint loss than do smaller arrays for a given instantaneous bandwidth.

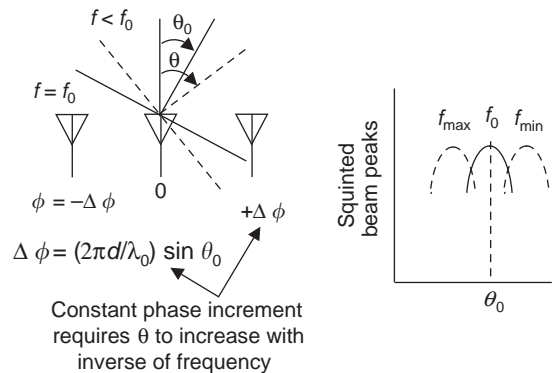

Figure 2. Frequency-sensitive beam “squint” for phase steered array.

Bandwidth requirements that result in the need to introduce time delays at every element become a major constraint in array design.

2.2. Grating Lobes

A second constraint restricts array element spacing and is a result of the array periodicity. The periodicity imposes constraints on element spacing in order to avoid the formation of unwanted radiation peaks, called *grating lobes*.

The grating lobe phenomenon is apparent from an inspection of Eq. (10). Consider the one-dimensional array with elements at the locations nd_x and operating at the frequency λ scanned by phase shifters. The pattern given by Eq. (7) becomes

$$E(\theta, \phi) = f(\theta, \phi) \sum_{n=1}^N |a_n| e^{jknd_x(\sin \theta - \sin \theta_0)} \quad (10)$$

The summation has its maximum when the exponent is zero for all n . This occurs at the peak of the mainbeam of the array, but the summation is also maximum when the exponent is set equal to any multiple p times $j2\pi n$. At these peaks, or grating lobes, the array factor is as large as it is at the mainbeam location $\theta = \theta_0$. These grating lobe angles are given by the angles θ_p for which

$$\sin \theta_p = \sin \theta_0 + \frac{p\lambda}{d_x} \quad p = \pm 1, \pm 2, \dots \quad (11)$$

for

$$\sin |\theta_p| \leq 1$$

Grating lobes can be avoided by restricting the element normalized spacing d_x/λ and the scan angle θ_0 . Using Eq. (11) and imposing the criteria that $\sin |\theta_p| \leq 1$ gives the spacing that excludes all grating lobes

$$\frac{d_x}{\lambda_0} < \frac{1}{1 + \sin \theta_0} \quad (12)$$

This condition means that the spacing must be less than $\lambda/2$ for scanning to endfire ($\theta_0 = 90^\circ$) and accordingly somewhat greater for lesser scan angles. Spacings greater than one wavelength always produce grating lobes.

The two-dimensional rectangular lattice array of Fig. 1 also has sets of grating lobes. These arise from the evident periodicities in the array factor. The pattern of this array is (at frequency f_0)

$$E(\theta, \phi) = f(\theta, \phi) \sum_{n=1}^N \sum_{m=1}^M |a_{nm}| e^{jk[(u-u_0)nd_x + (v-v_0)md_y]} \quad (13)$$

where $u = \sin \theta \cos \phi$ and $v = \sin \theta \sin \phi$. This pattern has grating lobes at

$$u_p = u_0 + \frac{p\lambda}{d_x} \quad (14)$$

$$v_q = v_0 + \frac{q\lambda}{d_y}$$

subject to the condition that these lobes fall within the unit circle

$$u_p^2 + v_q^2 < 1 \quad (15)$$

Figure 3. Grating lobe locations for two-dimensional rectangular grid array.

A sketch of the location of these lobes is given in Fig. 3, which indicates the primary beam at (u_0, v_0) and others at various (u_p, v_q) locations. The spacing d_x is chosen to illustrate a case such that for $u_0 = 0$ there are no other u_p lobes ($u_p \neq 0$) within the allowed circle, but with the scan angle (and direction cosine) u_0 were increased, as shown, the lobe at the left with u_{-1}, v_0 enters the circle and therefore radiates. In the other plane the spacing d_y/λ_0 is chosen larger and even with $v_0 = 0$ there already is a lobe (u_0, v_{-1}) that radiates. The specific criterion for excluding these lobes is given by Eq. (15), but for wide scan angles in both planes, this amounts to keeping the spacings very close to one-half wavelength.

2.3. Array Elements and Mutual Coupling

Scanned arrays can use a wide variety of basic elements, provided that they can fit within the allowed interelement spacing of Eq. (12). This poses no problem at the lower frequencies, but above 3 GHz or so it becomes a major constraint, since elements, phase control, and often TR modules may need to fit in a spacing on the order of a half-wavelength on a side. Figure 4 shows several of the basic elements used for array antennas. These are ordered relative to bandwidth, even though bandwidth is only one among many criteria for selection. The microstrip patch antenna of Fig. 4a as described by Herd [1] is one variation of this printed circuit antenna that is inexpensive to fabricate with computer controlled fabrication processes. The traditional microstrip patch (not shown) is driven by an inline microstrip transmission line on the dielectric substrate over ground. That technology is very narrowband, but the proximity-coupled patch in this figure uses a smaller patch or open-ended line on a substrate beneath the surface patch. The resulting double-tuning broadens the operating bandwidth to 10–15%. The dielectric loaded waveguide element of Fig. 4b is more expensive to fabricate and feed, although large two-dimensional grids of waveguides are efficiently fabricated and used for high-power radar arrays. Typically the bandwidth of waveguides in arrays is less than 40%. Figure 4c shows

Figure 4. Elements for scanning arrays: (a) proximity-coupled microstrip patch (ground screen beneath lower substrate); (b) dielectric-loaded waveguide; (c) dipole/balun radiating element; (d) stripline-fed flared-notch element.

one version of a horizontal dipole element fed by a balun. This particular feed combination [2] operates over about 40% bandwidth, but some dipole arrays operate over bandwidths in excess of 2:1. The flared-notch element of Fig. 4d is the widest-band element used to date in arrays [3]. The element can be designed and balun fed to achieve up to 10:1 bandwidth in a scanning environment when spaced approximately a half-wavelength apart at the highest frequency.

Restricting element spacings to about a half-wavelength improves the scanning characteristics of the array in addition to eliminating grating lobes. Scan behavior is dictated by electromagnetic coupling between the various array elements, and this coupling, called *mutual coupling* or *mutual impedance*, must be accounted for in the array design. This subject is treated in many journal publications, for example the paper by Wu [4] and texts by Balanis [5] and others, and won't be described further here except to note that it causes the element impedance to vary with each scan and so makes array matching difficult. In addition, it can cause a phenomenon called *array blindness* as described by Farrell and Kuhn [6] that can reduce the array radiation to zero within the normal scan range. This disastrous result appears as an effective open or short circuit at the array input ports, with all signal reflected back from the elements. To avoid building an array that is "blind" at some angles, designers now typically perform the full electromagnetic analysis of the array (or an infinite array with the same elements and spacings) before construction, or they perform measurements in an electromagnetic simulator or a small test array.

Whatever the element and array grid, the occurrence of blindness is usually reduced by decreasing the spacing beyond that given in Eqs. (12) and (15). For normally well-behaved elements that do not have a dielectric substrate at the array face (like waveguides or dipoles), Knittel et al. [7] have shown that making the dimensions smaller than required by 10% or so will avoid blindness. Arrays with

dielectric covers or with antennas printed on dielectric substrates may have additional blindness due to surface waves that propagate along the dielectric.

2.4. Array Pattern Synthesis

A number of very useful pattern synthesis procedures have been developed over the years. These fall roughly into two categories: methods for synthesizing "shaped" patterns that follow some prescribed shape like a conical sector to fill a given area or a cosecant-squared pattern for ground radar, and methods for providing a very narrow beam in one or two orthogonal planes. These latter are often called "pencil beam" synthesis procedures. It is not generally necessary to solve the full electromagnetic coupling problem when performing the synthesis studies, for one can synthesize on the basis of antenna currents or slot aperture fields, and then later use the computed mutual impedances to obtain the array excitation parameters. In addition, it is seldom necessary to synthesize scanned patterns since, for a periodic array, scanning just translates the pattern in u - v coordinates.

The basis for most aperture syntheses is the Fourier transform relationship between aperture field and far field for a continuous aperture. Arrays periodic in one or two dimensions have far-field patterns describable by discrete Fourier transform pairs. In one dimension the array factor at wavelength λ is written

$$F(u) = \sum_{n=-(N-1)/2}^{(N-1)/2} a_n e^{jkn d_x u} \quad (16)$$

where the sum is taken symmetrically about the array center. The coefficients a_n are the array element excitation and are given from orthogonality as

$$a_n = \frac{d_x}{\lambda} \int_{-\lambda/2d_x}^{+\lambda/2d_x} F(u) e^{-jkn d_x u} du \quad (17)$$

In this expression the integral is taken over the periodic distance in u space, namely, halfway to the two nearest grating lobes for a broadside beam. Used in this way, the technique gives the best mean-square approximation to the desired pattern. This feature is lost if spacings are less than a half-wavelength, although the technique is still useful. This Fourier transform synthesis is especially useful for shaped beam patterns, but it also serves as basis for many pencil-beam procedures as well.

A second technique that has found extensive application to shaped beam pattern synthesis is the Woodward synthesis method [8]. This approach uses an orthogonal set of pencil beams to synthesize the desired pattern. The technique has important practical utility because the constituent orthogonal beams are naturally formed by a Butler [9] matrix or other multiple-beam system.

Other techniques for periodic array synthesis are based on the polynomial structure of the far-field patterns. These include the method of Schelkunov [10] and the Dolph–Chebyshev method [11]. Among the most successful and used methods are the pencil-beam synthesis technique of Taylor [12] and the associated monopulse synthesis technique of Bayliss [13] (see Fig. 5). These techniques are derived as improvements to the equal-ripple method of Dolph–Chebyshev, and result in more realizable aperture distributions, improved gain, and other advantages. Figures 5a–b show the array factors for 50-element arrays with -40 dB Taylor and Bayliss distribution with $\bar{n} = 8$. Note that the first sidelobe in both cases is very close to -40 dB with respect to the pattern maximum. In general, the discretizing of continuous distributions introduces errors in the synthesized pattern, and these are more significant for small arrays or for arrays that are forced to have very low sidelobes. Usually discretizing the continuous distribution is not a problem, but when it is, a number of iterative techniques are used to converge to the original desired pattern. Space here precludes giving a detailed description of these procedures, but they are described in detail in a number of references. Notable among these is the work of Elliott [14].

Finally, in addition to these classic synthesis procedures, there have been many iterative numerical solutions to the synthesis problem. These have, in general, been shown to be efficient and useful. One such procedure has utility for both shaped and pencil beams. This procedure, described by Bucci et al. [15], is called the “method of alternating projection” or the “intersection” method, and produces a synthesis that is a best fit, or projection subject to some specified norm, to a desired pattern function, usually the region between an upper and lower “mask.” Space precludes including the details of this procedure, but Fig. 6 shows the upper (dashed) and lower (dotted) masks and the synthesized pattern. The mechanics of the process is to choose an initial guess at the currents (or the far-field pattern itself), compute the radiated power pattern using Eq. (16), “project” this to the nearest point on or between the upper or lower masks, and then use Eq. (17) to compute the exciting currents a_n , truncating the series at $n = N$. This new set of currents is subjected to the same procedure, and the process is repeated until the pattern is converged. The procedure is dependent on making a real-

Figure 5. Pattern synthesis by discretized continuous distributions (50-element array examples): (a) Taylor pattern for -40 -dB sidelobes using $\bar{n} = 8$; (b) Bayliss difference pattern for -40 -dB sidelobes using $\bar{n} = 8$.

istic initial guess, and on choosing a mask set that bounds a realizable solution, but has been found very convenient for many situations.

2.5. Array Error Effects

The ability to actually produce the synthesized patterns with a real array depends on the errors in the amplitude and phase of the currents or fields at the array aperture. Fundamental limits on phase shifter or amplitude control tolerance, the discretization of the desired phase, and amplitude in the aperture can lead either to random or correlated errors across the array. The average array sidelobe level (SL), far from the beam peak, and due to random error in amplitude and phase errors is given below in a form normalized to the beam peak

$$SL_{d10} = 10 \log_{10} \sigma^2 \quad (18)$$

Figure 6. Antenna pattern synthesis using the method of alternating projections (32-element array).

where the variance $\sigma^2 = (\bar{\Phi}^2 + \bar{\delta}^2)/N\epsilon_a$ and $\bar{\Phi}^2$ and $\bar{\delta}^2$ are the amplitude ratio variance and phase variance, N is the number of array elements, and ϵ_a is aperture efficiency.

2.6. Adaptive Arrays for Radar and Communication

Military systems have used adaptive antenna principles for jammer and other interference suppression for many years. In most early military systems these took the form of sidelobe cancelers, with one or several low-gain auxiliary antennas used to form nulls in the sidelobe regions of the composite pattern formed by the primary antenna and the cancelers. Fully adaptive arrays, wherein all elements of the array are controlled according to the adaptive algorithms, provide far more control than do sidelobe cancelers, but are far more costly and complex. One method, used when the direction of arrival of some desired signal is known, is due to Howells and Applebaum [16]. In terms of the total signal received by all ports of the array and weighted by the feed network, the array output is

$$E = \sum w_n e_n \quad (19)$$

or in vector form

$$E = \mathbf{W}^T \mathbf{e}, \quad (20)$$

where the signals and weights are shown as column vectors. The signal to noise ratio is given as

$$S/N = \frac{\mathbf{W}^\dagger \mathbf{M}_s \mathbf{W}}{\mathbf{W}^\dagger \mathbf{M} \mathbf{W}} \quad (21)$$

where \dagger denotes the conjugate transpose (Hermetian transpose).

The matrices \mathbf{M}_s and \mathbf{M} are the covariance matrices of the signal and noise. The noise covariance matrix is

Figure 7. Pattern adapted to suppress interference at $\sin \theta = 0.50, 0.52, 0.54, \text{ and } 0.56$.

written as the outer product

$$\mathbf{M} = \overline{\mathbf{e}^* \mathbf{e}^T} = \begin{bmatrix} \overline{e_1^* e_1} & - & - & \overline{e_1^* e_N} \\ - & - & - & - \\ - & - & - & - \\ \overline{e_N^* e_1} & - & - & \overline{e_N^* e_N} \end{bmatrix} \quad (22)$$

where the included terms are only the noise sources, with no desired signal present. The \mathbf{M}_s has the same form, but includes only the desired signal. Subject to these conditions, the optimum weight vector \mathbf{W} is given as

$$\mathbf{W} = \mathbf{M}^{-1} \mathbf{W}_0 \quad (23)$$

where \mathbf{W}_0 is the quiescent steering vector, which is usually known for most radar applications. Communication networks can use this algorithm using known or measured direction of arrival data.

Figure 7 shows the pattern of an array with the same -40 dB steering vector as Fig. 5a, but subject to strong interfering sources at $\sin \theta = 0.5, 0.52, 0.54, 0.56$. The resulting pattern isn't significantly distorted from that of Fig. 5a, but it does have nulls moved to the required angles. More serious pattern distortion would occur if the elimination of many more interfering signals were needed or if the interfering signals occupied a part of the main-beam.

3. ARRAY APPLICATIONS, CONTROL, AND ARCHITECTURE

3.1. Applications

The preceding sections of this article have outlined a number of the constituents that make up phased-array technology, as well as a number of constraints that dictate element spacing, bandwidth, achievable sidelobe levels,

and other properties. Present and future applications place new demands on this ubiquitous technology, but actually place separate groups of demands that result in quite different array architectures, and using very different modes of control.

Wireless mobile communication alone includes a huge number of varied requirements, from various satellite links to aircraft and ground-based users to base station needs and even to new projections for array needs in individual handheld cellphones. Many of these requirements are detailed in the review papers by Godora [17] and Dietrich et al. [18] and the book edited by Tsoulos [19].

Arrays will reduce the problem of limited channel bandwidth, multipath fading, and insufficient range by providing higher directivity with tailored beamshapes and the suppression of cochannel interference. The various wireless requirements span frequency ranges from UHF (Ultrahigh Frequency) to EHF (Extrahigh Frequency) and define array sizes from a few to many hundreds of elements. Of these requirements, the satellite systems often require large antenna systems at both ends of the communication link, with highly complex scanning or multibeam systems on the satellites and usually single-beam arrays with tens to hundreds of elements at airborne or Earth stations. Bands of frequencies up to approximately 44 GHz are used by civilian and military systems. Military airborne satellite terminals might have arrays with hundreds of elements.

Most existing wireless base station systems use fixed-beam arrays with a single element in azimuth, but enough elements in the vertical plane to provide narrow elevation beamwidths ($<10^\circ$). The typical three-sided cluster arrangement of Fig. 8 has three groups of three arrays each to cover three contiguous 120° sectors. Of the three-column arrays that face any particular sector, one transmits while the other two receive independent channels and provide time diversity to eliminate multipath fading. Some systems offer orthogonal polarizations to provide polarization diversity. Systems with small arrays are also being developed to provide angle diversity with scanning or fixed multiple beams. Either function can result in increased range and elimination of interference from competing signals [17].

Figure 8. Typical wireless cellular telephone base station arrays using four-column arrays for each 120° sector.

More recent experiments conducted with handheld and vehicle mounted arrays have shown significantly reduced fading and multipath interference rejection, so it seems that soon even handheld cellphones may have small arrays of a few elements.

Applications to military and civilian radar occupy the high-end array technology needs, with airborne multi-function arrays requiring hundreds to a few thousands of elements, while ground- and space-based arrays with tens to hundreds of thousands of elements have been investigated.

3.2. Array Control Modalities

Analog, optical, and digital technologies have been applied to the control of array antennas. The application of one or another of these technologies depends on system requirements and the constraints described earlier. This choice is also a function of time, since microwave analog technology is well established and still advancing rapidly through the use of circuit and solid-state device integration, while optical and digital technologies are far less mature but offer significant advantageous features for certain applications.

The most basic control circuits for each of these modalities are shown in Fig. 9. Analog control, shown in its simplest form in Fig. 9a, might consist of a circulator or TR switch to separate transmit and receive channels at the array level, followed by a corporate power divider network that weights the element level signals to provide for low sidelobe array illumination. This network could include simultaneous or switched sum-and-difference beam formation. Phase shifters or time-delay devices scan the beam in one or two dimensions. This basic network suffers from losses in the circulator, the power divider, and the phase or time control devices, and at microwave frequencies these could add to half the power. For this reason it is becoming more common to use solid-state TR modules at some subarray level or at each element as shown in Fig. 9b. Here separate feeds are used for transmit and receive that often have very different sidelobe requirements, and each port is routed to a TR module where it passes through a power amplifier on transmit or a low-noise amplifier on receive. The solid-state module usually includes a circulator for separating the two channels. Two fundamental constraints come into play: (1) time-delay devices are required if the instantaneous system bandwidth exceeds that of Eq. (9), and (2) spacing must be on the order of a half-wavelength at the highest frequency. However, these analog devices are basically switched lines, and must be on the order of the array aperture length, so at the higher frequencies it is difficult to fit the lines and control switches in the interelement area. These two constraints lead to the use of a subarray architecture for wideband arrays, discussed in a later section.

Figure 9c shows a basic optical network for array control. In this simplified circuit an optical signal is amplitude-modulated by an RF signal, the optical power divided into a channel for each antenna element, and then time-delayed by a switched-fiber time-delay unit. After detec-

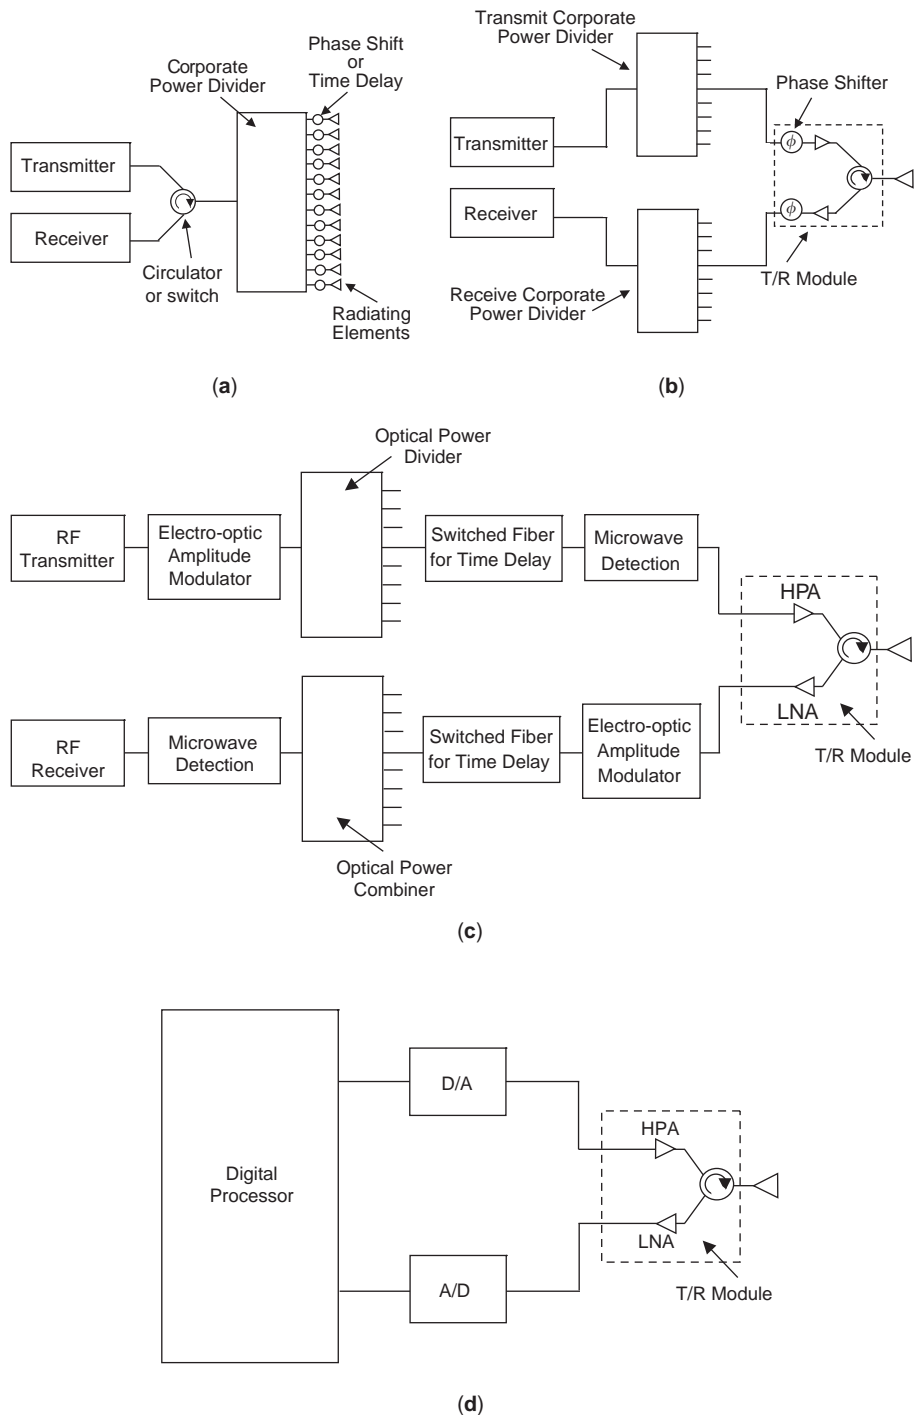

Figure 9. Array control modalities: (a) analog control using passive components; (b) analog control using active components; (c) optical control; (d) digital control.

tion the RF signal is amplified and radiated. The received signal is handled in a similar manner. This RF/optical path is very inefficient and may require amplification elsewhere in the network. The technology can provide accurate time delay with little dispersion, as required for large arrays with wide bandwidth.

Actual networks that are configured for photonic array control are often far more complex than the simple one shown in the figure, and may use independent optical

sources for each control port, as done by Lee et al. [20]. Still further in the future, photonic systems may use multiple interconnect networks for forming independent multiple beams with MEMS (micro-electromechanical system) mirror switches as described by Morris [21].

The primary obstacles to widespread use of photonic array control are network losses and device size constraints. Without amplification in the transmit and receive channels, modulation, detection, and power divider

losses can exceed 10dB, and this, coupled with the size constraints, may mean that for many years photonic time-delay control will be useful primarily at the subarray level.

Figure 9d shows a rudimentary digital beamforming network. This technology will eventually provide the ultimate degree of antenna control, and will present the signal processing computer with digital signals that are preprocessed to give optimal antenna performance. The digital beamforming network will obtain sidelobes as low as achievable from a given calibration network, provide multiple simultaneous beams or receive with arbitrary weightings on each beam, provide time-delay and wide-band operation using subbanding techniques, provide for array failure detection and correction, and “idealize” the antenna system itself by providing entirely separate control for each channel path through the array or subarray. Finally, it will allow fully adaptive control using virtually any algorithm without network changes.

This digital control is well within the state-of-the-art now, but currently not practical for large arrays. Limiting factors are A/D and D/A (or synthesizer) bandwidth, computer speed and storage requirements, power requirements, and size. The loss in the digitizing process also mandates use of solid-state modules at the array elements and the A/D sampling is usually done after downconversion to a suitable intermediate frequency. Considering all these factors leads to some very real and practical applications for relatively small arrays (or for some large but narrowband military arrays), and for many more applications for digital beamforming at the subarray level.

3.3. Control Architectures

3.3.1. Space-Fed Lens and Reflector Antennas. Figure 10a shows a space-fed lens array, which, in its simplest form, is just an alternate to the constrained “corporate feed” implied in Figs. 1a and 1b. This configuration shows an array face, fed by a single antenna that illuminates the back face of the aperture. The lens is active in that there is phase control at every element in the lens. The main advantage of this configuration is that it reduces the cost and weight of the system by eliminating the corporate feed. It is therefore applicable to lower-cost ground-based arrays as well as to very large space-based radar systems. Not shown are active reflect arrays that are configured like the lens geometry, but with shorted (short-circuited) lines that use phase shifters to vary the effective line lengths. This is a wide-angle scanning technology similar to that in the space-fed lens. In addition there is a class of space-fed structures including passive reflectors that can be scanned over limited angular regions. All of these space-fed scanning systems have instantaneous bandwidths limited by the use of phase control (or passive reflector) at the objective aperture.

3.3.2. Multiple-Beam Arrays. One last category of scanner is the multiple-beam array shown schematically in Fig. 10b, where each input port excites and independent beam in space. These can be produced with a digital beamformer, but in addition there are a variety of antenna

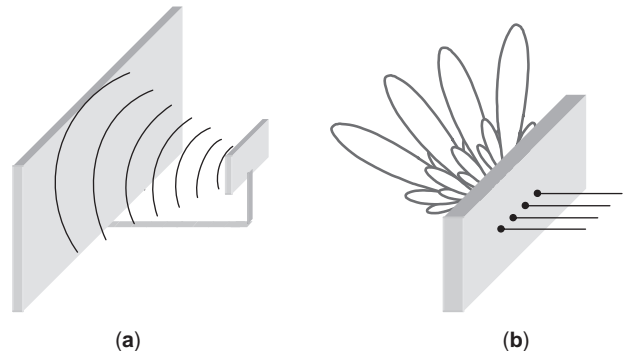

Figure 10. Phase shift and passive lens arrays: (a) space-fed array; (b) multiple-beam array.

hardware concepts that produce multiple beams, including Butler matrices [9,22] (Fig. 11), which involve a circuit implementation of the fast Fourier transform (FFT) and radiate orthogonal sets of beams with uniform aperture illumination. Lens and reflector systems have the advantage of being wideband scanners, since their beam locations do not vary with frequency. A particularly convenient implementation is the Rotman lens [23] of Fig. 12, a variant of the earlier Gent bootlace lens [24] that has the special feature of forming three points of perfect focus for one plane of scan. The Rotman lens can provide good wide-angle scanning out to angles exceeding 45°. Multiple-beam lenses and reflectors have been chosen for satellite communication systems, and in that application serve to either produce switched individual beams or use clusters of beams to cover particular areas on Earth. Figure 12 shows a sketch of a Rotman lens, illustrating the

$x = \pi/8$ radians phase shift
 ⊗ Hybrid coupler convention: Straight through arms have no phase shift, while coupled arms have 90° phase shift

Figure 11. Eight-element, eight-beam Butler matrix and radiated beams.

Figure 12. Rotman lens showing ray tracings and radiated wavefront.

several ray paths through the lens, and the associated radiating wavefront.

3.3.3. Control for Wideband and Fractional Bandwidth “Wideband” Arrays. The phenomenon called “squint” [see Fig. 2 and Eqs. (8), (9)] dictates the need for including time-delay steering for very wideband arrays and for very large arrays with even modest “fractional” bandwidth. These two categories of wideband arrays are distinctly different, and require completely different architectures. Figures 13 and 14 outline several approaches to providing time delay for the various relevant conditions. Figure 13 shows two possible architectures for very wideband (octave or multioctave) or multiple-band control. The sketch at left (Fig. 13a) shows one TR module and one time delay unit per element, and provides exact time delay and the ultimate bandwidth subject to antenna element

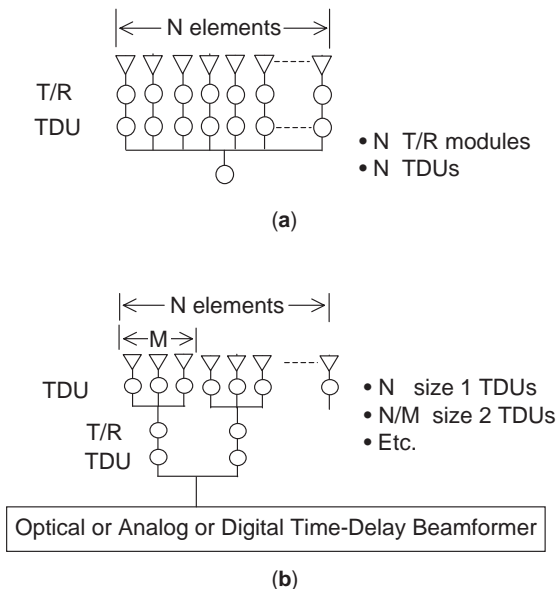

Figure 13. Array architectures for multioctave bandwidth or multiple-band antennas: (a) array with time-delay units; (b) array with cascaded time-delay units.

design (which can now be up to 10:1 in some cases). The TR amplification at the elements is necessary because time-delay units are lossy (depending on their length and technology). Recalling that an array 100 wavelengths long needs nearly 100 wavelengths of excess line switched in series with the outermost elements for scan to 60°, it becomes clear that significant loss can be expected. In addition to loss, there is little room behind each element to include the time-delay units and amplification, so this most basic of architectures is impractical for most applications except for relatively small, very wideband arrays.

Figure 13b shows a more practical configuration for providing element-level time-delay, and, like the sketch in Fig. 13a, provides the exact time delay at every element. This configuration provides small increments of time delay at each element, perhaps up to two or three wavelengths, then after grouping these elements into subarrays and amplifying, provides longer delays at successive levels of subarraying. Very long delays can then be pro-

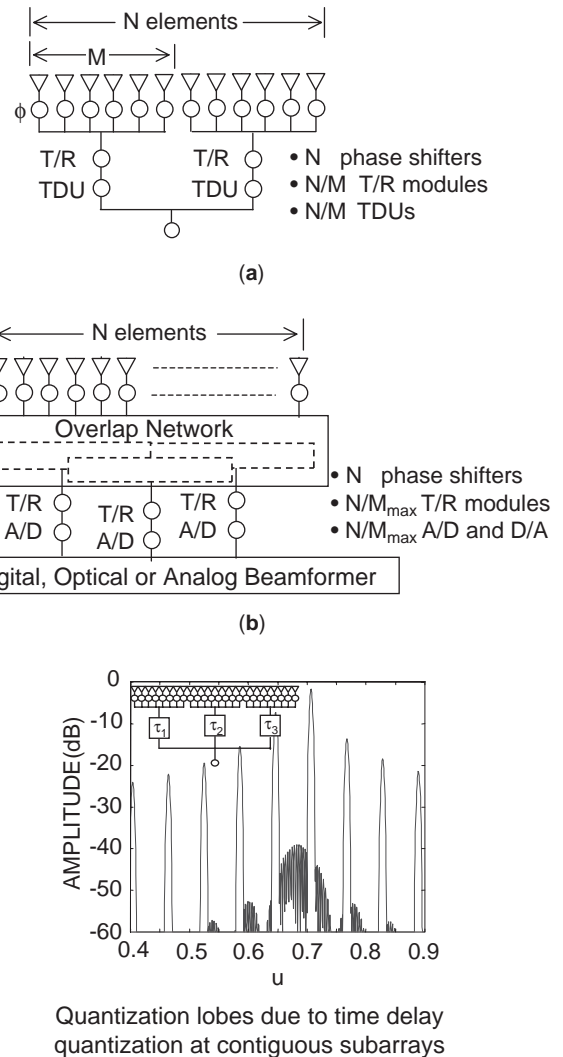

Figure 14. Architectures for large “wideband” arrays with fractional bandwidth: (a) phased arrays with time-delayed contiguous subarrays; (b) phased array with time-delayed overlapped subarrays.

vided by a beamformer using optical, analog, or digital time delay. In this case the optical and analog time delay is provided by a switched line configuration, and so retains the wideband features of the basic apertures. Digital beamformers don't presently support octave or multioctave bandwidth at microwave frequencies, but can provide accurate time delay over narrower bandwidths at a multitude of frequencies through subbanding and filtering. In these cases, the digital beamformer can provide multiband beams that point in the same direction using the network of cascaded time-delay units.

Figure 13a addressed truly wideband signal control, but very large arrays require time delay when the instantaneous bandwidth may be only a few percent, but still exceeding that of Eq. (9). Certainly the configuration of Fig. 13b will readily satisfy this condition, too, but several other options are available when the bandwidth is modest. Architectural solutions for such fractional bandwidth, but "wideband" arrays are shown in Fig. 14. The obvious solution, shown in Fig. 14a, consists of using phase shifters at the element level, and after amplification, inserting time delays at the subarray level. This solution is simple, is easy to build, and provides room for including analog, optical, or digital time delay at the subarray level, but can produce significant quantization lobes as shown in the insert. The configuration in Fig. 14b is highly schematic, but intended to indicate that by producing special, shaped subarray patterns, one can use the subarray patterns as an angular filter to remove the quantization lobes. These special networks, called *overlapped subarray* or *transform feeds*, have been developed as space-fed or constrained microwave networks, and, as detailed by Mailloux [25], do provide good pattern control at the expense of increased complexity. Digital control seems particularly appropriate for these overlapped feed networks because of the added degree of flexibility it provides.

4. CONCLUSION

This article has briefly described a variety of technologies and concepts that are fundamental to antenna scanning arrays. This technology has grown out of the military investments for radar, but now has an increasing role in commercial as well as military systems. One goal of the article has been to explain how the physical constraints of the interelement spacing and array squint necessary lead to different system architectures depending on the desired application. A second goal has been to briefly address present and new applications in light of the changing availability of analog, optical, and digital control technology. It seems reasonable to expect that this growing list of new array applications will continue to require an expanding collection of control modalities, components, and architectures for the foreseeable future.

ANTENNA TESTING AND MEASUREMENTS

W. NEILL KEFAUVER
 LOCKHEED MARTIN
 Denver, Colorado

Antenna testing uses many creative technological solutions to get what is an easily stated and critical function of a wireless communication, radar, or remote sensing system. The criterion is simply what level of power will my antenna deliver to or receive from a remote location defined by the antenna's usage. This remote location is almost always in the "far field" of the antenna, the far field of an antenna is the distance beyond which the pattern of antenna can be accurately approximated as $F(\theta, \phi) e^{-jkr}/r$. The engineering criterion for this distance is $2D^2/\lambda$, where λ is the wavelength of the signal and D is the antenna aperture's largest dimension in the same units as the wavelength; this relationship corresponds to a phase error of 22.5° across the antenna aperture relative to ideal. This article discusses the techniques used to evaluate antennas and the decades of effort to get the answer without having to put up with all the risks and delays of trying to obtain the information after the system is in the field.

1. HISTORY

In the early days of antenna measurements the technology was based on simple approximation of the operational environment, where measurements were performed outdoors at a sufficient distance to assume that the pattern was not changing with distance. One would build a tower outside to minimize antenna interactions with the ground, mount the antenna, and point it toward a transmitter a great distance away on the basis of the $2D^2/\lambda$ criterion. Using conventional motor control mechanisms already developed for telescopes and artillery among other applications, the user could obtain a reasonable response with the microwave detector—sometimes a crystal detector for just power, but over time the mixer became the sensor of choice as it has better dynamic range, can give phase information, and allows one to further filter the signal after converting the transmit signal to an intermediate-frequency signal. The data were recorded by synchronizing the motors of the range controller to a turntable and plotting using a pen and translation motor keyed to the amplitude of the received signal.

With the advent of widespread computing in the 1970s, the ranges began to automate, alleviating the menial task of manually reading data off charts and inputting them into the analysis computer. One of the first algorithms

implemented in the computer was calculation of circularly polarized data from linear measurements, eliminating the need for the rotating linear measurement to determine axial ratio of the antenna where the source antenna was spun continuously while scanning the remaining axes. The calculation of polarization using this method led to investigation of other information that could be derived from having digital data of the complex fields. Test articles no longer needed to be precisely aligned in the range; only knowledge of the location was necessary. Data processing could be used to correct misalignment, calibrate against gain standards, compensate for range polarization impurity, and software time-gate the data to reduce multipath. With all this improved capability to measure data, the increase in the technical knowledge, particularly mathematical, was dramatic. The arrival of compact range and near-field testing in the same decade represented an outgrowth of the metrology breakthroughs in automated testing spearheaded by several universities (particularly Ohio State) and the National Institute of Standards and Technologies (NIST). Since then the equipment has increased in complexity and capability to support the increasingly stringent antenna operational requirements.

2. APPLICATIONS

The vast majority of antennas are used in communications; however, there are more specialized antennas used for remote sensing and power transfer.

2.1. Communications

Beginning with Marconi, we have been using antennas to communicate at a distance, and the applications of these antennas have become more sophisticated over the decades. Today the most complex antennas are built for spacecraft to exacting requirements to optimize the distribution of power and reception of signals from geosynchronous orbit. These antennas will often have hundreds of beams working simultaneously to transfer received signals to transmit back to the final destination through a sophisticated communication subsystem. These antennas will often transmit two different signals simultaneously on the same frequency using polarization orthogonality to optimize the bandwidth utilization. In addition, the beams will be shaped to match specified coverage areas on Earth so that power is not wasted outside the coverage area. At the other end of the scale of complexity is the venerable monopole found on your radio, pager, or cellular phone and most portable communication devices; the only requirement expected of the monopole is to transfer some small percentage of the power to and from space into the communication device. In between these two antennas there are a host of applications requiring varying complexity, base-station antennas with single or multiple beams for cellular phones, television and radio transmit antennas for more efficient horizon coverage, reflectors for deep-space probes, whip antennas for cars, blade antennas for planes, and GPS patches for location finding.

2.2. Remote Sensing

An antenna used for remote sensing is either trying to measure a physical phenomenon, such as temperature or a radiated signal. Radar and astronomy antennas are specific examples of this application, where the information is not embedded in the signal but arises from the properties of the detected signal. Antennas used in radiometer work (a type of astronomy) need to have high-beam efficiency because the signal is very similar to the entire surrounding environment. Antennas used for signal detection need to have sensitivity over the desired coverage area and frequency, but are typically of a much broader band than are communication antennas because the signal source may change over time intentionally.

2.3. Radar

Radar is the one application where a device learns useful information while trying to talk to itself; the antennas employed for radar applications are typically highly directional in order to maximize power in a desired location. In specialized applications the pointing can be done using sophisticated microwave electronics almost instantaneously such as the AEGIS or AWACS system. More generally the radar is either pointed or swept through an area using rotation mechanisms, or for the radar gun, the antenna is manually pointed by the operator.

2.4. Astronomy

Most ground-based antennas used in astronomy have to be measured after installation because the individual antenna is too large to fit into a conventional measurement facility; range testing of these antennas is normally limited to the feed assembly and final performance is predicted using detailed modeling. Space-based astronomy usually has antennas that are thoroughly tested on the ground but require additional calibration as they settle into orbital operation. Antennas used in astronomy are some of the most efficient power conversion systems built because they have to resolve a signal of millikelvins from the background radiation of the universe. Also, because of the high sensitivity with which they are designed, the final assembly will need calibration to achieve optimal performance.

3. ANTENNA PATTERN MEASUREMENT REQUIREMENTS

Requirements for radiation performance of antennas can easily be divided into three areas by physical properties—frequency, solid angle, and polarization. Within each of these properties, depending on the application, there will be a large list of more specific requirements. Section 4 details many of these terms; the important item to remember is that all radiation behavior of the antenna is based on these three fundamental properties.

4. TERMINOLOGY

Antenna technology, like all technical specialties, has its own language, and I will now review some of the common

parameters when specifying an antenna's performance against system requirements using nonrigorous terminology. All of these terms have a pure mathematical relationship that can be developed rigorously and that can be found in any of the reference materials [1–6]. Antenna measurements require development of the method to convert raw response to an accurate, widely accepted version of these parameters. One reliable source of standard definitions for antennas is the IEEE [7]. These parameters are as follows:

Isotropic—a theoretical antenna that radiates a pure polarization uniformly in all directions¹

Gain—the improvement in the signal strength over an isotropic radiator

Directivity—the ratio of the signal received in the direction of interest relative to a standard radiating source, usually isotropic, less frequently a dipole

Beam width—usually half-power, the angular width in a plane containing the beam peak between the crossover points on either side of the peak

Cross-polarization—amount of power in the field polarization that is orthogonal to the one you are using

Polarization—relationship between the two orthogonal components of a traveling wave normal to the direction of propagation

Mainbeam—solid angle between the beam peak and the sign reversal of the detected signal (the signal usually goes through zero)

Sidelobes—pattern structure outside the main beam, usually desired to be minimal

Efficiency—amount of power delivered to the antenna that is radiated

Beam efficiency—amount of power radiated that is in the mainbeam

Axial ratio—ratio of the minimum to maximum linear response of measured signal at a specific angle

VSWR/return loss—amount of power reflected by antenna into the desired impedance

Mechanical boresight—orientation of the test article relative to coordinate system, usually defined as the z axis

Electrical boresight—location of the pattern peak relative to the mechanical boresight specified through test article physical geometry

Link margin—amount of power available relative to the required power to close the communication link between two antennas

Geometry—typically either θ/ϕ or azimuth/elevation coordinate system

G/T—gain of the antenna above the system noise temperature; defines sensitivity to received signals

¹Such a device is not even remotely achievable physically but is the most commonly used reference for all performance parameters.

EIRP—effective isotropic radiated power or power density at a defined distance, measured complete efficiency of the transmitter

Bandwidth—frequency range over which the antenna meets design requirements

Because of the brevity of this section, I will only try to introduce the function of each of these particular parameters for evaluating an antenna. The physical entity most easily understood is also one of the hardest to measure to the desired accuracy is gain. Gain is so significant because all other system performance parameters are limited by this entity. It is difficult to measure with high accuracy because there are so many possible ways to get significant error. For instance, the antenna must be aligned with a known gain standard to high accuracy (less than 0.5°), and it must not be significantly affected by the test environment. If the antenna picks up a stray emission 30 dB below the test signal, the error will be 0.27 dB or $\pm 6\%$. Because of the strong interaction of the antenna with its environment, it is very difficult to go below this level. Measurements at frequencies below 1 GHz are typically not directive and sensitive to multipath, and measurements above 1 GHz have stability problems due to the thermal drift moving the response significantly from the time when a standard was measured to when the antenna data were completed.

5. METHODS

The methods of evaluating antenna performance have diversified as the computational capabilities have increased. An antenna generates a three-dimensional radiation field, which for the purposes of most antenna applications can be described using an angular coordinate system; the dependence on distance is inversely proportional to distance, with no higher-order terms in the far field of the antenna. Unfortunately, reducing the field description problem to two spatial dimensions still leaves a great deal of complexity, especially if frequency is still a variable as well. Conventionally, a range has to be designed to rotate an antenna on two orthogonal axes to create a surface about the antenna (a sphere). Usually the antenna is rotated because it is easier than building an arch to allow the antenna to remain stationary. If this method is used, then a complete set of radiation data can be collected utilizing either three rotational axes or two axes and a dual-polarized source antenna with a switch.

5.1. Far-Field Range

Far-field ranges are either indoor or outdoor—indoor ranges became common after the development of commercially inexpensive anechoic materials to reduce multipath of the signal inside the room in the 1950s. Outdoor ranges were the first method developed as the need to characterize antennas became prevalent during World War II and are still used to this day for specific applications at low frequencies and involving extremely large test articles. Multipath problems in outdoor ranges usually

arise from one source—the reflection from the ground approximately halfway between the source antenna and the test article. The ground reflection is typically controlled through geometry by using ground bounce coherently at low frequencies (below 1 GHz). Otherwise the ground bounce is reduced by radiation fences or building sites on opposite sides of canyons or adjacent hills to reduce the power reflected into the test article by most of the ground outside the mainbeam of the source antenna.

5.1.1. Outdoor. The outdoor range often employs a secondary reference antenna in close proximity to the test article. This second antenna is used to deal with the outdoor range phenomenon of scintillation and to minimize cable runs. Outdoor ranges tend to be expensive to maintain because of property costs and frequent weather-related outages. The outdoor range does have the advantage of testing the article in an environment similar to production usage in some cases such as cellular base stations. If an outdoor range is retrofitted with a modern frequency-agile receiver, the user can take advantage of the same techniques pioneered in RCS (radar cross section) measurements, where you can apply either a software or hardware time gate to reduce multipath in the measured signal. The concept is simple—if the bounce from the ground is delayed by 10 ns, for example, then all signals are filtered out outside of approximately ± 5 ns from arrival in the direct path. The limitation to this technique is the bandwidth of the antenna and the separation of the arrival time—the longer the range and the shorter the towers, the less able the operator is to eliminate the ground bounce.

Figure 1 shows a typical range walk depicted the contribution of different signals to the response of the antenna separated in range and shows how time gating can be applied to eliminate some of the extraneous signal paths. The data were generated by using postprocessing of a stepped-frequency measurement. Making simple changes to the range configuration can isolate several of the additional pulses shown in the figure. If a cable length is introduced in between the source antenna and the

Figure 1. Antenna range “range walk.”

Figure 2. Chamber geometries: (a) rectangular; (b) tapered.

transmitter, the pulses associated with the cable should move out twice as far as the direct-path signal in the cable within the same time. The reflection of the test article should change as it is rotated relative to the antenna. Replacing the source antenna with a load can isolate the transmitter leakage. These diagnostic techniques are typical in any range setup and are key in ensuring that the antenna measurements are as good as can be done with the equipment. More importantly, these techniques have universal application and show the importance of a range walk in evaluating the performance of the range.

5.1.2. Indoor. Indoor ranges come in several types—rectangular (Fig. 2a), tapered (Fig. 2b), and dual-tapered are the most common. The rectangular chamber ideally has two square faces with long rectangles forming the walls, ceiling, and floor. The center of each face is treated with thick anechoic material to minimize specular reflections. This type of chamber typically provides a very clean quiet zone but is limited to higher frequencies due to the reflectivity of the sidewalls. The tapered chamber is specifically optimized for low-frequency measurements. The tapered chamber is intentionally flared from a point near the source's physical location to a large square aperture at volume where the antenna under test (AUT) is located. The chamber then terminates in a backwall of an extra-deep absorber to eliminate further chamber reflections. This chamber is more costly to build than a rectangular one and is plagued by a frequency-sensitive source point to mount the source antenna for optimal performance. The dual-tapered chamber basically bolts two large metal horns together and applies thick anechoic to the AUT end while attempting to reduce the bounce off the throat for a conventional tapered chamber. Full reciprocity does not apply straightforwardly to either the tapered or dual-tapered range because the source antenna is not in “free” space; therefore the anechoic material is used to optimize the delivery of fields to the region in which the AUT is located and the source that is selected has to be compatible with the chamber geometry. The operator does not care which antenna transmits and which receives but is extremely concerned as to how the antenna interacts with the chamber throat. This behavior makes three antenna calibrations impossible in a taper chamber. For a rectangular chamber, spatial reciprocity does apply since typically antennas can be physically interchanged with

the same response resulting, so multipath can be evaluated with ambivalence to it arising from the AUT or the source. The theoretical reciprocity of the antenna to transmit or receive is not what is important in measurements. Since the traditional method of calibrating an antenna for gain is by substituting a standard, the reciprocity of physical location is important since we are replacing an antenna with a known standard and neglecting the coupling to the chamber. This step usually predominates over all other error sources in the measurement because the accuracy of knowledge of the gain standard in the AUT environment is often poorly known or assumed to be much better than it really is. The uncertainty comes from the two devices that have significantly different patterns and are sensitive to multipath from different directions. In narrow ranges the gain standard may often interact with the source, causing significant errors, particularly if there are large flat surfaces. Often the test article itself will have large collimated reflections due to testing it in the environment in which it will be used. These terms can usually be isolated by time-domain (range walk) methods and can be surprisingly large. The important criterion is the tradeoff of facility size for article testing, namely, if you test in a small facility, the risk of the test article having a large RCS that interferes with the direct antenna measurement increases; as R increases, the contribution from the RCS decreases much faster than does the total loss on the link. The chamber can and will introduce additional errors depending on the type of antenna and measurement being performed. Possible errors include specular scattering off the flat surfaces of the absorber, reflections from the positioners, and even radiation from some lighting systems (particularly for antenna temperature measurements).

5.1.3. Pattern Synthesis. A specialized case for antenna measurements are techniques specifically modified to synthesize plane waves using means other than distance. The obvious reason for developing these other techniques was to eliminate the need for facilities many times the size of the antenna under test. However, if the cross section of the chamber is only slightly larger than the antenna, the far-field criterion causes the length of the range to increase in direct proportion to frequency. This type of range, although the cost would increase linearly, would degrade quickly once the range length increases to more

than twice the range width. This ratio applies when the angle of incidence on the wall is 60° off normal.

Unfortunately, as the chamber becomes longer, the specular wall reflections are at a lower angle, causing increased multipath as the reflectivity of the absorber decreases with angle. Absorber reflectivity decreases off normal incidence because the medium has been intentionally thinned geometrically to match to free space over several wavelengths using pyramids or wedges. As the field becomes parallel to the top of the absorber, the faces of geometric structures become visible and the transition from free space to carbon-loaded dielectric is instantaneous instead of spread over wavelengths.

Three well-known types of ranges are applied to eliminate the need for a long range: compact, near-field, and extrapolation. The following sections will briefly cover each type.

5.2. Compact Range

Although this concept is covered extensively in another article, briefly, the basic concept is that a point source of a conventional range is converted into an approximate plane wave using a reflector system. This concept was explored in the 1960s and perfected in the 1980s as modeling tools became more effective. Primary limitations to this measurement technique are the purity of the plane wave, which is limited by the reflector size and surface accuracy in addition to conventional multipath. Since the plane wave is synthesized instantaneously, this solution is desirable for applications in which speed is more important than accuracy. In particular, for situations where the amount of data required is minimal, such as peak gain, beamwidth, and cross-polarization, this type of range will allow the user to turn around hardware more quickly than using near-field scanning methods since only the data needed for the direct measurement of requirements are gathered. In the case of RCS measurements, the sheer volume of positional data required by near-field measurements necessitate that any realistic measurements be done using either a compact or far-field range.

5.3. Near-Field Range

Near-field measurements were developed in the 1970s to improve the accuracy of measurement methods. With near-field measurements, the far-field criterion ($2D^2/\lambda$) was eliminated and the concern over the purity of the plane wave was eliminated as well using powerful mathematical function space transforms. The ultimate limitation in far-field measurements has always been knowledge of the real distance between two antennas asymptotically to the far field. When one wishes to determine the coordinate system of the test antenna, all the uncertainties in the gain standard, the source, and the test antenna must be minimized to push measurement uncertainties under 0.5 dB. An example of this concern is that if one measures an antenna in a 100 m range, the knowledge of the relative position of the two antennas to the source must be less than 50 cm to get the positional error of the gain measurement under 0.05 dB. The quiet-zone variance over that 50 cm will need to be less than 0.05 dB to achieve an overall accuracy of <0.1 dB. In near-field ranges the first term is not rele-

vant and the second term is minimized by probe compensation. For many users this level of accuracy is beyond their needs and requires excellent mathematical skills, which has slowed the proliferation of this technology. One advantage of near-field measurement is that data can accurately be calculated for any position in space outside the measurement surface and fairly accurately calculated all the way into the test antenna. The limitations of near-field measurements are threefold: volume of data, processing of data, and knowledge of the probe pattern that has been convolved into the near-field measurement data.

5.3.1. Planar. Planar near-field measurements were the first geometry attempted because of the simplicity of the associated mathematics, which can be distilled to the following pair of simple equations, although it took a decade of research to become confident with the results:

$$\begin{aligned} \mathbf{P}(\mathbf{k})\mathbf{A}(\mathbf{k}) &= \iint [\mathbf{P}(x, y, 0) \otimes \mathbf{E}(x, y, 0)] \\ &\quad \times e^{-j\vec{k} \cdot \vec{r}(x, y, 0)} dx dy \\ \mathbf{E}(\mathbf{r}) &= \iint \mathbf{A}(\mathbf{k}) \frac{e^{j\vec{k} \cdot \vec{r}}}{r} \sin \theta d\theta d\phi \end{aligned} \quad (1)$$

When the probe being used to measure the fields over the planar surface is nonisotropic (*reality*), then the near-field measured value is the convolution of the probe pattern ($\mathbf{P}(x, y, 0)$) with the test antenna pattern which then must be divided out using known probe pattern characteristics by wavenumber ($\mathbf{P}(\mathbf{k})$) before the second equation. Obviously, to find the test antenna fields, the probe fields must be quantified. Often the isotropic approximation is used when the test antenna is highly directive and pointed perpendicular to the scan plane. Along the way to making this measurement method viable, many approximations had to be evaluated to quantify their contribution to a real measurement. First, the surface of a planar scanner is not closed except at infinity; this error term is called *truncation*. Moreover, the measured voltage is at discrete locations—the maximum sample spacing is limited by the Nyquist criterion to a half-wavelength without significant loss of information. The Nyquist criterion is normally applied in signal processing where the maximum frequency is harder to define sometimes, for antenna measurements the maximum frequency has to be the transmit frequency of the antenna, and sampling at twice the transmit frequency corresponds to sampling every half-wavelength. There are additional new error terms quantified by Newell and Yaghjian [8] in their papers on error analysis of this method. Note that for the far-field pattern case the second integral degenerates to an identity because wavenumber and direction are equivalent and the distance dependence is eliminated. Orthogonality with the Green function ensures that $\mathbf{A}(\mathbf{k}) = \mathbf{A}(\theta, \phi)$ with $\mathbf{A}(r) = 0$ since radial fields do not propagate.

5.3.2. Spherical. Because many antennas have important pattern characteristics extending into the back hemisphere and the method of near-field measurements had worked so well in the planar geometry, the mathematical

extraction techniques were extended to spherical data collection methods. The mathematics is far more complicated computationally by the need for spherical Bessel functions and Legendre polynomials to perform the spatial function decomposition; planar function expansions required only trigonometric functions that are conveniently self-inverting through the FFT (fast Fourier transform). The spherical function coefficient calculations require the use of full two-dimensional integrations to determine the best fit of coefficients to the antenna pattern. The positional sensitivity of the function expansion also increases dramatically as the near fields are measured over spheres closer to the size of the antenna. The implementation commercially usually involves building a facility that is identical to a far-field range except for having higher-grade rotary stages for accurate location of the test article. Several ranges have been built that move the probe instead of the test antenna to minimize the dynamic loading of the test antenna as its center of mass moved about the support tower. In this special case the positional uncertainty of the sphere surface can be reduced relative to the coordinate system, allowing for much more accurate measurements on antennas that have significant deflection under gravity.

5.3.3. Cylindrical. Cylindrical near-field measurement capabilities are easily added to either of the ranges described above by adding an extra axis of position control. Cylindrical measurements are optimized for fan beam antennas such as cellphone base stations and some more sophisticated radar applications such as the cosecant squared beams. The mathematical function set is more easily dealt with because we are back to using trigonometric functions for evaluating the function coefficients—with processing times for a similar-sized collection process such as planar data by taking advantage of the FFT. Typically the antenna will be rotated while a linear scan mechanism takes the second axis of data. The following equation expresses the mathematical flow of the processing:

$$\begin{aligned}
 & \mathbf{P}_A(k_z, n)\mathbf{A}(k_z, n) \\
 &= \oint \int [\mathbf{P}(0, \theta, z) \otimes \mathbf{E}(r_0, \theta, z)] e^{-j \vec{k} \bullet (z \sin n\theta)} \\
 & \mathbf{P}_B(k_z, n)\mathbf{B}(k_z, n) \\
 &= \oint \int [\mathbf{P}(0, \theta, z) \otimes \mathbf{E}(r_0, \theta, z)] e^{-j \vec{k} \bullet (z \cos n\theta)} \quad (2) \\
 \mathbf{E}(\mathbf{r}) &= \int \sum_n \left(\mathbf{A}(k_z, n) \times \frac{H_n^1(r)}{H_n^1(r_0)} \right. \\
 & \left. + \mathbf{B}(k_z, n) \times \frac{H_n^2(r)}{H_n^2(r_0)} \right) \frac{e^{jk_z \bullet \vec{r}}}{r}
 \end{aligned}$$

Note that the values in the final fields require both a summation and degenerate integral for far-field evaluation. Similar to the planar case, as r becomes large, the k and r vectors provide a significant product only when coincident, due to the function space orthogonality for a particular angle in θ . The other obvious introduction is a normalization factor for Bessel function H to resolve the

r dependence of the function. The magnitude of trigonometric functions does not vary with distance and thus does not have to be normalized to the integration surface. The cosine and sine functions are mathematically similar to the $+$ and $-$ of the conventional k -space expansions; the only difference is that the function has to be mapped to a finite number of functions in θ . Further reading on each of the geometries is available; for instance, the work by Yaghjian [8] is excellent in detailing the nuances of the measurement method.

5.4. Extrapolation Range

An extrapolation range measurement is used to very precisely determine the gain of an antenna at one orientation angle. The method measures the fields in the direction desired over an extended range from the near field to at least a reasonable far-field distance. Obviously this method is limited to antennas where this set of data can be taken with reasonably small structure—antennas typically have gains from 0 to 30 dB and frequencies above 500 MHz. The set of data from the antenna is then fitted to a polynomial, and the coefficient equivalent to the conventional power drop of distance squared is used to calculate the gain of the antenna. This method has the advantage that multipath is measured and then filtered directly by the processing. The obvious disadvantage of this method is that it requires a priori knowledge of the beam peak location if that is the direction in which accurate knowledge of gain is required. In conventional applications to general gain standards, this information is not considered to be in question, but for a generalized case this knowledge would have to be obtained by one of the other methods mentioned above.

6. OTHER REQUIREMENTS AND MEASUREMENT CRITERIA

6.1. Health Checks

All the methods described above require extensive checking during operation to obtain reasonable accuracies—margins for accurate gain measurements are small since the residual error terms, even in the best facilities, can quickly approach the system requirements. Additionally, only rarely is the measurement repeated let alone checked in an alternate facility, so the performance of the range must be carefully monitored. The result is that any range delivering data on high-performance antennas has an extensive health check capability—items regularly evaluated are the repeatability of the working standards in the range, the long-term stability of the range measurement system, the range alignment, the range multipath, range polarization purity, and system crosstalk.

6.2. Standards

Standards are needed for traceability of measurements to the engineering definitions we covered above. The most ubiquitous standard is the pyramidal horn; these antennas are widely accepted as working standards because direct gain calibration of each arbitrary antenna would require three antennas in the same frequency band and

the pyramidal horn is sufficiently accurate without direct evaluation to allow measurements to be calibrated by substitution with reasonable accuracy. Also, the gain of the horn is accurately predicted to less than 0.25 dB, often by computation, due to its excellent match and directivity. Other antennas are often used as standards of comparison but tend to be less robust in a working laboratory environment and are also difficult to model with the same confidence of accuracy. Of less concern because their error contributions are usually smaller by an order of magnitude are standards of distance, angle, frequency, and linearity. However, to accurately evaluate antenna performance parameters, these other items need to be quantified and documented. With the advent of automated network analyzers, lasers, and synthesizers, these terms should always be less than 0.1 dB.

6.3. Calibration

Range calibration is typically done by introducing one of the standards mentioned above in place of the antenna under test and comparing the measured response. In cases where the response would greatly differ between the two antennas, the one with the high power level is attenuated using a device of known loss and low mismatch, and a commercial microwave attenuator will often suffice. In some of the more complex facilities calibration will also evaluate polarization and will be required on multiple ports because of the antenna complexity. The accuracy of the calibration always is a cost driver in any measurement activity, and therefore tradeoffs must be made between accuracy and speed.

6.4. Gain by Comparison

Gain by comparison is used in all except the most exacting requirements because of the simplicity described in the standards section. Additionally, although the standard agreed to by industry for antenna gain excludes the device mismatch, it is usually embedded in the data and addressed by the device mismatch requirement for microwave measurements. Why I raise this piece of specific information is to emphasize that measured data do not typically correspond to a specific definition for a parameter—harmless approximations are frequently made, and since they do not change the uncertainty of most measurements, they are seldom mentioned in the final data. One obvious exception to this generally relaxed measurement approach is the calibration of a gain standard. When a customer requires the antenna measurement knowledge more accurately than the theoretical prediction of the gain standard, other measurement methods are applied. The best known of these is the three-antenna calibration.

6.5. Three-Antenna Measurements

In theory, three-antenna measurements only require the operator to introduce an alternate antenna at both ends of the chamber sequentially and take an additional measurement. In practice, this measurement is complicated by the source interaction with the chamber and is thus

limited to rectangular chambers. The other readily available solution is to have two nearly identical source antennas allowing one to use the second antenna as the source and also as the test antenna. The equation system is fairly simple if device mismatch is neglected:

$$\begin{aligned} P_{r1} &= P_t \frac{G_1 G_2}{4\pi r^2} \\ P_{r2} &= P_t \frac{G_3 G_2}{4\pi r^2} \\ P_{r3} &= P_t \frac{G_1 G_3}{4\pi r^2} \end{aligned} \quad (3)$$

The term P is treated as a vector of received voltage at the receive reference plane and is a vector because of the unknown polarization of the antennas tested, thus requiring two orthogonal orientations to measure the overall polarization. If this effect is neglected (which is usually possible when determining gain standards), then the antenna can be aligned for optimal delivered power and the only requirement is inversion of the set of equations, resulting in the following scalar result:

$$\begin{aligned} G_1 &= \frac{P_{r1} P_{r3} 4\pi r^2}{P_{r2} P_t} \\ G_2 &= \frac{P_{r1} P_{r2} 4\pi r^2}{P_{r3} P_t} \\ G_3 &= \frac{P_{r2} P_{r3} 4\pi r^2}{P_{r1} P_t} \end{aligned} \quad (4)$$

The result still requires knowledge of the total power transmitted, which is, of course, impacted by mismatch losses, as well as knowledge of the distance between the two antennas. When this result is combined with the extrapolation measurement mentioned above, the distance dependence of the calculation can be eliminated with the polynomial fit. The method also works best for antennas of matched polarization because of the ability to neglect the additional measurements, reducing test drift and detailed understanding of the interaction between gain and polarization. The importance of the result in Eq. (4) is that no calibrated components are required in the measurement, eliminating the need for traceability to an externally calibrated standard.

7. CONCLUSIONS

Antennas are a major component of any wireless application, including telephony, the Internet, and even many remote control systems as well as important science tools such as remote Earth sensing and radio astronomy. Since the build to tolerance of antenna patterns is always unknown through direct physical probing of the device or visual inspection, a different technology was required. As a result, a myriad of solutions have been used to gather information on the radiation characteristics of antennas. The solution can be as simple as a point-to-point connection of two antennas in the far field and as complicated as a multiport spherical near field with many options in between. The most important item in any measurement

solution is that precision (repeatability) of the measurement is significantly better than the measurement accuracy. As a result, good antenna ranges can provide reasonable error estimates for an arbitrary antenna measurement based on knowledge of the range without requiring significant modifications for the particular antenna pattern. The range design selection can then be based on the electrical/physical size of the test article, the weight of the article, the amount of data required, and the frequency to be tested. No particular range design is the best solution to all problems, but understanding how all the types work is key to making a good selection.

 Blacksburg, Virginia

1. INTRODUCTION

This article introduces the foundation concepts of antennas. Radiation of antennas provide the emphasis of the presentation. Methods of describing antennas include critical characteristics such as impedance, gain, beamwidth, and bandwidth. These parameters provide the primary information needed for full analysis of a communication system. To address a basic question raised by communication system designers, the fundamental limits of antennas are also presented to relate antenna size and bandwidth. The presentation is closed with a brief overview of the transient analysis of antennas as is appropriate for ultra wideband systems.

2. FUNDAMENTALS

2.1. Maxwell's Equations

Antenna properties are analyzed according to the basic laws of physics. These laws have been collected into a set of equations commonly referred to as *Maxwell's equations*. (The presentation in this section follows the textbook by Stutzman and Thiele [1] where a more detailed treat may be found.) In most antenna applications, we analyze sinusoidally varying sources in a linear environment. For such time-harmonic fields with a radian frequency of ω , the phasor form of Maxwell's equations as

$$\nabla \times \mathbf{E} = -j\omega \mathbf{B} - \mathbf{M} \quad (1)$$

$$\nabla \times \mathbf{H} = j\omega \mathbf{D} + \mathbf{J} \quad (2)$$

$$\nabla \cdot \mathbf{D} = \rho \quad (3)$$

$$\nabla \cdot \mathbf{B} = m \quad (4)$$

The quantities, \mathbf{E} , \mathbf{H} , \mathbf{D} , and \mathbf{B} , describe the physical terms of electric and magnetic field intensities and the electric and magnetic field densities, respectively. The cross and dot are the curl and divergence differential operators respectively. A supplementary equation that can be deduced from the second and third equations is

$$\nabla \cdot \mathbf{J} = -j\omega \rho \quad (5)$$

and is denoted the continuity equation to explicitly describe the electric current density \mathbf{J} in terms of the movement of volumetric electric charge, ρ . A similar relationship holds for the magnetic current density \mathbf{M} and volumetric magnetic charge m . These latter two quantities have not been identified as actual physical quantities to date, but are found to be extremely useful in analysis. In fact, the concept of magnetic current is identical to the concept of ideal voltage sources in electrical networks.

Maxwell's equations define relationships between the field quantities, but do not explicitly provide information about the media in which the fields exist. The material is usually characterized by three terms: permittivity ϵ , permeability μ , and conductivity σ . Sometimes the material conductivity is given in inverse form as the resistivity $\rho = 1/\sigma$. These terms relate the field density and intensity terms as well as the portion of the current due to conduction. Thus, we have $\mathbf{D} = \epsilon \mathbf{E}$, $\mathbf{B} = \mu \mathbf{H}$, and $\mathbf{J} = \sigma \mathbf{E}$ to give

$$\nabla \times \mathbf{E} = -j\omega \mu \mathbf{H} - \mathbf{M}_i \quad (6)$$

$$\nabla \times \mathbf{H} = (\sigma + j\omega \epsilon) \mathbf{E} + \mathbf{J}_i \quad (7)$$

$$\left(\epsilon - \frac{\sigma}{j\omega} \right) \nabla \cdot \mathbf{E} = \rho_i \quad (8)$$

$$\mu \nabla \cdot \mathbf{H} = m_i \quad (9)$$

and

$$\nabla \cdot \mathbf{J}_i = -j\omega \rho_i \quad (10)$$

where the i subscript denotes the impressed sources in the system, equivalent to the independent sources of circuit

theory. We find the medium description in the above equations limited in two ways: (1) the medium is described by scalar quantities, implying isotropic medium, and (2) the material parameters have been extracted from the derivatives, implying a constant, homogeneous medium. These simplifications are valid for antenna problems. It should be noted that Eqs. (8) and (9) can be obtained from Eqs. (7) and (6), respectively, with the appropriate continuity relations, such as Eq. (10).

If multiple frequencies are present, the solution to the equations can be found for each frequency separately and the results combined to form the total solution. A linearity restriction is used to ensure that the analysis would be properly performed for a single frequency. For nonlinear media and some complex problems, it is advantageous to solve the equivalent time-domain equations and obtain the frequency-domain fields through a Fourier (or Laplace) transform process. Computationally, the Fourier transform is usually obtained using a fast Fourier transform (FFT).

2.2. Wave Equations

In the far field of antennas, the solution of Maxwell's equations are solutions to the wave equation in source-free regions. The wave equation can be obtained by eliminating either \mathbf{E} or \mathbf{H} from Eqs. (6)–(9) with no impressed sources as

$$(k^2 + \nabla^2) \begin{Bmatrix} \mathbf{E} \\ \mathbf{H} \end{Bmatrix} = 0 \quad (11)$$

where $k = \omega \sqrt{\mu(\epsilon - \sigma/j\omega)}$. The quantity k is referred to as the *propagation constant* or *wavenumber* and can be written in terms of the phase and amplitude constants as $(\beta - j\alpha)$. In most antenna problems of interest, it is common to use β instead of k since the media is generally lossless. We will retain k for generality.

The solutions to Eq. (11) can be written in terms of either traveling or standing waves; traveling waves are more common for antenna applications. The traveling-wave solution to the electric field has a plane-wave solution form of

$$\mathbf{E}(\mathbf{r}) = \mathbf{E}_+ e^{-j\mathbf{k}\cdot\mathbf{r}} + \mathbf{E}_- e^{j\mathbf{k}\cdot\mathbf{r}} \quad (12)$$

The corresponding magnetic field is given by

$$\mathbf{H}(\mathbf{r}) = \frac{1}{\eta} \mathbf{k} \times [\mathbf{E}_+ e^{-j\mathbf{k}\cdot\mathbf{r}} - \mathbf{E}_- e^{j\mathbf{k}\cdot\mathbf{r}}], \quad \eta = \sqrt{\frac{\mu}{\left(\epsilon - \frac{\sigma}{j\omega}\right)}} \quad (13)$$

The form of Eq. (13) is called a *generalized plane wave* propagating along $\pm \mathbf{k}$ with the restriction that $\mathbf{k}\cdot\mathbf{E} = 0$, since the divergence is zero. The direct solution of the general differential forms of Maxwell's equations can be obtained analytically in special cases and numerically in most other cases. Numerical procedures typically use finite differences (FD), the finite difference-time domain (FDTD) method, or finite-element (FE) techniques [2]. The alternative is to transform the equations into integral forms for solution, where the solution structure is written

in integral form and the integral equation are used to solve for the field quantities.

2.3. Auxiliary Functions

Auxiliary functions are used to extend the solution of the wave equation beyond the simple traveling plane-wave form. If the magnetic sources are zero, then we can expand the magnetic flux density in terms of the curl of an auxiliary function, the magnetic vector potential \mathbf{A} [3], or

$$\mathbf{H} = \frac{1}{\mu} \nabla \times \mathbf{A} \quad (14)$$

The corresponding electric field intensity in simple media (using the Lorentz gauge for the potential) is given by

$$\mathbf{E} = \frac{1}{j\omega\mu\epsilon} [k^2 \mathbf{A} + \nabla \nabla \cdot \mathbf{A}] \quad (15)$$

This use of a gauge condition completes the specification of the degrees of freedom for \mathbf{A} . The magnetic-vector potential must satisfy the Helmholtz equation given by

$$(k^2 + \nabla^2) \mathbf{A} = -\mu \mathbf{J} \quad (16)$$

having a solution in free space (no boundary) of

$$\mathbf{A}(\mathbf{r}) = \mu \int_V \mathbf{J}(\mathbf{r}') \frac{e^{-jk|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} dv \quad (17)$$

for the geometry of Fig. 1. This general form can be specialized to the far-field case for an antenna located near the origin by expanding $R = |\mathbf{r}-\mathbf{r}'|$ in a binomial series as

$$\begin{aligned} R = |\mathbf{r}-\mathbf{r}'| &= \sqrt{r^2 - 2\mathbf{r}\cdot\mathbf{r}' + r'^2} \\ &= r - \frac{\mathbf{r}\cdot\mathbf{r}'}{r} + \frac{r'^2}{2r} - \frac{(\mathbf{r}\cdot\mathbf{r}')^2}{2r^3} + \dots \end{aligned} \quad (18)$$

for r' sufficiently small. Only the first term in this expansion, r , needs to be retained for use in the denominator of Eq. (17). However, more accuracy is needed for R in the exponential to account for phase changes; so the second term of the expansion is also used in the exponential:

$$R \approx r - \hat{\mathbf{r}}\cdot\mathbf{r}' \quad (19)$$

The complete far-field approximation becomes

$$\mathbf{A}(\mathbf{r}) \approx \mu \frac{e^{-jkr}}{4\pi r} \int_V \mathbf{J}(\mathbf{r}') e^{j\mathbf{k}\cdot\mathbf{r}'} dv \quad (20)$$

which is the familiar Fourier transform representation.

Figure 1. Coordinates and geometry for solving radiation problems.

In the far field where Eq. (20) is applicable, we may approximate the corresponding electric and magnetic fields as

$$\mathbf{E} \approx -j\omega[\mathbf{A} - \hat{\mathbf{r}}(\hat{\mathbf{r}} \cdot \mathbf{A})] \quad (21)$$

and

$$\mathbf{H} \approx \frac{k}{j\mu} [\hat{\mathbf{r}} \times \mathbf{A}] \quad (22)$$

The second term in Eq. (21) simply removes the radial portion \mathbf{A} from the electric field.

The definition of the minimum far-field distance from the source is where errors resulting in the parallel-ray approximation to the radiation become insignificant. The distance where the far field begins r_{ff} is taken to be that value of r for which the pathlength deviation due to neglecting the third term of Eq. (18) is a 16th of a wavelength. This corresponds to a phase error (by neglecting the third term) of $2\pi/\lambda \times \lambda/16 = \pi/8$ rad = 22.5° . If D is the maximum dimension of the source, r_{ff} is found to be

$$\frac{(D/2)^2}{2r_{\text{ff}}} = \frac{\lambda}{16} \quad (23)$$

Solving for r_{ff} gives

$$r_{\text{ff}} = \frac{2D^2}{\lambda} \quad (24)$$

The far-field region is $r \geq r_{\text{ff}}$ and r_{ff} is called the *far-field distance*, or *Rayleigh distance*. The far-field conditions are summarized as follows:

$$r \gg \frac{2D^2}{\lambda} \quad (25a)$$

$$r \gg D \quad (25b)$$

$$r \gg \lambda \quad (25c)$$

The condition $r \gg D$ is needed in association with the approximation $R \approx r$ the denominator of Eq. (17) for use in the magnitude dependence. The condition $r \gg \lambda$ follows from $kr = (2\pi r/\lambda) \gg 1$ which was used to reduce Eq. (15) to Eq. (21), neglecting terms that are inversely proportional to powers of kr greater than unity. Usually the far field is taken to begin at a distance given by Eq. (24), where D is the maximum dimension of the antenna. This is usually a sufficient condition for antennas operating in the UHF region and above. At lower frequencies, where the antenna can be small compared to the wavelength, the far-field distance may have to be greater than $2D^2/\lambda$ as well as D and λ in order that all conditions in Eq. (25) are satisfied.

The far-field region is historically called the *Fraunhofer region*, where rays at large distances from the transmitting antenna are parallel. In the far-field region the radiation pattern is independent of distance. For example, the $\sin \theta$ pattern of an ideal dipole is valid anywhere in its far field. The zone interior to this distance from the center of the antenna, called the *near field*, is divided into two subregions. The reactive near-field region is closest to the antenna and is that region for which the reactive field dominates over the radiative fields. This region extends to a distance $0.62\sqrt{D^3/\lambda}$ from the antenna, as long as $D \gg \lambda$. For an ideal dipole, for which $D = \Delta z \ll \lambda$, this distance is

$\lambda/2\pi$. Between the reactive near-field and far-field regions is the radiating near-field regions in which the radiation fields dominate and where the angular field distribution depends on the distance from the antenna. For an antenna focused at infinity, this region is sometimes referred to as the Fresnel region. We can summarize the field region distances for cases where $D \gg \lambda$ as follows [1]:

<u>Region</u>	<u>Distance from antenna (r)</u>	
Reactive near field	0 to $0.62\sqrt{D^3/\lambda}$	(26a)
Radiating near field	$0.62\sqrt{D^3/\lambda}$ to $2D^2/\lambda$	(26b)
Far field	$2D^2/\lambda$ to ∞	(26c)

2.4. Duality

Duality provides an extremely useful way to complete the development of the solution form as well as equating some forms of antennas. To complete the previous set of equations for the magnetic current and charge, we simply note that we can change the variable definitions to obtain an identical form of equations. Specifically, we replace

$$\mathbf{E} \rightarrow \mathbf{H} \quad (27a)$$

$$\mathbf{H} \rightarrow -\mathbf{E} \quad (27b)$$

$$\mathbf{J} \rightarrow \mathbf{M} \quad (27c)$$

$$\mathbf{A} \rightarrow \mathbf{F} \quad (27d)$$

$$\mu \rightarrow \varepsilon, \varepsilon \rightarrow \mu \quad (27e)$$

and

$$k \rightarrow k, \eta \rightarrow \frac{1}{\eta} \quad (27f)$$

The quantity \mathbf{F} is the electric vector potential for \mathbf{M} , analogous to the magnetic vector potential for \mathbf{J} . The solution forms for \mathbf{J} and \mathbf{M} can be combined for the total solution as

$$\mathbf{E} = \frac{1}{j\omega\mu\varepsilon} [k^2\mathbf{A} + \nabla\nabla \cdot \mathbf{A}] - \varepsilon\nabla \times \mathbf{F} \quad (28a)$$

and

$$\mathbf{H} = \frac{1}{j\omega\mu\varepsilon} [k^2\mathbf{F} + \nabla\nabla \cdot \mathbf{F}] + \mu\nabla \times \mathbf{A} \quad (28b)$$

The alternate use of duality is to equate similar dual problems numerically. A classic problem is the relationship between the input impedance of a slot dipole and strip dipole. The two structures are complements within the plane and have input impedances that satisfy

$$Z_{\text{slot}}Z_{\text{strip}} = \frac{\eta^2}{4} = \frac{\mu}{4\varepsilon} \quad (29)$$

This relationship incorporates several equivalencies, but most importantly the electric and magnetic quantities are scaled appropriately by η to preserve the proper units in the dual relationship. For a $72\text{-}\Omega$ strip dipole, we find the complementary slot dipole has an input

Figure 2. Images of electric (I) and magnetic (I_m) elemental currents over a perfect electric ground plane.

impedance of $Z_{\text{slot}} = 493.5 \Omega$. Self-complementary planar antennas such as spirals have an input impedance of 188.5Ω .

2.5. Images

Many antennas are constructed above a large metallic structure referred to as a *ground plane*. As long as the structure is greater than a half-wavelength in radius, the finite plane can be modeled as an infinite structure for all but radiation behind the plane. The advantage of the infinite structure that is a perfect electric conductor (PEC) is that the planar sheet can be replaced by the images of the antenna elements in the plane. For the PEC, the images are constructed to provide a zero, tangential electric field at the plane. Figure 2 shows the equivalent current structure for the original and the image problems.

It is common to feed antennas at the ground plane through a coaxial cable. If the ground is a good conductor, planar, and very large in extent, it approximates a perfect, infinite, ground plane. Then the equivalent voltage for the imaged problem is twice that of the source above the ground plane. The vertical electric current in Fig. 2 fed at the ground plane is called a monopole; it together with its image form a dipole and

$$Z_{\text{monopole}} = \frac{1}{2} Z_{\text{dipole}} \quad (30)$$

Since the corresponding field is radiated into only a half-space, the directivity of the antenna defined as the peak power density in the far field compared to the average power density over a sphere is double for the ground-plane-fed antenna as

$$D_{\text{monopole}} = 2 D_{\text{dipole}} \quad (31)$$

3. ANTENNA CHARACTERISTICS

There are a number of characteristics used to describe an antenna as a device. Characteristics such as impedance and gain are common to any electrical device. On the other hand, a property such as radiation pattern is unique to the antenna. In this section we discuss patterns and impedance. Gain is discussed in the following section. We begin with a discussion of reciprocity.

3.1. Reciprocity

Reciprocity plays an important role in antenna theory and can be used to great advantage in calculations and mea-

Figure 3. Two-port device representation for coupling between antennas.

surements. Fortunately, antennas usually behave as reciprocal devices. This permits characterization of the antenna as either a transmitting or receiving antenna. For example, radiation patterns are often measured with the test antenna operating in the receive mode. If the antenna is reciprocal, the measured pattern is identical when the antenna is in either a transmit or a receive mode. In fact, the following general statement applies: If nonreciprocal materials are not present in an antenna, its transmitting and receiving properties are identical. A case where reciprocity may not hold is when a ferrite material or active devices are included as a part of the antenna.

Reciprocity is also helpful when examining the terminal behavior of antennas. Consider two antennas, a and b shown in Fig. 3. Although connected through the intervening medium and not by a direct connection path, we can view this as a two-port network. For an antenna system, a property of reciprocity is the equality of the mutual impedances:

$$Z_{ab} = Z_{ba} \text{ for reciprocal antennas} \quad (32)$$

If one antenna is rotated around the other, the output voltage as a function of rotation angle becomes the radiation pattern. Since the coupling mechanism is via mutual impedances Z_{ab} and Z_{ba} , they must correspond to the radiation patterns. For example, if antenna b is rotated in the plane of Fig. 3, the pattern in that plane is proportional to the output of a receiver connected to antenna b due to a source of constant power attached to antenna a . For reciprocal antennas, Eq. (32) implies the transmitting and receiving patterns for the rotated antenna are the same.

Reciprocity can be stated in integral form by cross-multiplying Maxwell's equations by the opposite field for two separate problems, integrating and combining, and taking the resultant enclosing surface to infinity to obtain [4]

$$\int_V [(\mathbf{J}_a \cdot \mathbf{E}_b - \mathbf{M}_a \cdot \mathbf{H}_b)] dv = \int_V [(\mathbf{J}_b \cdot \mathbf{E}_a - \mathbf{M}_b \cdot \mathbf{H}_a)] dv \quad (33)$$

This form will be used in the next section to develop a formula for antenna impedance.

3.2. Antenna Impedance

Reciprocity can be used to obtain the basic formula for the input impedance of an antenna. If we define the two systems (a and b) for Eq. (33) as (a) the antenna current distribution in the presence of the antenna structure and (b) the same antenna current in free space ($\mathbf{J}_a = \mathbf{J}_b = \mathbf{J}$),

then we can apply Eq. (33) to obtain

$$\int_V (\mathbf{J} \cdot \mathbf{E}_b) dv = \int_V (\mathbf{J} \cdot \mathbf{E}_a) dv = -IV_a \quad (34)$$

Since $V_a = IZ$,

$$Z = -\frac{1}{I^2} \int_V (\mathbf{J} \cdot \mathbf{E}_b) dv \quad (35)$$

Thus, if the current distribution on the antenna is known, or can be estimated, then (35) simply provides a means for computing the antenna impedance Z by integrating the near field radiated by the antenna current in free space times the current distribution itself. A common approach to this computation results in the induced EMF method [5] for determining the input impedance to an antenna. The radiation resistance can be estimated using conservation of energy.

3.3. Radiation Patterns

The radiation pattern of an antenna is the angular variation of the radiation level around the antenna. This is perhaps the most important characteristic of an antenna. In this section we present definitions associated with patterns and develop the general procedures for calculating radiation patterns.

3.3.1. Radiation Pattern Basics. A radiation pattern (or, antenna pattern) is a graphical representation of the radiation (far-field) properties of an antenna. The radiation fields from a transmitting antenna vary inversely with distance (e.g., $1/r$). The variation with observation angles (θ, ϕ), however, depends on the antenna.

Radiation patterns in general can be calculated in a manner similar to that used for the ideal dipole if the current distribution on the antenna is known. This calculation is performed by first finding the vector potential using Eq. (20). As a simple example consider a filament of current along the z axis and located near the origin. Many antennas can be modeled by this line source; straight-wire antennas are good examples. In this case the vector potential has only a z component and the vector potential integral is one-dimensional:

$$A_z = \mu \frac{e^{-j\beta r}}{4\pi r} \int_z I(z') e^{j\beta z' \hat{\mathbf{z}} \cdot \hat{\mathbf{r}}} dz' \quad (36)$$

where β has been used for typical radiation media. Because of the symmetry of the source, we expect that the radiation fields will not vary with ϕ . This lack of variation is because as the observer moves around the source, such that ρ and z are constant, the appearance of the source remains the same; thus, its radiation fields are also unchanged. Therefore, for simplicity we will confine the observation point to a fixed ϕ in the xy plane ($\phi = 90^\circ$) as shown in Fig. 5. Then from Fig. 5 we see that

$$\rho^2 = x^2 + y^2 \quad (37)$$

$$z = \rho \cos \theta \quad (38)$$

$$y = \rho \sin \theta \quad (39)$$

Applying the general geometry of Fig. 1 to this case, $\mathbf{r} = y\hat{\mathbf{y}} + z\hat{\mathbf{z}}$ and $\mathbf{r}' = z'\hat{\mathbf{z}}$ lead to $\mathbf{R} = \mathbf{r} - \mathbf{r}' = y\hat{\mathbf{y}} + (z - z')\hat{\mathbf{z}}$ and

$$R = \sqrt{y^2 + (z - z')^2} = \sqrt{y^2 + z^2 - 2zz' + (z')^2} \approx r - z' \cos \theta \quad (40)$$

in the far field. This expression for R is used in the radiation integral of Eq. (36) to different degrees of approximation. In the denominator (which affects only the amplitude) we let

$$R \approx r \quad (41)$$

We can do this because in the far field r is very large compared to the antenna size, so $r \gg z' \geq z' \cos \theta$. In the phase term, we must be more accurate when computing the distance from points along the line source to the observation point and use both terms in Eq. (40). Using this far-field approximation in Eq. (36) yields

$$A_z = \mu \int I(z') \frac{e^{-j\beta(r-z' \cos \theta)}}{4\pi r} dz' = \mu \frac{e^{-j\beta r}}{4\pi r} \int I(z') e^{j\beta z' \cos \theta} dz' \quad (42)$$

where the integral is over the extent of the line source.

The electric field is found from Eq. (21), which is

$$\mathbf{E} \approx -j\omega [\mathbf{A} - \hat{\mathbf{r}}(\hat{\mathbf{r}} \cdot \mathbf{A})] = -j\omega A_\theta \hat{\boldsymbol{\Theta}} = j\omega \sin \theta A_z \hat{\boldsymbol{\Theta}} \quad (43)$$

Note that this result yields the components of \mathbf{A} that are perpendicular to $\hat{\mathbf{r}}$. This form is an important general result for z -directed sources that is not restricted to line sources.

The radiation fields from a z -directed line source (any z -directed current source in general) are E_θ and H_ϕ , and are found from Eqs. (21) and (22). The only remaining problem is to calculate A_z , which is given by Eq. (20) in general and by Eq. (42) for z -directed line sources. Calculation of A_z is the focus of linear antenna analysis. We will return to this topic after pausing to further examine the characteristics of the far-field region.

The ratio of the radiation field components as given by Eqs. (21) and (22) yields

$$E_\theta = \frac{\omega\mu}{\beta} H_\phi = \eta H_\phi \quad (44)$$

where $\eta = \sqrt{\mu/\epsilon}$ is the intrinsic impedance of the medium, 377Ω in a vacuum. An interesting conclusion can be made at this point. The radiation fields are perpendicular to each other and to the direction of propagation $\hat{\mathbf{r}}$, and their magnitudes are related in general by η .

These are the familiar properties of a plane wave. They also hold for the general form of a transverse electromagnetic (TEM) wave, which has both the electric and magnetic fields transverse to the direction of propagation. Radiation from a finite antenna is a special case of a TEM wave, called a *spherical wave*, which propagates radially outward from the antenna and the radiation fields have no radial components. Spherical-wave behavior is also characterized by the $e^{-j\beta r}/4\pi r$ factor in the field expressions; see Eq. (42). The $e^{-j\beta r}$ phase factor indicates a traveling wave propagating radially outward from the

origin and the $1/r$ magnitude dependence leads to constant power flow just as with the infinitesimal dipole. In fact, the radiation fields of all antennas of finite extent display this dependence with distance from the antenna.

Radiation patterns can be understood by examining the ideal dipole. The fields radiated from an ideal dipole are shown in Fig. 4a over the surface of a sphere of radius r that is in the far field. The length and orientation of the field vectors follow from Eq. (43); they are shown for an instant of time for which the fields are peak. The angular variation of E_θ and H_ϕ over the sphere is $\sin \theta$. An electric field probe antenna moved over the sphere surface and oriented parallel to E_θ will have an output proportional to $\sin \theta$ (see Fig. 4b). Any plane containing the z axis has the same radiation pattern since there is no ϕ variation in the fields. A pattern taken in one of these planes is called an *E-plane pattern* because it contains the electric vector. A pattern taken in a plane perpendicular to an *E-plane* and cutting through the test antenna (the xy plane in the dipole case) is called an *H-plane pattern* because it contains the

magnetic field H_ϕ . The *E-* and *H-plane* patterns, in general, are referred to as *principal plane patterns*. The *E-* and *H-plane* patterns for the ideal dipole are shown in Figs. 4b and 4c. These are polar plots in which the distance from the origin to the curve is proportional to the field intensity; they are often called polar patterns or polar diagrams.

The complete pattern for the ideal dipole is shown in isometric view with a slice removed in Fig. 4d. This solid polar radiation pattern resembles a doughnut with no hole. It is referred to as an *omnidirectional pattern* since it is uniform in the xy plane. Omnidirectional antennas are very popular in ground-based applications with the omnidirectional plane horizontal. When encountering new antennas, one should attempt to visualize the complete pattern in three dimensions.

Another way to view radiation field behavior is to note that spherical waves appear to an observer in the far field to be a plane wave. This “local plane-wave behavior” occurs because the radius of curvature of the spherical wave is so large that the phase front is nearly planar over

Figure 4. Radiation from an ideal dipole: (a) field components; (b) *E*-plane radiation pattern polar plot; (c) *H*-plane radiation pattern polar plot; (d) three-dimensional pattern plot. From [1]

Figure 5. Geometry used for field calculations of a line source along the z axis.

a local region. If parallel lines (or rays) are drawn from each point in current distribution as shown in Fig. 6, the distance R to the far field is geometrically related to r by Eq. (19), which was derived by neglecting high-order terms in the expression for R in Eq. (18). The parallel-ray assumption is exact only when the observation point is at infinity, but it is a good approximation in the far field. Radiation calculations often start by assuming parallel rays and then determining R for the phase by geometrical techniques. From the general source shown in Fig. 6, we see that

$$R = r - r' \cos \alpha \quad (45)$$

Using the definition of dot product, we again have Eq. (19):

$$R = r - \hat{\mathbf{r}} \cdot \mathbf{r}' \quad (46)$$

This form is the same general approximation to R for the phase factor in the radiation integral for the general case previously developed. Notice that if $\mathbf{r}' = z' \hat{\mathbf{z}}$, as for line sources along the z axis, (46) reduces to (40).

3.3.2. Steps in the Evaluation of Radiation Fields. The derivation for the fields radiated by a line source can be generalized for application to any antenna. The analysis of

Figure 6. Parallel-ray approximation for far-field calculations of radiation from a general source.

the line source, and its generalizations, can be reduced to the following three-step procedure:

1. Find \mathbf{A} . Select a coordinate system most compatible with the geometry of the antenna, using the notation of Fig. 1. In general, use Eq. (17) with r in the magnitude factor and the parallel-ray approximation of Eq. (46) for determining phase differences over the antenna. These yield

$$\mathbf{A} = \mu \frac{e^{-j\beta r}}{4\pi r} \int_V \mathbf{J} e^{j\beta \hat{\mathbf{r}} \cdot \mathbf{r}'} dv' \quad (47)$$

For z -directed line sources on the z axis

$$\mathbf{A} = \hat{\mathbf{z}} \mu \frac{e^{-j\beta r}}{4\pi r} \int_z I(z') e^{j\beta z' \cos \theta} dz' \quad (48)$$

which is Eq. (42).

2. Find \mathbf{E} . In general, use the component of

$$\mathbf{E} = -j\omega \mathbf{A}_t \quad (49)$$

(where the “ t ” subscript denotes transverse to $\hat{\mathbf{r}}$). This result is expressed formally as

$$\mathbf{E} = -j\omega \mathbf{A} + j\omega (\hat{\mathbf{r}} \cdot \mathbf{A}) \hat{\mathbf{r}} = -j\omega (A_\theta \hat{\Theta} + A_\phi \hat{\Phi}) \quad (50)$$

which arises from the component of \mathbf{A} tangent to the far-field sphere. For z -directed sources, this form becomes

$$\mathbf{E} = j\omega A_z \sin \theta \hat{\Theta} \quad (51)$$

which is Eq. (43).

3. Find \mathbf{H} . In general, use the plane-wave relation

$$\mathbf{H} = \frac{1}{\eta} \hat{\mathbf{r}} \times \mathbf{E} \quad (52)$$

This equation expresses the fact that in the far field the directions of \mathbf{E} and \mathbf{H} are perpendicular to each other and to the direction of propagation, and also that their magnitudes are related by η . For z -directed sources

$$H_\phi = \frac{E_\theta}{\eta} \quad (53)$$

which is Eq. (44).

The most difficult step is the first, evaluating the radiation integral. This topic will be discussed many times throughout this encyclopedia, but to immediately develop an appreciation for the process, we will present an example. This uniform line source example will also serve to provide a specific setting for introducing general radiation pattern concepts and definitions.

3.3.3. Example: The Uniform Line Source. The uniform line source is a line source for which the current is constant along its extent. If we use a z -directed uniform line source centered on the origin and along the z axis, the current is

$$I(z') = \begin{cases} I_0 & x' = 0, y' = 0, |z'| \leq \frac{L}{2} \\ 0 & \text{elsewhere} \end{cases} \quad (54)$$

where L is the length of the line source (see Fig. 5). We first find A_z from Eq. (48) as follows:

$$A_z = \mu \frac{e^{-j\beta r}}{4\pi r} \int_{-L/2}^{L/2} I_0 e^{j\beta z' \cos \theta} dz' \tag{55}$$

$$= \mu \frac{e^{-j\beta r}}{4\pi r} I_0 L \frac{\sin [(\beta L/2) \cos \theta]}{(\beta L/2) \cos \theta}$$

The electric field from (51) is then

$$\mathbf{E} = j\omega A_z \sin \theta \hat{\Theta} = j\omega \mu I_0 L \frac{e^{-j\beta r}}{4\pi r} \sin \theta \frac{\sin [(\beta L/2) \cos \theta]}{(\beta L/2) \cos \theta} \hat{\Theta} \tag{56}$$

The magnetic field is simply found from this result using $H_\phi = \mathbf{E}_\theta / \eta$.

3.3.4. Radiation Pattern Definitions. Since the radiation pattern is the variation over a sphere centered on the antenna, r is constant and we have only θ and ϕ variations of the field. It is convenient to normalize the field expression such that its maximum value is unity. This is accomplished as follows for a z -directed source that has only a θ component of \mathbf{E}

$$F(\theta, \phi) = \frac{E_\theta}{E_\theta(\max)} \tag{57}$$

where $F(\theta, \phi)$ is the normalized field pattern and $E_\theta(\max)$ is the maximum value of the magnitude of E_θ over a sphere of radius r .

In general, E_θ can be complex-valued and, therefore, so can $F(\theta, \phi)$. In this case the phase is usually set to zero at the same point that the magnitude is normalized to unity. This is appropriate since we are interested only in relative phase behavior. This variation is, of course, independent of r .

As an example, an element of current on the z axis has a normalized field pattern of

$$F(\theta) = \frac{(I\Delta z/4\pi)j\omega\mu(e^{-j\beta r}/r)\sin\theta}{(I\Delta z/4\pi)j\omega\mu(e^{-j\beta r}/r)} = \sin\theta \tag{58}$$

and there is no ϕ variation.

The normalized field pattern for the uniform line source is from Eq. (56)

$$F(\theta) = \sin\theta \frac{\sin [(\beta L/2) \cos \theta]}{(\beta L/2) \cos \theta} \tag{59}$$

and again there is no ϕ variation. The second factor of this expression is the function $\sin(u)/u$, and we will encounter it frequently. It has a maximum value of unity at $u=0$; this corresponds to $\theta=90^\circ$, where $u=(\beta L/2)\cos\theta$. Substituting $\theta=90^\circ$ in Eq. (59) gives unity, and we see that $F(\theta)$ is properly normalized.

In general, a normalized field pattern can be written as the product

$$F(\theta, \phi) = g(\theta, \phi) f(\theta, \phi) \tag{60}$$

where $g(\theta, \phi)$ is the element factor and $f(\theta, \phi)$ is the pattern factor. The pattern factor comes from the integral over the current and is due only to the distribution of current in space. The element factor is the pattern of an infinitesimal

current element in the current distribution as in Eq. (58). For example, for a z -directed current element the total pattern is given by the element factor

$$F(\theta) = g(\theta) = \sin\theta \tag{61}$$

Actually this factor originates from Eq. (43) and can be interpreted as the projection of the current element in the θ direction. In other words, at $\theta=90^\circ$ we see the maximum length of the current, whereas at $\theta=0^\circ$ or 180° we see the end view of an infinitesimal current that yields no radiation. The $\sin\theta$ factor expresses the fraction of the size of the current as seen from the observation angle θ . On the other hand, the pattern factor $f(\theta, \phi)$ represents the integrated effect of radiation contributions from the current distribution, which can be treated as being made up of many current elements. The pattern value in a specific direction is then found by summing the parallel rays from each current element to the far field with the magnitude and phase of each included. The radiation integral of Eq. (47) sums the far-field contributions from the current elements and, when normalized, yields the pattern factor.

Antenna analysis is usually easier to understand by considering the antenna to be transmitting as we have here. However, most antennas are reciprocal and thus their radiation properties are identical when used for reception, as discussed in Section 3.1.

For the z -directed uniform line-source pattern (59), we identify the factors as

$$g(\theta) = \sin\theta \tag{62}$$

and

$$f(\theta) = \frac{\sin [(\beta L/2) \cos \theta]}{(\beta L/2) \cos \theta} \tag{63}$$

For long line sources ($L \gg \lambda$) the pattern factor of Eq. (63) is much sharper than the element factor $\sin\theta$, and the total pattern is approximately that of Eq. (63), that is, $F(\theta) \approx f(\theta)$. Hence, in many cases we need work only with $f(\theta)$, which is obtained from Eq. (48). If we allow the beam as in Fig. 7 to be scanned, the element factor

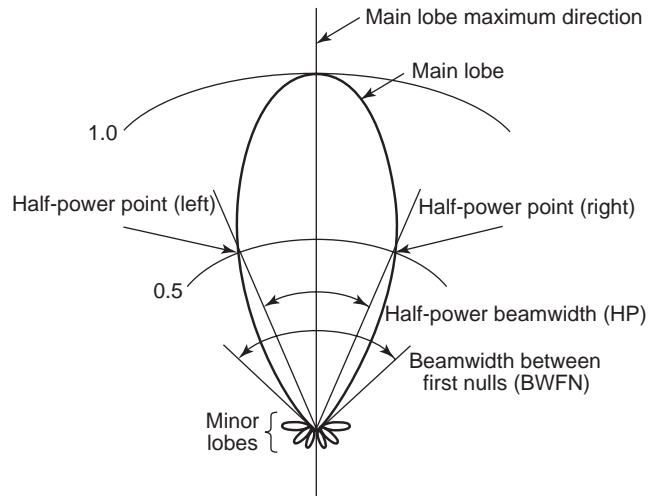

Figure 7. A typical power pattern polar plot. From [1].

becomes important as the pattern maximum approaches the z axis.

This concept of element and pattern factors can also be extended to arrays. If we consider an array to be made of a collection of identical elements with input currents of I_n , we can write the vector potential as

$$\begin{aligned} \mathbf{A} &= \mu \frac{e^{-j\beta r}}{4\pi r} \int_V \mathbf{J} e^{j\beta \hat{\mathbf{r}} \cdot \mathbf{r}'} dv' \\ &= \sum_n I_n \mu \frac{e^{-j\beta r}}{4\pi r} \int_V \mathbf{J}_0(\mathbf{r}' - \mathbf{r}_n) e^{j\beta \hat{\mathbf{r}} \cdot \mathbf{r}'} dv' \\ &= \sum_n I_n e^{j\beta \hat{\mathbf{r}} \cdot \mathbf{r}_n} \left[\mu \frac{e^{-j\beta r}}{4\pi r} \int_V \mathbf{J}_0(\mathbf{r}') e^{j\beta \hat{\mathbf{r}} \cdot \mathbf{r}'} dv' \right] \\ &= \mathbf{A}_0(\mathbf{r}) \sum_n I_n e^{j\beta \hat{\mathbf{r}} \cdot \mathbf{r}_n} = \mathbf{A}_0(\mathbf{r}) AF \end{aligned} \quad (64)$$

Expanding this result to the electric field and then to pattern, we have

$$\mathbf{F}(\theta, \phi) = g_a(\theta, \phi) f(\theta, \phi) \quad (65)$$

where g_a represents the *element pattern* of the basic array element and f represents AF which is called the *array factor*. The array factor includes the phasing effects between the elements. For a large array, the array factor dominates the far-field pattern of the array.

Frequently the directional properties of the radiation from an antenna are described by another form of radiation pattern, the power pattern. The power pattern gives angular dependence of the power density and is found from the θ, ϕ variation of the r component of the Poynting vector [1]. For z -directed sources $H_\phi = E_\theta/\eta$ so the r component of the Poynting vector is $\frac{1}{2} E_\theta H_\phi = |E_\theta|^2/(2\eta)$ and the normalized power pattern is simply the square of its field pattern magnitude $P(\theta) = |F(\theta)|^2$. The general normalized power pattern is

$$P(\theta, \phi) = |F(\theta, \phi)|^2 \quad (66)$$

The normalized power pattern for a z -directed current element is

$$P(\theta, \phi) = \sin^2 \theta \quad (67)$$

and for a z -directed uniform line source is

$$P(\theta) = \left\{ \sin \theta \frac{\sin[(\beta L/2) \cos \theta]}{(\beta L/2) \cos \theta} \right\}^2 \quad (68)$$

Frequently patterns are plotted in decibels. It is important to recognize that the field (magnitude) pattern and power pattern are the same in decibels. This follows directly from the definitions. For the field intensity in decibels

$$|F(\theta, \phi)|_{\text{dB}} = 20 \log |F(\theta, \phi)| \quad (69)$$

and for power in decibels

$$\begin{aligned} P(\theta, \phi)_{\text{dB}} &= 10 \log P(\theta, \phi) = 10 \log |F(\theta, \phi)|^2 \\ &= 20 \log |F(\theta, \phi)| \end{aligned} \quad (70)$$

and we see that

$$P(\theta, \phi)_{\text{dB}} = |F(\theta, \phi)|_{\text{dB}} \quad (71)$$

3.3.5. Radiation Pattern Parameters. A typical antenna power pattern is shown in Fig. 7 as a polar plot in linear units (rather than decibels). It consists of several lobes. The *main lobe* (or *main beam* or *major lobe*) is the lobe containing the direction of maximum radiation. The direction of the main lobe is often referred to as the *boresight direction*. There is also usually a series of lobes smaller than the main lobe. Any lobe other than the main lobe is called a *minor lobe*. Minor lobes are composed of side lobes and back lobes. Back lobes are directly opposite the main lobe, or sometimes they are taken to be the lobes in the half-space opposite the main lobe. The term *side lobe* is sometimes reserved for those minor lobes near the main lobe, but is most often taken to be synonymous with *minor lobe*; we will use the latter convention.

The radiation from an antenna is represented mathematically through the radiation pattern function $F(\theta, \phi)$ for the field and $P(\theta, \phi)$ for power. This angular distribution of radiation is visualized through various graphical representations of the pattern, which we discuss in this section. Graphical representations also are used to introduce definitions of pattern parameters that are commonly used to quantify radiation pattern characteristics.

A three-dimensional plot as in Fig. 4d gives a good overall impression of the entire radiation pattern, but cannot convey accurate quantitative information. Cuts through this pattern in various planes are the most popular pattern plots. They usually include the E - and H -plane patterns; see Figs. 4b and 4c. Pattern cuts are often given various fixed ϕ values, leaving the pattern a function of θ alone; we will assume that is the case here. Typically the sidelobes are alternately positive- and negative-valued. In fact, a pattern in its most general form may be complex-valued. Then we use the magnitude of the field pattern $|F(\theta)|$ or the power pattern $P(\theta)$.

A measure of how well the power is concentrated into the mainlobe is the (relative) sidelobe level, which is the ratio of the pattern value of a sidelobe peak to the pattern value of the mainlobe. The largest sidelobe level for the whole pattern is the maximum (relative) sidelobe level, frequently abbreviated as SLL. In decibels it is given by

$$\text{SLL} = 20 \log \left| \frac{F(\text{SLL})}{F(\text{max})} \right| \quad (72)$$

where $|F(\text{max})|$ is the maximum value of the pattern magnitude and $|F(\text{SLL})|$ is the pattern value of the maximum of the highest sidelobe magnitude. For a normalized pattern, $F(\text{max}) = 1$.

The width of the main beam is quantified through the half-power beamwidth (HPBW), which is the angular separation of the points where the mainbeam of the power pattern equals one-half the maximum value

$$\text{HPBW} = |\theta_{\text{HPleft}} - \theta_{\text{HPright}}| \quad (73)$$

where $\theta_{\text{HPBW, left}}$ and $\theta_{\text{HPBW, right}}$ are points to the "left" and "right" of the main beam maximum for which the

Figure 8. Polar plots of uniform line source patterns: (a) broadside; (b) intermediate; (c) endfire.

normalized power pattern has a value of one-half (see Fig. 8). On the field pattern $|F(\theta)|$ these points correspond to the value $1/\sqrt{2}$. For example, the $\sin \theta$ pattern of an ideal dipole has a value of $1/\sqrt{2}$ for θ values of $\theta_{\text{HPBW, left}} = 135^\circ$ and $\theta_{\text{HPBW, right}} = 45^\circ$. Then $\text{HPBW} = |135^\circ - 45^\circ| = 90^\circ$. This is shown in Fig. 4b. Note that the definition of HPBW is the magnitude of the difference of the half-power points and the assignment of left and right can be interchanged without changing HPBW. In three dimensions the radiation pattern major lobe becomes a solid object and the half-power contour is a continuous curve. If this curve is essentially elliptical, the pattern cuts that contain the major and minor axes of the ellipse determine what the Institute of Electrical and Electronic Engineers (IEEE) defines as the principal half-power beamwidths.

Antennas are often referred to by the type of pattern they produce. An isotropic antenna, which is hypothetical, radiates equally in all directions, giving a constant radiation pattern. An omnidirectional antenna produces a pattern that is constant in one plane; the ideal dipole of Fig. 4 is an example. The pattern shape resembles a doughnut. We often refer to antennas as being broadside or endfire. A broadside antenna is one for which the mainbeam maximum is in a direction normal to the plane containing the antenna. An endfire antenna is one for which the mainbeam is in the plane containing the antenna. For a linear current on the z axis, the broadside direction is $\theta = 90^\circ$ and the endfire directions are 0° and 180° . For example, an ideal dipole is a broadside antenna. For z -directed line sources several patterns are possible. Figure 8 illustrates a few $|f(\theta)|$ patterns. The entire pattern (in three dimensions) is imagined by rotating the pattern about the z axis. The full pattern can then be generated from the E -plane patterns shown. The broadside pattern of Fig. 8a is called the *fan beam*. The full three-dimensional endfire pattern for Fig. 8c has a single lobe in the endfire direction. This single lobe is referred to as a *pencil beam*. Note that the $\sin \theta$ element factor, which must multiply these patterns to obtain the total pattern, will have a significant effect on the endfire pattern.

4. ANTENNA PERFORMANCE MEASURES

Antennas are devices that are used in systems for communications or sensing. There are many parameters used to quantify the performance of the antenna as a device, which in turn impacts on system performance. In this

section we consider the most important of these parameters when they are employed in their primary application area of communication links, such as the simple communication link shown in Fig. 9. We first discuss the basic properties of a receiving antenna. The receiving antenna with impedance Z_A and terminated in load impedance Z_L is modeled as shown in Fig. 10. The total power incident on the receiving antenna is found by summing up the incident power density over the area of the receive antenna, called *effective aperture*. How an antenna converts this incident power into available power at its terminals depends on the type of antenna used, its pointing direction, and polarization. In this section we discuss the basic relationships for power calculations and illustrate their use in communication links.

4.1. Directivity and Gain

For system calculations it is usually easier to work with directivity rather than its equivalent, maximum effective aperture. The maximum effective aperture of an antenna is related to the effective length of the antenna. Using reciprocity, it can be shown that the effective length is given by

$$\mathbf{h}(\theta, \phi) = \left[\frac{\mathbf{E}(\theta, \phi)}{j\omega\mu I_{\text{in}} \frac{e^{-jkr}}{4\pi r}} \right]^* = \left[\frac{1}{I_{\text{in}}} \int_V \mathbf{J} e^{j\beta\hat{\mathbf{r}} \cdot \mathbf{r}'} dv' \right]^* \quad (74)$$

with the corresponding open-circuit voltage given as

$$V_{\text{oc}} = \mathbf{h}^*(\theta, \phi) \cdot \mathbf{E}^i(\theta, \phi) \quad (75)$$

The power available from the antenna is realized when the antenna is terminated in a conjugately matched impedance of $Z_L = R_r - jX_A$ assuming $R_{\text{ohmic}} = 0$. The maximum available power is then

$$P_{\text{Am}} = \frac{1}{8} \frac{|V_{\text{oc}}|^2}{R_{\text{rad}}} = \frac{1}{8} \frac{|\mathbf{h}^*(\theta, \phi) \cdot \mathbf{E}^i(\theta, \phi)|^2}{R_{\text{rad}}} = \frac{1}{8} \frac{|\mathbf{h}|^2 |\mathbf{E}^i|^2}{R_{\text{rad}}} p \quad (76)$$

Figure 9. A communication link.

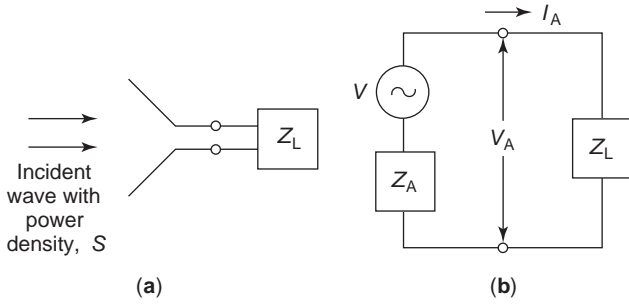

Figure 10. Equivalent circuit for a receiving antenna: (a) receive antenna connected to a receiver with load impedance Z_L ; (b) equivalent circuit.

where p is the polarization factor

$$p(\theta, \phi) = \frac{|\hat{h}^* \cdot \bar{\mathbf{E}}_{\text{inc}}|^2}{|\hat{h}^*|^2 |\bar{\mathbf{E}}_{\text{inc}}|^2} \quad (77)$$

The quantity represents the fractional power received compared to the total possible received power under perfect polarization match conditions. It is also called polarization efficiency and varies from 0 to 1.

The available power can also be calculated by examining the incident wave. The power density, Poynting vector magnitude, in the incoming wave is

$$S = \frac{1}{2} |\mathbf{E} \times \mathbf{H}^*| = \frac{1}{2} \frac{|\mathbf{E}^i|^2}{\eta} \quad (78)$$

with $\eta \approx 120\pi$ in a vacuum. The available power is found using the maximum effective aperture A_{em} , which is the collecting area of the antenna. The receiving antenna collects power from the incident wave in proportion to its maximum effective aperture

$$P_{\text{Am}} = S A_{\text{em}} p \quad (79)$$

and using Eq. (74) for the effective length, we have

$$A_{\text{em}} = \frac{\eta |\mathbf{h}_{\text{max}}|^2}{4R_{\text{rad}}} = \frac{\eta |\mathbf{E}_{\text{max}}|^2}{4R_{\text{rad}} |\omega \mu I_{\text{in}} \frac{e^{-jkr}}{4\pi r}|^2} = \frac{\eta^2 S_{\text{max}}}{(\omega \mu)^2 \frac{P_{\text{rad}}}{\pi} \frac{1}{4\pi r^2}} = \frac{\lambda^2}{4\pi} D \quad (80)$$

where the radiated power is given in terms of the input current and radiation resistance. The factor D in Eq. (80) is directivity defined as the ratio of the maximum radiated power density to the total radiated power defines the antenna directivity as

$$D = \frac{S_{\text{max}}}{P_{\text{rad}}/4\pi r^2} = \frac{\text{maximum power density}}{\text{average power density}} \quad (81)$$

For a short dipole, the effective length and radiation resistance R_r are respectively equal to $\Delta z \left[\frac{2\pi}{3} \eta \left(\frac{\Delta z}{\lambda} \right)^2 \right]$, giving and effective aperture of [1]

$$A_{\text{em}}(\text{short dipole}) = \frac{3}{2} \frac{\lambda^2}{4\pi}, \quad \text{where } D = \frac{3}{2} \quad (82)$$

The maximum effective aperture of an ideal dipole is independent of its length Δz (as long as $\Delta z \ll \lambda$). However, it is important to note that R_{rad} is proportional to $(\Delta z/\lambda)^2$ so

Figure 11. Illustration of directivity: (a) radiation intensity distributed isotropically; (b) radiation intensity from an actual antenna.

that even though A_{em} remains constant as the dipole is shortened, its radiation resistance decreases rapidly and it is more difficult to realize this maximum effective aperture because of the required conjugate impedance match of the receiver to the antenna.

Directivity is defined more directly through an inverse dependence on beam solid angle as

$$D = \frac{4\pi}{\Omega_A} \quad (83)$$

where

$$\Omega_A = \iint |F(\theta, \phi)|^2 d\Omega \quad (84)$$

This directivity definition has a simple interpretation. Directivity is a measure of how much greater the power density at a fixed distance is in a given direction than if all power were radiated isotropically. This view is illustrated in Fig. 11. For an isotropic antenna, as in Fig. 11a, the beam solid angle is 4π , and thus Eq. (83) gives a directivity of unity.

The directivity of the ideal dipole can be written in the following manner:

$$D = \frac{3}{2} = \frac{4\pi}{\lambda^2} \frac{3}{8\pi} \lambda^2 \quad (\text{ideal dipole}) \quad (85)$$

Grouping factors this way permits identification of A_{em} from Eq. (80). Thus

$$D = \frac{4\pi}{\lambda^2} A_{\text{em}} \quad (86)$$

This relationship is true for any antenna. For an isotropic antenna the directivity by definition is unity, so from Eq. (86) with $D = 1$, or

$$A_{\text{em}} = \frac{\lambda^2}{4\pi} \quad (\text{isotropic antenna}) \quad (87)$$

Comparing this to $D = 4\pi/\Omega_A$, we see that

$$\lambda^2 = A_{\text{em}} \Omega_A \quad (88)$$

which is also a general relationship. We can extract some interesting concepts from this relation. For a fixed wavelength, A_{em} and Ω_A are inversely proportional; that is, as the maximum effective aperture increases (as a result of increasing its physical size), the beam solid angle decreases, which means that power is more concentrated in angular space (i.e., directivity goes up).

For a fixed maximum effective aperture (i.e., antenna size), as wavelength decreases (frequency increases), the beam solid angle also decreases, leading to increased directivity.

In practice, antennas are not completely lossless. Earlier we saw that power available at the terminals of a transmitting antenna was not all transformed into radiated power. The power received by a receiving antenna is reduced to the fraction e_r (radiation efficiency) from what it would be if the antenna were lossless. This is represented by defining effective aperture

$$A_e = e_r A_{em} \quad (89)$$

and the available power with antenna losses included, analogous to Eq. (79), is

$$P_A = S A_e \quad (90)$$

This simple equation is very intuitive and indicates that a receiving antenna acts to convert incident power (flux) density in W/m^2 to power delivered to the load in watts. Losses associated with mismatch between the polarization of the incident wave and receiving antenna as well as impedance mismatch between the antenna and load are not included in A_e . These losses are not inherent to the antenna, but depend on how it is used in the system. The concept of gain is introduced to account for losses on an antenna, that is, $G = e_r D$. We can form a gain expression from the directivity expression by multiplying both sides of Eq. (86) by e_r and using Eq. (89):

$$G = e_r D = \frac{4\pi}{\lambda^2} e_r A_{em} = \frac{4\pi}{\lambda^2} A_e \quad (91)$$

For electrically large antennas effective aperture is equal to or less than the physical aperture area of the antenna A_p , which is expressed using aperture efficiency ϵ_{ap} :

$$A_e = \epsilon_{ap} A_p \quad (92)$$

It is important to note that although we developed the general relationships of Eqs. (76), (80), and (92) for receiving antennas, they apply to transmitting antennas as well. The relationships are essential for communication system computations, which we consider next.

4.2. Antennas in Systems

Antennas are used in a variety of applications. The primary application that most people think of is communications. The other major application is sensing, including radar (navigational, surveillance, and ground-penetrating) and radiometry. There is a new interest in transient, broadband application — called “ultrawideband” because of the large bandwidth. This section will consider these systems aspects of antennas.

4.3. Communication Links

We are now ready to completely describe the power transfer in the communication link of Fig. 9. If the transmitting antenna were isotropic, it would have power

density at distance R of

$$S = \frac{U_{av}}{R^2} = \frac{P_t}{4\pi R^2} \quad (93)$$

where P_t is the time-average input power (P_{in}) accepted by the transmitting antenna. The quantity U_{av} denotes the time-average radiation intensity given in the units of power per solid angle (see Fig. 11). For a transmitting antenna that is not isotropic but has gain G_t and is pointed for maximum power density in the direction of the receiver, we have for the power density incident on the receiving antenna:

$$S = \frac{G_t U_{av}}{R^2} = \frac{G_t P_t}{4\pi R^2} \quad (94)$$

Using this in Eq. (90) gives the available received power as

$$P_r = S A_{er} = \frac{G_t P_t A_{er}}{4\pi R^2} \quad (95)$$

where A_{er} is the effective aperture of the receiving antenna and we assume it to be pointed and polarized for maximum response. Now from Eq. (91) $A_{er} = G_r \lambda / 4\pi$, so Eq. (95) becomes

$$P_r = P_t \frac{G_t G_r \lambda^2}{(4\pi R)^2} \quad (96)$$

which gives the available power in terms of the transmitted power, antenna gains, and wavelength. Or, we could use $G_t = 4\pi A_{et} / \lambda^2$ in Eq. (91), giving

$$P_r = P_t \frac{A_{et} A_{er}}{R^2 \lambda^2} \quad (97)$$

which is called the *Friis transmission formula* [1].

The power transmission formula Eq. (96) is very useful for calculating signal power levels in communication links. It assumes that the transmitting and receiving antennas are matched in impedance to their connecting transmission lines, have identical polarization, and are aligned for polarization match. It also assumes the antennas are pointed toward each other for maximum gain. If any of the abovementioned conditions are not met, it is a simple matter to correct for the loss introduced by polarization mismatch, impedance mismatch, or antenna misalignment.

The antenna misalignment effect is easily included by using the power gain value in the appropriate direction. The effect and evaluation of polarization and impedance mismatch are additional considerations. Figure 10 shows the network model for a receiving antenna with input antenna impedance Z_A and an attached load impedance Z_L , which can be a transmission line connected to a distant receiver. The power delivered to the terminating impedance is

$$P_D = pq P_r \quad (98)$$

where

P_D = power delivered from antenna

P_r = power available from receiving antenna

p = polarization efficiency (or polarization mismatch factor), $0 \leq p \leq 1$

q = impedance mismatch factor, $0 \leq q \leq 1$
 A_e = effective aperture (area)

An overall efficiency, or total efficiency ϵ_{total} , can be defined that includes the effects of polarization and impedance mismatch:

$$\epsilon_{\text{total}} = pq \epsilon_{\text{ap}} \quad (99)$$

Then $P_D = \epsilon_{\text{total}} P_r$. It is convenient to express Eq. (98) in decibel form

$$P_D(\text{dBm}) = 10 \log p + 10 \log q + P_r(\text{dBm}) \quad (100)$$

where the unit dBm is power in decibels above a milliwatt; for example, 30 dBm is 1 W. Both powers could also be expressed in units of decibels above a watt, dBW. The power transmission formula Eq. (96) can also be expressed in dB form as

$$\begin{aligned}
 P_r(\text{dBm}) &= P_t(\text{dBm}) + G_t(\text{dB}) + G_r(\text{dB}) \\
 &\quad - 20 \log R(\text{km}) - 20 \log f(\text{MHz}) - 32.44
 \end{aligned} \quad (101)$$

where $G_t(\text{dB})$ and $G_r(\text{dB})$ are the transmit and receive antenna gains in decibels, R (km) is the distance between the transmitter and receiver in kilometers, and f (MHz) is the frequency in megahertz.

4.4. Effective Isotropically Radiated Power (EIRP)

A frequently used concept in communication systems is that of effective (or equivalent) isotropically radiated power, EIRP. It is formally defined as the power gain of a transmitting antenna in a given direction multiplied by the net power accepted by the antenna from the connected transmitter. Sometimes it is denoted as ERP, but this term, effective radiated power, is usually reserved for EIRP with antenna gain relative to that of a half-wave dipole instead of gain relative to an isotropic antenna.

As an example of EIRP, suppose an observer is located in the direction of maximum radiation from a transmitting antenna with input power P_t . Then the EIRP can be expressed as

$$\text{EIRP} = P_t G_t \quad (102)$$

For a radiation intensity U_m , as illustrated in Fig. 11b, and $G_t = 4\pi U_m / P_t$, we obtain

$$\text{EIRP} = P_t \frac{4\pi U_m}{P_t} = 4\pi U_m \quad (103)$$

The same radiation intensity could be obtained from a lossless isotropic antenna (with power gain $G_i = 1$) if it had an input power P_{in} equal to $P_t G_t$. In other words, to obtain the same radiation intensity produced by the directional antenna in its pattern maximum direction, an isotropic antenna would have to have an input power G_t times greater. Effective isotropically radiated power is a frequently used parameter. For example, FM radio stations often mention their effective radiated power when they sign off at night.

Figure 12. Antenna temperature: (a) an antenna receiving noise from directions (θ, ϕ) producing antenna temperature T_A ; (b) equivalent model.

4.5. Noise and Antenna Temperature

Receiving systems are vulnerable to noise and a major contribution is the receiving antenna, which collects noise from its surrounding environment. In most situations a receiving antenna is surrounded by a complex environment as shown in Fig. 12a. Any object (except a perfect reflector) that is above absolute zero temperature will radiate electromagnetic waves. An antenna picks up this radiation through its antenna pattern and produces noise power at its output. The equivalent terminal behavior is modeled in Fig. 12b by considering the radiation resistance of the antenna to be a noisy resistor at a temperature T_A such that the same output noise power from the antenna in the actual environment is produced. The antenna temperature T_A is not the actual physical temperature of the antenna, but is an equivalent temperature that produces the same noise power, P_{NA} , as the antenna operating in its surroundings. This equivalence is established by assuming the model of Fig. 12b, the noise power available from the noise resistor in bandwidth Δf at temperature T_A is

$$P_{\text{NA}} = k T_A \Delta f \quad (104)$$

where

P_{NA} = available power due to antenna noise (W)
 k = Boltzmann's constant = 1.38×10^{-23} J/K
 T_A = antenna temperature (K)
 Δf = receiver bandwidth (Hz).

Such noise is often referred to as *Nyquist* or *Johnson noise* for system calculations. The system noise power P_N is calculated using the total system noise temperature T_{sys} in place of T_A in Eq. (104) with $T_{\text{sys}} = T_A + T_r$ where T_r is the receiver noise temperature.

Antenna noise is important in several system applications including communications and radiometry. Communication systems are evaluated through "carrier-to-noise ratio," which is determined from the signal power and the system noise power as

$$\text{CNR} = \frac{P_D}{P_N} \quad (105)$$

where $P_N = kT_{\text{sys}}\Delta f$ denoting the system noise power. This noise power $kT_{\text{sys}}\Delta f$ equals the sum of P_{NA} and noise power generated in the receiver connected to the antenna.

Noise power is found by first evaluating antenna temperature. As seen in Fig. 12a, T_A is found from the collection of noise through the scene temperature distribution $T(\theta, \phi)$ weighted by the response function of the antenna, the normalized power pattern $P(\theta, \phi)$. This is expressed mathematically by integrating over the temperature distribution:

$$T_A = \frac{1}{\Omega_A} \int_0^\pi \int_0^{2\pi} T(\theta, \phi) P(\theta, \phi) d\Omega \quad (106)$$

If the scene is of constant temperature T_0 over all angles, T_0 comes out of the integral and then

$$T_A = \frac{T_0}{\Omega_A} \int_0^\pi \int_0^{2\pi} P(\theta, \phi) d\Omega = \frac{T_0}{\Omega_A} \Omega_A = T_0 \quad (107)$$

using Eq. (84) for Ω_k . The antenna is completely surrounded by noise of temperature T_0 and its output antenna temperature equals T_0 independent of the antenna pattern shape.

In general, antenna noise power P_{NA} is found from Eq. (104) using T_A from Eq. (106) once the temperature distribution $T(\theta, \phi)$ is determined. Of course, this depends on the scene, but in general $T(\theta, \phi)$ consists of two components: sky noise and ground noise. Ground noise temperature in most situations is well approximated for soils by the value of 290 K, but is much less for surfaces that are highly reflective as a result of reflection of low temperature sky noise. Also, smooth surfaces have high reflection for near grazing incidence angles.

Unlike ground noise, sky noise is a strong function of frequency. Sky noise is made up of atmospheric, cosmic, and manmade noise. Atmospheric noise increases with decreasing frequency below 1 GHz and is due primarily to lightning, which propagates over large distances via ionospheric reflection below several MHz. Atmospheric noise increases with frequency above 10 GHz due to water vapor and hydrometeor absorption; these depend on time, season, and location. It also increases with decreasing elevation angle. Atmospheric gases have strong, broad spectral lines, such as water vapor and oxygen lines at 22 and 60 GHz, respectively.

Cosmic noise originates from discrete sources such as the sun, moon, and “radio stars” as well as our (Milky Way) galaxy, which has strong emissions for directions toward the galactic center. Galactic noise increases with decreasing frequency below 1 GHz. Manmade noise is produced by power lines, electric motors, and other equipment and usually can be ignored except in urban areas at low frequencies. Sky noise is very low for frequencies between 1 and 10 GHz, and can be as low as a few K for high elevation angles.

Of course, the antenna pattern strongly influences antenna temperature; see Eq. (106). The ground noise temperature contribution to antenna noise can be very low for high-gain antennas having low sidelobes in the direction of Earth. Broadbeam antennas, on the other hand, pick up a significant amount of ground noise as well as sky noise. Losses on the antenna structure also contribute to antenna

noise. A figure of merit used with satellite Earth terminals is G/T_{sys} , which is the antenna gain divided by system noise temperature usually expressed in dB/K. It is desired to have high values of G to increase signal and to have low values of T_{sys} to decrease noise, giving high values of G/T_{sys} .

4.5.1. Example: Direct Broadcast Satellite Reception. Reception of high-quality television channels at home in the 1990s, with an inexpensive, small terminal, is the result of three decades of technology development, including new antenna designs. DirecTV (trademark of Hughes Network Systems) transmits from 12.2 to 12.7 GHz with 120 W of power and an EIRP of about 55 dBW in each 24 MHz transponder that handles several compressed digital video channels. The receiving system uses a 0.46-m (18-in.)-diameter offset fed reflector antenna. In this example we perform the system calculations using the following link parameter values:

$$f = 12.45 \text{ GHz (midband)}$$

$$P_t(\text{dBW}) = 20.8 \text{ dBW (120 W)}$$

$$G_t(\text{dB}) = \text{EIRP (dBW)} - P_t(\text{dBW}) = 55 - 20.8 = 34.2 \text{ dB}$$

$$R = 38,000 \text{ km (typical slant pathlength)}$$

$$G_r = \frac{4\pi}{\lambda^2} e_{\text{ap}} A_p = \frac{4\pi}{(0.024)^2} 0.7 \left(\pi \frac{0.46}{4} \right)^2 = 2538$$

$$= 34 \text{ dB (70\% aperture efficiency)}$$

The received power of a polarized matched system from Eq. (101) is

$$P_D(\text{dBm}) = 20.8 + 34.2 + 34 - 20 \log(38,000)$$

$$- 20 \log(12,450) - 32.44 = -113.9 \text{ dBm} \quad (108)$$

This is 2×10^{-12} W! Without the high gains of the antennas (68 dB combined), this signal would be hopelessly lost in noise.

The receiver uses a 67 K noise temperature low-noise block downconverter. This is the dominant receiver contribution, and when combined with antenna temperature leads to a system noise temperature of $T_{\text{sys}} = 125$ K. The noise power in the effective signal bandwidth $\Delta f = 20$ MHz is

$$P_N = kT_{\text{sys}} \Delta f$$

$$= 1.38 \times 10^{-23} \cdot 125 \cdot 20 \times 10^6 = 3.45 \times 10^{-14} \quad (109)$$

$$= -134.6 \text{ dBW}$$

Thus the carrier-to-noise ratio from Eqs. (105) and (108) is

$$\text{CNR}(\text{dB}) = P_D(\text{dBW}) - P_N(\text{dBW})$$

$$= -116.9 - (-134.6) = 17.7 \text{ dB} \quad (110)$$

4.6. Antenna Bandwidth

Bandwidth is a measure of the range of operating frequencies over which antenna performance is acceptable.

Bandwidth is computed in one of two ways, percentage bandwidth or ratio bandwidth. Let f_U and f_L be the upper and lower frequencies of operation for which satisfactory performance is obtained. The center (or sometimes the design frequency) is denoted as f_C . Then bandwidth as a percent of the center frequency B_p is

$$B_p = \frac{f_U - f_L}{f_C} \times 100 \quad (111)$$

Bandwidth is also defined as a ratio B_r by

$$B_r = \frac{f_U}{f_L} \quad (112)$$

The bandwidth of narrowband antennas is usually expressed as a percent, whereas wideband antennas are described with B_r . Resonant antennas have small bandwidths. For example, the half-wave dipoles have bandwidths of up to 16%, (f_U and f_L determined by the voltage standing-wave ratio $\text{VSWR}=2.0$). On the other hand, antennas that have traveling waves on them rather than standing waves (as in resonant antennas) have larger bandwidths.

5. FUNDAMENTAL LIMITS OF ANTENNAS

Antenna designers are often asked to make an antenna smaller without sacrificing performance from the system. To be able to address this design possibility with communications system designers, the fundamental limits of antennas have been developed. The basic work, by Wheeler [6] and Chu [7], resulted in an approximate expression for the minimum radiation Q , or quality factor, of a small antenna. Extensions and corrections have been presented by Harrington [8], Collin and Rothschild [9], Fante [10], and McLean [11]. Further work by the authors improved the lower bound estimate on the fundamental limit by evaluating the total stored energy that is available for energy dissipation in a cycle. For small antennas, all the approaches provide the same result. The total stored energy approach allows an extension to larger structures, providing a higher bound for larger antenna structures as well as correcting the inconsistent results for circular polarized antennas.

The bound for the radiation Q is given by [7]

$$Q = \frac{1 + 2(ka)^2}{(ka)^3 [1 + (ka)^2]} \quad (113)$$

where the Q or quality factor of the antenna provides a measure of the center frequency compared to bandwidth. This Q is based on the bandwidth of the input impedance to the antenna and does not account for the source impedance, commonly called the “unloaded” Q . To give a common measure for experimental data, we translate the commonly used VSWR measure of 2 relative to the resistance at the center of the band to an equivalent 3-dB quality factor. For a given VSWR and bandwidth, Q may be determined as [12]

$$Q = \frac{\text{VSWR} - 1}{\text{BW}_{\text{VSWR}} \sqrt{\text{VSWR}}} \quad (114)$$

Figure 13. Sample antennas and their fundamental limits from experiment/computation.

It is customary to calculate VSWR based on a perfect matched impedance, so that $\text{VSWR}=1$ at the center frequency where the reactance of the antenna at midband is tuned out. This leaves the antenna resistance at midband as the characteristic impedance. For a $\text{VSWR}=2$, Eq. (114) reduces to

$$Q = \frac{1}{\sqrt{2} \text{BW}_{\text{VSWR}=2}} \quad (115)$$

Also, from Eq. (114) we see that a $\text{VSWR}=2.62$ gives bandwidth is equivalent to a 3dB bandwidth of the unloaded input impedance.

The relationship between Q and antenna size given by Eq. (113) is plotted in Fig. 13 as the solid line. Also shown are data for several typical antennas for communication applications. In order to provide a consistent application of fundamental limits, we evaluate the Q as the inverse of the fractional bandwidth with respect to the 3dB impedance limits as used in Eq. (111). All the antennas evaluated do indeed fall above the fundamental limit definition. To go below the limit, it is generally required that loss must be added to the antenna, producing an inefficient antenna.

6. TRANSIENT ANTENNA CONCEPTS

Current technology is demanding extremely wideband antennas for ultrawideband (UWB) applications. UWB antennas typically require a minimum of a 25% bandwidth and are best evaluated using time-domain approaches. We present some of the concepts to give the reader a start toward understanding UWB antenna systems.

A fundamental view of the antenna first comes from the Friis transmission forms of Eqs. (96) and (97). If an antenna system has constant gain with frequency, the received signal is inversely proportional to frequency squared. Conversely, if the system has constant effective aperture, the received signal is proportional to frequency squared. A more direct view is to modify the effective length definition in Eq. (74) for frequency domain applica-

tions to the transient domain:

$$\mathbf{h}(\theta, \phi; t) = \frac{1}{I_{\text{in}}} \int_V \mathbf{J} \left(\mathbf{r}'; t + \frac{\hat{\mathbf{r}} \cdot \mathbf{r}'}{c} \right) dv' \quad (116)$$

and

$$V_{\text{oc}}(t) = \mathbf{h}(\theta, \phi; t) \odot \mathbf{E}^i(\theta, \phi; t) \quad (117)$$

where the “ \odot ” denotes a vector dot product with time convolution. Transient fields radiated from an antenna are obtained from the field forms previously developed as

$$\mathbf{A}(\mathbf{r}; t) \approx \mu \frac{1}{4\pi r} \int_V \mathbf{J} \left(\mathbf{r}'; t - \frac{r}{c} + \frac{\hat{\mathbf{r}} \cdot \mathbf{r}'}{c} \right) dv \quad (118)$$

with the corresponding electric and magnetic fields given as

$$\mathbf{E} \approx -\frac{\partial}{\partial t} [\mathbf{A} - \hat{\mathbf{r}}(\hat{\mathbf{r}} \cdot \mathbf{A})] \quad (119)$$

and

$$\mathbf{H} \approx -\frac{1}{\eta} [\hat{\mathbf{r}} \times \mathbf{E}] \quad (120)$$

The two important aspects of this transient representation are the computation of the effective length, which is also fundamental to the radiated field. In addition to this effective length of the antenna, the field also contains a time derivative. For an impulse-type system, it is desired that the effective length be a transient impulse. For such impulse antennas, the reception is given by the time derivative of the transmitter waveform.

The input reflection properties of the antenna are indicative of the efficiency of the antenna and should not be considered as the primary aspect needed for transient radiation. Several broadband antennas such as the Archimedian spiral and the log-periodic dipole provide excellent reflection properties over the bandwidth. However, these antennas have poor UWB transmission properties, leading to a chirp response due to phase dispersion of the structures. Excellent results are obtained with the TEM horn, disk-cone, and Vivaldi antennas, but these antenna are too large for many applications. These antennas provide a smooth transition of the transmit waveform to space, with minimal reflection over the band of interest.

The pattern properties of a transient antenna are typically represented by a transient waveform in selected directions rather than a continuous plot in for a single frequency. All of these transient properties are transformations from the basic concepts presented in the frequency domain, but with concepts of convolution and pulse response becoming dominant players. Further discussion of transient properties of antennas is beyond the scope of this article, but may be inferred from the development presented in the frequency domain.

7. SUMMARY

This article has provided the foundation concepts of antennas. The emphasis has focused on the radiation properties of antennas and the methods of characterizing antennas. Critical components include impedance, gain, beamwidth, and bandwidth as are needed for communication systems.

A system designer must incorporate these parameters into a full analysis of the communication system.

Orlando, Florida

1. HISTORY OF ANTENNAS

Since Marconi's first experiments with transmitting electromagnetic waves in 1901, antennas have found several important applications over the entire radiofrequency range, and numerous designs of antennas now exist. Antennas are an integral part of our everyday lives and are used for a multitude of purposes, such as cell phones, wireless laptop computers, TV, and radio. An antenna is used to either transmit or receive electromagnetic waves, and it serves as a transducer converting guided waves into free-space waves in the transmitting mode or vice versa, in the receiving mode. All antennas operate on the same basic principles of electromagnetic theory formulated by James Clark Maxwell. Maxwell put forth his unified theory of electricity and magnetism in 1873 [1] in his famous

Figure 1. Heinrich Hertz' radio system.

book *A Treatise on Electricity and Magnetism*. His theory was met with much skepticism and it wasn't until 1886 that Heinrich Hertz [2], considered the father of radio, was able to validate this theory with his experiments. The first radio system, at a wavelength of 4 m, consisted of a $\lambda/2$ dipole (transmitting antenna) and a resonant loop (receiving antenna) as shown in Fig. 1 [3]. By turning on the induction coil, sparks were induced across gap A, which were detected across gap B of the receiving antenna.

Almost a decade later, Guglielmo Marconi, in 1901, was able to receive signals across the Atlantic in St. Johns, Newfoundland, sent from a station he had built in Poldhu, Cornwall, England. Marconi's transmitting antenna was a fan antenna with 50 vertical wires supported by two 6-m guyed wooden poles. The receiving antenna was a 200-m wire pulled up with a kite [3]. For many years since Marconi's experiment, antennas operated at low frequencies, up to the UHF region and were primarily wire-type antennas. The need for radar during World War II launched antenna design into a new era and opened up the entire RF spectrum for their use. Since the 1950s many antennas types such as reflector, aperture, and horn antennas came into use, most of them operating in the microwave region. Their use ranged from communications to astronomy to various deep-space applications. These antennas have been discussed in a plethora of books, some of these have been included in the Bibliography [4–23].

A good explanation of how an antenna can act as a radiator or a receiver is given in Refs. 20 and 23. To understand how an antenna radiates, consider a pulse of electric charge moving along a straight conductor. A static electric charge or a charge moving with a uniform velocity does not radiate. However, when charges are accelerated along the conductor and decelerated on reflection from its end, radiated fields are produced along the wire and at each end [20,21]. The *IEEE Standard Definitions of Terms for Antennas* [24] and Balanis [25] provide good sources of definitions and explanations of the fundamental parameters associated with antennas.

2. TYPES OF ANTENNAS

Modern antennas or antenna systems require careful design and a thorough understanding of the radiation

mechanism involved. Selection of the type of antenna to be used is determined by electrical and mechanical constraints and operating costs. The electrical parameters of the antenna include the frequency of operation, gain, polarization, radiation pattern, and impedance. The mechanical parameters of importance include the size, weight, reliability, and manufacturing process. In addition, the environment under which the antenna is to be used also must be considered, including the effects of temperature, rain, wind vibrations, and the platform that the antenna is mounted. Antennas are shielded from the environment through the use of radomes whose presence is taken into account while designing the antenna.

Antennas can be classified broadly into the following categories: wire antennas, reflector antennas, lens antennas, traveling-wave antennas, frequency-independent antennas, horn antennas, and conformal antennas. In addition, antennas are very often used in array configurations, such as in phased-array or adaptive array antennas, to improve the characteristics of an individual antenna element.

2.1. Wire Antennas

Wire antennas were among the first type of antennas used and are the most familiar type to the average person. These antennas can be linear or in the form of closed loops. The thin linear dipole antenna is used extensively, and the half-wavelength dipole antenna has a radiation resistance of $73\ \Omega$, very close to the $75\text{-}\Omega$ characteristic impedance of feedlines such as the coaxial cable. It has an omnidirectional pattern as shown in Fig. 2, with a half-power beamwidth of 78° . Detailed discussions on dipole antennas of different lengths and their various applications can be found in Ref. 25.

Loop antennas can have several different shapes, such as circular, square, or rectangular. Electrically small loops are those whose overall wire extent is less than one-tenth of a wavelength. Electrically large loops have circumferences that are of the order of a wavelength. An electrically small circular or square loop antenna can be treated as an infinitesimal magnetic dipole with its axis perpendicular to the plane of the loop. Various configurations of polygonal loop antennas have been investigated [26,27], including the ferrite loop, where a ferrite core is placed in the loop antenna to increase its efficiency. Loop antennas are inefficient with high ohmic losses and are often used as receivers and as probes for field measurements. The radiation pattern of a small loop antenna has a null perpendicular to the plane of the loop and a maximum along the plane of the loop. An electrically large antenna has a maximum radiation perpendicular to the plane of the loop and is regarded as the equivalent to the half-wavelength dipole.

Dipole and loop antennas find applications in the low-medium-frequency ranges. They have wide beamwidths, and their behavior is greatly affected by nearby obstacles or structures. These antennas are often placed over a ground plane. The spacing above the ground plane determines the effect of the ground plane has on the radiation pattern and the increase in directivity [21].

Thick dipole antennas are used to improve the narrow bandwidth of thin dipole antennas. Examples of these are

Figure 2. A half-wavelength dipole and its radiation pattern.

the cylindrical dipole, the folded dipole, and the biconical antennas. The use of a sleeve around the input region and the arms of the dipole also results in broader bandwidths.

2.2. Reflector Antennas

Since World War II, when reflector antennas gained prominence for their use with radar systems, these antennas have played an important role in the field of communications. Love [28] has published a collection of papers on reflector antennas. Reflector antennas have a variety of geometrical shapes and require careful design and a full characterization of the feed system (the system that illuminated the reflector surface with electromagnetic fields). Silver [5] presents the technique for analysis based on aperture theory and physical optics. Other methods such as the geometric theory of diffraction (GTD) and fast Fourier transform (FFT) along with various optimization tech-

niques [29] are now used for a more accurate design of these antennas.

The plane reflector is the simplest type of a reflector and can be used to control the overall system radiation characteristics [21]. The corner reflector has been investigated by Kraus [30], and the 90° corner reflector is found to be the most effective. The feeds for corner reflectors are generally dipole antennas placed parallel to the vertex. These antennas can be analyzed in a rather straightforward manner using the method of images. Among curved reflectors, the paraboloid is the most commonly used. The paraboloid reflector shown in Fig. 3 is formed by rotating a parabolic reflector about its axis. The reflector transforms a spherical wave radiated from a feed at its focus into a plane wave.

To avoid blockage caused by the feed placed at the focal point in a front-fed system, the feed is often offset from the axis [31]. The Cassegrain reflector is a dual-reflector system using a paraboloid as the primary and a hyperboloid as the secondary reflector with a feed along the axis of the paraboloid.

The Gregorian dual-reflector antenna uses an ellipse as the subreflector. The aperture efficiency in a Cassegrain antenna can be improved by modifying the reflector surfaces [28]. Most paraboloidal reflectors use horn antennas (conical or pyramidal) for their feeds. With a paraboloidal reflector, beam scanning by feed displacement is limited. A spherical reflector provides greater scanning but requires more elaborate feed design since it fails to focus an incident plane to a point. Spherical reflectors can suffer from a loss in aperture and increased minor lobes due to blockage by the feed.

Figure 3. A parabolic reflector antenna with its feed.

2.3. Lens Antennas

At larger wavelengths, reflectors become impractical because of the necessity for large feed structures and tolerance requirements. At low frequencies, the lens antenna is prohibitively heavy. Both lens antennas and parabolic reflectors use free space as a feed network to excite a large aperture. The feed of a lens remains out of the aperture and thus eliminates aperture blockage and high sidelobe levels. Dielectric lens antennas are similar to optical lenses, and the aperture of the antenna is equal to the projection of the rim shape. Lenses are divided into two categories: single-surface and dual-surface. In the *single-surface lens* one surface is an equiphase surface of the incident or emergent wave and the waves pass through normal to the surface without refraction.

In a *dual-surface lens*, refraction occurs at both lens surfaces. Single-surface lenses convert either cylindrical or spherical waves to plane waves. Cylindrical waves require a line source and a cylindrical lens surface, and spherical waves require a point source. The far field is determined by diffraction from the aperture. Dual-surface lenses allow more control of the pattern characteristics. Both surfaces are used for focusing, and the second surface can be used to control the amplitude distribution in the aperture plane. These simple lenses are many wavelengths thick if their focal length and aperture are large compared to a wavelength. The surface of the lens can be zoned by removing multiples of wavelengths from the thickness. The zoning can be done in either the refracting or nonrefracting surface as shown in Fig. 4. The zoned

Figure 4. Zoned lenses.

lens is frequency-sensitive and can give rise to shadowing losses at the transition regions [5].

Artificial dielectric lenses in which particles such as metal spheres, strips, disks, or rods are introduced in the dielectric have been investigated by Kock [32]. The size of the particles has to be small compared to the wavelength. Metal plate lenses using spaced conducting plates are used at microwave frequencies. Since the index of refraction of a metal plate medium depends on the ratio of the wavelength to the spacing between the plates, these lenses are frequency-sensitive. The Luneberg lens is a spherically symmetric lens with an index of refraction that varies as a function of the radius. A plane wave incident on this lens will be brought to a focus on the opposite side. These lens antennas can be made using a series of concentric spherical shells, each with a constant dielectric.

2.4. Traveling-Wave Antennas

Traveling-wave antennas [33] are distinguished from other antennas by the presence of a traveling wave along the structure and by the propagation of power in a single direction. Linear wire antennas are the dominant type of traveling-wave antennas. Linear wave antennas with standing-wave patterns of current distributions are referred to as *standing-wave* or *resonant antennas*, where the amplitude of the current distribution is uniform along the source but the phase changes linearly with distance. There are in general two types of traveling-wave antennas: (1) the *surface-wave antenna*, which is a slow-wave structure, where the phase velocity of the wave is smaller than the velocity of light in free space and the radiation occurs from discontinuities in the structure; and (2) a *leaky-wave antenna*, which is a fast-wave structure, where the phase velocity of the wave is greater than the velocity of light in free space. The structure radiates all its power with the fields decaying in the direction of wave travel.

A long-wire antenna, many wavelengths in length, is an example of a traveling-wave antenna. The "beverage" antenna is a thin wire placed horizontally above a ground plane. The antenna has poor efficiency but can have good directivity and is used as a receiving antenna in the low-mid-frequency range. The V antenna is formed by using two beverage antennas separated by an angle and fed from a balanced line. By adjusting the angle, the directivity can be increased and the sidelobes can be made smaller. Terminating the legs of the V antenna in their characteristic impedances makes the wires nonresonant and greatly reduces backradiation. The rhombic antenna consists of two V antennas. The second V antenna brings the two sides together, and a single terminating resistor can be used to connect the balanced lines. An inverted V over a ground plane is another configuration for a rhombic antenna.

The pattern characteristics can be controlled by varying the angle between the elements, the lengths of the elements, and the height above ground. The helical antenna [21] is a high-gain broadband endfire antenna. It consists of a conducting wire wound in a helix. It has found applications as feeds for parabolic reflectors and for various space communications systems. A popular and practical antenna is the Yagi-Uda antenna [34,35], shown

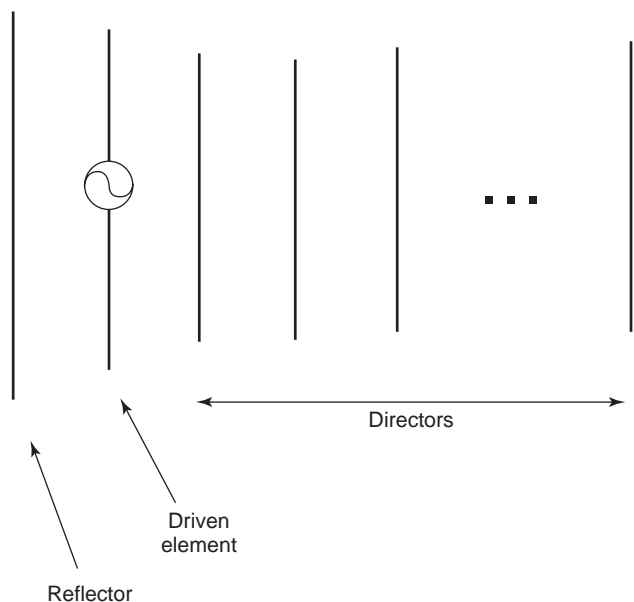

Figure 5. A Yagi-Uda antenna.

in Fig. 5. It uses an arrangement of parasitic elements around the feed element to act as reflectors and directors to produce an endfire beam. The elements are linear dipoles with a folded dipole used as the feed. The mutual coupling between the standing-wave current elements in the antenna is used to produce a traveling-wave unidirectional pattern.

2.5. Frequency-Independent Antennas

Frequency-independent antennas or self-scaling antennas were introduced in the early 1950s, extending antenna bandwidths by greater than 40% [36]. Ideally, an antenna will be frequency-independent if its shape is specified only in terms of angles. These antennas have to be truncated for practical use, and the current should attenuate along the structure to a negligible value at the termination. Examples of these antennas are the eight-element log-periodic circular configuration shown in Fig. 6.

2.6. Horn Antennas

The electromagnetic horn antenna is characterized by attractive qualities such as a unidirectional pattern, high gain, and purity of polarization. Horn antennas are used as feeds for reflector and lens antennas and as a laboratory standard for other antennas. A good collection of papers on horn antennas can be found in Ref. 37. Horns can be of a rectangular or circular shape as shown in Fig. 7.

Rectangular horns derived from a rectangular waveguide can be pyramidal or sectoral E -plane and H -plane horns. The E -plane sectoral horn has a flare in the direction of the E -field of the dominant TE_{10} mode in the rectangular waveguide, and the H -plane sectoral horn has a flare in the direction of the H -field. The pyramidal horn has a flare in both directions. The radiation pattern of the horn antenna can be determined from a knowledge of the aperture dimensions and the aperture field distribution. The flare angle of the horn and its dimensions affect the

Figure 6. An eight-element log-periodic circular antenna.

radiation pattern and its directivity. Circular horns derived from circular waveguides can be either conical, biconical, or exponentially tapered.

The need for feed systems that provide low cross-polarization and edge diffraction and more symmetric patterns led to the design of the corrugated horn [38]. These horns have corrugations or grooves along the walls that present equal boundary conditions to the electric and magnetic fields when the grooves are $\lambda/4$ to $\lambda/2$ deep. The conical corrugated horn, referred to as the *scalar horn*, has a larger bandwidth than do the small-flare-angle corrugated horns.

2.7. Conformal Antennas

Microstrip antennas have become a very important class of antennas since they received attention in the early 1970s. These antennas are lightweight, easy to manufacture using printed-circuit techniques, and compatible with MMICs (monolithic microwave integrated circuits). An additional attractive property of these antennas is that they are low-profile and can be mounted on surfaces; that is, they can be made to “conform” to a surface and hence are referred to as *conformal antennas*. The microstrip antenna consists of a conducting “patch” or radiating element that may be square, rectangular, circular, triangular, or of another shape, etched on a grounded dielectric substrate as shown in Fig. 8.

These antennas are an excellent choice for use on aircraft and spacecraft. Microstrip antennas have been investigated extensively over the past twenty years and the two volumes published by James and Hall [39] provide an excellent description of various microstrip antennas, including their design and usage. Microstrip antennas are fed either using a coaxial probe, a microstrip line, or proximity coupling or through aperture coupling. A major disadvantage of these antennas is that they are poor radiators and have a very narrow frequency bandwidth.

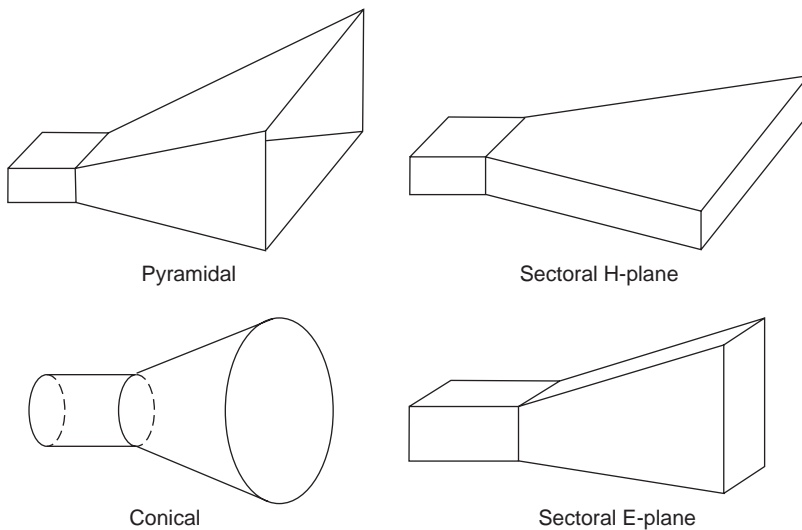

Figure 7. Examples of horn antennas.

They are often used in an array environment to achieve the desired radiation characteristics. Larger frequency bandwidths are obtained by using stacked microstrip antennas.

2.8. Antenna Arrays

Antenna arrays are formed by suitably spacing radiating elements in a one- or two-dimensional lattice. By suitably feeding these elements with relative amplitudes and phas-

es, these arrays produce desired directive radiation characteristics. The arrays allow a means of increasing the electric size of the antenna without increasing the dimensions of the individual elements. Most arrays consist of identical elements such as dipoles, helices, large reflectors, or microstrip elements. The array has to be designed such that the radiated fields from the individual elements add constructively in the desired directions and destructively in the other directions. Arrays are generally classified as *endfire* arrays that produce a beam directed along the axis of the array, or *broadside* arrays producing a beam directed in a direction normal to the array. The beam direction can be controlled or “steered” using a phased-array antenna in which the phase of the individual elements is varied. Frequency-scanning arrays are an example where beam scanning is done by changing the frequency. Adaptive array antennas produce beams in predetermined directions. By suitably processing the received signals, the antenna can steer its beam toward the direction of the desired signal and simultaneously produce a null in the direction of an undesired signal.

2.9. Reconfigurable Antennas

With the advent of RF microelectromechanical system (MEMS) switches, a new class of antennas has emerged that are capable to radiate more than one pattern, at different frequencies and with multiband characteristics [40–42]. A MEMS-switched reconfigurable antenna can be dynamically reconfigured within a few microseconds to serve different applications at different frequency bands, which are necessary in radar and modern telecommunication systems. RF MEMS switches are used to connect antennas together to create different configurations (linear, planar, circular arrays, etc.), which results in a reduction of architectural complexity, and hence cost, of any communication devices while simultaneously enhancing performance. Figure 9 depicts a fractal antenna with only its diagonal elements activated through RF MEMS switches. By activating six diagonal elements, the antenna works as a rotated array consisting of triangular elements.

Figure 8. (a) A microstrip antenna and (b) a stacked microstrip antenna.

Figure 9. A fractal antenna with six activated elements.

3. APPLICATIONS AND IMPACT ON SYSTEMS

Antennas enjoy a very large range of applications, in both the military and commercial sectors. The most well known applications of antennas to the average person are those associated with radio, TV, and communication systems. Today, antennas find extensive use in biomedicine, radar, remote sensing, astronomy, navigation, RF identification, controlling space vehicles, collision avoidance, air traffic control, GPS, pagers, wireless telephone, and wireless local-area networks (LANs). These applications cover a very wide range of frequencies as shown in Table 1 [2,3,43]:

3.1. Antennas in Communication Systems

Antennas are one of the most critical components in a communication system since they are responsible for the proper transmission and reception of electromagnetic waves. The antenna is the first part of the system that will receive or transmit a signal. A good design can relax some of the complex system requirements involved in a

communication link and increase the overall system performance.

The choice of an antenna for a specific application (cellular, satellite-based, ground-based, etc.) depends on the platform to be used (car, ship, building, spacecraft, etc.), the environment (sea, space, land), the frequency of operation, and the nature of the application (video, audio data, etc.). Communication systems can be grouped in several different categories.

3.1.1. Direct (Line-of-Sight) Links. This is transmission link established between two highly directional antennas. The link can be between two land-based antennas (radio relays); between a tower and a mobile antenna (cellular communication), between a land-based antenna and a satellite antenna (Earth–space communication), or between two satellite antennas (intraspace communication). Usually these links operate at frequencies between 1 and 25 GHz. A typical distance between two points in a high capacity, digital microwave radio relay system is about 30 mi.

3.1.2. Satellites and Wireless Communications. Antennas on orbiting satellites are used to provide communications between various locations around Earth. In general, most telecommunication satellites are placed in a geostationary orbit (GEO), about 22,235 mi above Earth as shown in Fig. 10. There are also some satellites at lower-Earth orbits (LEOs) that are used for wireless communications. Modern satellites have several receiving and transmitting antennas that can offer services such as video, audio, data transmission, and telephone communication in areas that are not hardwired. Moreover, direct TV is now possible through the use of a small 18-in. reflector antenna, with 30 million users in the United States today [44,45].

Satellite antennas for telecommunications are used either to form a large area-of-coverage beam for broadcasting or spot beams (with a small area of coverage) for point-to-point communications. Also, multibeam antennas

Table 1. Frequency Bands and General Usage

Band Designation	Frequency Range	Usage
Very low frequency (VLF)	3–30 kHz	Long-distance telegraphy, navigation; antennas are physically large but electrically small; propagation is accomplished using Earth’s surface and the ionosphere; vertically polarized waves
Low frequency (LF)	30–300 kHz	Aeronautical navigation services; long-distance communications; radio broadcasting; vertical polarization
Medium frequency (MF)	300–3000 kHz	Regional broadcasting and communication links; AM radio.
High frequency (HF)	3–30 MHz	Communications, broadcasting, surveillance, CB (Citizens’ band) radio (26.965–27.225 MHz); ionospheric propagation; vertical and horizontal propagation
Very high frequency (VHF)	30–300 MHz	Surveillance, TV broadcasting (54–72 MHz), (76–88 MHz), and (174–216 MHz), FM radio (88–108 MHz); wind profilers
Ultrahigh frequency (UHF)	300–1000 MHz	Cellular communications, surveillance TV (470–890 MHz).
L	1–2 GHz	Long-range surveillance, remote sensing
S	2–4 GHz	Weather, traffic control, tracking, hyperthermia
C	4–8 GHz	Weather detection, long-range tracking
X	8–12 GHz	Satellite communications, missile guidance, mapping
Ku	12–18 GHz	Satellite communications, altimetry, high-resolution mapping
K	18–27 GHz	Very-high-resolution mapping
Ka	27–40 GHz	Airport surveillance
Submillimeter waves	—	In experimental stage

Figure 10. A satellite communication system.

are used to link mobile and fixed users that cannot be linked economically via radio or land-based relays [46–49].

The impact of antennas on satellite technology continues to grow. For example, very-small-aperture terminal (VSATs) dishes at Ku band, which can transmit any combination of voice, data, and video using satellite network-

ing, have become valuable tools for several small and large companies. Most satellites operate at the L, S, or Ku band, but increasing demand for mobile telephony and high-speed interactive data exchange is pushing the antenna and satellite technology into higher operational frequencies [50]. Future satellites will be equipped with antennas at both the Ku and the Ka bands. This will lead to greater bandwidth availability. For example, the ETS-VI (Engineering Test Satellite) [a Japanese satellite comparable to NASA’s TDRS (tracking and data relay satellite)], carries five antennas: an S-band phased array, a 0.4-m reflector for 43/38 GHz, for uplinks and downlinks, an 0.8-m reflector for 26/33 GHz, a 3.5-m reflector for 20 GHz, and a 2.5-m reflector for 30 and 6/4 GHz. Figure 11 shows a few typical antennas used on satellites and spacecrafts. It is expected that millions of households, worldwide, will have access to dual Ku/Ka band dishes later in this (twenty-first) century.

3.1.3. Personal/Mobile Communication Systems. The vehicular antennas used with mobile satellite communications constitute the weak link of the system. If the antenna has high gain, then tracking of the satellite becomes necessary. If the vehicle antenna has low gain, the capacity of the communication system link is diminished. Moreover, handheld telephone units require ingenious design because of the lack of “real estate” on the portable device.

There is more emphasis now on enhancing antenna technologies for wireless communications, especially in cellular communications, which will enhance the link

Figure 11. Line drawing of the Galileo spacecraft showing several of the antennas used on board. [Courtesy NASA, JPL (Jet Propulsion Laboratory).]

performance and reduce the undesirable visual impact of antenna towers. Techniques that utilize “smart” antennas, fixed multiple beams, and neural networks are now being utilized to increase the capacity of mobile communication systems, whether it is land-based or satellite-based [51]. It is anticipated that later in this century the “wire” will no longer dictate where we must go to use the telephone, fax, send or receive electronic mail (e-mail), or run a computer. This will lead to the design of more compact and more sophisticated antennas.

3.2. Antennas for Biomedical Applications

In many biological applications the antenna operates under very different conditions than do the more traditional free-space, far-field counterparts. Near fields and mutual interaction with the body dominate. Also, the antenna radiates in a lossy environment rather than free space. Several antennas, from microstrip antenna to phased arrays, operating at various frequencies, have been developed to couple electromagnetic energy in or out of the body. Most medical applications can be classified into two groups [52]: (1) therapeutic and (2) informational. Examples of therapeutic applications are hyperthermia for cancer therapy, enhancement of bone and wound healing, nerve stimulation, neural prosthesis, microwave angioplasty, treatment of prostatic hyperplasia, and cardiac ablation. Examples of informational applications are tumor detection using microwave radiometry, imaging using microwave tomography, measurement of lung (pulmonary) water content, and dosimetry.

Therapeutic applications are further classified as invasive and noninvasive. Both applications require different types of antennas and different restrictions on their design. In the noninvasive applications (not penetrating the body), antennas are used to generate an electromagnetic field to heat some tissue. Antennas such as helical coils, ring capacitors, dielectrically loaded waveguides, and microstrip radiators are attractive because of their compactness. Phased arrays are also used to provide focusing and increase the depth of penetration. The designer has to choose the right frequency, size of the antenna, and the spot size that the beam has to cover in the body. The depth of penetration, since the medium of propagation is lossy, is determined by the total power applied or available to the antenna. Invasive applications require some kind of implantation in the tissue. Many single antennas and phased or nonphased arrays have been used extensively for treating certain tumors. A coaxial cable with an extended center conductor is a typical implanted antenna. This type of antenna has also been used in arteries to soften arterial plaque and enlarge the lumen of narrowed arteries.

Antennas have also been used to stimulate certain nerves in the human body. As the technology advances in the areas of materials and in the design of more compact antennas, more antenna applications will be found in the areas of biology and medicine.

3.3. Radio Astronomy Applications

Another field where antennas have made a significant impact is astronomy. A *radio telescope* is an antenna

system that astronomers use to detect RF radiation emitted from extraterrestrial sources. Since radio wavelengths are much longer than those in the visible region, radio telescopes make use of very large antennas to obtain the resolution of optical telescopes. Today, the most powerful radio telescope is located in the plains of San Augustin, near Socorro, New Mexico. It is made of an array of 27 parabolic antennas, each about 25 m in diameter. Its collecting area is equivalent to a 130-m antenna. This antenna is used by over 500 astronomers to study the solar system, the Milky Way Galaxy, and extraterrestrial systems. Arecibo, Puerto Rico is the site of the world's largest single-antenna radio telescope. It uses a 300-m spherical reflector consisting of perforated aluminum panels. These panels are used to focus the received radiowaves on movable antennas placed about 168 m above the reflector surface. The movable antennas allow the astronomer to track a celestial object in various directions in the sky.

Antennas have also been used in constructing a different type of a radio telescope, called a *radio interferometer*. It consists of two or more separate antennas that are capable of receiving radiowaves simultaneously but are connected to one receiver. The radiowaves reach the spaced antennas at different times. The idea is to use information from the two antennas (interference) to measure the distance or angular position of an object with a very high degree of accuracy.

3.4. Radar Applications

Modern airplanes, both civilian and military, have several antennas on board used for altimetry, speed measurement, collision avoidance, communications, weather detection, navigation, and a variety of other functions [43,53–55]. Each function requires a certain type of antenna. It is the antenna that makes the operation of a radar system feasible. Figure 12 shows a block diagram of a basic radar system.

Scientists in 1930 observed that electromagnetic waves emitted by a radio source were reflected back by aircrafts (echoes). These echoes could be detected by electronic equipment. In 1937, the first radar system, used in Britain for direction finding of enemy guns, operated at 20–30 MHz. Since then, several technological developments have emerged in the area of radar antennas. The desire to operate at various frequencies lead to the development of several very versatile and sophisticated antennas. Radar antennas can be ground-based, mobile, satellite-based, or placed on any aircraft or spacecraft. The space shuttle orbiter, for example, has 23 antennas. Among these, four C-band antennas are used for altimetry, two to receive and two to transmit. There are also six L-band antennas and three C-band antennas used for navigation purposes.

Today, radar antennas are used for coastal surveillance, air traffic control, weather prediction, surface detection (ground-penetrating radar), mine detection, tracking, air defense, speed detection (traffic radar), burglar alarms, missile guidance, mapping of Earth's surface, reconnaissance, and other applications.

In general, radar antennas are designed as part of a very complex system that includes high-power klystrons,

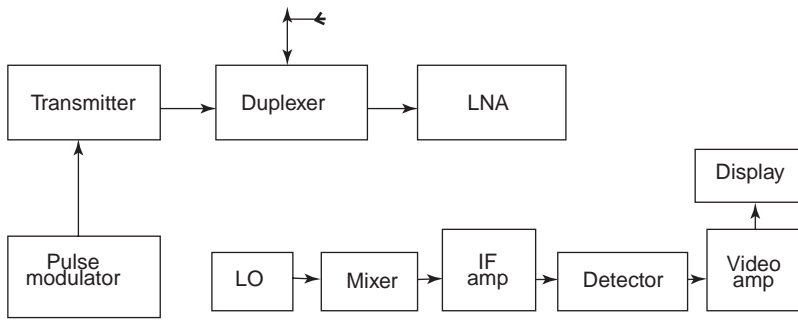

Figure 12. A basic radar system (IF = intermediate frequency; LNA = low-noise amplifier; LO = local oscillator).

traveling-wave tubes, solid-state devices, integrated circuits, computers, signal processing, and a myriad of mechanical parts. The requirements of the radar antennas vary depending on the application (continuous-wave, pulsed radar, Doppler, etc.) and the platform of operation. For example, the 23 antennas on the space shuttle orbiter must have a useful life of 100,000 operational hours over a 10-year period or about 100 orbital missions. The antennas also have to withstand a lot of pressure and a direct lightning strike. The antenna designer will have to meet all of these constraints along with the standard antenna problems such as polarization, scan rates, and frequency agility.

3.5. Impact of Antennas in Remote Sensing

Remote sensing is a radar application in which antennas such as horns, reflectors, phased arrays, and synthetic apertures are used to monitor conditions on Earth from an airplane or a satellite to infer the physical properties of the planetary atmosphere and surface or to photograph or map images of objects.

There are two types of remote sensing—active and passive (radiometry)—and both are in wide use. In the *active* case, a signal is transmitted and the reflected energy, intercepted by radar as shown in Fig. 13, is used to determine several characteristics of the illuminated object such as temperature or shape. In the *passive* case, the antenna detects energy radiated by thermal radiation from the objects on Earth. Radiometers are used to measure the ther-

Figure 13. Active remote sensing (scatterometer).

mal radiation of the ground surface and/or atmospheric conditions [13,56,57].

Most antennas associated with radiometers are downward-looking, where radiation patterns possess small, close-in sidelobes. Radiometer antennas require a very careful design to achieve high beam efficiency, low antenna losses, low sidelobes, and good polarization properties. The ohmic loss in the antenna is perhaps the most critical parameter since it can modify the apparent temperature observed by the radiometer system.

The degree of resolution of a remote-sensing map depends on the ability of the antenna system to separate closely spaced objects in range and azimuth. To increase the azimuth resolution, a technique called *synthetic aperture* is employed. Basically, as an aircraft flies over a target, the antenna transmits pulses assuming the value of a single radiating element in a long array. Each time a pulse is transmitted, the antenna, in response to the aircraft's motion, is further along the flight path. By storing and adding up the returned signals from many pulses, the single antenna element acts as the equivalent of a very large antenna, hundreds of feet long. Using this approach, an antenna system can produce maps approaching the quality of good aerial photographs. This synthetic aperture antenna becomes a "radio camera" that can yield excellent remote imagery. Figure 14 shows an image of the air (thick with dust and smoke) over the Mediterranean Sea.

Today, antennas are used in remote-sensing applications for both the military and civilian sectors. For example, in the 1960s the United States used remote-sensing imaging from satellites and aircraft to track missiles activities over Cuba. In 1970s, remote sensing provided NASA with needed maps of the lunar surface before the *Apollo* landing. Also, in July 1972, NASA launched the first Earth Resource Technology Satellite (ERTS-1). This satellite provided data about crops, minerals, soils, urban growth, and other Earth features. This program still continues its original success using the new series of satellites "the Landsats." In 1985, British scientists noted the "ozone depletion" over the Antarctica. In 1986, U.S. and French satellites sensed the Chernobyl nuclear reactor explosion that occurred in the Ukraine. Landsat images from 1975 to 1986 proved to be very instrumental in determining the deforestation of Earth, especially in Brazil. In 1992, hurricane "Andrew," the most costly natural disaster in the history of the United States, with winds of 160 miles per hour, was detected on time by very-high-resolution radar on satellites. Because of the ability to detect the hurricane from a distance, on time, through sophisticated antennas and imagery, the casualties

Figure 14. The air over the Mediterranean Sea (thick with smoke and dust). This sea image shows most of the Algerian coastline to be on fire. (Courtesy NASA Goddard Center.)

from this hurricane were low. In 1993, during the flooding of the Mississippi River, antenna images were used to assist in emergency, planning, and locating threatened areas. Finally, NASA, using antennas, managed to receive signals from Mars and have the entire world observe the “pathfinder” maneuver itself through the Rocky Martian terrain.

ANTENNAS FOR HIGH-FREQUENCY BROADCASTING

RONALD WILENSKY
 GORDON G. SINCLAIR
 RICHARD R. GREENE
 Technology for Communications
 International
 Fremont, California

1. INTRODUCTION

High-frequency (HF) broadcasting uses discrete bands within the frequency range from 2 to 30 MHz (Table 1). These bands are based on international agreements that also permit broadcasting at other frequencies on a non-interference basis. HF, also known as *shortwave*, is very effective for transmitting voice and program material over distances of thousands of kilometers. While HF broadcasting's role is changing as the world becomes more interconnected by satellites and cable, it is still used extensively for broadcasting across national borders by governmental and private organizations. The implementation of digital HF broadcasting will improve the quality of the received signals and is likely to increase the popularity of HF broadcasts.

2. GENERAL CHARACTERISTICS

The path between an HF transmitter and a receiver may be either along Earth's surface, by means of ground waves, or via the ionosphere, by means of sky waves. Ground waves are reliable but at HF frequencies are limited to a few kilometers over land. HF broadcasting uses sky waves exclusively. Sky waves are radiowaves that radiate away from Earth's surface at some "takeoff angle" (TOA) above the horizon. Sky waves may pass through the ionosphere, or they may be absorbed or refracted back to Earth's surface. The refraction mode is the propagation mode of interest to shortwave broadcasters. The electrical characteristics of the ionosphere change with time of day and hours of daylight (season), and electrical activity of the sun (sunspot number). In addition, the ionosphere's ability to propagate and refract HF radiowaves varies significantly with frequency; therefore, broadcasters must carefully select frequencies that will produce the best propagation paths at any given time.

HF signals propagate by refraction from the E and F layers of the ionosphere, regions of charged particles located approximately 100–400 km above Earth's surface. HF broadcasts must use optimum frequencies in order to obtain useful signal strength at the receiver. Optimum frequencies, normally referred to as FOTs (frequency of optimum transmission) vary widely during a 24-h period. A typical day's ionospheric activity begins with the buildup of a D layer, a layer that forms only on the sunlit side of Earth. The D layer strongly absorbs low HF frequencies, so daytime frequencies must always be high enough to get through it. At night the D layer disappears and FOTs drop. Late at night even the E and F layers may

Table 1. HF Broadcast Bands

Band (MHz)	Frequencies (MHz)	Comments
2	2.300–2.495	
3	3.200–3.400	
4	3.950–4.000	ITU regions 1 and 3 only
5	4.750–5.060	5.0 MHz excluded for time signals
6	5.900–6.200	
7	7.100–7.350	7.1–7.3 MHz excluded in ITU region 2
9	9.400–9.900	
11	11.600–12.100	
13	13.570–13.870	
15	15.100–15.800	
17	17.480–17.900	
19	18.900–19.020	
21	21.450–21.850	
26	25.670–26.100	

diminish significantly, especially at times of low solar activity or long winter nights, when FOTs may drop to the bottom of the band. The subject of propagation of radiowaves via the ionosphere is vast; additional references may be found in this encyclopedia and in the Further Reading list at the end of this article. Because the FOT can vary widely over the course of a single day, HF broadcasting antennas should be capable of transmitting over as many of the allocated bands as possible.

Coverage area is a function of the antenna's takeoff angle and beamwidth. Local coverage requires high TOAs, on the order of 90° , while long-range coverage requires that the signal takeoff at a low angle. The coverage area where the signal is first refracted back to Earth is known as the *first-hop footprint*. The angle of arrival will normally be the same as the takeoff angle. The "hopping" process may continue as many as 2 or 3 more times, ionospheric conditions permitting. Multihop signals are usually terminated if they reach longitudes of dawn or dusk. The limit of good-quality HF service is generally taken to be 6000 km; this distance represents the approximate end of the second-hop coverage area.

HF broadcasting typically uses transmitter carrier powers of 50–500 kW, with a few systems using 1000 kW. Currently, HF transmissions use double-sideband (DSB) amplitude modulation to allow signals to be received and demodulated by simple and inexpensive receivers. More recent plans calling for the conversion of HF broadcasting to single sideband have been shelved in favor of conversion to digital broadcasting using a worldwide standard that was promulgated in 2003. Digital test transmissions commenced in 2003 with encouraging initial results, and some broadcasters predict widespread implementation of digital broadcasting by 2010.

A DSB AM signal with carrier power P and modulation index m , where $0 < m \leq 1$, has an average power of $(1 + m^2/2)P$ and peak envelope power of $(1 + m)^2P$. For 100% modulation ($m = 1$), average and peak power levels are thus $1.5P$ and $4P$, respectively. An antenna excited by a fully modulated 500-kW transmitter must therefore be designed to withstand the currents of a 750-kW source and the voltages and fields of a 2000-kW source.

3. GENERAL ANTENNA CHARACTERISTICS

HF broadcasting antennas must have radiation patterns that match the requirements for a particular target service area. The antenna's gain, horizontal beamwidth, and vertical angle of radiation [takeoff angle (TOA)] must be chosen carefully in order to provide a strong signal in the audience area. This requires taking into account the ionospheric propagation characteristics, distance to the audience area, and geometric shape of the audience area. Antenna selection is aided by computerized propagation prediction programs such as VOACAP and IONCAP, which calculate TOAs, FOTs, gain, and signal strengths.

Despite the variability of the ionosphere as a refracting medium, some general rules apply to the selection of HF broadcasting antennas. HF broadcasting antennas generally operate in the 6–21 MHz frequency bands. Antennas that serve distant audiences have low TOAs, narrow horizontal beams, and high gain of 15–30 dBi (dBi is the antenna gain in decibels above an isotropic radiator). Antennas that serve nearby audiences have higher TOAs, broader or even omnidirectional beams, and lower gains in the range 9–14 dBi. These antennas are often designed to operate down to 2.3 or 3.2 MHz, frequencies that are required for propagation over short distances, particularly at night and when sunspot activity is low.

HF broadcasting antennas are almost without exception horizontally polarized. Although vertically polarized HF antennas have many desirable characteristics, such as low TOA and broad azimuthal patterns, their gain is reduced by several decibels if the ground in front of the antenna is not highly conductive. The gain of horizontally polarized antennas is much less dependent on ground conductivity. At low TOAs poor ground conductivity reduces the gain of a horizontally polarized antenna by only a few tenths of a decibel. The ground losses associated with vertically polarized antennas may be partially overcome by siting the antenna very close to seawater, which has excellent electrical conductivity, or by installation of an artificially enhanced ground made from a large mesh of copper wires. In most situations, such solutions are neither desirable nor possible; consequently, horizontal polarization remains the primary choice for HF broadcasting antennas.

HF broadcasting antennas fall into two main classes: log-periodics and dipole arrays. Log-periodics are wide-band, generally not steerable, and limited to 250 kW of carrier power. Dipole arrays are limited in bandwidth, but can handle more power and are capable of being steered, or "slewed" electrically by up to $\pm 30^\circ$. This allows broadcasters to serve different target areas with the same antenna. An alternative approach to steering the beam rotates the entire antenna; rotatable antennas are rarely used, however, owing to the cost and complexity of the steering mechanisms and the associated structures.

4. LOG-PERIODIC ANTENNAS

Log-periodic antennas (LPAs) are a class of frequency-independent antennas first developed in the 1960s. In the HF band LPAs have been used mainly for communications, but

since the 1970s have been increasingly used for broadcasting. Unlike a single-dipole array, whose operation is limited to a one-octave (2–1) frequency range, an LPA can operate over nearly a 4-octave (16–1) frequency range, covering all of the international broadcast bands from 5.9 through 21 MHz.

LPAs constitute a series of half-wave dipoles spaced along a transmission line where all electrical lengths (lengths of both the dipoles and intervening transmission lines) follow a geometric progression. The ratio of successive smaller lengths is a constant, commonly called the *scaling constant* and represented by the Greek letter τ . By convention, the progression starts with the longest element so that τ is less than 1 and typically in the range 0.8–0.92. LPAs are fed at their high-frequency end, where the radiators are smallest. Current flows up the internal antenna feedline until it reaches a group of radiators, called the *active region*, which are approximately one-half wavelength wide at the excitation frequency. The active region radiates in the direction of the smaller radiators. LPAs typically have balanced input impedances of 100–400 Ω and maximum VSWR of 1.8–1 or less.

A highly desirable feature of LPAs is the ability to tailor their radiation patterns to satisfy different broadcasting requirements. The designer can control the way the radiation pattern varies with frequency by making the pattern dependent on frequency. This is not true for dipole arrays, whose patterns vary with frequency in a way that cannot be controlled.

The radiation pattern of an LPA is determined by the number and arrangement of the curtains. In some LPAs the TOA is designed to decrease as frequency increases. This helps reach audiences at varying distances, since long paths generally propagate best using higher frequencies, while at the same time requiring low TOAs. In other cases the TOA is kept constant, which is very useful for broadcasting to a fixed geographic area. The horizontal beamwidth of an LPA can also be controlled by the designer, although in most situations a fixed beamwidth is most useful.

The physical size of an LPA depends on the antenna's frequency range (principally its low-frequency limit) and radiation pattern characteristics. While the relationships among these characteristics are complex, the following relationships generally apply:

1. The largest radiators of an LPA are approximately one-half wavelength long at the lowest operating frequency. Thus, the lower an antenna's frequency limit, the larger the physical size.
2. The TOA of any horizontally polarized antenna is given by the formula

$$\text{TOA} = \sin^{-1} \frac{\lambda}{4h} \quad (1)$$

where λ is the wavelength at the operating frequency and h is the height above ground of the radiating element with the highest current. Thus, for a low TOA, an antenna's height will be large compared to its wavelength; conversely, high TOAs require lower heights.

3. The horizontal beamwidth of an antenna varies inversely with its horizontal radiating aperture

(the physical width of the active region relative to the wavelength at the operating frequency). Narrow beamwidths require larger apertures and physical size than do broad beamwidths.

LPAs have been designed to operate at transmit powers of 500 kW with 100% amplitude modulation; however, these antennas are large and expensive. Power levels exceeding 250 kW are better handled by dipole arrays. The most cost-effective power range for high-power LPAs is 50–250 kW, with 100-kW versions the most common.

Antenna radiators must have a large electrical diameter to prevent corona discharge at high power levels, since the electric field perpendicular to the surface of a conductor is inversely proportional to the electrical diameter of the conductor. Although radiators can be made from large-diameter tubes or pipes, the resulting structures are expensive and mechanically unreliable. A more reliable and less expensive means of increasing electrical diameter is to form two small-diameter (8–12 mm) wire cables into a triangular tooth (Fig. 1). Radiators with large electrical diameters have lower Q and broader bandwidth than do thin radiators. In an LPA, lower Q results in a greater the number of radiators in the active region, which decreases the power in each radiator. The larger active region also provides a small increase in antenna gain.

4.1. Examples of Log-Periodic Antennas

4.1.1. Short-Range LPAs. To cover short distances, an HF antenna must direct energy at high angles with peak radiation at vertical incidence (i.e., TOA = 90°). According to Eq. (1), the active region at each frequency must be approximately 0.25 wavelength at the operating frequency. Figure 1 illustrates a two-curtain LPA that provides a vertically incident pattern giving primary coverage from 0 to 1500 km. Short-range antennas have low-frequency operating limits in either the 2.3- or 3.2-MHz bands. The upper frequency limit is usually set at 18 MHz to cover areas in the 1000–1500 km range.

The short-range LPA has a maximum gain of 9 dBi at vertical incidence and produces a nearly circular horizon-

Figure 1. Two-curtain short-range omnidirectional log-periodic antenna.

Figure 2. Two-curtain medium-range directional log-periodic antenna.

tal pattern. The elevation pattern has its -3 -dB points at approximately 50° above the horizon. The antenna obtains its high-angle coverage by firing energy downward into the ground, which in turn reflects it upward. A ground screen minimizes losses in the imperfectly conducting Earth. The short-range LPA is the only horizontally polarized antenna for which a ground screen provides meaningful gain enhancement.

4.1.2. Medium-Range LPAs. A two-curtain LPA suitable for broadcasting over distances of 700–2000 km is illustrated in Fig. 2. While similar to the LPA shown in Fig. 1, this antenna fires obliquely into the ground, rather than vertically, producing a lower TOA and narrower elevation pattern than the short-range LPA. Antennas of this type have TOAs in the range of 20 – 45° , with gains of 14 and 10 dBi respectively, and horizontal patterns having -3 -dB beamwidths of 68 – 90° .

4.1.3. Long-Range LPAs. A four-curtain LPA (Fig. 3) provides vertical and horizontal patterns that are narrower than those of the two-curtain LPA. This antenna provides gain of up to 18 dBi and low TOA in the range of 12 – 20° . The -3 -dB horizontal beamwidth is 38° . This pattern provides excellent coverage for broadcasts beyond 1500 km.

5. DIPOLE ARRAYS

Dipole arrays are rectangular or square arrays of half-wave dipoles mounted in front of a reflecting screen (Fig. 4). Dipole arrays have high power handling capacity and provide a wide variety of different radiation patterns

Figure 3. Four-curtain long-range directional log-periodic antenna.

Figure 4. 4×4 dipole array with reflecting screen.

to serve different broadcasting requirements. Beams of dipole arrays can be steered in both the vertical and horizontal planes without moving the entire antenna.

Dipole arrays containing four or more dipoles have low VSWR over a 1-octave frequency range. Arrays with fewer than four dipoles generally have narrower impedance bandwidths. Unlike an LPA, one dipole array cannot cover the entire shortwave frequency range, which is 4 octaves wide. However, two dipole arrays, one operating in the 6/7/9/11-MHz bands and the other in the 13/15/17/19/21/26-MHz bands, can cover the frequencies used in international broadcasting. The dimensions of a dipole array are determined by its design frequency f_0 , which is approximately equivalent to the arithmetic mean of the lowest and highest operating frequencies. The design wavelength, λ_0 (meters) is $300/f_0$ (MHz). Horizontal and vertical centers of the dipoles are spaced at $0.5\lambda_0$ wavelengths.

The dipoles in the array are interconnected by a set of balanced transmission lines. The transmission lines terminate at a single feedpoint having a balanced impedance of 200 – 330Ω . The input VSWR of a dipole array is generally 1.5 – 1 or less in its operating bands.

The most commonly used dipole arrays are described by the standard nomenclature AHRS $m/n/h$; “H” indicates that the antenna is horizontally polarized; “R” that it has an aperiodic (i.e., nonresonant) reflecting screen, and “S” (if present) that the antenna beam can be slewed horizontally or vertically. m and n are integers that indicate, respectively, the number of vertical columns and the number of dipoles in each column; h is the height of the lowest dipole above ground in wavelengths at the antenna design frequency. The m , n , and h parameters determine the antenna’s radiation patterns. Most common values are $m = 2$ or 4 , $n = 2, 4$, or 6 , and $h = 0.5$ – 1.0 . The radiation patterns for various dipole arrays (Table 2) demonstrate the wide variety of radiation patterns which dipole arrays can provide.

The number of vertical columns m determines the horizontal aperture of the antenna. For $m > 1$, the -3 dB horizontal beamwidth (HBW) at frequency f is approximately $100^\circ(f_0/mf)$. At $f = 1.34f_0$, the upper frequency limit of a 1-octave bandwidth, the minimum HBW is 75° divided by m .

The number of dipoles in each column (n) and height of the lowest dipole (h) determine the TOA and elevation

Table 2. Radiation Patterns of Typical Dipole Arrays over 2–1 Bandwidth

Array Type	TOA	– 3 dB HBW	– 3 dB VBW	Gain (dBi)
AHRS 2/2/0.5	13–25°	40–70°	13–25°	18–15
AHRS 4/2/0.5	13–25°	20–35°	13–25°	21–18
AHRS 2/4/0.5	7–14°	40–70°	7–14°	21–18
AHRS 4/3/0.5	8–16°	20–35°	8–16°	23–18
AHRS 4/4/0.5	7–14°	20–35°	7–14°	24–19
AHRS 4/4/1.0	5–10°	20–35°	5–10°	24–19
AHRS 4/6/0.5	4–8°	30–35°	4–8°	25–20

Note: The first value in the range is the highest frequency; the second value is the lowest frequency.

pattern beamwidth. In typical dipole arrays $h \leq 1.0$ and $n \leq 6$ (larger values would result in very tall and expensive antennas). The effective height of radiation is the average height above ground of all the excited dipoles. The effective height can be used in Eq. (1) to calculate the TOA.

Modern dipole arrays use reflecting screens to suppress radiation behind the antenna and increase forward gain by nearly 3 dB. A typical screen consists of horizontal wires with a vertical separation of $0.04\text{--}0.06\lambda_0$. The screen is placed approximately $0.25\lambda_0$ behind and parallel to the plane of the dipoles. It extends approximately $0.125\text{--}0.25\lambda_0$ beyond the edges of this plane. Screens for 2-, 4-, and 6-high arrays have 25–35 wires, 50–75 wires, and 75–100 wires. These parameters produce a backlobe which is 12–15 dB below the gain of the mainbeam. The backlobe may be reduced further by adding more screen wires. Halving the vertical spacing by doubling the number of wires reduces the backlobe by 6 dB, although there is a tradeoff—screens with more wires impose greater loads on the support towers.

6. SLEWING DIPOLE ARRAYS

Phase delays can be inserted via RF switches in the internal feedlines of a dipole array to slew, or steer, the pattern in the horizontal plane. Horizontal slews of up to $\pm 30^\circ$ relative to boresight are accomplished by switching in delay lines that introduce a progressive phase delay from column to column. Phase delays greater than 30° should not be used since the result would be high VSWR and excessive sidelobe levels. For maximum horizontal coverage with minimum complexity and cost, slewing systems should provide angular steps equal to approximately 50–75% of the HBW. Thus, a five-position slewing system providing 10–15° steps is suitable for a 4-wide array, which has a minimum HBW of 19°.

Vertical slew may be accomplished by switching off one or more pairs of dipoles in each column. For example, 6-high arrays commonly have three vertical slew positions. The lowest TOA is obtained with all six dipoles excited. Medium/high-angle slews are obtained by exciting only the bottom four and bottom two dipoles, respectively.

Slewing of a dipole array can cause resonances near the lower frequency limit. Resonances always produce voltages much higher than normal, and may also cause excessive VSWR. Resonances are caused by circulating currents that flow between the interconnected dipoles. At a circulating current resonance, some dipoles have nega-

tive input resistance and thus act as a power source rather than a power sink. Circulating current resonances are 50–250 kHz wide, comparable to the width of a broadcast band. In 4- and 6-high arrays, multiple resonances can occur, preventing operation in one or more bands. Resonant frequencies are determined by the pathlength between the dipoles and can be changed by altering this length. The prediction and measurement of circulating current resonances is an important part of both the design and construction of dipole arrays.

7. TRANSMISSION LINES, SWITCHING SYSTEMS, AND BALUNS

A broadcast station's transmitters are connected to its antennas via a feed system that includes balanced and/or coaxial transmission lines. All but the simplest feed systems also include switching, usually provided by a matrix of switches, which select the antennas that are to be connected to the transmitters. Feed systems generally include balanced-to-unbalanced (balun) transformers to match the balanced impedance of most high-power HF antennas to the unbalanced impedance of modern transmitters.

8. RIGID COAXIAL LINE

RF output is typically taken from the transmitter by means of a rigid coaxial transmission line. Coax sizes range from $6\frac{1}{8}$ -in. EIA standard for 100 kW to 9-in. standard (nominal, not standardized) for 500 kW. Characteristic impedance is usually 50 or 75 Ω . Coax lines outside the transmitter building require constant pressurization with 3–10 psi (lb/in.²) of dry air to prevent condensation of moisture. Lines within the building do not require pressurization.

9. SWITCH MATRIX

The typical switch matrix comprises a number of rows and columns of motorized single-pole, double-throw switches. Typically, transmitters feed the rows of switches; in turn, the columns of switches feed the antennas. The matrix configuration allows any transmitter–antenna combination while prohibiting the connection of two transmitters to a single antenna, or two antennas to a single transmitter. A typical switch matrix comprising 5 rows and 6 columns is shown in Fig. 5.

Switch matrices can be either balanced or unbalanced. Balanced matrices have impedance levels of 300–330 Ω .

Figure 5. Coaxial switch matrix, 5 rows \times 6 columns.

Unbalanced matrices are either 50 or 75 Ω . Balanced matrix switches are generally shielded to minimize RF radiation in the vicinity of the switch. Coaxial matrix switches are inherently shielded by nature of their construction. Coaxial switch matrices generally preferred in new installations because they are smaller in size and have greater RF isolation between the switches.

10. BALUNS

The input of a balun matches the impedance of the coaxial portion of the system, usually 50 or 75 Ω ; the output matches the balanced impedance of the antenna, usually 300 Ω . Some transmitters are equipped with baluns that use a network of motorized adjustable components that are set to different values for each transmitter operating frequency. Another type of balun is a completely passive device designed to operate over a wide range of frequencies without tuning. A broadband balun consists of a coaxial section that converts the RF power to a balanced mode, and a tapered balanced transmission line that transforms the impedance to 300 Ω . A typical broadband balun is 33 m long and operates at 5.9–26 MHz.

11. BALANCED TRANSMISSION LINE

A balanced, or “open wire,” transmission line is commonly used to feed high-power RF to antennas. This line usually consists of two pairs of copper, aluminum, aluminum-clad steel, or copper-clad steel wire cables held at a fixed distance by means of high-voltage insulators. The line is

held under tension 3–6 m above ground by poles spaced at 15–25-m intervals. Open wire transmission line costs less than rigid coax and is much easier to repair.

12. FEED SYSTEM CONFIGURATIONS

HF broadcasting stations generally use one of three types of feed systems: (1) all balanced, (2) all unbalanced, or (3) combined balanced–unbalanced. The balanced system is used when the transmitter includes its own balun and therefore provides a balanced output. The RF switches and transmission lines will be balanced and have an impedance level that matches that of the antennas. In the unbalanced system, all feeders from the transmitter to the RF switches and from the switches to the antenna are coaxial lines. Each antenna has a broadband balun whose frequency range matches that of the antenna. In the combined unbalanced/balanced system, coaxial feeders are used between the transmitters and switch matrix and from the switch matrix to an area outside but near the transmitter building in which broadband baluns are placed. Balanced open wire transmission lines interconnect the baluns to the antennas.

The balanced system is used primarily at small stations that contain a small number of transmitters and antennas. It is the least expensive of the three systems. In stations containing a large number of transmitters, a balanced switch matrix will occupy a large amount of space and is therefore not desirable. The unbalanced system is the most expensive and is preferred when there are environmental concerns that necessitate maximum shielding of the transmission-line system. The combined unbalanced/balanced system is the one most commonly used at modern stations because it provides a good trade-off between cost, size, and performance.

ANTENNAS FOR MEDIUM-FREQUENCY BROADCASTING

RONALD RACKLEY
MATTHEW FOLKERT
du Treil, Lundin, & Rackley
Sarasota, Florida

The beginnings of medium-frequency broadcast antennas (530–1700 kHz) can be traced to the early 1920s. The first antennas constructed were made of a pair of steel or wooden masts supporting an antenna structure consisting of a vertical wire or wire cage, sometimes accompanied by a horizontal section consisting of a wire or flat surface or cage of wires. The antennas with the horizontal members were referred to as T- or L-type antennas. Figure 1 illustrates the physical characteristics of the early medium-frequency antennas. Most of these antennas did not exceed a physical height of 50–70 electrical degrees. In 1924, Ballantine [1] showed that longer antennas would result in a substantial gain in the horizontal plane radiation. Heights were then increased to as much as 135 electrical degrees with the first commercial antennas being constructed in the early 1930s.

During the 1930s the present type of medium-frequency broadcast antenna, a self-supporting or guyed tower in which a base-insulated tower is utilized as the radiating element with an accompanying ground system, was developed. The classic paper by Chamberlain and Lodge [2] spearheaded this development and offered many advantages over the earlier antennas. The radiation efficiency of a nondirectional radiator was often more than double when this new type of design was put into service and the cost of such a structure decreased significantly as the number of required towers was cut in half. It was also found necessary to use breakup insulators to reduce guywire current. Figure 2 shows a single-tower radiator of this type. As the number of medium-frequency broadcast stations increased during the 1930s, it was necessary to develop directional antenna systems to minimize interference between stations. A directional antenna consists of multiple towers used in a phased-array configuration and excited with various amplitude and phase relationships to form a pattern in the desired shape. The single excited tower radiating element made the directional antenna concept an economically feasible possibility. The first directional antenna system designed by Dr. Raymond M. Wilmotte, was constructed by WSUN in St. Petersburg, Florida and

Figure 1. Early AM antenna utilizing two vertical masts supporting the radiating structure.

Figure 2. Present antenna configuration using the tower as the radiating element. Structure can be self-supporting or supported with guywires.

employed two towers to produce a radiation pattern null toward cochannel station WTMJ in Milwaukee, Wisconsin to resolve a nighttime interference controversy.

The 1940s brought further development to the design of medium-frequency broadcast antennas. Top-loading, sectionalizing, and improved ground systems were introduced to improve antenna efficiency as well as to control vertical radiating characteristics. The number of towers used in directional arrays was increased to as many as nine elements as the power dividing and phasing systems were improved.

Since the 1940s, there has not been significant development in the area of the antenna element itself as self-supporting and guyed radiating towers continue to be used much as they were at that time. In the 1960s, three 12-tower arrays were constructed at WJBK in Detroit, Michigan, CFGM in Toronto, Canada, and KLIF in Dallas, Texas. These were the largest arrays of driven elements ever constructed for medium-frequency broadcast use. New developments since then have principally involved auxiliary equipment used to test and monitor the antenna system and the means by which the antenna is theoretically analyzed. Digital antenna monitors are used today to accurately monitor the relative current magnitudes and phase relationships of the towers in a directional array while portable solid-state field strength meters are used to measure radiation patterns. Advances have also been made with improved RF current meters, sampling transformers, and impedance measuring equipment. The design of medium-frequency broadcast antennas for optimized performance has also seen tremendous advances with the introduction of numerical solutions to electromagnetic problems and nodal modeling of feeder systems made economically possible with personal computers vastly simplifying both design and implementation.

1. GENERAL ANTENNA CHARACTERISTICS

The medium-frequency range is generally defined from 300 to 3000 kHz. The portion of the band allocated to AM

broadcasting is from 530 to 1700 kHz in North America. The channels for the individual broadcast stations are spaced 10 kHz apart. In contrast, within the medium-frequency broadcast band in other regions of the world, the stations are spaced 9 kHz apart.

1.1. Electrical

The typical antenna used for medium-frequency broadcasting is electrically equivalent to one or more base-excited monopoles over a finite perfectly conducting ground plane. In directional antenna systems, where more than one element is employed, the amplitude and phase of the current to each monopole are varied in relationship to one another to determine the pattern size and shape. The height of each monopole can vary in height from as little as 45 to as much as 225 electrical degrees. This translates to a range of physical heights of 25–200 m within the medium-frequency band. In a few rare instances taller towers are employed; they are center-fed and known as *Franklin Antennas*.

1.2. Mechanical

A self-supported or guyed steel tower is usually used as the radiating element. The tower can be triangular or square in cross section and can have a face width ranging from a fraction of a meter to several meters. A ground system consisting of copper wires typically extends radially from the base of each tower a length of 90 electrical degrees from the tower base. Normal practice is to use 120 wires equally spaced (every 3 degrees) and equal in length except where they would overlap between adjacent towers for the ground system. Overlapping of wires is avoided by shortening them and bonding them to a transverse conductor (usually a copper strap).

1.3. Propagation

The electromagnetic field propagates from a medium-frequency antenna system in two modes. The first mode travels along the surface of the ground and is referred to as *ground-wave propagation*. The second mode radiates directly into space and refracts from the ionosphere before reaching the target area and is referred to as *sky-wave propagation*. Effective sky-wave propagation is severely attenuated during daytime hours and is significant only at night. Ground-wave propagation is dependent on the characteristics of the terrain over which the signal propagates. Propagation models for ground-wave and sky-wave signals, as they affect spectrum management and individual station authorization, are prescribed by the government agency having jurisdiction within the country where a station is located. The agency with jurisdiction over stations operation within the United States is the Federal Communications Commission (FCC), while many foreign countries use propagation standards published by the ITU/CCIR.

2. STATION CLASSIFICATIONS

The FCC of the United States regulates all medium-wave radio broadcasting in the United States. The FCC has

classified all medium-frequency radio stations into categories defining their coverage areas and power levels [3]. An *unlimited* time station can broadcast at all times during the daytime and nighttime, whereas a *limited* time station (usually daytime) can only broadcast at certain specified times. A *primary* service area is defined as the area within close proximity to the station and where ground-wave propagation provides a high-quality signal. A *secondary* service area is more distant from the station and usually depends on sky-wave propagation during nighttime hours.

Under the international agreements governing medium-wave broadcasting in the Western Hemisphere (ITU Region III), there are three classes of frequency allotments. By bilateral agreements among the North American countries, certain channels or frequencies are reserved for use by stations providing various classes of service.

2.1. Clear Channel

A *clear channel* classification is assigned to stations covering wide service areas and is subdivided into three classes:

1. *Class A*. Unlimited stations assigned to primary and secondary service area. Power levels range between 10 and 50 kW.
2. *Class B*. Unlimited service assigned to primary service areas only. Power levels range between 0.25 and 50 kW.
3. *Class D*. Limited service daytime or unlimited service with no nighttime service or nighttime power less than 0.25 kW. Power levels range between 0.25 and 50 kW.

2.2. Regional Channel

A *regional channel* classification is assigned to stations serving a principal center of population and the surrounding rural areas and is subdivided into two classes:

1. *Class B*. Unlimited service assigned to a primary service area. Power levels range between 0.25 and 50 kW.
2. *Class D*. Limited service daytime or unlimited service with no nighttime service or nighttime power less than 0.25 kW. Power levels range between 0.25 and 50 kW.

2.3. Local Channel

A *local channel* classification is assigned to stations serving a community and the surrounding suburban and rural areas and consists of one class:

1. *Class C*. Unlimited service assigned to a primary service area. Power level range between 0.25 and 1 kW.

3. ALLOCATION STUDIES

Before a medium-frequency station can be licensed, an analysis is required to determine compliance with rules governing acceptable interference levels between stations. In the United States, the analysis is based on propagation models and conductivity maps as defined in the Code of Federal Regulations [3].

3.1. Propagation Models

Field strength algorithms exist that can be used to predict the coverage of a particular antenna system. The *equivalent-distance ground-wave model* is a prediction method used for daytime ground-wave field strength calculations when signals propagate over one or more conductivity regions. The *1992 FCC Skywave Model* (47 CFR 73.183) is a prediction method used for most nighttime field strength calculations within the United States. The *Region 2 Annex II Figure 4 Skywave Model* is a predication method used for nighttime sky-wave field strength calculations between the United States and Central and South America, and the Caribbean Islands. Also, the *US–Canada Bilateral Agreement, Annex II Figure 4A Skywave Model* is a predication method used for nighttime sky-wave field strength calculations between the United States and Canada. Propagation models and techniques for determining allowable interference differ substantially from one part of the world to another. Propagation models for other regions of the world are specified in regional agreements administered by the International Telecommunications Union (ITU) in Geneva, Switzerland.

3.2. Ground Conductivity Maps

The calculation of ground-wave field strength levels depend on predicted ground conductivity and dielectric constant values for the area of interest. It is an acceptable simplification for most engineering analysis to define ground conductivity with a fixed dielectric constant. Predicted conductivities are usually presented in the form of a map or computer model delineating boundaries between regions of different conductivities. The M3 map is included in the FCC rules and shows predicted ground conductivity for the continental United States. The region 2 map covers a larger area and shows predicted ground conductivity for much of the Western Hemisphere. The M3 map is used for calculations between stations within the United States while the region 2 map is used between stations in the United States and stations in Canada, Central America, and the Caribbean. Other countries utilize conductivity maps developed for their own regions.

3.3. Field Strength Contours

When analyzing the coverage from a given antenna system, it is useful to calculate field strength contours at various levels to determine if the station is providing adequate coverage to the target area and if interference exists between stations on cochannel or adjacent channel frequencies. A field strength level of 50–25 mV/m is considered necessary to provide premium service to heavily

Frequency separation (kHz)	Contour of proposed station (classes B, C and D) (mV/m)	Contour of any other station (mV/m)
0	0.005	0.100 (Class A)
	0.025	0.500 (Other classes)
	0.500	0.025 (All classes)
10	0.250	0.500 (All classes)
	0.500	0.250 (All classes)
20	5.0	5.0 (All classes)
30	25.0	25.0 (All classes)

Figure 3. Daytime protection limits as specified by the Federal Communications Commission. Protection limits are instituted to reduce cochannel and adjacent-channel interference.

built-up urban and industrialized areas, whereas a field strength of 5 mV/m is often considered to be satisfactory for the less heavily built-up surrounding areas. A field strength of 2.0 mV/m provides service to residential areas and 0.5 mV/m is the minimum signal level for service to rural areas in nontropical regions of the world.

3.4. Daytime Allocation Study

A daytime allocation study involves the calculation of ground-wave field strength contours to determine if interference exists between stations on cochannel or adjacent channel frequencies. The required protections as specified by the FCC are given in Fig. 3. The most stringent protection is afforded to cochannel stations with decreasing protection levels to the first, second, and third adjacent channels chosen to eliminate *splatter* between the signals of nearby stations.

3.5. Nighttime Allocation Study

A nighttime allocation study involves the calculation of nighttime skywave field strength levels to determine if interference exists between stations on cochannel or adjacent frequency channels. In contrast to the daytime study in which field strength contours are determined, the nighttime study involves point-to-point calculations. In the United States, the method for determining protection between stations requires calculating the received interfering field strengths from all cochannel and first-adjacent-channel stations. The square root of the sum of the squares (RSS) is calculated using all the interfering signals in descending order and determines the overall interference level. The levels of interference which are defined by the FCC are the 50% and 25% RSS levels. The 50% RSS level includes only the stations that contribute a signal level of at least 50% to the running RSS total, whereas the 25% RSS level includes all stations that contribute a signal level of at least 25% to the running RSS total. When a station is newly licensed or undergoes a major change (increase in power or modified pattern), it cannot increase interference to existing stations above the 25% RSS level. If a station presently causes interference at a level between 25 and 50% of another station, its interference contribution cannot be increased at all, and, if it presently caused interference above the 50% level, its

interfering signal must be decreased at the affected station by at least 10% under the present FCC rules. The service area of a station during nighttime hours is considered to be the area that is defined by the 50% RSS boundary.

4. ANTENNA DESIGN

Antenna design involves the selection of physical and electrical parameters that meet all design requirements as determined by the allocation studies while simultaneously providing a satisfactory level of interference-free coverage to the proposed coverage area, including the “community of license,” from the selected transmitter site.

4.1. Mechanical

4.1.1. Radiating Elements. Two types of radiating elements are typically used in medium-frequency broadcast antenna system today: self-supporting or guyed towers. A self-supporting tower consists of a free-standing tapered steel structure. A guyed tower is usually of uniform cross section and is supported by insulated steel guy cables or nonconductive cables attached at multiple levels. Either type of tower can be top-loaded (with a horizontal steel circular cap or a portion of the guy wires connected directly to the tower to achieve greater electrical height with a physically shorter structure) or sectionalized (when the tower is broken into sections and a series inductance is inserted between them to reduce the reactance of the upper sections). In some cases, where towers on the order of a wavelength tall are employed, they are center fed. Such center-fed towers are known as *Franklin antennas*.

4.1.2. Feedpoint. The feedpoint is the location at which the radiating element is fed power from the transmission line. A series feed system feeds the power across a tower’s base insulator, whereas a tower may be shunt-fed either with a slant wire attached part way up its structure or with a wire skirt at its base. A major advantage of grounded tower radiators with skirt wires is the elimination of isolation components for lighting circuits. This is especially true for very high-power operation of stations outside the United States. A Franklin antenna may be fed across either an insulator or gap in a wire skirt at approximately one half of its height. Some type of balun (usually a quarter-wave line section) must be employed to isolate the circuit across the ground level insulator of a Franklin antenna.

4.1.3. Ground System. The ground system is a conductive screen or grid of wires imbedded in the ground around the base of each radiating element to allow ground currents to return directly to its base. A typical ground system consists of 120 buried copper wires, equally spaced, extending radially outward from each radiating element base to a minimum distance of 90 electrical degrees. An exposed copper mesh may also be used around the base when high voltages are expected.

When multiple elements are used to form an array, the ground radial wires from adjacent towers will often over-

lap. When this occurs, a copper transverse strap or cable is employed for bonding the radials together so that they do not extend into the area where they would overlap.

4.1.4. Lighting System. A system of beacons or continuously illuminated lights mounted on each tower at various heights is often required for towers above a certain height. Series excited towers must have some means of coupling the ac power to the lighting circuit on the towers while the wiring may proceed directly from ground level up a shunt-fed grounded tower. Lighting chokes, which provide a high impedance at the RF frequency while conducting ac current are often used for connecting the lighting circuits on towers across their base insulators. Another method employed uses a *ring* transformer that is constructed so that the primary and secondary have sufficient spacing between them to withstand typical base voltages while adding only a slight amount of capacitance across the base as far as the RF energy is concerned.

4.1.5. Lightning Protection. Because of the relatively tall and conductive nature of a medium-frequency antenna system, they are very susceptible to lightning strikes. Additionally, high transient voltages can be induced at their bases due to distant lightning strikes and they are subject to high static buildup under certain environmental conditions. Therefore it is necessary to include a system to protect the radiating elements and associated tuning components from being damaged by lightning strikes. A tower protection system usually consists of a pointed vertical rod or rods at its top, extending above the tower lighting beacon if one is employed, a conductive circuit such as an RF choke across the tower base to provide a low impedance path to ground (for series-excited towers) and a set of arc gaps directly across its feedpoint.

4.2. Electrical

Electrical parameters are chosen such that size and shape of an antenna pattern meet the radiation limits identified in the allocation studies. Antenna patterns fall into two broad categories: directional and nondirectional. Where a power level to provide satisfactory coverage can be had without any interference to other stations, a new facility may employ a nondirectional antenna consisting of only one radiating element. Otherwise, a multielement array (directional antenna) must be employed to meet the protection requirements. The parameters used to design a directional antenna pattern include the field ratios and phase relationships between elements, the number of elements, the height of each element, and the physical orientation of each element. These are the factors that determine the size and shape of the pattern such that the amount of energy radiated is controlled in any given direction.

4.2.1. Electrical Parameters. The following example (Table 1) shows how the electrical design parameters are typically specified for a four element array. Note that

Table 1. Electrical Design Parameters in a Four-Element Array

Tower No.	Field Ratio	Phase (degrees)	Spacing (degrees)	Bearing (degrees)	Height (degrees)
1	1.000	0.0	0.0	0.0	90.0
2	1.000	+90.0	90.0	0.0	90.0
3	1.000	+180.0	180.0	0.0	90.0
4	1.000	+270.0	270.0	0.0	90.0

tower 1 is used as reference with phase, spacing, and bearing set to zero.

The field ratio gives the relative magnitude of the radiated field from each element. The spacing and bearing of each element is given with respect to the reference element. The relative electrical phase relationships between the elements are also specified. The bearing of each element (physical orientation) is given in true degrees azimuth. The spacing and height of each element are given in electrical degrees. A plan of the preceding example is shown in Fig. 4, while the horizontal pattern is shown in Fig. 5.

4.2.2. Pattern Shape. The shape of a radiation pattern is controlled by varying the electrical parameters and the geometry of the individual radiating elements (usually towers). The most elementary directional antenna radiation patterns are developed using two-tower arrays of elements. More towers are added as necessary to meet more complicated radiation pattern requirements.

4.2.2.1. Theoretical Pattern. A theoretical radiation pattern can be calculated using the following formulation, which represents the inverse distance field at 1 km for a given azimuth and elevation angle

$$E(\phi, \theta)_{th} = \left| K \sum_{i=1}^n F_i f_i(\theta) / S_i \cos \theta \cos(\phi_i - \phi) + \phi_i \right| \quad (1)$$

where

K = multiplying constant that determines basic pattern size

Figure 4. Orientation of antenna array for a given set of field parameters. The current magnitude and phase is given relative to tower 1.

- n = number of elements in directional array
- i = i th element in array
- F_i = field ratio of i th element in array at $\theta = 0$
- θ = vertical elevation angle measured from horizontal plane
- $f_i(\theta)$ = vertical plane radiation characteristic of i th element in array
- S_i = electrical spacing of i th element from reference point
- ϕ_i = orientation (with respect to true north) of i th element in array
- ϕ = azimuth (with respect to true north)
- ϕ_i = electrical phase angle of current in i th element in array

Figure 6 shows the reference coordinate system.

4.2.3. K Factor. The multiplying constant K can be obtained by numerically integrating the effective field intensity as calculated at each vertical angle in half space. Calculation at 5° or 10° intervals is satisfactory for results that are acceptable from an engineering standpoint

$$K = \frac{E_s \sqrt{P}}{e_h} \quad (2)$$

where E_s is the horizontal radiation from a standard isotropic radiator in half-space at 1 km distance and 1 kW power level, P is the antenna input power, and e_h is the

Figure 5. Horizontal pattern of field parameters given in Fig. 4. Use of multiple towers produces pattern directivity.

Figure 6. Definition of reference coordinate system. $\theta = 0$ in the x - y plane.

root-mean-square effective field strength in half space

$$e_h = \left\{ \frac{\pi\Delta}{180} \left[\frac{e_a^2(0)}{2} + \sum_{m=1}^N e_a^2(m\Delta) \cos(m\Delta) \right] \right\}^{1/2} \quad (3)$$

where Δ is the interval between vertical elevation angles, $N = (90/\Delta) - 1$ (number of intervals minus one), and $e_a(m\Delta)$ is the RMS field strength at angle $m\Delta$.

$$e_a(m\Delta) = \left\{ \sum_{i=1}^n \sum_{j=1}^n F_i f_i(m\Delta) F_j f_j(m\Delta) \cos \psi_{ij} J_0[S_{ij} \cos(m\Delta)] \right\}^{1/2} \quad (4)$$

where

- $j = j$ th element
- $f_i(m\Delta)$ = vertical radiation characteristic of i th element
- F_j = field ratio of j th element
- $f_j(m\Delta)$ = vertical radiation characteristic of j th element
- ψ_{ij} = difference in phase angles of currents in i th and j th elements
- S_{ij} = spacing between i th and j th elements
- $J_0(x)$ = Bessel function of first kind and zero order

4.2.3.1. Vertical Plane Radiation Characteristic. The vertical plane radiation characteristics show the relative field being radiated at a given vertical angle (θ), with respect to the horizontal plane. The general form is

$$f(\theta) = \frac{E(\theta)}{E(0)} \quad (5)$$

where $E(\theta)$ is the radiation from an element at angle θ and $E(0)$ is the radiation from an element in the horizontal plane.

Assuming sinusoidal current distribution for a typical element that is not top-loaded or sectionalized, the vertical

radiation is

$$f(\theta) = \frac{\cos(G \sin \theta) - \cos G}{(1 - \cos G) \cos \theta} \quad (6)$$

where G is the electrical height of the element. For a top-loaded element, the vertical radiation is

$$f(\theta) = \frac{\cos B \cos(A \sin \theta) - \sin \theta \sin B \sin(A \sin \theta) - \cos(A + B)}{\cos \theta [\cos B - \cos(A + B)]} \quad (7)$$

where A is the physical height of the element in electrical degrees, B is the difference between the apparent electrical height and the actual physical height in electrical degrees, and G is the apparent electrical height, $A + B$.

For a sectionalized element the vertical radiation is

$$f(\theta) = \frac{\sin J[\cos B \cos(A \sin \theta) - \cos G] + \sin B[\cos D \cos(C \sin \theta) - \sin \theta \sin D \sin(C \sin \theta)] - \cos J \cos(A \sin \theta)}{\cos \theta [\sin J(\cos B - \cos G) + \sin B(\cos D - \cos J)]} \quad (8)$$

where A is the physical height of the lower section of the element in electrical degrees, B is the difference between the apparent electrical height of the lower section of the element and the physical height of the lower section of the element, C is the physical height of the entire element in electrical degrees, D is the difference between the apparent height of the element and the physical height of the entire element (D will be zero if the sectionalized tower is not top loaded), and

$$G = A + B$$

$$H = C + D$$

$$J = H - A$$

4.2.3.2. Standard Pattern. The FCC has also defined a standard pattern that is an envelope around the theoretical pattern and is intended to provide a tolerance within which the actual operating pattern can be maintained. All designs must be based on the standard pattern and are calculated as follows:

$$E_{std} = 1.05 \sqrt{E^2 + Qg^2(\theta)} \quad (9)$$

where

- $Q = 10\sqrt{P}$ or $0.025E_{rss}$ (whichever is greater)
- P = power (kW)
- $E_{rss} = E_1 \sqrt{\sum_i^n F_i^2}$
- E_1 = reference field
- F_i = field ratio of the i th element
- $g(\theta) = f_s(\theta)$, if the shortest element is shorter than $\lambda/2 = \sqrt{f_s^2(\theta) + 0.0625/1.030776}$, otherwise
- $f_s(\theta)$ = vertical radiation characteristic of the shortest element

4.2.3.3. Pattern Augmentation. The FCC rules include a provision to augment the standard pattern to take into account actual operating conditions when radiation is greater than the standard pattern in certain directions. Radiation is augmented over a specified azimuthal span and is calculated as follows:

$$E_{\text{aug}}(\theta) = \sqrt{E_{\text{std}}^2(\theta) + A \left[g(\theta) \cos\left(\frac{180D_a}{S}\right) \right]^2} \quad (10)$$

where

E_{std} = standard radiation pattern

$A = E_{\text{aug}}^2(\theta) - E_{\text{std}}^2(\theta)$ at central azimuth of augmentation

S = azimuthal span of augmentation centered on central azimuth of augmentation

D_a = absolute difference between azimuth of calculation and central azimuth of augmentation; note that D_a cannot exceed $S/2$ for augmentation within a particular span

4.2.4. Pattern Size. The size of an antenna pattern is the magnitude of the radiation and is determined by the term K as introduced in the previous section. The term K is evaluated by calculating the total power radiated from the antenna. The total power radiating from any antenna structure can be determined by integrating the power flowing outward from a closed surface completely enclosing the antenna. The Poynting vector expresses the rate of power flow in watts/meter² at a given point in space and is expressed as

$$P = \mathbf{E} \times \mathbf{H} \quad (11)$$

where P is the power flow (W/m²), \mathbf{E} is the electric field intensity vector (V/m), and \mathbf{H} is the magnetic field intensity vector (A/m).

In the far field, the two field vectors \mathbf{E} and \mathbf{H} are orthogonal and related in free space by the permeability and permittivity of air and is expressed as

$$H = \sqrt{\varepsilon_0/\mu_0} E \quad (12)$$

where $\mu_0 = 4\pi \times 10^{-7}$ permeability (H/m), $\varepsilon_0 = 1/\mu_0 c^2$ permittivity (f/m), and $c = 299.776 \times 10^6$ velocity of light (m/s).

The intrinsic impedance of free space is defined as

$$Z_c = \mathbf{E}/\mathbf{H} = \sqrt{\varepsilon_0/\mu_0} = 376.71 \Omega \quad (13)$$

The total amount of power flowing in free space from a given source is

$$p = E^2/Z_c \quad (14)$$

The total power radiated is calculated by integrating over a closed surface enclosing the source and can be

expressed as

$$P = \int p dS = (1/Z_c) \int E^2 dS \quad (15)$$

where P is the total power radiated (watts), Z_c is the intrinsic impedance (ohms), E is the total field at the closed surface (V/m), and dS is the incremental area on the closed surface (m²).

If a sphere is chosen as the closed surface then the integration becomes

$$dS = d \cos \theta d\theta d\phi \quad (16)$$

Substituting Eq. (16) into Eq. (15) yields the total power radiating from a given source:

$$P = (1/Z_c) \int_0^{2\pi} \int_{-\pi/2}^{+\pi/2} E^2 d^2 \cos \theta d\theta d\phi \quad (17)$$

4.2.4.1. Isotropic Antenna in Free Space. If the radiating source is isotropic, the power radiates equally in all directions and Eq. (17) becomes

$$P = (1/Z_c) E_0^2 d^2 \int_0^{2\pi} \int_{-\pi/2}^{+\pi/2} \cos \theta d\theta d\phi \quad (18)$$

$$P = 4\pi(1/Z_c) E_0^2 d^2 \quad (19)$$

Solving Eq. (19) for E_0 , the root-mean-square (RMS) field intensity of an isotropic radiator is

$$E_0 = \sqrt{\frac{PZ_c}{4\pi d^2}} \quad (20)$$

For 1 kW of power at a distance of 1 km, Eq. (20) yields

$$E_0 = 173.14 \text{ mV/m}$$

4.2.4.2. Isotropic Antenna in Half-Space. On placing the isotropic radiator in a half-space over a perfectly conducting plane, the limits of integration change and Eq. (18) becomes

$$P = (1/Z_c) E_0^2 d^2 \int_0^{2\pi} \int_0^{+\pi/2} \cos \theta d\theta d\phi \quad (21)$$

Solving Eq. (21) for E_0 , the maximum RMS field intensity of an isotropic radiator half-space is

$$E_0 = \sqrt{\frac{PZ_c}{2\pi d^2}} \quad (22)$$

For 1 kW of power at a distance of 1 km, Eq. (19) yields

$$E_0 = 244.86 \text{ mV/m}$$

4.2.4.3. Current Element in Free Space. If we replace the isotropic radiating source with an infinitesimally small

vertical current element, the field intensity term is

$$E = E_0 \cos \theta \tag{23}$$

and Eq. (17) becomes

$$P = (1/Z_c) \int_0^{2\pi} \int_{-\pi/2}^{+\pi/2} (E_0 d \cos \theta)^2 d\theta d\phi \tag{24}$$

Solving Eq. (24) for E_0 , the maximum RMS field intensity at $\theta = 0$ is

$$E_0 = \sqrt{\frac{3PZ_c}{8\pi d^2}} \tag{25}$$

For 1 kW of power at a distance of 1 km, Eq. (25) yields

$$E_0 = 212.05 \text{ mV/m}$$

4.2.4.4. Current Element in Half-Space. On placing the current element just above a perfectly conducting plane, the limits of integration change and Eq. (24) becomes

$$P = (1/Z_c) \int_0^{2\pi} \int_0^{+\pi/2} (E_0 d \cos \theta)^2 d\theta d\phi \tag{26}$$

Solving Eq. (26) for E_0 , the maximum RMS field intensity at $\theta = 0$ is

$$E_0 = \sqrt{\frac{3PZ_c}{4\pi d^2}} \tag{27}$$

For 1 kW of power at a distance of 1 km, Eq. (27) yields

$$E_0 = 299.89 \text{ mV/m}$$

4.2.4.5. Center-Fed Conductor in Free Space. Now replace the radiating source with a center-fed conductor in free space of length $2G$ having a sinusoidal current distribution, the field intensity term is

$$E = E_0 \left[\frac{\cos(G \sin \theta) - \cos G}{(1 - \cos G) \cos \theta} \right] \tag{28}$$

and Eq. (14) becomes

$$P = (1/Z_c) \int_0^{2\pi} \int_{-\pi/2}^{+\pi/2} \left\{ E_0 \left[\frac{\cos(G \sin \theta) - \cos G}{(1 - \cos G) \cos \theta} \right] \right\}^2 \times d^2 \cos \theta d\theta d\phi \tag{29}$$

Equation (29) has been solved by Ramo and Whinnery [15], the maximum RMS field intensity of a center-fed

conductor in free space

$$E_0 = \frac{\left[\frac{\cos(G \sin \theta) - \cos G}{\cos \theta} \right] \sqrt{\frac{PZ_c}{2\pi d^2}}}{\{\gamma + \ln(2G) - \text{Ci}(2G) + 0.5[\text{Si}(4G) - 2 \sin(2G)] \sin(2G)\} + 0.5[\gamma + \ln G - 2\text{Ci}(2G) + \text{Ci}(4G)] \cos(2G)}^{1/2} \tag{30}$$

where γ is Euler's constant = 0.57721566, Ci is the cosine integral function, Si is the sine integral function, and $2G$ is the length of the conductor.

For 1 kW of power at a distance of 1 km and defining the angle of radiation as well as the electrical length of the radiating element.

$$\theta = 0^\circ \quad \text{and} \quad G = 90^\circ$$

Equation (30) yields a maximum field intensity of

$$E_0 = 221.78 \text{ mV/m}$$

4.2.4.6. Vertical Conductor in Half-Space. The final step in this process is to determine the maximum field intensity of a vertical conductor in half-space (a monopole over perfecting conducting ground plane of infinite extent). Again, the limits of integration change such that Eq. (29) becomes

$$P = (1/Z_c) \int_0^{2\pi} \int_0^{+\pi/2} \left\{ E_0 \left[\frac{\cos(G \sin \theta) - \cos G}{(1 - \cos G) \cos \theta} \right] \right\}^2 \times d^2 \cos \theta d\theta d\phi \tag{31}$$

It follows from the previous analysis that solving for Eq. (31) yields

$$E_0 = \frac{\left(\frac{\cos(G \sin \theta) - \cos G}{\cos \theta} \right) \sqrt{\frac{PZ_c}{2\pi d^2}}}{\{\gamma + \ln(2G) - \text{Ci}(2G) + 0.5[\text{Si}(4G) - 2 \sin(2G)] \sin(2G)\} + 0.5[\gamma + \ln G - 2\text{Ci}(2G) + \text{Ci}(4G)] \cos(2G)}^{1/2} \tag{32}$$

For 1 kW of power at a distance of 1 km, and

$$\theta = 0^\circ \quad \text{and} \quad G = 90^\circ$$

Equation (32) yields a maximum field intensity of

$$E_0 = 313.66 \text{ mV/m}$$

4.2.5. Pattern Synthesis. The antenna designer is required to fit a pattern within a given set of radiation limits as defined by the allocation studies. As this defines the general shape and size of the pattern, a set of field parameters must be chosen with regard to the number, height, and physical orientation of the towers. Useful

techniques have been developed to synthesize the design of antenna patterns. The general expression given in Eq. (1) for calculating the pattern shape is simplified for a two-element array, which is used as the basic building block for pattern synthesis.

Using element 1 as the reference, the field ratio F_2 can be defined as

$$F_2 = E_1/E_2 \quad (33)$$

The difference in phase angle, α_2 , has two components:

$$\alpha_2 = S \cos \phi \cos \theta + \Psi_2 \quad (34)$$

The first term of Eq. (34) relates to the space phase difference, and the second term relates to the time phase difference between E_1 and E_2 .

If the towers are of equal height, it can be shown that the total field is

$$E = E_1 f(\theta) \sqrt{2F_2} \left[\frac{1 + F_2^2}{2F_2} + \cos(S \cos \phi \cos \theta + \Psi_2) \right]^{1/2} \quad (35)$$

where

$$f(\theta) = f_1(\theta) = f_2(\theta)$$

If $F_2 = 1$ and $f(0) = 1$, Eq. (35) further reduces to

$$E = 2E_1 \cos\left(\frac{S}{2} \cos \phi + \frac{\Psi_2}{2}\right) \quad (36)$$

It follows from Eq. (36) that nulls occur in the pattern when

$$S \cos \phi + \Psi_2 = \pm 180^\circ \quad (37)$$

Any number of horizontal plane patterns from Eq. (36) can be generated by varying spacing and phase relationships of one element to the other. These patterns are then used as basic building blocks when computing patterns for multielement arrays. The most common technique for computing these patterns is known as *pattern pair multiplication*.

4.2.5.1. Pattern Pair Multiplication. Multielement arrays can be designed by multiplying the pattern of individual elements with the pattern of an array of vertical radiators having the same locations, relative amplitudes, and phases as the individual elements. As an example, take the two array patterns as shown in Figs. 7 and 8. Using Eq. (36), the array patterns can be expressed as follows

$$E_a = 2E_{1a} \cos\left(\frac{\pi}{4} \cos \phi + \frac{\pi}{4}\right) \quad (38)$$

Figure 7. Horizontal pattern of a two-element array ($S = 90^\circ$ and $\Psi_2 = 90^\circ$). Pattern is broad with no radiation at 0° .

when $S = \pi/2$ and $\Psi_2 = \pi/2$

$$E_b = 2E_{1b} \cos\left(\frac{\pi}{2} \cos \phi + \frac{\pi}{2}\right) \quad (39)$$

when $S = \pi$ and $\Psi_2 = \pi$.

The resulting equation for the combined pattern is simply the product of individual arrays

$$E_a = 2E_{1a} \cos\left(\frac{\pi}{4} \cos \phi + \frac{\pi}{4}\right) 2E_{1b} \cos\left(\frac{\pi}{2} \cos \phi + \frac{\pi}{2}\right) \quad (40)$$

and Fig. 5 shows the combined pattern.

4.2.5.2. Array Simplification. The four-tower array as illustrated in the previous section can be simplified if equal spacing is maintained between the towers, which is frequently the case for medium-frequency inline arrays used in broadcasting. Using Eqs. (38) and (39) the following field relationships can be defined as

$$F_a = 1.0/\underline{+90}$$

$$F_b = 1.0/\underline{+180}$$

The four-tower array can be reduced to a three-tower array using the following relations:

$$\text{Tower 3} = F_a \times F_b = 1.00/\underline{+270}$$

$$\text{Tower 2} = F_a \times F_b = 1.41/\underline{+135}$$

$$\text{Tower 1} = \text{reference} = 1.00/\underline{+0}$$

The horizontal pattern for this set of parameters is shown in Fig. 9. Comparing Fig. 5 with Fig. 9 reveals little

Figure 8. Horizontal pattern of a two-element array ($S = 180^\circ$ and $\Psi_2 = 180^\circ$). Pattern is symmetric with equal radiation at 0° and 180° .

difference in pattern shape with the economical advantage of saving the cost of one tower.

4.2.6. Antenna Impedance. The base impedance defines the relationship of the voltage to the current in both magnitude and phase at the base of each radiating element. This is a complex quantity and is typically given in the following form:

$$Z_b = R_b + jX_b \tag{41}$$

where R_b is the base resistance (ohms) and X_b is the base reactance (Ω).

The base resistance R_b has two components

$$R_b = R_r + R_1 \tag{42}$$

Figure 9. Horizontal pattern of a three-element array. Combined pattern produces greater directivity with no radiation at 0° .

where R_r is the radiation resistance (Ω) and R_1 is the loss resistance (Ω).

The radiation resistance determines the total power radiated from the antenna while the loss resistance takes into account all dissipative losses associated with the antenna and the ground system. It is the ratio of these two quantities that determines the efficiency of an antenna system. As the height of the radiating element decreases below 90 electrical degrees, the loss resistance becomes an appreciable percentage of the radiation resistance, thus decreasing the overall efficiency of the antenna system.

It is important to take into account all series and shunt reactance found between the base of the antenna and the point at which the matching networks are connected to the antenna. Knowing an accurate impedance at this point of the antenna is very important when designing the feeder system for a multielement antenna system.

It follows then that the power radiated from a given antenna element is given as

$$P_r = I_b^2 R_r \tag{43}$$

where I_b is the base current (A).

4.2.6.1. Self-Impedance Using Traditional Methods. The traditional method of determining the self-impedance (the impedance of a single radiating element apart from the influence of other radiating elements in close proximity) of a vertical radiating element uses the theory of nonuniform transmission lines as introduced by Schelkunoff [4]. This method assumes a single radiator of uniform cross section over an infinite perfectly conducting ground plane. The first order approximation is given as

$$Z_b = Z_0 \left[\frac{A \sin G + j(B - C) \sin G - j(2Z_0 - D) \cos G}{(2Z_0 + D) \sin G + (B + C) \cos G - j(A \cos G)} \right] \tag{44}$$

where

- $Z_b = R_b + jX_b$ base self-impedance (Ω)
- $Z_0 = 60[\ln(2G/a) - 1]$ average characteristic impedance (Ω)
- $G =$ antenna height (degrees)
- $a =$ antenna height (degrees)
- $A = 60[\gamma + \ln(2G) - \text{Ci}(2G)] + 30[\gamma + \ln G - 2\text{Ci}(2G) + \text{Ci}(4G)] \cos(2G) + 30[\text{Si}(4G) - 2\text{Si}(2G)] \sin(2G)$
- $B = 60\text{Si}(2G) + 30[\text{Ci}(4G) - \ln G - \gamma] \sin(2G) - 30\text{Si}(4G) \cos(2G)$
- $C = 60[\text{Si}(2G) - \sin(2G)]$
- $D = 60[\ln(2G) - \text{Ci}(2G) + \gamma - 1 + \cos(2G)]$
- $\gamma = 0.5772$ Euler's constant
- $\text{Ci} =$ cosine integral function
- $\text{Si} =$ sine integral function

4.2.6.2. Impedance of the Elements in Directional Array Using Traditional Methods. The impedance for an individual element of a directional array is not only dependent on its own current but also the current induced in it due to

mutual coupling from other elements in the array. The relationship between the voltages and currents of the individual elements are given in terms of mutual impedance. The matrix of equations for a three-element array will be

$$V_1 = I_1 Z_{11} + I_2 Z_{21} + I_3 Z_{31}$$

$$V_2 = I_1 Z_{12} + I_2 Z_{22} + I_3 Z_{32}$$

$$V_3 = I_1 Z_{13} + I_2 Z_{23} + I_3 Z_{33}$$

where V_1 and I_1 are the base voltage and current for element 1, Z_{11} is the self-impedance of element 1, and Z_{21} is the mutual impedance between element 1 and element 2.

The values for mutual impedance as a function of element separation and height have been solved by Brown [5] and Cox [6]. The equations are

$$Z_{21} = R_{21} + jX_{21} \quad (45)$$

where

$$\begin{aligned} R_{21} = & \frac{15}{\sin \beta l_1 \sin \beta l_2} \{ \cos \beta \Delta [\text{Ci}(u_1) - \text{Ci}(u_0) + \text{Ci}(v_1) - \text{Ci}(v_0)] \\ & + 2\text{Ci}(y_0) - \text{Ci}(y_1) - \text{Ci}(s_1)] \\ & + \sin \beta \Delta [\text{Si}(u_1) - \text{Si}(u_0) + \text{Si}(v_0) - \text{Si}(v_1) \\ & - \text{Si}(y_1) + \text{Si}(s_1)] \\ & + \cos \beta L [\text{Ci}(w_1) - \text{Ci}(v_0) + \text{Ci}(x_1) - \text{Ci}(u_0) + 2\text{Ci}(y_0) \\ & - \text{Ci}(y_1) - \text{Ci}(s_1)] \\ & + \sin \beta L [\text{Si}(w_1) - \text{Si}(v_0) + \text{Si}(u_0) - \text{Si}(x_1) \\ & - \text{Si}(y_1) + \text{Si}(s_1)] \} \end{aligned} \quad (46)$$

$$\begin{aligned} X_{21} = & \frac{15}{\sin \beta l_1 \sin \beta l_2} \{ \cos \beta \Delta [\text{Si}(u_0) - \text{Si}(u_1) + \text{Si}(v_0) - \text{Si}(v_1) \\ & + \text{Si}(y_1) - 2\text{Si}(y_0) + \text{Si}(s_1)] \\ & + \sin \beta \Delta [\text{Ci}(u_1) - \text{Ci}(u_0) + \text{Ci}(v_0) - \text{Ci}(v_1) \\ & - \text{Ci}(y_1) + \text{Ci}(s_1)] \\ & + \cos \beta L [\text{Si}(v_0) - \text{Si}(x_1) + \text{Si}(u_0) - \text{Si}(x_1) \\ & - 2\text{Si}(y_0) + \text{Si}(y_1) + \text{Si}(s_1)] \\ & + \sin \beta L [\text{Ci}(w_1) - \text{Ci}(v_0) + \text{Ci}(u_0) - \text{Ci}(x_1) \\ & - \text{Ci}(y_1) + \text{Ci}(s_1)] \} \end{aligned} \quad (47)$$

where l_1 and l_2 are the heights of elements 1 and 2, respectively, d is the distance between elements, and

$$L = l_1 + l_2$$

$$\Delta = l_2 - l_1$$

$$w_0 = \beta \left[\sqrt{d^2 + l_1^2} + l_1 \right] = v_0$$

$$w_1 = \beta \left[\sqrt{d^2 + L^2} + L \right]$$

$$v_1 = \beta \left[\sqrt{d^2 + \Delta^2} - \Delta \right]$$

$$x_0 = \beta \left[\sqrt{d^2 + l_1^2} - l_1 \right] = u_0$$

$$x_1 = \beta \left[\sqrt{d^2 + L^2} - L \right]$$

$$u_1 = \beta \left[\sqrt{d^2 + \Delta^2} + \Delta \right]$$

$$y_0 = \beta d = s_0$$

$$y_1 = \beta \left[\sqrt{d^2 + l_2^2} + l_2 \right]$$

$$s_1 = \beta \left[\sqrt{d^2 + l_2^2} - l_2 \right]$$

Once the mutual impedances are known, the preceding matrix of equations is solved for the ratio of the voltage to the current in each element that defines the impedance of that element.

Operating impedances may be calculated with fair accuracy using the traditional method of calculating self- and mutual impedances as presented herein for tower heights up to approximately 120 electrical degrees. For taller towers, it has been standard practice to design matching units very conservatively and with components to provide a wide adjustment range. As presented in the next section, modern moment method analysis gives excellent results for all tower heights with properly chosen assumptions.

4.2.6.3. Impedance Determination Using Moment Methods. Moment method antenna modeling has proved to be a very useful tool in overcoming the limitations of traditional antenna theory. The moment method technique divides each radiator into a large number of individual segments for which corresponding current values can be calculated. In order for this technique to be useful in the design of a medium-frequency antenna system, it is necessary to relate the fields as produced by the antennas system to the drive point conditions of the antenna (voltage, current, and impedance).

A convenient method for specifying a medium-frequency directional antenna system uses field parameters that easily allow the designer to determine the radiation characteristics of any given antenna configuration. The field parameters for each tower in a directional antenna array are the ratios of the magnitudes and phases, relative to an arbitrary reference, of the electric field component of the radiation that results from integrating the current

over the length of that particular tower or element of the directional antenna. Because field parameters are the standard method of specifying directional antennas, most notably with the FCC, it is necessary to relate these parameters to the driving point conditions (base voltage and current) in order to utilize modern moment method techniques to design these antennas. Once the driving point conditions are determined, the antenna feed system can be designed to provide the necessary power division and phase relationship between the elements in the array.

The means of exciting the antenna model with numerical electromagnetics code (NEC) [18] and MININEC [19] involves voltage sources. A problem involving a monopole over perfectly conducting ground plane excited with $1 + j0$ volts at the base would yield the current distribution on the monopole and the fields, both electric and magnetic, produced by the monopole.

4.2.7. Field Parameters versus Voltage Drives [21]. The field parameters are calculated by ratioing the electric fields as produced by each element in the directional array to an arbitrary reference. The electric field produced by a finite current element over a perfectly conducting ground plane is proportional to the current in the wire and can be expressed as follows

$$\vec{E} \propto \int_0^l \vec{I} dz \tag{48}$$

where \vec{I} is the current distribution of the current element, dz is the incremental distance along the current element, and l is the length of the current element.

A close approximation for the solution of Eq. (48) is found using moment method techniques by summing the current moments of each element. The mathematical representation is

$$\vec{E} \propto \sum_{i=0}^n \vec{I}_i l_i \tag{49}$$

where \vec{I}_i is the current in the i th segment and l_i is the length of the i th segment.

Four terminal network theory can now be used to relate the field parameters to the driving voltages for each tower in a directional array. Using a two-tower array as an example, the following set of equations is formulated

$$\begin{aligned} \vec{E}_1 &= \vec{T}_{11}\vec{V}_1 + \vec{T}_{12}\vec{V}_2 \\ \vec{E}_2 &= \vec{T}_{21}\vec{V}_1 + \vec{T}_{22}\vec{V}_2 \end{aligned}$$

where \vec{E}_1 is the field radiated from tower 1, \vec{V}_1 is the voltage drive of tower 1, \vec{T}_{11} is the current moment summation of tower 1, and \vec{T}_{12} is the current moment summation of tower 2 (as induced by the current in tower 1).

As can be seen from the above equations, to determine the T elements of the matrix, it is necessary to calculate the current summations by individually exciting each tower in the array. For example, to determine the elements, T_{11} and T_{21} it is necessary to excite tower 1 with voltage V_1 while grounding tower 2. The current moment summations are calculated for each tower. The same procedure is

used to determine the elements, T_{21} and T_{22} , by exciting tower 2 with voltage V_2 while grounding tower 1. Using matrix algebra, the drive point voltages can be determined from the field parameters by inverting the T matrix and multiplying by the field parameters

$$[\vec{V}] = [\vec{F}][\vec{T}]^{-1} \tag{50}$$

where $[\vec{F}]$ is the set of field parameters as determined from the calculated electric fields and $[\vec{T}]^{-1}$ is the inverted current summation matrix.

The drive voltages for a given set of field parameters can now be determined. With these drive voltages the drive point currents and impedances are calculated, which determines the power division and phase relationships of the directional array elements.

It is possible to adjust an antenna system using moment method modeling with little, if any, experimentation, if the conditions at the site approach the ideal in terms of flat terrain and an absence of nearby reradiating structures. Even where conditions are not ideal, moment method modeling is a very useful tool in relating current drives to field parameters and reducing the amount of trial-and-error work necessary to achieve the required radiation pattern.

5. DIRECTIONAL ANTENNA FEEDER SYSTEMS

Once the base impedances of the individual elements in the antenna system have been calculated, it is possible to design the feeder system to provide the required current amplitude and phase for each tower in the array. Figure 10 shows a block diagram of the basic components that comprise a directional antenna feeder system.

Computer modeling techniques have been developed to analyze the feeder systems making it possible to obtain exact theoretical solutions for bandwidth analysis. The advance of computational capabilities has allowed the

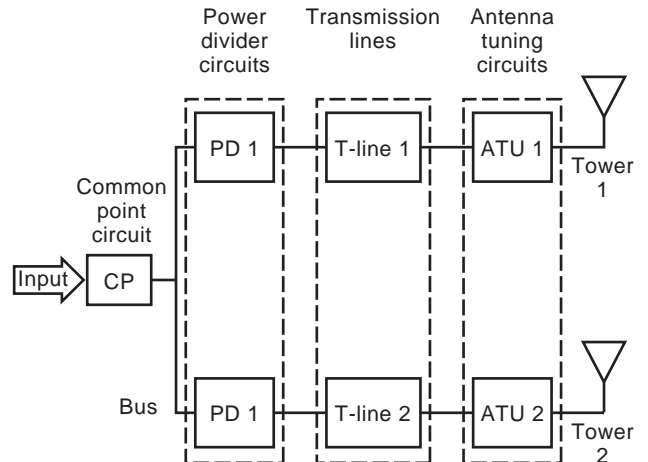

Figure 10. Basic components of a two-tower directional antenna feeder system. Additional towers can be added to the bus using similar networks.

development of new approaches for the design of power dividing, phasing, and matching networks. The two areas of concern when designing the feeder system are the impedance and the pattern bandwidth which directly impact the quality of the audio within the entire coverage area.

5.1. Nodal Analysis

The technique of nodal analysis is well known in the field of electrical engineering. This technique works very well when predicting the bandwidth performance of directional antenna phasing and coupling equipment, since admittance values can be given for each component and the tower bases can be modeled as nodes with self- and mutual admittance values determined using moment method analysis. An exact solution for carrier and side-band currents and impedances can be found for every branch in a system. This solves the problem with simpler techniques that assume a set of base current parameters to determine operating impedances, which, when presented to the system of networks, yield a different set of base current parameters and render the starting assumptions invalid.

5.2. Power Dividing Circuits

Prior to the 1970s, two traditional circuits were used for the purpose of dividing the power between the towers of a directional antenna system in virtually all cases. The circuits are shown on Fig. 11. The first circuit is a *series* or *tank* type of power divider which goes back to the earliest days of radio and the *parallel* or *Ohm's law* design, which became popular during the 1950s.

Both circuits of Fig. 11 function primarily as power dividers, with separate networks necessary for phase adjustments. Both can introduce high system Q, thus possibly restricting bandwidth. The series circuit circulates all of the power fed into the system through a parallel tuned antiresonant circuit, and the parallel circuit can result in relatively high circulating current due to the low resistance presented when several tower feeds are tied together across a common bus. The high Q of such circuits could

Figure 11. Traditional power divider circuits principally used in early medium-wave antenna designs.

Figure 12. General power divider principle. The bus voltage is determined by the parallel combination of admittances produced by each tower and the input power.

serve to counteract bandwidth problems inherent in an array design. This would require careful system modeling to be effective and was not practical when such systems were built.

The general principle for all power divider circuits is illustrated in Fig. 12. If the common feed for all power dividing circuits is considered to be a voltage bus, the power delivered to each tower is determined by the conductance value presented to the bus by that tower's power dividing circuit. The voltage for the desired bus impedance can be determined and then the circuits necessary to present the required conductances, when terminated in the transmission lines, can be designed.

It is usually desirable to design for a bus impedance of 50 Ω when 50-Ω transmission lines are used, unless another factor suggests otherwise. Such an alternative situation would arise where one tower in a system needs much higher power than any of the others and could be fed directly off the bus without adjustment capability and satisfy the requirements for optimum overall phase shift. For example, a 25-Ω bus would feed half of its power directly to a 50-Ω transmission line.

5.2.1. Modern Power Divider Circuits. Any network that can adjust the conductance presented across the bus for a tower feed can be used as a power divider circuit. It is not necessary to have the same type of power divider network for every tower in an array. From the standpoint of adjustability and bandwidth, it is often desirable to have different types of intermixed networks in a given system.

Figures 13a–13f show several power divider circuits. Each one shown is capable of serving for control of both power and phase, making separate phase adjustment networks unnecessary. If properly applied, the circuits of Fig. 13 can generally lead to lower power dividing and phasing network Q than attainable with either power divider from Fig. 11. Most of the circuits of Fig. 13 do not offer separate controls for both power and phase. This is not a great disadvantage, because the circuits that do only offer totally independent control when connected to load impedances that remain constant. This is not the case for any power divider that is feeding elements in an array

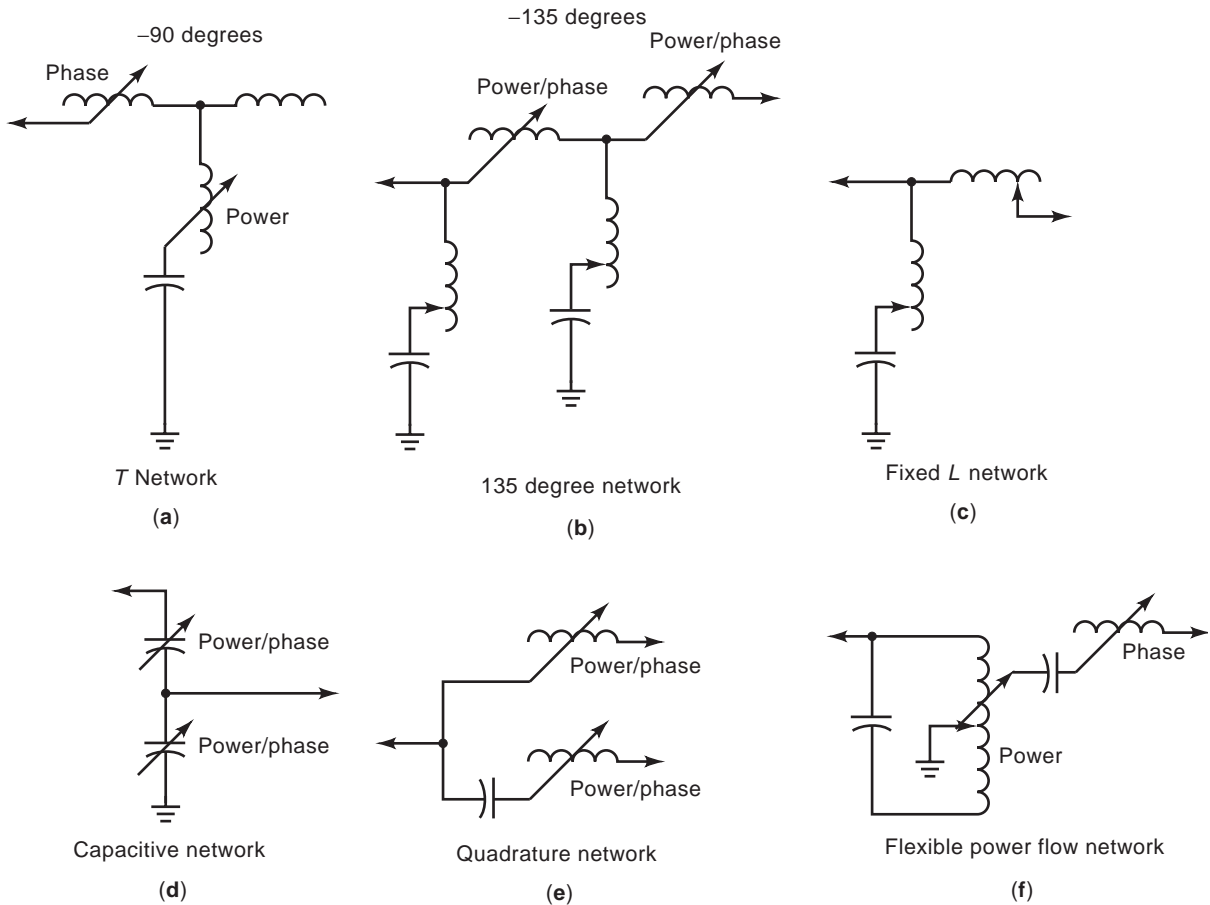

Figure 13. Modern power divider circuits. The selection of a particular circuit is dependent on overall system and load characteristics.

because effects of mutual coupling between the elements make each tower’s impedance change as the current flowing in the other towers change.

The low *Q* circuits of Fig. 13 are popular modern alternatives to the traditional power dividers of Fig. 11. For some directional arrays with highly volatile power division, however, the traditional power dividers, with their higher *Q*, may be desirable if easy adjustability is important. Proper system modeling could be used to minimize the high-*Q* effects or actually use them to improve overall system bandwidth.

Figures 14–17 show how the basic power divider circuits of Fig. 13 can be applied in phasing system design. Figure 14 offers good control and a 50-Ω bus, but can be simplified to Fig. 15 if the proper value is chosen for the power divider coil of the lowest power tower so that the capacitor necessary to antiresonate it is of the same reactance magnitude as the top tower’s fixed *L* network shunt coil. This would be possible in a case where the lowest power tower would not change power flow direction. In the process, the power divider *Q* is lowered by the elimination of a parallel antiresonant circuit across the bus.

Figure 16 shows how, if the phase shift requirements allow it, the high-power tower feed can be connected directly to the bus, eliminating the three components of the

L network. The circuit of Fig. 17 is identical to the circuit of Fig. 16, except that the bus has been divided with the series *L*–*C* slope network. In the case shown, the high-power towers need to have the phase shift of their feed tailored to track the lower-power tower in order to preserve pattern bandwidth. This is the purpose of the *L*–*C* slope network as shown.

As can be seen from the circuit of Fig. 17, high-*Q* circuits can be inserted at appropriate locations in phasing equipment to effectuate broadbanding. Such processes require modeling of total system performance, such as with nodal analysis, in order to be effective. In many cases, it may be necessary to improve pattern bandwidth with high-*Q* circuits added after the common bus, with an additional network to improve impedance bandwidth included in the common point matching circuit.

5.3. Phasing and Matching Circuits

The conventional *T* network is the basic building block for antenna matching and phase shifting functions. Figure 18 shows the circuit for this network type. If the series input and output branches exhibit overall inductive reactance with the shunt branch having overall capacitive reactance,

Figure 14. Mixed use of power divider circuits. Power division and system phase shifts determine the best combination of power divider circuits.

the network will produce negative phase shift and is said to be lagging. Conversely, if the series branches are capacitive and the shunt branch is inductive, the network will produce a positive phase shift and is said to be leading. The values chosen for each component determine the impedance transformation, the phase shift as well as the bandwidth performance.

Referring to Fig. 18, the following equations can be used to determine the impedance transformation and

Figure 15. Simplification by elimination of parallel components as compared to Fig. 14.

Figure 16. Direct feed to highest power tower. Another simplification which reduces the number of components.

phase shift of a *T* network

$$X_1 = \frac{\sqrt{R_i R_o}}{\sin \beta} - \frac{R_i}{\tan \beta} \tag{51}$$

$$X_2 = \frac{\sqrt{R_i R_o}}{\sin \beta} - \frac{R_o}{\tan \beta} \tag{52}$$

$$X_3 = -\frac{\sqrt{R_i R_o}}{\sin \beta} \tag{53}$$

where R_i is the input resistance (ohms), R_o is the output resistance (Ω), and β is the phase angle.

Although conventional thinking would suggest that optimum bandwidth performance results with the phase

Figure 17. Split bus with pattern bandwidth improvement. Improved pattern bandwidth is most noticeable in the minima regions of radiation.

Figure 18. *T* network: basic circuit for impedance matching and phase shift. Circuit shown is for a phase lagging network.

shift of a *T* network adjusted to 90°, the family of curves on Fig. 19 indicate otherwise. There is an optimum *T* network phase shift for each transformation ratio and these values are generally lower than 90°.

Figure 19 also shows that the VSWR bandwidth worsens as the transformation ratio increases. The negative impact of transforming an impedance to one that is very much higher (or lower) can be lessened by cascading networks together. Figure 20 shows how two networks can be cascaded to achieve a gradual stepup of resistance that requires that only one additional shunt branch be added alongside the normal *T* network configuration. Figure 21 shows the bandwidth performance of such a circuit designed with two cascaded networks. For the cost of an additional network branch, there is an approximate three to one improvement in sideband VSWR.

6. PROCUREMENT AND INSTALLATION

Once authorization has been received to construct a new or modify an existing medium-wave antenna system, it is necessary to prepare a request for quotation to procure the necessary equipment. The document necessary to receive a competitive quotation includes a detailed description of the required equipment usually in the form of a specification as well as a detailed statement of work that outlines all additional labor required outside of the manufacturing of the equipment. This usually includes any labor associ-

Figure 19. *T* network sideband VSWR versus phase shift for various transformation ratios. Smaller transformation ratios produce better sideband VSWR.

Figure 20. Cascaded *T* and *L* networks for optimizing phase shift and transformation ratio. Such a configuration results in better impedance bandwidth with fewer components.

ated with installation and adjustments in the field. It is also important to specify the terms of a warranty if it is not already expressed in an off-the-shelf product. A line item must also be included for shipping.

It is recommended to request quotations from a number of reputable manufacturers to encourage a competitive bid. The evaluation of the bids should not only consider the price but also the quality of the product being proposed as well as how long it will take to deliver the product. It may be necessary to visit the prospective proposers’ plants to ascertain their interest and commitment in providing you a quality product in a timely manner. Recommendations from others in the field of broadcasting are also invaluable when making a decision between quotations.

When overseeing the installation of a medium-wave antenna system there are a number of areas to which one should pay special attention. For each tower, the connections of the ground system must be made and checked very carefully, since they will ultimately be below ground level and not visible. For directional antennas, the spacings and orientations of the elements must be carefully determined with reference to true north with a careful survey using celestial reference data.

The governing authorities of the country in which the new or modified medium-frequency antenna system is being constructed will usually require the system to be tested to confirm compliance with the radiation characteristics as outlined in the construction permit. Once the system has been adjusted to theoretical parameters,

Figure 21. VSWR introduced by network for transformation ratio of 20:1. Cascaded networks produce significant improvement with sideband VSWR for high transformation ratios.

a number of measurements are necessary to confirm compliance.

7. ANTENNA ADJUSTMENT

After the equipment has been installed and properly connected, the branches of the individual networks must be set to their design values. This involves using an impedance bridge and a frequency generator or a network analyzer to set the required reactance value at the operating frequency. Care must be taken when making these measurements to take into account all stray reactances that are inherent in an antenna system with long conductors between components (series inductive reactance) with close proximity to a grounded surface (shunt capacitive reactance). High-power systems, where physical dimensions are large, have very large stray impedances.

The electrical lengths of the sampling transmission lines must be measured to determine the values to which the antenna monitor will be adjusted. This is a critical step in the adjustment of the antenna system as errors interjected at this juncture will make it very difficult if not impossible to bring the antenna system into adjustment. A procedure has been developed for making such a measurement using an impedance bridge and a frequency generator by measuring the adjacent resonant frequencies of the line when it is in a short-circuited condition. The equation for calculating the length based on the two measurements is

$$\Psi_L = \frac{180}{(f_H/f_L) - 1} \quad (54)$$

where Ψ_L is the line length at lower frequency (degrees), f_H is the higher frequency (kHz), and f_L is the lower frequency (kHz).

Once the network branches have been set to their theoretical levels, low power can be applied to the system and the common point impedance adjusted to match the system to the transmitter. The phasor is then adjusted to bring the antenna monitor to the theoretical values as previously calculated. During this process it is oftentimes found that the adjustment of the ratio or phase to one tower will have an affect on the ratios and phases of other towers. The amount of interdependence between towers is determined by how closely the towers are coupled as well the component layout design within the phasor and ATU cabinets. While making these adjustments, the common point impedance must continually be readjusted to insure a proper load to the transmitter.

When the antenna monitor has been adjusted to theoretical parameters, a field strength meter is used to measure the radiated field levels at critical radials. The critical radials are usually located at the places where the pattern shape has inflections, that is, the pattern minima and minor lobe maxima. In the United States, the FCC requires that a number of measurements be made on each radial, ratioed to nondirectional reference measurements, averaged, and then multiplied by the measured unattenuated nondirectional measured field to determine the predicted

level of radiation in a given direction. The inherent accuracy of a field intensity meter is largely dependent on the local environment in which a measurement is taken. Powerlines and other reradiating structures necessitate that a number of measurements be taken to achieve reasonable results. The FCC requires at least twenty measurements be made on each radial between the distances of 2 and 20 m. A number of close-in measurements, less than 2 miles, are also required for the nondirectional analysis.

At this point, there may be a one or more radials at which the measured radiation exceeds the maximum level specified in the construction permit. It may be necessary to adjust the antenna parameters away from their initial values to bring the pattern into compliance. A common approach used to bring a radiation pattern into compliance involves placing a number of field intensity monitors at locations on the critical radials and adjusting parameters until the pattern is in. While one person adjusts the parameters, the monitors at locations on the critical radials report variations in signal strength after each adjustment. Once the pattern appears to come into adjustment based on individual measurements at each point, the entire radial must be remeasured to confirm the adjustment. If the pattern is still out of adjustment, the procedure must be repeated. This method requires that the points monitored all represent their associated radials, a condition that often is not obtained, particularly with directional antenna patterns with deep radiation nulls. This method is generally a useful technique for patterns with minima that are not extremely deep, and where conductivity near the antenna is uniform and few reradiation sources affect the measurements.

7.1. Complex-Plane Mapping

Complex-plane mapping is an alternate approach that has been developed to adjust an antenna pattern. This technique is based on the knowledge that the field found at any point as produced by the antenna system is a vector quantity, having both magnitude and phase. In theory, the resultant vector field at any point in the far field can be calculated by adding the individual vectors as contributed from each radiating element in the array. It is theoretically straightforward to determine the change in the resultant vector at a point of interest when one or more of the ratios or phases of the radiating element is varied. In the real world, however, it is often impossible to accurately correlate the field strength measurements taken with a field intensity meter that measures only the magnitude of a signal with a theoretically determined resultant due to reradiation and variations in the ground characteristics.

The problem of how to determine the magnitude and phase of the resultant vector for each radial of interest is solved by making a series of trial measurements. First, a reference measurement is made by taking a sample of field strength readings at each radial of interest. These measurements are ratioed with the nondirectional measurements and for each critical measurement radial. Next, only one of the parameters of antenna is changed. Usually, the tower having the least interaction with the others in the array is chosen so that the adjustment is simplified.

The magnitude is changed by an appropriate amount with all other parameters remaining the same and the field strength measurements are taken at the same points. Again the readings are ratioed with the nondirectional measurements and averaged. Finally, the magnitude of the tower that has changed is returned to the original value and the phase of that tower is changed by an appropriate amount. The measurements are retaken and analyzed as before. The results of all three trials (A, B, and C) are plotted on polar paper as circles with radii corresponding to the calculated averages for each measurement radial. The theoretical vectors for each radiating element are also plotted. Knowing that the field of the radiating element was changed in both magnitude (trial B) and phase (trial C), the delta (difference) vectors can be plotted. The magnitudes and phases of the delta vector gives the necessary information to determine the positions of the resultant vectors for the various radials for the beginning (trial A) operating parameters.

Once the actual resultant vectors have been determined for each radial of interest, one is able to predict the impact of parameter variations to the individual radials themselves. In extremely difficult cases of signal scatter along measurement radials corresponding to deep radiation pattern nulls, it may be necessary to apply the complex plane mapping technique to individual measurement points rather than to entire radials in order to avoid analysis ambiguity. The pattern is brought into adjustment by making changes that will simultaneously change the field strengths at each radial in accordance with the previously calculated limits. Once the required adjustment has been determined and made, measurements are taken at all radials to access compliance. If compliance is confirmed, a full set of measurements is made to be filed with the proof of performance to be submitted to the proper governing authorities.

8. DETUNING TO CONTROL RERADIATION

Sometimes there are objects, usually other radio antenna towers or high-tension power lines, capable of scattering sufficient radiofrequency (RF) energy to distort a medium-wave radio station's antenna radiation pattern located near its transmitter site. Most such objects can be made transparent to the medium-wave RF energy if properly treated.

A tower located near a transmitter site may be detuned by installing the necessary apparatus to control its current distribution to minimize reradiation. For a short tower (shorter than a quarter-wavelength), it is often sufficient to insulate its base or produce an impedance pole at its base with an arrangement of skirt wires and a detuning network.

For a taller tower or any critically located shorter tower, a null in tower current at a height somewhat above its base may be necessary for proper detuning. The correct treatment to produce the detuned condition and the corresponding current distribution for verification are best determined using the moment method directional antenna

analysis procedures (with the field of the tower to be detuned set to zero) described herein.

Control over the tower current may be achieved by either placing a reactance across its base or tuning the open end of a wire skirt mounted on it. In general, it will be necessary to place the null in tower current at approximately one-third of its height for towers up to approximately a half-wavelength tall. For structures taller than a half-wavelength, it may be necessary to produce more than one current distribution null. Two or more wire skirts may be required for this purpose.

Sampling loops may be mounted at the appropriate height or heights on a tower to verify the placement of current nulls corresponding to the detuned condition. They may be connected to detectors near the tower's base to facilitate observation during adjustment efforts and to verify continued detuning. For such sampling loops to be useful, they must not be mounted within a wire skirt span.

It is often sufficient to eliminate objectionable reradiation from a high tension power line by insulating the ground conductor running along the tops of adjacent support towers, thus breaking up the loops of current flowing in them. To maintain the integrity of the power line's protection system, insulators with arc gaps to conduct transient energy from the ground conductor to the support towers may be employed. When ground wire insulation is not sufficient to reduce high-tension powerline reradiation to an acceptable level, individual towers may be detuned utilizing wire skirts and detuning networks to control their current distribution.

9. MULTIPLE-FREQUENCY DIPLEXING

It is possible for a medium-wave antenna to radiate more than one frequency. Filters are employed to keep RF energy at each frequency out of a transmitter at the other frequency where a spurious signal might be generated.

For a nondirectional antenna, a series network providing an impedance zero at the desired frequency and an impedance pole at the undesired frequency and a shunt network providing an impedance pole at the desired frequency and an impedance zero at the undesired frequency to ground are normally placed at the feedpoint. For diplexed directional antennas, it is typical to have series filters at the tower bases but shunt filters only across the system input terminals (the common point).

ANTENNAS FOR MOBILE COMMUNICATIONS

KYOHEI FUJIMOTO
University of Tsukuba
Fujisawa, Japan

1. GENERAL

Antennas used for mobile communications are not necessarily specialized types of antenna; ordinary antenna types can be used. However, there are several distinctions in performance between mobile and fixed communications with respect to design methodology for antennas in mobile communications:

1. Parameters for antenna design are variations of field strength, which decays in proportion to the distance

between the fixed station and the mobile terminals, as mobile terminals move.

2. The field strength at a receiving point varies irregularly, depending on the environmental conditions, mainly due to the multipath propagation, which causes multipath fading. This variation usually takes a statistically Rayleigh distribution or Nakagami-Rice distribution.

3. Environmental conditions are also varied as mobile terminals move and affect mobile system performance, sometimes significantly. A typical example is the proximity effect caused by materials near an antenna element, which vary the antenna performance. The operator who holds a portable mobile terminal can significantly perturb antenna performance, which could be hazardous to humans. The human interface remains one of the most important issues in operating mobile terminals. The proximity effect is a problem that virtually cannot be avoided in mobile terminals; in particular, as equipment becomes smaller, the influence of nearby materials may not be easily reduced; it must be allowed for in the antenna design. Also, the equipment onto which an antenna element is mounted may itself act as a radiator, so the antenna element and the body of the equipment must be treated together as an antenna system.

4. Antennas for mobile terminals should also be designed to be robust against mechanical and physical environmental conditions. In the field, antennas should be mechanically tolerable against the operator's rough handling and also shock, vibration, and other disturbances that might rupture the antenna elements. It should also be durable against the variation of outdoor physical conditions such as temperature and humidity.

5. Requirements for system performance, concerning both mechanical and electrical conditions, should be satisfied. Small size, light weight, low cost, and yet realization of highest performance obtainable are desired. Antenna performance should meet the system specifications. In zoned systems, radiation patterns have to match the zoned patterns to avoid interference, and performance is also subject to variations in field strength according to movement of the mobile terminals and environmental conditions in the propagation path. Antennas should have sufficiently high gain to satisfy requirements for the link budget, and should function properly for rejection of interference and mitigation of multipath fading.

Frequency reuse capabilities, the type of information, modulation, and personalization of mobile terminals are some of the many factors that are of concern to antenna designers. Table 1 summarizes the influence of system requirements on antenna design [1].

Design of antennas for mobile communications thus must focus on propagation, the system, the environment, and the antenna. The antenna should be considered as an integral part of the overall system as depicted in Fig. 1. Mobile antenna design is no longer confined to small, lightweight, low-profile, or flush-mounted, omnidirectional radiators on a well-defined flat ground plane; rather, it involves the creation of a sophisticated electromagnetic

Table 1. Requirements for Mobile Antenna Design (from [1] with permission from Wiley)

Requirement	Implication
Antenna as a system	Not as an isolated receive/transmit terminal
Designed to accommodate propagation effects	Some degree of polarization or pattern diversity control embodied, leading to “smart” adaptive antenna arrays
Compatible with environmental conditions	Pattern characteristics to match stone requirements and allow for nearby obstacles
Integration of antenna with vehicle or platform	To include hand and body effects and possible hazard considerations
Latest manufacturing technology	Exploitation of new composite materials and integrated electronic technology
User-friendly and reliable performance	Minimum of moving parts and switches; high reliability of mechanical design
EMC constraints	Reduction of spurious radiation and coupling
Multimedia applications	Increased bandwidth requirements

configuration that plays a significant role in signal processing during operation in a generally ill-defined time-varying environment. It should be emphasized again that antennas employed for mobile communications should be designed while factoring in all the parameters that concern propagation, system requirements, and environmental conditions.

2. BRIEF HISTORICAL REVIEW

Variation of related parameters and evolution of antenna systems with time are shown in Table 2 in

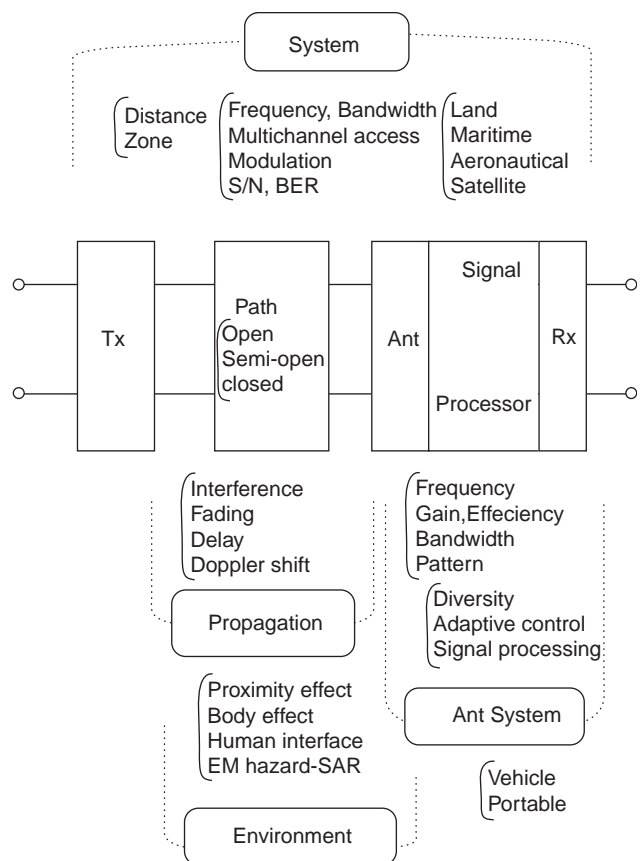

Figure 1. Antenna systems as an integral part of a mobile communication system. (From [1] with permission from Wiley.)

terms of frequency bands, systems, antenna, and propagation.

The first mobile communication was initiated in 1885 with wireless telegraph between trains and stations, which was developed by Thomas Edison [2]. Trolley wires were used as the antenna, which coupled electrostatically with a metal sheet installed on the ceiling of the train, and thereby the telegraph signal was received. Edison also experimented with communication on a vehicle in 1901 [3] using a thick cylindrical antenna placed on the roof of the vehicle. The practical mobile communication services started with wireless telegraph on ships in 1889 developed by Guglielmo Marconi using long vertical wire antennas in various forms such as T, inverted L, and umbrella shapes. It is interesting to note that portable equipment appeared in 1910 [4].

World Wars I and II both introduced the need for advanced antenna systems and promoted evolution of novel design and technology [5]. Wire antennas were firmly established in the 1920s, while present-day microwave antenna design and technology was commonplace in the 1950s. In the 1960s a new antenna era emerged, triggered by the revolutionary progress in semiconductors and integrated circuits, attributed initially to the Cold War defense industry but subsequently carried forward into the commercial sector. Quite simply, the demand instigated designers to create compact, lightweight, low-cost, easy-to-manufacture radiating structures, compatible with the newly conceived integrated electronic packages. The most notable one has been the creation of printed antenna technology, which lends itself to multifunction antenna devices [6]. Some of the salient factors that have increasingly influenced antenna design in this era and continue to do so today are noted in Table 3, which clearly emphasizes that communications, particularly mobile communication systems, are the most significant drivers of antenna technology at present.

Mobile communication systems have made rapid progress since mobile phone systems were introduced in 1979. The early analog systems, called the *first-generation* (1G) systems, conveyed mostly voice, but demonstrated benefit of communication on the move. This then became a good impetus for advances in mobile systems, which dealt with both voice and data in digital form. The digital systems were referred to as *second-generation* (2G) systems, and subsequently advanced to the *third*

Table 2. Developments in Mobile Communication Antenna Technology (from [1] with permission from Wiley.)

	1900–	1950–	1970–	1990–	2000–
Frequency System	Telegraph/telephone for train, ship, aircraft, police cars, portable receiving and transmitting	150 MHz < Voice system for business, navigation, taxis, tone pagers	800 MHz < Mobile phones	1.9 GHz < Satcom, voice, and data channel for aircraft, personal phones, microzones, TV-type images, wireless local-area network	2 GHz < Wireless-IP
Antenna	Monopole/dipole, whip, top-loaded monopole, inverted L, loop	Blades, coil loaded ferrite, helical	Corner reflector, leaky coaxial cable, diversity configurations, body-integrated planar inverted F, bifilar helix, microstrip antenna and arrays, parallel-plate, printed antennas	Adaptive signal processing, meanderline, normal mode helix, ceramic chip antennas	Intelligent software algorithms, wideband, multi-band antennas

generation (3G), which has demonstrated transmission of image, both still and moving. Table 4 outlines the evolution of mobile systems with time. Some typical widely used systems worldwide are also shown. The second-generation systems had shown advantages of digital systems over analog systems with respect to increasing the available capacity and services provided. More significantly, the digital system has enabled the achievement of global standardization of mobile communications. The typical European digital system, GSM (Global Systems for Mobile Communications), which initiated the operation of digital mobile system in the world, has paved the way for the third-generation systems, in which CDMA (code-division multiple-access) technology has been applied with increased capacity and services, including access to the Internet.

Now the systems referred to as the IMT-2000 (International Mobile Telecommunication Systems)/UMTS (Universal Mobile Telecommunication Services) have made even further progress toward fourth-generation systems, which can deploy extended services with higher-quality and higher-capacity transmission.

Antenna technology has progressed with the advancement of these mobile systems. The macrozone systems have been changed to smaller zones such as microzone and even picozones. Propagation problems have been modified according to changes in zone size, and antenna design has followed suit. Mobile phone systems initiated with automobile telephone systems have now evolved into handheld phone systems, and today the number of handheld phone users has far surpassed that of automobile phone users. There have been notable changes in antenna design for mobile phones since the early 1990s. Monopole was the main antenna for mobile phones; however, planar antennas, typically a planar inverted-F antenna (PIFA), have prevailed in most mobile phones and in some systems, particularly GSM systems, and variations of PIFA have been used as built-in antennas. Presently, use of a built-in antenna has become a worldwide trend in mobile phones. Further advancement is expected to include antenna systems such as adaptive arrays, antennas capable of adaptive performance control of environmental conditions, and antennas with more sophisticated functions, yet with smaller and more compact structure.

Table 3. Salient Factors Influencing Antenna Design (from [1] with permission from Wiley)

Factor	Trends
Spectral congestion and utilization	Wider bandwidth operation, improved performance, interference rejection, use of millimeter and submillimeter antennas
Explosive growth in mobile/personal communication systems	New compact user-friendly higher-performing antennas for cellular terrestrial operation of handsets and vehicles
Escalating information and processing speeds	Wide-bandwidth “smart” antennas with pattern agility and fast scan acquisition, antennas for microwaves
Growth in satellite communications	Higher-performance spaceborne antennas offering multifunction operation and reduced payloads, small high-performance handset antennas
Link with IN and ATM networks	Small high-performance antennas for mobile terminals
Traffic information and control	Specifically designed antennas for systems
New materials	Redesign of existing, and creation of new, robust antenna structures to simplify manufacture and operation
Impact of computer modeling and computer-controlled measurement	Strengthens design methods to create higher-performing equipment, compatible antennas at lower cost
Public awareness of electromagnetic radiation	Preference for lower transmitted powers, environmentally friendly antennas, and antenna platforms

Table 4. Evolution of Mobile Communication Systems (from [1] with permission from Wiley)

		Year	
1980–	1990–	2000–	2010–
1G (analog)	2G (digital)	3G (CDMA)	4G
Voice AMPS,	Voice and data IS-54, GSM, PDC PHS DECT	Multimedia UMTS, IMT- 2000, Wireless ATM	Wireless LAN
TACS, JTACS		Mobile SAT- COM	Ubiquitous NW
NTT, NMT	Cdma-one	Mobile + IP NW Cdma – 2000	Mobile–optical NW ITS

3. TRENDS

Mobile systems are now being advanced toward fourth-generation systems, beyond IMT-2000/UMTS, which offer various new services with higher data rate, video transmission capability, and other advanced facilities. Main regional standards bodies have decided the preferred technology for IMT-2000, for example

- UWC-1336, a TDMA-based proposal from the United States
- WCDMA, a joint proposal from Japan and Europe
- cdma-2000, advanced from cdma-one, adopted in the United States and Japan

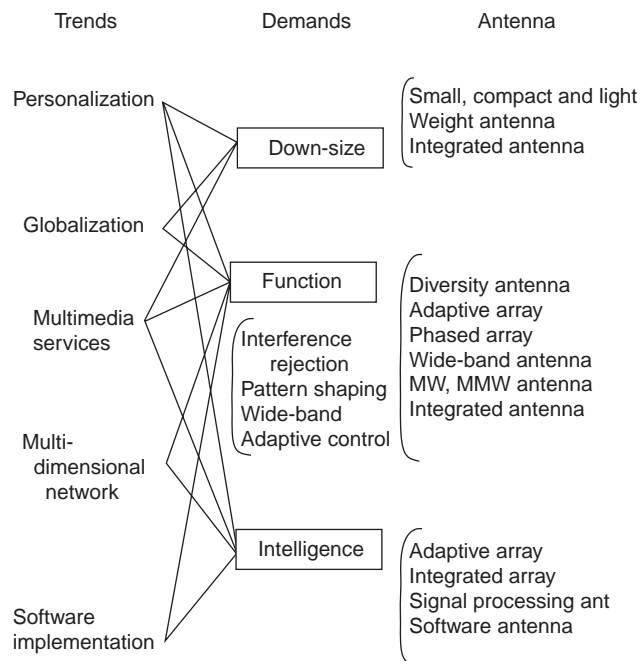

Figure 2. Typical trend of mobile communication and antennas. (From [1] with permission from Wiley.)

The WCDMA (wideband CDMA) system features high-quality and variable multirate services, multimedia transmission, and international roaming. Antenna systems with intelligent functions realized by adaptive signal processing and software implementation are expected to appear in future advanced systems. The typical trends in modern mobile communications are listed in Fig. 2 [1] and discussed in the following paragraphs.

3.1. Personalization

Personalization has been accelerated by downsizing hardwares in both mobile and base stations. Increase in information content, including games, movies, and music, which attracted many users, also accelerated the development of personalization features for mobile phone users. Mobile phones are presently no longer “telephones,” but information terminals, which deal with computer data, moving images, message exchange, and so forth. In other aspects, the downsizing of mobile terminals has also provided impetus for the personalization of mobile systems because the smaller handsets are more convenient to carry and easier to operate. One of the main problems encountered is the realization of smaller antennas for downsized handsets without degrading system performance. Downsizing of base stations (BSs) has also required antennas to be small in size and light in weight as a consequence of the increased number of base stations to serve an increased number of subscribers and the need for more efficient use of each channel.

Zone size has decreased; hence BS antennas are provided with less space for installation. Lightweight antennas are required for mounting on the wall of a building, and microstrip antenna (MSA) arrays are a typical example of downsized and lightweight antennas.

3.2. Globalization

Globalization has been realized by using satellite on the orbits of LEO or MEO (low- or medium-Earth orbit) as well as GEO (geostationary or geosynchronous orbit). Globalization is realized by not only satellite systems but also by wired network systems such as IP (Internet Protocol) cored network and wireless systems that enable mobile terminals to roam worldwide. One objective of IMT-2000 is the establishment of worldwide multimedia services.

3.3. Multimedia Services

Mobile systems are now capable of transmitting video images, both still and moving, as well as voice and data. Since the transmission rate has gradually increased from the order of kilo- to megabits per second (kbps to Mbps), various services, including TV-phone, movies, and large-scale packet data transmission, have become available. FOMA (the third-generation system in Japan), for instance, which employs WCDMA, can presently carry data of 384 kbps; however, it will be 2 Mbps in near future

and eventually 10 Mbps, by which various multimedia services will be provided. Antenna should have enough wideband to meet the requirements for multimedia transmissions.

3.4. Multidimensional Networks

Mobile communication systems are now being integrated into multidimensional networks that embrace multiinformational media, multitransmission media, and multilayered networks. Information media consist of both voice and nonvoice systems, including digital voice, sound, still and moving images, and computer data. Transmission media consist of both wire and wireless lines, including IP networks, radio, and optical links. Land, maritime, aeronautical, and satellite systems will be integrated into complex multilayered networks, thus allowing seamless communications worldwide regardless of time and space. The demand for more intelligent antennas that are integrated with signal processing, adaptive control, and software will continue unabated.

3.5. Software Implementation

Implementation of software to antenna systems will be increased in order to enhance the performance of antennas, including intelligent performance. An example is a mobile terminal that installs software, in which one system can be switched to another system, when a user desires to use a different system. For example, a user who is operating GSM may switch to operating PDC when entering a PDC [Personal Digital Cellular (Japan)] zone.

4. TYPICAL ANTENNA ELEMENTS

Various antenna elements have been used for mobile communications. There are no specific type of antenna elements, but the design differs when it is applied to practical mobile systems. In particular, specific design considerations are taken for antennas used in mobile terminals, as was mentioned in the previous section.

Typical antenna elements are shown in Fig. 3. Linear elements are (see Fig. 3) (a) dipole, (b) monopole, (c) loop, (d) inverted-L antenna, (e) inverted-F antenna, (f) normal-mode helical antenna (NMHA), and (g) meanderline antenna. Typical planar elements are (h) microstrip antenna (MSA), (i) planar inverted-F antenna (PIFA), (j) parallel-plate antenna, and (k) slot. Typical bulk-structured antennas are (l) small chip antennas, in which an antenna element such as small normal-mode helix, inverted L, or inverted F is encapsulated by ceramic material with high permeability. In the ceramic chip antenna, an inverted-F, meanderline, or other pattern may be printed on the surface of the ceramic substrate.

5. ANTENNAS FOR BASE STATIONS

Figure 4 shows important items to consider in designing a base-station antenna. Although “antenna design” in the narrow sense means electrical design, in reality it includes a wider area, and it is important to derive the antenna

hardware specifications from system requirements. In order to determine the hardware specifications, it is necessary to perform an evaluation that compares electrical and mechanical characteristics with a tradeoff between performance and cost, as shown in Fig. 5. Performance and cost considerations are sometimes the first step, while determination of the electrical and mechanical design is the second step [1].

In designing the practical antenna, it is important to assess how the antenna hardware will be installed after manufacturing. Installation fees may exceed the cost of the antennas themselves. It is important to consider not only the reduction of construction cost, but also the creation of an antenna design that facilitates installation.

5.1. Propagation Problems

Propagation problems differ depending on the environmental conditions. Propagation in mobile communication occurs within a diffraction region and is not free-space propagation. Propagation path loss in free space is simple and is proportional to the square of the distance, whereas in mobile communications it depends on various factors, such as the propagation environment, antenna height, and frequency.

Mobile propagation environments are very complex, but are roughly categorized into four basic types [7]:

- *Open Area.* There are few obstacles, such as high trees or buildings, in the propagation path. Roughly speaking, free spaces measuring about 300–400 m in length lie between the base and mobile stations.
- *Suburban Area.* There are some obstacles around the mobile stations, but they are not dense. Roughly speaking, this may be an area of trees and low-height houses.
- *Urban Area.* There are many buildings or other high structures. Roughly speaking, this is an area with high, adjacent buildings, or a densely mixed area of buildings and high trees.
- *Closed Area.* Propagation is confined to limited areas such as building, tunnels, subway stations, and underground streets.

5.2. Propagation Path Loss Characteristics

Although there are many aspects of mobile propagation, path loss characteristics are most closely related to the antenna design. Path loss in a mobile propagation environment exceeds that in free space because of the existence of various obstacles. Figure 6 shows measured field strength versus distance from the antenna with respect to base-station antenna height. These measurements were recorded at a frequency of 453 MHz with vertical polarization and a mobile station height of 3 m [7].

5.3. Base-Station Antenna Techniques

5.3.1. Requirements for Base Station Antenna Systems. The earliest mobile phone systems were installed in automobiles and other moving vehicles; then the

Figure 3. Typical antenna elements: (a) dipole; (b) monopole; (c) loop; (d) inverted L; (e) inverted F; (f) normal-mode helical antenna; (g) meanderline antenna; (h) microstrip antenna; (i) planar inverted F; (j) parallel plate; (k) slot; (l) chip antenna.

development of portable telephone systems subsequently followed. Mobile phone systems adopt a cellular structure, and antennas are designed to meet the requirements for the systems that operate within that structure. The necessary antenna technology is illustrated in Fig. 7. In order for the base station to communicate with the mobile stations located in the service area, base-station antennas must radiate uniformly inside the area. Moreover, antenna gain should be as high as possible. Since the pattern of the service area is specified, antenna gain cannot be increased by narrowing the beamwidth in the horizontal plane. Therefore, the antenna beam is usually narrowed in the vertical plane to increase gain; a vertical array of linear antennas is used for this purpose. Antennas with a gain from 7 to 15 dBi are normally used for base-station antennas in cellular systems.

Since a base station communicates with many mobile stations simultaneously, multiple channels must be

handled. This requires wide-frequency characteristics and a function for branching and/or combining the channels. Hence, base stations in the cellular system use one antenna for both transmitting and receiving. The required bandwidth of the antenna, for example, in the 800-MHz band Japanese PDC system, is more than 7% for the specified voltage standing-wave ratio (VSWR) of < 1.5. Furthermore, antennas are designed for sharing by several systems (e.g., analog and digital systems), for which a wider frequency bandwidth is required. Thus the PDC antenna in the 800-MHz band requires a frequency coverage of 810–960 MHz, with a 17% relative bandwidth.

Due to the rapid growth of mobile phone subscribers, effective use of communication channels has been encouraged worldwide. The cellular system has been introduced to increase the channel capacity by adopting the frequency reuse concept, and base-station antennas are designed to

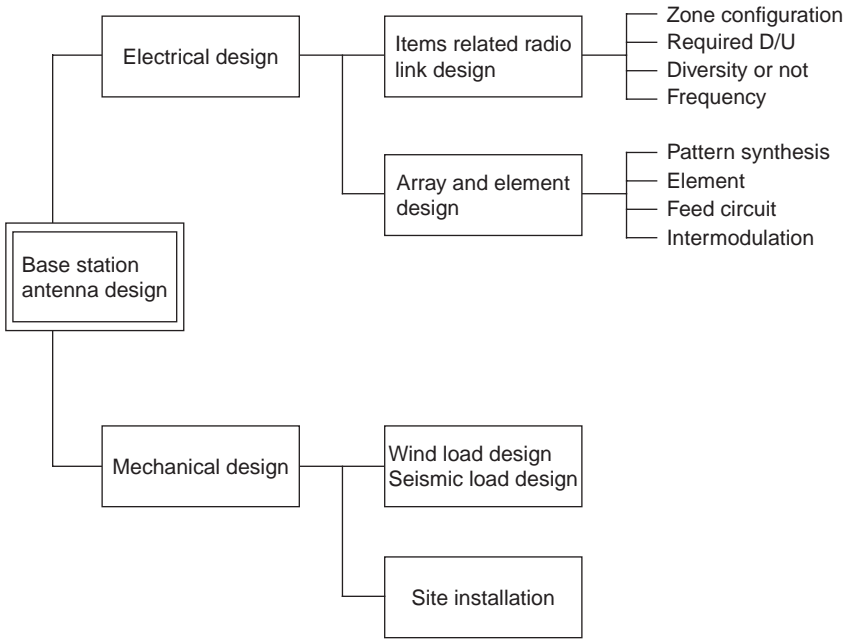

Figure 4. Important items in designing base-station antenna. (From [1] with permission from Wiley.)

match the frequency reuse concept. Tilted mainbeam and shaped patterns are two major design concepts.

Another important issue that warrants specific consideration in mobile communications is mitigation of multipath fading. One way to overcome this problem is to apply diversity antenna systems. Diversity systems have been studied since the 1960s, and thus far their effectiveness has been confirmed both experimentally and theoretically. Reception diversity first applied to commercial systems was for the “advanced mobile phone system” (AMPS) in the United States in 1982. It was also employed in the large-capacity mobile systems in Japan.

Various antenna technologies for base stations other than diversity systems have been developed to enhance the system performance. Adaptive array is one of them and has been studied extensively in the United States, Europe, and Japan. Major issues in the process of adaptive array development are communication frame format for beamforming, beamforming algorithms, array calibration, and simplification of hardware. The world’s first application of the adaptive array was to the PHS (personal handy-phone system) base-station antennas in Japan in

1998. PHS system is a likely system for application of the adaptive array, because PHS employs a TDD (time-division duplex) system and allows slow movement of mobile terminals, so that estimation of the propagation channel property for downlink can also be used for uplink, resulting in rendering application of adaptive array feasible.

A field test using the adaptive array in IMT-2000 has been performed and the usefulness of the adaptive array was confirmed; however, practical allocation has not yet been completed.

5.3.2. Type of Antenna. Base-station antenna configurations depend on the size and shape of the service area, the number of cells, and the number of channels. For the limited service areas within a restricted angle in the horizontal plane, a corner reflector antenna is often used. When the service area is wide, as in a macrozone system, a linear array antenna, which has high directivity in the vertical plane, is used.

In the early stage of cellular system development, the base-station antenna was designed mainly to achieve higher gain, and array antennas excited uniformly were

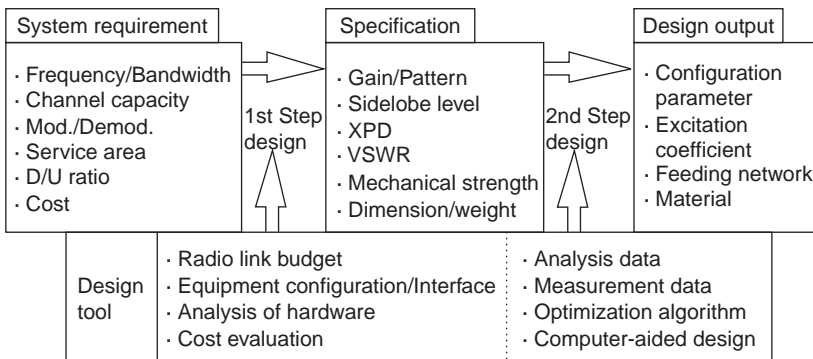

Figure 5. Design steps of base-station antenna. (From [1] with permission from Wiley.)

Figure 6. Measured field strength with respect to distance from a base station ($f = 450$ MHz, urban area). (From [1] and [7] with permission from Wiley and IEICE, respectively.)

often used. However, the design concept of the base-station antenna has shifted from attaining not only high gain but also a greater ratio of desired-to-undesired (D/U) signal strength, as cells have been divided into smaller sub-cells in order to increase the effectiveness of frequency reuse. Mainbeam tilting, either mechanically or electrically, has been adopted throughout the world and cochannel interference was reduced by about 10 dB, as can be observed in Fig. 8. Beam tilting was recognized to be essential for enhancing frequency reuse, and suppression of sidelobes adjacent to the mainbeam, achieved by synthe-

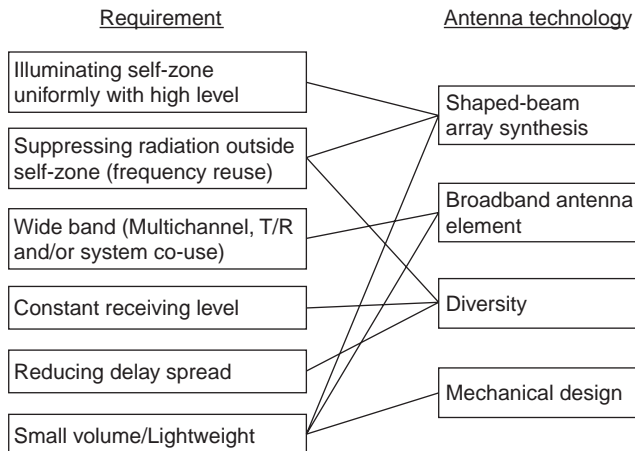

Figure 7. System requirements and necessary antenna technology. (From [1] with permission from Wiley.)

Figure 8. Interference reduction by means of beam tilting. (From [1] and [7] with permission from Wiley and IEICE, respectively.)

sizing array antenna patterns appropriately, was also effective in decreasing the distance between cells. Figure 9 depicts the effectiveness of reducing the sidelobe.

As for diversity antennas, space diversity, in which two antennas are used with separation of 5–10 wavelengths, has been commonly used. Other diversity schemes such as the pattern diversity [8] and polarization diversity [8] have also been applied to base-station antennas in commercial systems.

Polarization diversity has gained new understanding, as improved performance compared with that using space diversity has been recognized in urban areas, particularly in dense metropolitan areas such as central Tokyo [9]. This is attributed to increase in cross-polarization components in mobile phone propagation with increase in mobile phone users. When a mobile phone is held at talk position, the unit is slanted and produces both vertical and horizontal polarization components. Consequently, polarization diversity performs better than does space diversity. Polarization diversity was employed in the cdma-one system, and presently in the IMT-2000 systems.

Figure 10 categorizes the types of base station antennas with respect to functions and antenna characteristics.

Figure 9. Sidelobe reduction for frequency reuse. (From [1] and [8] with permission from Wiley and IEICE, respectively.)

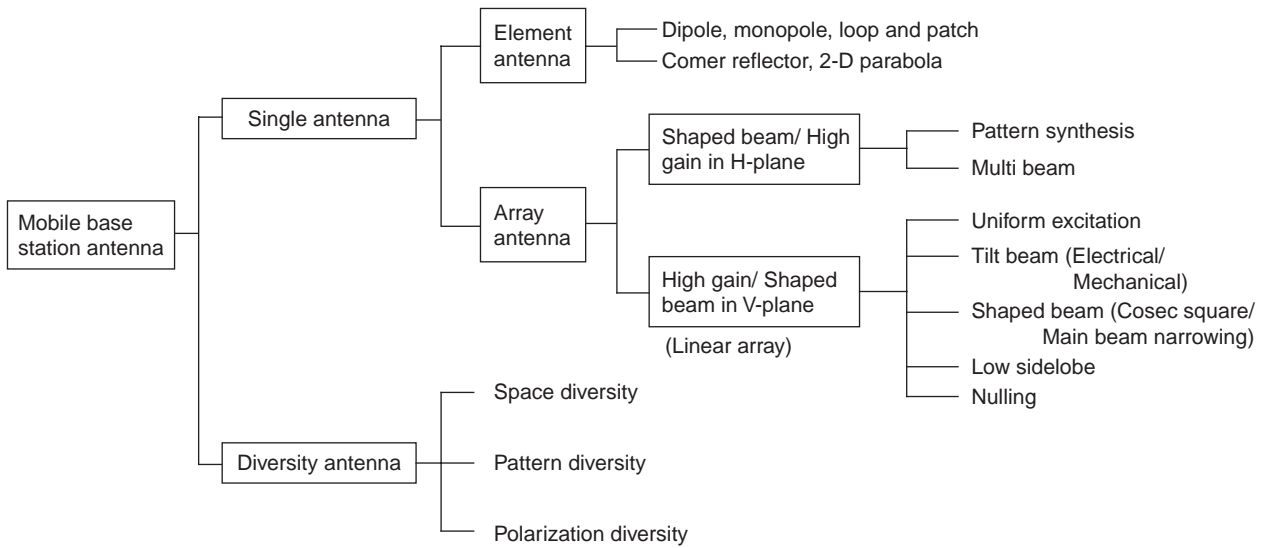

Figure 10. Types of base-station antennas categorized by function and characteristics. (From [1] with permission from Wiley.)

5.3.3. Design of Shaped-Beam Antennas. A base station antenna in a cellular system is required to radiate energy at as low a level as possible toward the cell where the same frequency is used; conversely, it must illuminate the service area at as high a level as possible. There are two types of shaped-beam antennas: (1) a sector beam in the horizontal plane and (2) a cosecant beam in the vertical plane.

5.3.3.1. Frequency Reuse Distance. From the cellular system shown in Fig. 11 [10], the following formula can be derived

$$N = \frac{1}{3} \left(\frac{D}{R} \right)^2, \tag{1}$$

where N is the number of cells, R is the radius of a cell, and D is the distance between the centers of adjacent cells [11]. The worst value of the carrier-to-interference ratio (CIR), expressed in decibels, appears at the edge of the cell and is given by

$$\text{CIR} = -\alpha \cdot 10 \log \frac{R}{D - R} \tag{2}$$

Figure 11. Cellular system. (From [1] and [10] with permission from Wiley and IEICE, respectively.)

where α is the attenuation constant of the path loss characteristic curve. In (2), $(C/I)_{\text{ANT}}$, the antenna pattern difference between the desired wave direction (θ_d, ψ_d) and the interference wave direction (θ_i, ψ_i) , expressed in decibels, is not included.

Therefore, the total CIR of antenna pattern $P(\theta, \psi)$, expressed in decibels, is obtained by

$$\text{CIR} = -\alpha \cdot 10 \log \frac{R}{D - R} + (C/I)_{\text{ANT}} \tag{3}$$

$$(C/I)_{\text{ANT}} = \frac{P(\theta_d, \psi_d)}{P(\theta_i, \psi_i)} \tag{4}$$

Figure 12 shows the relation between D/R and CIR when $(C/I)_{\text{ANT}}$ is varied and $\alpha = 3$ [10]. From this figure, the significance of $(C/I)_{\text{ANT}}$ can be understood.

Figure 13 shows the typical radiation pattern of a base station antenna in the vertical plane and radiation levels

Figure 12. Relation between D/R and CIR. (From [1] and [10] with permission from Wiley and IEICE, respectively.)

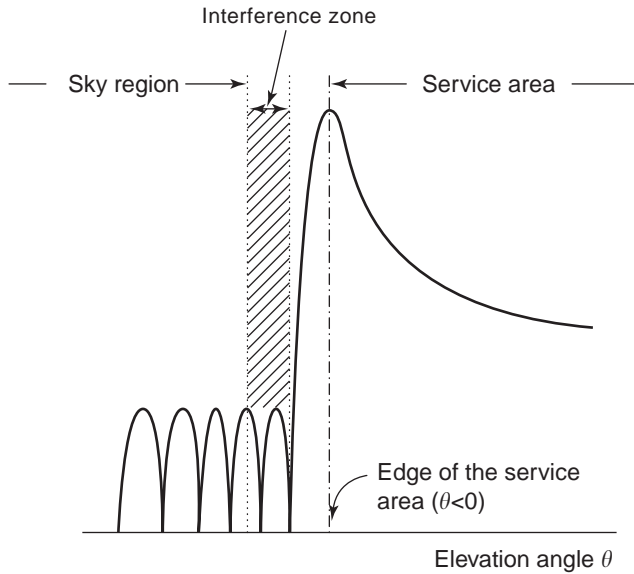

Figure 13. Typical radiation pattern of base station in the vertical (y) plane. (From [1] and [10] with permission from Wiley and IEICE, respectively.)

at the edge of the cell and toward the interference direction. If the two directions are sufficiently separated compared to 50% of the main beamwidth of the antenna, interference points exist in the sidelobe region of the radiation pattern, and the sidelobe level must be decreased to increase $(C/I)_{ANT}$.

If the interference direction approaches the desired direction (N becomes small), interference lines may exist in the mainbeam as well as the desired direction. To increase $(C/I)_{ANT}$ in this case, it is necessary to increase the length of the antenna or to narrow the main beamwidth with beam shaping techniques without increasing the length of the antenna.

When sector beams with the angle of θ_S are used in place of omnidirectional (circular) beams, the interference distance $(D-R)$ in Eq. (2) lengthens to $(D^2 + R^2 - 2DR \cos \theta_S)^{1/2}$,

Figure 14. Interference distance of (a) sector beam and (b) omnidirectional beams. (From [1] with permission from Wiley.)

Figure 15. Fundamental configuration of a corner reflector antenna. (From [1] with permission from Wiley.)

as shown in Fig. 14. These are more advantageous in frequency reuse than omnidirectional beams.

5.3.3.2. Sector Beams. A sector beam should effectively cover the service area of a hemisphere or a sector. In addition, the frequency reuse distance with a sector zone arrangement is shorter than that with a circular zone arrangement. Typical antennas having a sector beam are an antenna with a corner reflector, and a two-dimensional parabolic reflector fed by two primary radiators [12].

The corner reflector antenna has an advantage that the beamwidth can be adjusted by controlling the aperture angle of the reflector. Figure 15 shows the fundamental configuration of the corner reflector antenna. The antenna element may be a vertically arrayed antenna. With the vertically arrayed antenna, the corner reflector can achieve high directivity by narrowing the mainbeam in the vertical plane and can radiate a shaped radiation beam by controlling the excitation coefficient.

Figure 16 shows the relationship between the aperture angle of the corner reflector and a half-power beamwidth in the horizontal plane, as well as the relationship between the aperture angle and the directivity when the primary radiator is a half-wavelength dipole. Sector beams with 60–180° beamwidth can be obtained by

Figure 16. Aperture angle versus half-power beamwidth in a corner reflector antenna. (From [1] and [13] with permission from Wiley and IEICE, respectively.)

Figure 17. Omnidirectional pattern by combining two 180° sector beam antennas. (From [1] and [8] with permission from Wiley and IEICE, respectively.)

setting the aperture angle from 60° to 270° [13]. The results shown in Fig. 16 are somewhat different from those presented by Kraus [14], in which an infinite corner width is assumed. When the aperture angle is 180°, corresponding to a flat plate, the beamwidth becomes approximately 120°. To obtain a sector beam with a beamwidth more than 120°, a corner reflector with an aperture angle of more than 180° is needed.

If two sector beam antennas of 180° beamwidth are combined with moderate spacing (approximately $> 6\lambda$), an omnidirectional pattern is realized, as shown in Fig. 17. In this case, large ripples appear in the direction of $\pm 90^\circ$ due to the interference of the two patterns. However, measurements confirm that these ripples disappear in a multipath environment as shown in Fig. 17.

A design method of a corner reflector beam antenna having a dual frequency has been reported [15]. To realize a dual-frequency corner reflector antenna, it is necessary to prepare a dual-frequency primary radiator. This is possible with a dipole with a closely spaced parasitic element

Figure 19. Typical design curves for corner reflector antenna of 900 MHz and 1.5 GHz. (From [1] and [15] with permission from Wiley and IEICE, respectively.)

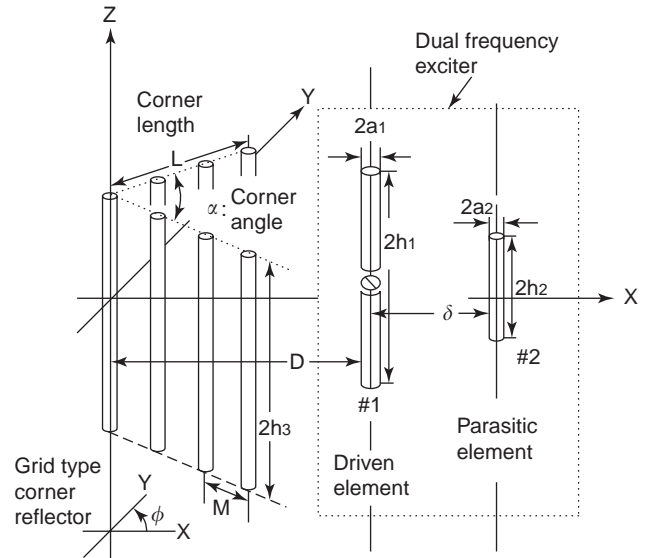

Figure 18. Geometry of a dual-frequency corner reflector antenna. (From [1] and [15] with permission from Wiley and IEICE, respectively.)

as shown in Fig. 18. This antenna has the advantage of being very compact. By using the primary radiator shown in Fig. 18, sector beams of equal beamwidth for frequencies f_1 and f_2 can be obtained by selecting the aperture angle α , distance d between reflector and primary radiator, and the width of the corner l . Typical design curves are shown in Fig. 19 for frequency bands of 900 and 1500 MHz.

5.3.3.3. Shaped Beams in the Vertical Plane. When a limited horizontal area is to be illuminated with equal received signal level from an antenna fixed at a certain height, as shown in Fig. 20, it is known that an antenna with a cosecant squared shaped-beam pattern in the vertical plane is used. If the path loss is larger than that in free space ($\propto r^2$) as in the case of mobile communication systems, the p th power order of a cosecant shaped-beam power pattern is necessary to achieve equal received signal levels at all points in the area. However, in cellular systems, the significance of the shaped beam is recognized

Figure 20. Shaped beam for illuminating service area uniformly and low sidelobes for interference reduction. (From [1] with permission from Wiley.)

in suppression of the radiation toward the cell, where the same frequency is reused, rather than in illumination of the self-zone uniformly, as illustrated in Fig. 21. If frequencies are reused, and the cells are closely spaced, a part of the mainbeam will illuminate the reuse cell. Therefore, it may be effective to tilt the mainbeam down to suppress the interference, even if the received signal level within the self-zone weakens. By reducing the main beamwidth while maintaining the length of the antenna, it is possible to increase $(C/I)_{ANT}$.

5.3.3.4. Beam Tilt. The principal idea of the beam tilt-down technique is to tilt the main beam in order to suppress the level toward the reuse cell and to increase $(C/I)_{ANT}$. In this case the carrier level also decreases in the zone edge. However, the interference level decreases more than the carrier level, so the total $(C/I)_{ANT}$ increases. This is an advantage from the viewpoint of

Figure 22. Beam tilting effect showing interference reduction with and without beam tilting. (From [1] with permission from Wiley.)

system design, and this technique is used in most cellular systems in the world. Figure 22 compares antennas with and without beam tilt, verifying the effectiveness of the beam tilt technique [16]. It can be easily understood from this figure that the distance from the base station inside which the interference level exceeds the threshold level of the system can be significantly reduced. In Japan, beam tilt is attained electrically by adjusting the excitation coefficient of the array, while in Europe it is achieved mainly mechanically.

5.3.3.5. Shaped Beam with a Locally Suppressed Sidelobe Level. For reducing the interference, sidelobe levels in some limited angles are suppressed. A pattern synthesized with locally suppressed sidelobe levels was first studied in the field of radar [17]. However, since sidelobe suppression is performed in the direction close to the mainbeam, and sidelobe level is closely related to the main beamwidth, it must be carried out very carefully. As shown in Fig. 23, a mainbeam 30% narrower than that of a uniformly excited array was obtained by suppressing only several sidelobes near the mainbeam and setting the other sidelobes at a comparatively high level [18]. An antenna with this radiation pattern can increase the

Figure 21. Synthesized patterns (a) with smooth cosecant beam having high sidelobe level and (b) constant rippled pattern having low sidelobe level. (From [1] with permission from Wiley.)

Figure 23. Narrow mainbeam designed by suppressing (a) sidelobe uniformly and (b) several restricted sidelobes. (From [1] with permission from Wiley.)

level at the zone edge by approximately 1.5 dB if the interference level is kept constant. This is a great advantage in system design.

5.4. Diversity Antenna Systems

5.4.1. Effect of Reception Diversity. The effect of reception diversity of the base station was first reported in 1965 [19]. It was shown that fading reduction could be achieved by placing two antennas approximately 10 wavelengths apart in the horizontal (*x*) plane. Figure 24 shows the cumulative probability of received level using either one isolated antenna or two antennas with a correlation coefficient ρ_e of 0, 0.5, and 0.8, respectively [20]. From this observation, it can be understood that the received level at a probability of 1% with the diversity antenna exceeds that with a single antenna by 8 dB.

Although two or more ports are necessary to carry out reception diversity, this method significantly reduces fading.

As a result, the transmitter power of the mobile station is reduced, and the quality of the transmission is enhanced. This is a great advantage from the total-system perspective. Reception diversity in the base station has been in commercial use in AMPS since 1982 in the United States and in NTT's large-capacity system since 1985 in Japan.

5.4.2. Configuration of Base-Station Diversity Antennas.

Many versions of base-station antennas are in use for commercial mobile systems in the United States, the United Kingdom, and Japan [10]. Sector beam antennas with a 3 dB beamwidth of 60° and 120° are used.

There are three types of diversity antenna schemes: space diversity, pattern diversity, and polarization diversity. In these three systems, space diversity is most commonly used.

Figure 25 depicts the pattern diversity antenna for an omnizone. Two antennas are arrayed as shown in Fig. 17 at 90° to each other [8]. Whereas 180° sector beam antennas for synthesizing an omnidirectional pattern are placed apart in space, the centers of the two omnidirectional antennas coincide with the center of the platform, and the spacing between the two antennas is regarded as zero.

Figure 24. Diversity effect versus correlation coefficient ρ_e . (From [1] and [20] with permission from Wiley and IEICE, respectively.)

Figure 25. A 180° sector beam antenna configuration. (From [1] with permission from Wiley.)

Figure 26. Configuration of a polarization diversity antenna configuration (60° sector beam). (From [1] with permission from Wiley.)

Therefore, the difference of the received power for each antenna is considered to produce the difference in the radiation pattern. When the space of two 180° sector beam antennas shown in Fig. 25 is six wavelengths, the correlation coefficient between two antennas is observed by the experiment to be less than 0.2 in urban areas. Figure 26 presents an example of a polarization diversity antenna developed by NTT [21]. It appears as a single antenna and has the advantage of small volume. The antenna element is a circular microstrip antenna with two feeding ports for diversity reception, which are orthogonal to each other. The correlation coefficient is as low as 0.2 in urban areas.

5.4.3. Design of the Base-Station Diversity Antenna. When the received power level at the receiving terminals of the antennas takes a Rayleigh distribution, the

Figure 27. Increased CNR level versus correlation coefficient. (From [1] with permission from Wiley.)

relationship between the correlation coefficient of the diversity terminals and carrier-to-noise (CNR) level at the cumulative probability of 1% is as shown in Fig. 27. From this figure, it can be understood that the ideal improvement of CNR is 9.5 dB (when the correlation coefficient is 0), and that the improvement of CNR remains at 8 dB even if the correlation coefficient rises to 0.6. It is usual, therefore, to design the diversity antenna using such antenna spacing or antenna radiation patterns in order to achieve a correlation coefficient of <0.6.

5.5. Practical Base-Station Antennas [22]

In Japan, mobile telephone services began in 1979. After the liberalization of mobile communication services in 1988 and terminal markets in 1994, the number of subscribers of mobile phones increased rapidly. The personal digital communication system PDC began service in 1994. Four operators provided digital cellular services using frequency bands of 900 MHz and 1.5 GHz. In 2001, the third-generation system IMT-200 using 2GHz began service. The frequency bands used for mobile communications in Japan are shown in Fig. 28.

Figure 28. Frequency allocation for the Japanese cellular systems. (From [23] with permission from IEICE.)

Base-station antennas are designed to operate in dual and triple bands, employ the electronic dual-beam beam tilting technique, and use diversity systems, not only the space diversity scheme but also polarization and pattern diversity schemes. The small cell, with a radius of < 1 km, has been used in the high-density areas such as metropolitan Tokyo. A large number of base station antennas were installed on civil buildings. Rigorous requirements such as conservation of installation space, light weight, and low wind load are also allowed for in the design.

PHS (personal handy-phone system) services began in 1995. The cell size was designed to be very small, with a radius of 100–500 m. Base-station antennas are installed on various structures such as telephone pole, building walls, and telephone booth rooftops. Low-cost and very-lightweight antennas have been used for base stations. PHS was the first system in the world to apply practical adaptive antennas. In addition, PHS has been employed to operate a WLL (wireless local loop) system, where 12 base-station antennas are used to compose an adaptive array based on the DBF (digital beamforming) technique, in which a multibeam is attained. The mainbeam and adaptive antenna performance contribute to increase the system capacity.

5.5.1. Base-Station Antennas for Cellular Systems. Typical cell parameters of second-generation mobile communication systems in Japan are shown in Table 5 [22]. Frequency reuse by means of four-cell repetition gives nearly the maximum frequency spectrum utilization within most mobile systems. To achieve this repetition pattern, interference reduction is essential. The antenna beam is tilted downward and sidelobes directing cells, where the same frequency is used, are suppressed. The three-sector cell configuration is also effective for achieving the four-cell repetition pattern, as it reduces the number of cells that might experience interference. For two-branch reception diversity, two antennas are employed. One of these antennas is shared as a transmitter antenna. As for the sector cell configuration, the six-sector format has been used in order to increase the system capacity.

Antenna specifications are shown in Table 6. The antenna gain in the 900-MHz band is 17 dBi for 120° beamwidth in the horizontal plane. Determination of antenna gain in the 1500-MHz band is based on the gain in the 900-MHz band by considering the loss increase in high-frequency bands. The bandwidth of the 900-MHz digital

Table 6. Specifications of Base Station Antenna

Item	Specifications
Antenna height	5.4 m
Antenna gain	17 dBi (810–956 MHz) 17.5 dBi (1429–1503 MHz)
Sidelobe level below the horizontal direction	Less than –20 dB
Electrical beam tilt	Type 1: 0–5° Type 2: 3–11°
Beamwidth in a horizontal plane	120°

system is 146 MHz, which is 17% in relative bandwidth. The relative bandwidth of the 1500-MHz band is 6%. The sidelobe levels are required to be less than –20 dB. By means of electrical beam tilting, the antenna can be designed flexibly to match a variety of cell radii and building heights. For building height H , beam tilt angle α is determined by the relation $\tan \alpha = H/R$, where R is the cell radius.

Figure 29 shows a typical base-station antenna installation [23].

5.5.2. Dual-Frequency Antenna. The outside view of a dual-frequency antenna is shown in Fig. 30. This antenna is composed of three cylindrical blocks. Beside the antenna, a beam tilt box is attended. The box has two terminals of 900- and 1500-MHz bands. The antenna is connected to the beam tilt box with six coaxial cables whose lengths are 5 m, respectively. The antenna and coaxial cables are used at the dual-frequency bands. The configuration of the antenna feed network is shown in Fig. 31. All antenna components such as radiators, transmission lines, and power dividers are mounted on the same dielectric substrate. The beam tilt panel (contained in the beam tilt box) is separated from the antenna body and placed on the antenna base. All components shown in Fig. 31 are

Table 5. Parameters and Specifications of Base Station (from [1] with permission from Wiley)

System Parameters	Specifications	
Frequency bands	Uplink	Downlink
800-MHz analog	915–940	860–885

Figure 29. Installation of dual-frequency base-station antennas. (From [23] with permission from IEICE.)

Figure 30. Exterior view of a base-station antenna. (From [1] with permission from Wiley.)

commonly used in dual-frequency bands. Array elements are excited through the feed network composed of transmission lines and power dividers. Each element of the feed network has wide frequency band characteristics. Array elements are designed for dual-frequency operation. An element number of 26 is selected to achieve the required antenna gain. Because grating lobe suppression at higher frequencies is important in determining radiator spacing, the array element spacing of one wavelength in the 1500-MHz band was chosen. At 900 MHz, the array element spacing becomes 0.6λ . The desired excitation coefficients (amplitude and phase) of array elements are achieved by designing the feed network. Excitation amplitudes are determined by setting power ratios at power dividers. Excitation phases are determined by setting the length of transmission lines. Here, because the line length is frequency-dependent, changes in excitation phases occur in dual-frequency operation. Accordingly, low-sidelobe characteristics will be degraded in dual-frequency operation.

The electrical beam tilt is achieved by imparting a specific phase difference to subarrays (composed of M array elements) [24]. This phase difference is achieved at a beam tilt panel. The wavefront of the subarrays is tilted by θ_{t0} as shown by solid lines. The beam tilt angle is set to θ_{tt} as shown by the broken line. Change in electrical beam tilt is achieved by replacing the beam tilt panel. When θ_{tt} does not equal to θ_{t0} , abrupt phase jumps between the edges of

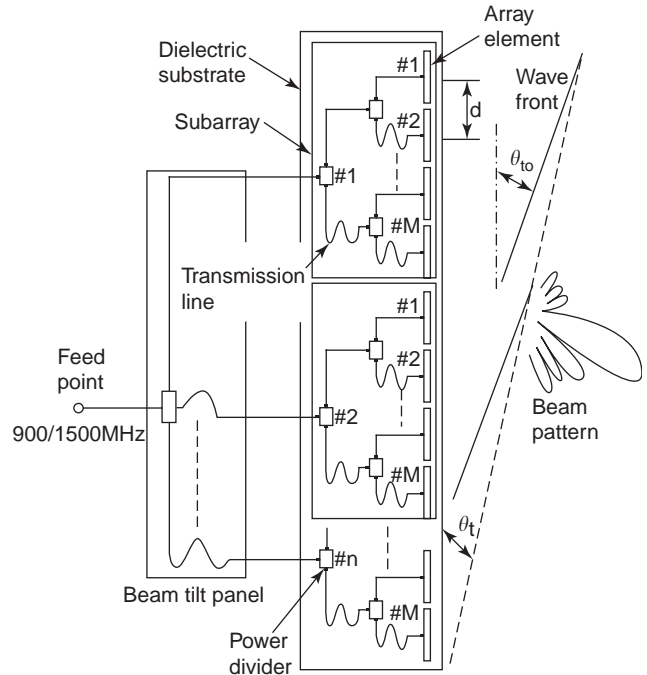

Figure 31. Feed network of a base-station antenna. (From [1] with permission from Wiley.)

subarrays occur. This phase jump produces many grating lobes in the low-sidelobe area. Here, the number of subarray element M is the key factor in determining the grating lobe positions. In this case, six subarrays, with element numbers 5, 4, 4, 4, 4, and 5, are employed (viz., M numbers are 4 and 5).

A practical base-station antenna is shown in Fig. 32. As dual-band array elements, the dual radiator configuration is employed. Printed dipole configurations are used as the 900- and 1500-MHz elements. The 1500-MHz element is placed in front of the 900-MHz element. Stubs are inserted between array elements in order to suppress mutual coupling due to small element spacing of 0.6λ . A reflector is placed behind these radiators to achieve a 120° beam in the horizontal plane. The radome diameter is 110 mm.

A cross-sectional view of the antenna is shown in Fig. 33. The main feature of this configuration is the sidewalls attached to both sides of the reflector. Adding sidewalls is effective to achieve 120° beamwidth using a small reflector size. Figure 34 shows the design chart for selecting radiator position. By using this chart, radiator position of 0.05 m is found for the 800-MHz band (810–960 MHz), and 0.07 m for the 1500-MHz band (1429–1501 MHz). Measured radiation patterns are shown in Figs. 35a (800-MHz band), and 35b (1500-MHz). The bandwidths of the 800- and 1500-MHz bands, respectively, are 17% and 5%. Measured antenna gains for the type 2 antenna are shown in Fig. 36. At a tilt angle of 6° , an antenna gain of 17.1 dBi is achieved in the 900-MHz band. Here, losses of the tilt panel of 1.2 dB and that of coaxial cables (5 min length) of 0.9 dB are included. At 1465 MHz, antenna gain is 17.7 dBi, loss of a tilt panel is 1.8 dB, and that of a coaxial cable is 1.0 dB.

Figure 32. Inside view of a base-station antenna. (From [1] with permission from Wiley.)

5.5.3. Triple-Band Antenna. The IMT-2000 system uses a 2-GHz band, and additional antennas to dual-band antennas or exchange of dual-band antennas have been required. Since there have been little space to install new antennas, multiband antennas have been developed: two types of dual-band antennas, which operate at 900 MHz/2GHz and 1.5 GHz/2GHz, and one triple-band antenna, covering 0.9, 1.5, and 2 GHz bands. In IMT-200 systems, new sector beam antennas having 60° beamwidth are required in addition to 90° and 120° sector beam antennas. By adding a parasitic element to dual-band antennas, triple-band antennas have been attained. Two horizontal parasitic elements are used for increasing the bandwidth at 900-MHz bands. Figure 37 illustrates antenna configuration [25]. Current flows shown by arrows on the elements in Fig. 38 indicate operation of three frequencies each [26]. Radiation patterns for each frequency are shown in Fig. 39 [26].

5.5.4. Dual-Beam Antenna. In cellular systems, six-sector cells are employed to increase the system capacity. Thus 18 antennas maximum are needed when the diversity system is applied; reduction of the number of antennas is desired to ease facilitate antenna installation on the tower.

Figure 40 shows a 60° dual-beam antenna [27]. Two radiators are combined by a 90° hybrid circuit. By excitation of ports A and B, respectively, beams of A and B are generated. By setting separation D of the radiator at 0.5λ , the beamwidth of each beam becomes 60°, centering at $\theta_T = 30^\circ$ directions. Two sidewalls are attached in order to

refine beam shapes. Antenna configuration is shown in Fig. 41. Two vertical array antennas are arranged side by side. Subarrays are combined with a hybrid circuit. By connecting each port of the hybrid circuits to a beam tilt panel, electrical beam tilt is achieved. Radiation pattern of this antenna is shown in Fig. 42. The main parameter in designing the low-sidelobe characteristic is length T of a sidewall. This result shows the effectiveness of the sidewall. By increasing the height, sidelobes near 70° can be reduced effectively. Measured and designed characteristics are shown in Fig. 43. A parasitic element is placed in front of the radiator to achieve excellent 60° beamwidth and low-sidelobe characteristics [28].

The dual-beam antenna is introduced into a six-sector system as shown in Fig. 44. Two dual-beam antennas are combined to achieve four-beam system as shown in Fig. 44a. Then, three 4-beam-antennas are mounted on an antenna tower. The diversity system is employed in all sectors. As a result, the six-sector system is achieved by employing six dual-beam antennas. This is very simple

Figure 33. Cross-sectional view of a corner reflector antenna. (From [1] with permission from Wiley.)

Figure 34. Design chart of corner reflector antenna; half-power beamwidth versus frequency with respect to location of radiator. (From [1] with permission from Wiley.)

Figure 35. Radiation patterns in the horizontal plane: (a) 800-MHz band; (b) 1500-MHz band. (From [1] with permission from Wiley.)

compared with the conventional antenna, which requires 12 antennas.

5.6. Diversity Antenna

5.6.1. Space Diversity. Shared use of an antenna element for reception and transmission is a mandatory necessity for reducing the number of antennas. The approach to accommodate two-sector elements inside a cylindrical radome is being applied to most base-station antennas in order to reduce the apparent number of antennas for multisector cell sites. An example of this scheme is illustrated in Fig. 45, which is a top view of a three-sector antenna system consisting of three poles that contain two radiating elements each.

Pole 1 contains two vertical arrays, $A_{1,1}$ and $A_{3,2}$, facing two azimuth angles of 0° for sector 1, and 240° for sector 3, respectively. Array $A_{1,1}$ is to receive the signal $Rx_{1,1}$ to be combined with $Rx_{1,2}$ received by array $A_{1,2}$, in pole 2 for diversity of sector 1. $A_{1,1}$ is commonly used for transmitting the signal Tx_1 for sector 1. Tx_2 is the signal transmitted by array $A_{2,1}$, which is shared for receiving the signal $Rx_{2,1}$ from the 120° direction. $Rx_{2,2}$ is received by array $A_{2,2}$ in pole 3 and combined with $Rx_{2,1}$ for diversity of sector 2. Transmission and diversity reception of sector 3 will be made in the same manner. This configuration needs three antenna poles separated by 10 wavelengths each for the three-sector space diversity system.

5.6.2. Polarization Diversity. Polarization diversity, on the other hand, does not require two spatially separated antennas. Multiple dipole elements with orthogonal polar-

Figure 36. Gain versus beam tilt angle. (From [1] with permission from Wiley.)

ization can be alternately mounted on one piece of dielectric substrate in a vertical radome. Elements for the orthogonal polarization may be of vertical/horizontal or $+45^\circ/-45^\circ$ cross-dipoles depending on the particular design.

Polarization diversity is a well-known diversity technique; however, it has not been used in cellular phone systems. This was because it was not necessarily useful in the propagation environment, where mobile terminals were found mostly in automobiles and vertical polarization components predominated, as the mobile station employed were a vertical trunk-lid element.

However, as the number of handheld phone subscribers has increased, propagation conditions have changed. Horizontal polarization components sometimes exceed vertical polarization components, as users hold their phones in a tilted position, typically 60° from zenith at talk position. The polarization diversity is then recognized effective in the field where both vertical and horizontal polarization components exist.

Figure 46 shows a top view of a polarization diversity antenna having compact structure, which should be compared with Fig. 45. This is an antenna consisting of a single piece of vertical pole containing three-sector transmitting and receiving arrays with diversity capability

Figure 37. Configuration of a triple-band antenna. (From [25] with permission from IEICE.)

Figure 38. Current flow on the dipole element: (a) 900-MHz band; (b) 1.5-GHz band; (c) 2-GHz band. (From [26] with permission from IEICE.)

inside. Three vertical arrays, A_1 , A_2 , and A_3 , are bound together in the shape of a triangular pillar and are accommodated in a cylindrical radome. Array A_1 , for example, contains a set of vertical and horizontal dipoles stacked alternately on a dielectric substrate to receive vertically polarized signal $Rx-V_1$ and horizontally polarized signal $Rx-H_1$ for sector 1. Either vertical or horizontal dipole elements of array A_1 , or both, can be shared for transmission of the signal Tx_1 . The other two arrays, A_2 and A_3 , have configurations identical to that of A_1 . A number of tests [29–32] have confirmed the effectiveness of polarization diversity.

Figure 47a shows the cumulative distribution of the received level at a base station using space diversity, while the handheld phone transmitted signals from a line-of-sight location in the base-station coverage area. The two solid lines on the left hand show the received levels at the two separate vertical ports, and the dotted line shows the cumulative distribution of selection-combine diversity. Figure 47b shows a line-of-sight location with polarization diversity reception. The two solid lines show the distribution of output levels of vertical and horizontal ports, and the dotted line again shows that of selection-combined diversity. As can be seen, the polarization diversity gain is 12.0 dB at the 1% level of cumulative distribution whereas that of space diversity is 6.2 dB, suggesting the effectiveness of polarization diversity. Similar results were ob-

Figure 39. Radiation patterns at three frequencies. (From [26] with permission from IEICE.)

Figure 40. A 60° dual-beam antenna configuration. (From [1] with permission from Wiley.)

tained for the case where the mobile transmitted signals from the out-of-sight area (see results shown in Figs. 47c and 47d). Although the effect is not as significant as that in the line-of-sight case, diversity gain still is greater for polarization diversity (PD) than space diversity (SD).

Polarization diversity antennas feature reduction in size and weight to cope with stringent environmental requirements. Presently, polarization diversity antennas have been employed in all cdma-one base stations and some PDC base stations of KDDI of Japan [33,34]. This has resulted in easy cell site selection and reduction of construction cost because of the simple structure of the antenna in addition to superior performance.

Figure 48 shows the inner structure of this type of antenna and radome housing. Arrays for three sectors are accommodated in the shape of triangular tube in a cylindrical radome of 23 cm diameter. In this example, three subarrays are stacked to achieve high gain. Downtilting is

Figure 41. Configuration of dual-beam antenna. (From [1] with permission from Wiley.)

performed by changing the phase angles of top and bottom subarrays in opposite sense relative to the central subarray. The tilting is given independently to each transmit/receive and vertical/horizontal polarization combination. Each subarray consists of three vertically polarized dipoles and horizontally polarized dipoles stacked alternately [35].

Figure 49 shows a simplified structure of the dipoles consisting of the vertical array in vertical polarization [36]. A pair of dipoles is arrayed to reduce the beamwidth

Figure 42. Radiation pattern with reduced sidelobes by means of sidewalls. (From [1] with permission from Wiley.)

Figure 43. Measured and calculated radiation patterns: $D = 0.32\lambda$, $W = 0.684\lambda$, and $H = 0.14\lambda$. (From [1] with permission from Wiley.)

in the H plane to match that of the E plane. Similar dipoles are used for the horizontal polarization arrays. The protruded portion of the parasitic element is effective in widening the frequency range in which the beamwidth in the magnetic plane is kept constant. Table 7 lists the specifications of newly developed antennas.

One major potential feature of this antenna is the capability of transmission diversity using different polarizations. Radiation patterns in the horizontal plane of this antenna for vertical and horizontal polarizations are shown in Fig. 50. Great care has been taken to keep the beamwidth in both polarizations for transmit and receive bands almost identical. Cross-polarization characteristics are quite important for such antennas. Figure 51 shows those of the polarization diversity antenna.

5.7. Antennas for Micro/Picocellular Systems [37]

Cellular phone services have been extended to include inside tunnels, subway stations, inside large buildings, underground shopping malls, and other highly populated areas. In order to provide services for these areas, the relay station is installed between the outside base station and the areas to be covered. The relay station has a booster, which receives a downlink signal from the outside station, amplifies it, and reradiates it. As for the uplink signal, the operation is reversed in the same way. A flat antenna is used for the booster. For example, for tunnel systems, a planar, notched structure, two-element half-wave dipole antenna is used. The antenna configuration is shown in Fig. 52. The antenna is installed on the wall of the tunnel at a very low height. The radiation pattern is Figure 8 in both E and H planes, with a null at the direction normal to the antenna element.

In the tunnel system, an optical fiber cable is used from the outside station to the relay station.

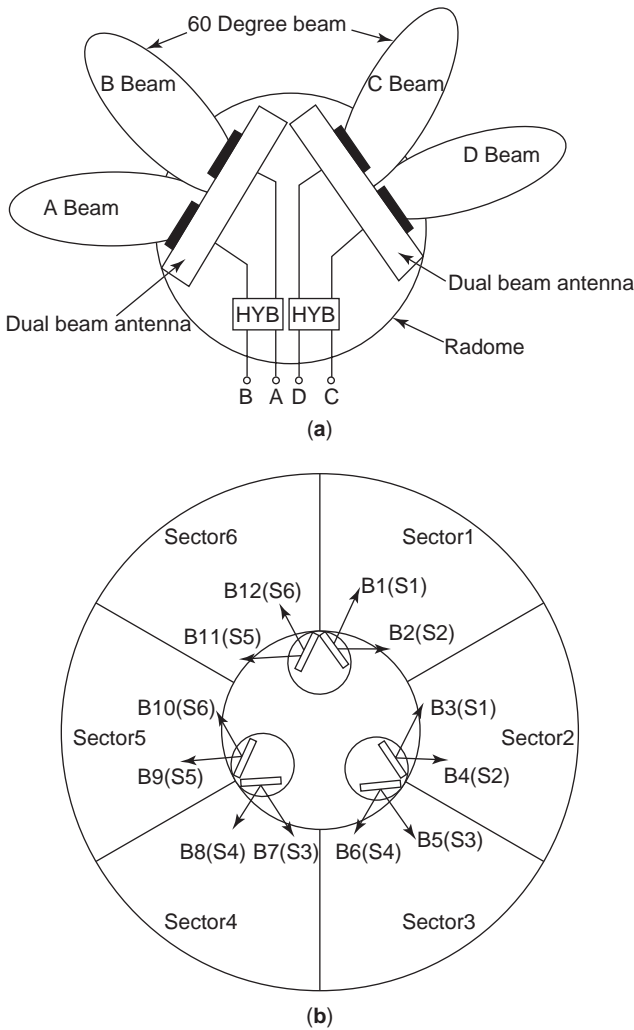

Figure 44. Installation of dual-beam antenna for a six-sector cell: (a) four-beam configuration with dual-beam antenna by four antenna elements; (b) diversity layout for six-sector cell. (From [1] with permission from Wiley.)

5.8. Antennas for PHS (Personal Handy-Phone System)

5.8.1. Collinear Array and Diversity Antennas. In the PHS system, the TDD (time-division duplex) transmission scheme is employed. This system provides service at the 1900-MHz band. A block diagram of the transmission systems with transmission diversity is shown in Fig. 53 [38]. The base station (BS) has two antennas and receivers. The portable station (PS) has only one antenna and receiver. In a TDD system, a single carrier frequency is used to provide two-way communication (upward channel; PS to BS, and downward channel; BS to PS). The BS is able to predict the received signal strength at the PS because of the reciprocity between upward and downward channels. The BS receives upward link signal from the PS using the reception diversity method, and measures the received signal strength during the receiving period. In addition, it predicts which antenna gives the highest received signal strength at the PS. Then, the selected antenna is used for transmission. The signal frame consists of four channels, in which CH1 is the control channel, and CH2 to CH4 are

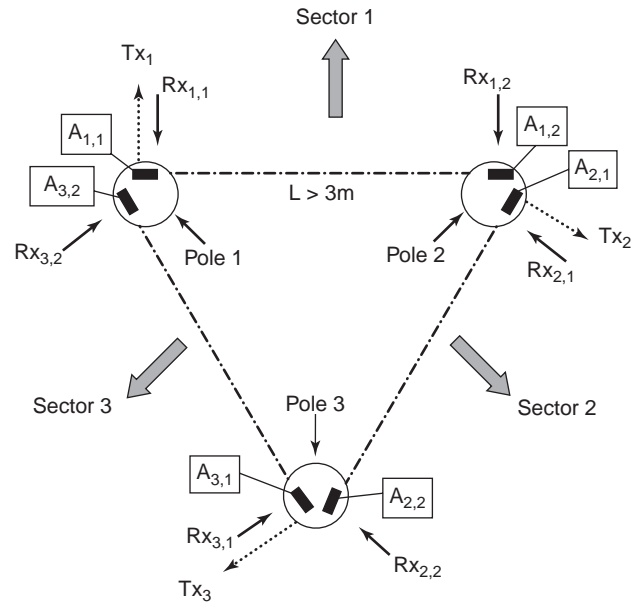

Figure 45. Three-sector space diversity system scheme. (From [1] with permission from Wiley.)

user channels. At CH2, transmission and reception is repeated in every 2.5 ms. In this short time interval, propagation conditions are supposedly stable. Thus, the same propagation condition in an upward channel is supposed to exist in a downward channel.

Diversity antenna setups are shown in Fig. 54. The antenna installed orthogonal to a road has superior diversity gain. For antenna separation (s) larger than 50 cm, sufficient diversity gains are achieved.

A typical omnidirectional collinear antenna configuration is shown in Fig. 55 [39]. The inner microstrip patch antennas are excited. The cylindrical parasitic elements are used as omnidirectional radiators. The element separation is 0.7 λ . Five radiation elements are employed for the upper and lower antennas, respectively. Antennas are covered with a radome whose diameter is 17 mm. Antenna beam-width in the vertical plane is 16°; antenna gain is 7.5 dBi.

5.9. Adaptive Array Antenna [40]

Among the endeavors to reduce the interference and improve the spectrum efficiency, as transmitting data and the number of users are increasing, the adaptive array antenna has been one of the most significant areas of study for antenna engineers. The first testbed for base stations in mobile communications in Japan was developed by the CRL (Communication Research Laboratories) in 1989. The four-element square array with an element spacing of 0.444λ was used and 256-kbps GMSK signals sent by a mobile station were received by the base station. Reduction of intersymbol interference (ISI) and about

20 dB improvement in E_b/N_0 performance with BER of 10^{-2} were obtained in the practical field test [41]. Since then, research activities concerned with the adaptive array antenna increased dramatically after 1995, aiming at application to PHS and IMT-2000.

The adaptive array system was first introduced in 1998. The block diagram of an adaptive base station antenna applied to PHS is shown in Fig. 56 [42]. Four antennas are used for transmission and reception. Adequate weight is determined in the CPU module for the output signal of each antenna to achieve the best BER value by using the constant-modulus algorithm (CMA) concept. An

Table 7. Specifications of Polarization Diversity Antenna (from [1] with permission from Wiley)

a. Electrical Specifications			
Type	AN-951-1	AN-951-3	
Antenna element	Array of two printed dipoles		
Frequency range	818–958 MHz		
Gain	16 dBi	12 dBi	
VSWR	1.5		
– 3 dB beamwidth (vertical plane)	~ 18°	~ 5.5°	
– 3 dB beamwidth (horizontal plane)	~ 70°		
Cross-polarization ratio	> 30 dB		
Isolation between V–H ports	> 40 dB		
Isolation between sector beams	> 40 dB		
b. Mechanical Specifications			
Type	AN-951-1	AN-951-3	
Radome height	~ 3200 mm	~ 1200 mm	
Radome diameter	239 mm		
Rated wind velocity	60 m/s (survival)		
Connector	BFX-20D		
Weight (with electrical tilt box)	~ 124 kg	~ 94 kg	

antenna radiation pattern maximum is achieved in the desired signal direction, and pattern nulls are achieved in the undesired signal directions. An example of a practical base-station adaptive antenna is shown in Fig. 57. Each antenna has gain of 10 dBi. Antenna spacing is 5 wavelengths. A radio unit is installed at the foot of the antenna.

A study to determine antenna spacing has been conducted [43]. The antenna setup is shown in Fig. 58. In this case, four $\frac{1}{2}\lambda$ dipole antennas are used for the base-station antenna. Here the antenna spacing is denoted as d . The measured results of SINR (signal-to-interference noise ratio) for various antenna spacing are shown in Fig. 59. Here, Φ_d and Φ_i , respectively, denote the direction of desired signal and interference. In every interference angle, SINR increases for wide antenna spacing. SINR saturates

near the antenna spacing of 5 wavelengths. Hence, antenna spacing of a base station is determined to be 5 wavelengths.

Variations in the antenna radiation pattern in the case of interference suppression are shown in Fig. 60 [44]. A deep pattern null is achieved in the direction of interference. Adaptive antenna performance of interference suppression is ensured.

A field test was conducted with a conventional space diversity antenna whose transmission power was 500 mW and an adaptive antenna whose total transmission power was 125 mW [45]. Nearly the same communication quality in the same cell size was confirmed. As a result, a 6 dB increase in antenna gain was obtained. Received power was also compared with that of a conventional diversity antenna. The average received power of the adaptive antenna was 3 dB higher than that of the conventional diversity antenna.

5.10. Adaptive Array Antenna for Wireless Local Loop (WLL) [46]

An adaptive array antenna system (AAAS) applied to the WLL system is called super-*PHS-WLL*, because the PHS standards are applied to the WLL, and wideband radios and spatial channel processing are employed to enhance system performance. By means of adaptive beamforming, the channel capacity is increased, the number of multipath signals is reduced, the coverage is expanded, and the flexible configuration of the coverage for each base station to match the local propagation environment is made feasible.

The system concept is briefly illustrated in Fig. 61 with an example of a system configuration composed of a BS (base station), single- and four-line SUs (subscriber units), and connection to the local exchange. The operating frequency of the system is the same as that of the PHS (1880–1930 MHz), and the TDMA-SDMA system for channel access and the duplex system TDD (time-division duplex) are employed.

Figure 50. Horizontal plane patterns of three-sector antenna in vertical and horizontal polarizations. (From [1] with permission from Wiley.)

Figure 51. Cross-polarization characteristics of polarization diversity antenna. (From [1] with permission from Wiley.)

The AAAS, which produces multibeam by DBF (digital beamforming) technology, performs the function of SDMA. The beams automatically direct to a plural number of SUs, wherever they are located. The received signal at the BS in the multipath environment is processed adaptively to enhance the processing gain, thereby improving the quality of the link. It also contributes to rejection of interference by directing a null against it and enhancing the reuse of the same frequency, thereby increasing the number of channels.

The system performance that can dynamically adapt to the changeable propagation environment is achieved by DBF technology. The DBF software processes in real time the phase and the time differences among the incoming signals in the multipath environment so that the signal transmission can be directed to each desired SU. By this means a stable and robust link can be established.

Other factors that enhance channel capacity are the multiple-frequency operation using a plural number of wideband radios in addition to the AAAS and use of the PHS standard TDD, which has four timeslots in one da-

taframe that can be used for both transmitting and receiving four channels at the same time in one frequency.

A base station of the super-PHS-WLL system, which has been operated, consists of 12 antennas and 12 radios, and uses 16 radiofrequencies for 16-multiplex operation. By combining the spatial channel processing with the AAAS, a spatial channel efficiency of ~ 2.5 is achieved. Consequently, the voice channel capacity achieved is ≤ 155 ; that is, 4 (timeslot) \times 16 (frequency) \times 2.5 (spatial channel efficiency) $- 5$ (control channel). It can serve 2730 subscribers as the total traffic capacity, and is capable of covering up to ~ 15 km.

6. ANTENNAS FOR SMALL MOBILE TERMINALS

6.1. Technical Subjects Pertaining to Design of Small Mobile Terminal Antennas

In designing antennas for handsets, the first considerations are generally that the antennas should have

- Small size
- Light weight
- Compact structure
- Low profile, or flush mounting
- Robustness
- Flexibility
- Low cost

plus additional requirements for specific applications. Parameters pertaining to communication system, propagation problems, and environmental conditions, are summarized in Fig. 1. In fact, all of these parameters should generally be considered in the handset antenna design. When systems require particular specifications, the antenna should be designed specifically to satisfy the requirements, depending on the systems. Propagation problems have now been diversified to include complicated environments such as indoor malls, subway stations, and bridge underpasses. Also, problems now include

Figure 52. Planar notched structure two-element half-wave dipole antenna. (From [23] with permission from IEICE.)

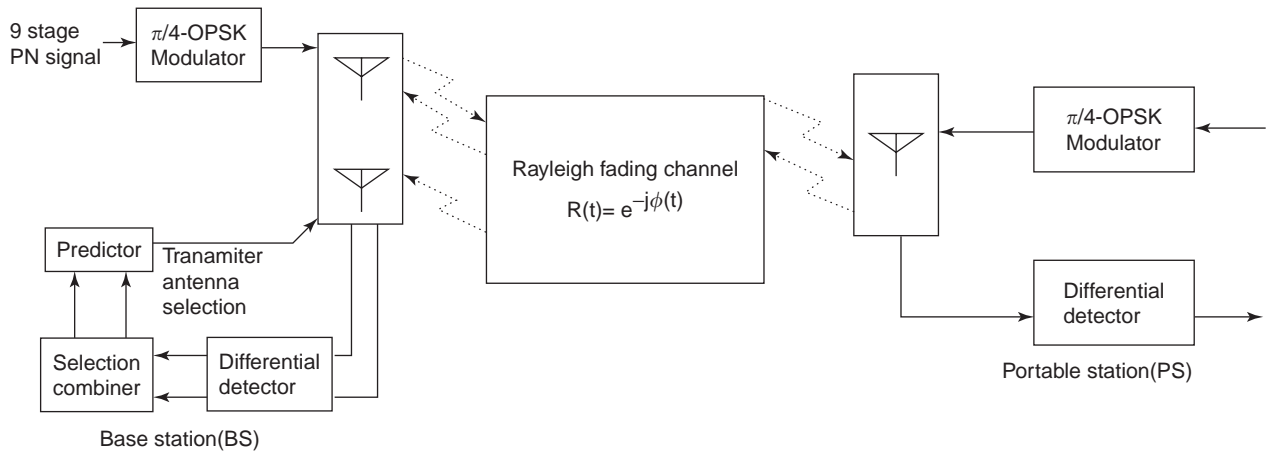

Figure 53. Block diagram of linear predictive transmitting diversity antenna system. (From [1] with permission from Wiley.)

higher-frequency regions such as microwaves and millimeter waves.

6.2. Design Concept of Antenna Systems for Small Mobile Terminals [47]

Figure 1 presents essential parameters necessary for designing antenna systems for mobile communications. Antenna design, as was mentioned previously, relates to system requirements, propagation problems, and environmental conditions. When designing an antenna, whether for a fixed station or a mobile station, designers should factor in these parameters.

In the 1950s and 1960s, antennas used for mobile terminals were mostly simple monopoles of about a quarter-wavelength. A monopole was usually mounted on top of the equipment case, as shown in Fig. 62. Figure 63a illustrates a model of this type of antenna. Since the case was

made of metal in those days, it was simply considered as a group plane (GPL), as shown in Fig. 63b. By taking the image of the antenna element into account, the model was treated as a half-wave dipole, as shown in Fig. 63c. Thus no particular attention was paid to designing this sort of antenna at that time, and just a quarter-wavelength element was used. When an antenna for small portable equipment was designed, the concept was expanded to consider the body of the equipment as a part of antenna, since it was noted that the antenna image could hardly be considered while current flow on the equipment body should have been accounted for. The model shown in Fig. 63 equivalently illustrates an antenna system that is composed of a monopole and the (metal) case. This model can be treated equivalently by an asymmetric dipole as shown in Fig. 64 and is further decomposed into two parts: a short, thick dipole and a long, thin dipole as shown in Fig. 65. Decomposed two parts are equivalently expressed

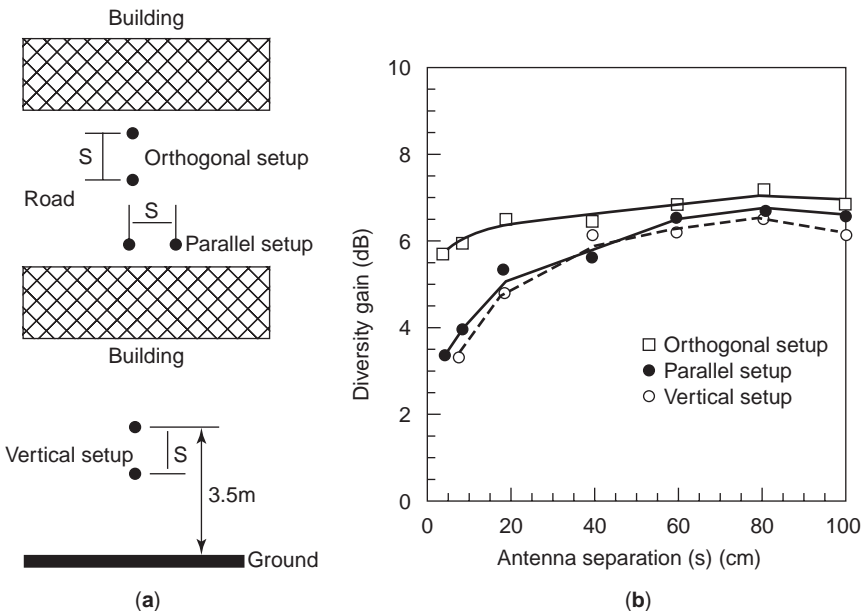

Figure 54. Diversity antenna: (a) antenna installation; (b) diversity gain. (From [1] with permission from Wiley.)

Figure 55. Configuration of typical omnidirectional collinear antenna. (From [23] with permission from IEICE.)

by two dipoles: one thin and long dipole and another one thick and short dipole. The antenna system shown in Fig. 64 is then treated as a parallel combination of these two dipoles. This was the first treatment that illustrated the concept in which the case was considered to be a part of the radiator [48]. However, this concept was not recognized until a detailed analysis of the antenna system was introduced, and the contribution of the case to the radia-

tion was clarified [49]. Through the analysis, the current distributions on the case as well as on the antenna element were shown for various dimensions of antenna element and the case. It was clarified that currents on the case, excited by the antenna element, may contribute to producing fields that have horizontal as well as vertical polarization, although this depends on the dimensions of the case. The more interesting result was that almost no

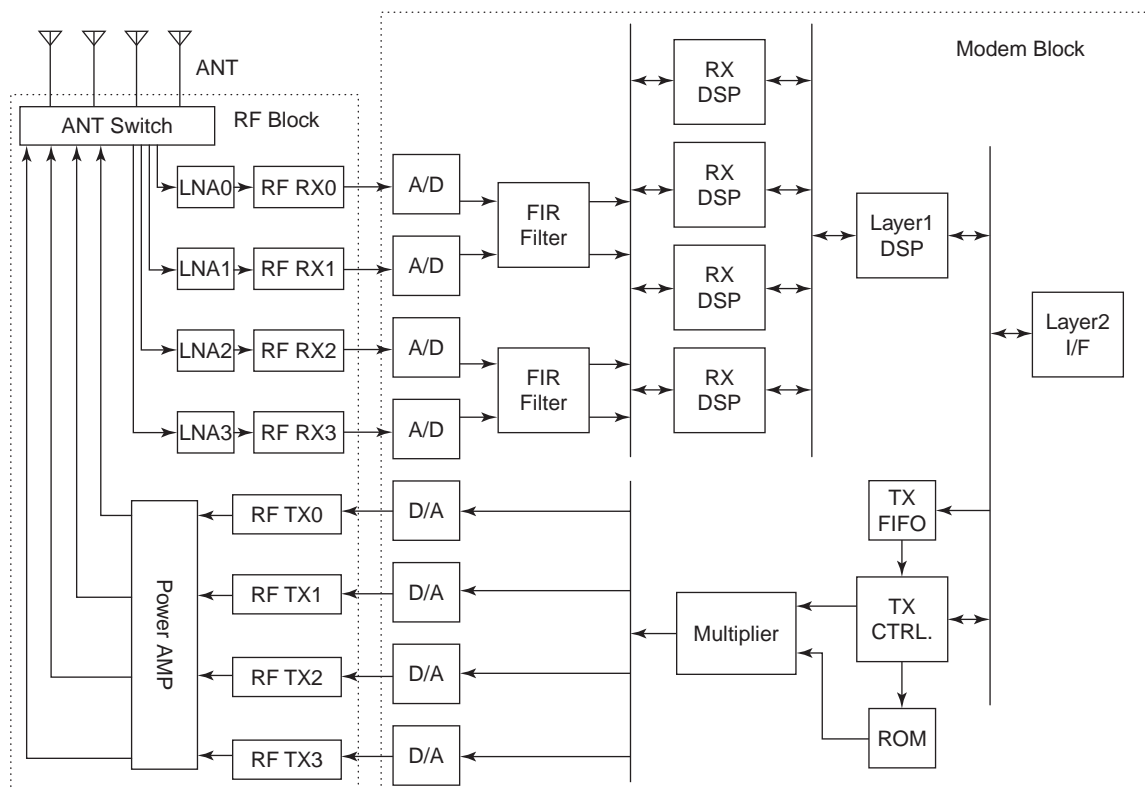

Figure 56. Block diagram of adaptive antenna system for a base station. (From [1] with permission from Wiley.)

Figure 57. An example of practical base-station adaptive antenna. (From [1] with permission from Wiley.)

current flow on the case was observed in the system where a half-wavelength element was used. This was advantageous in reducing the influence of the user's hand on antenna performance, because the variation of impedance or frequency due to the handheld effect can be decreased as a result of a reduction in the current on the case. In practice, however, a half-wavelength element that is fed between the element and the case cannot be used, because the feedpoint impedance becomes very high. Instead, a monopole with length of $\frac{3}{8}\lambda$ or $\frac{5}{8}\lambda$ has been employed in practice for PDC handsets or other mobile terminals, since it has the appropriate input impedance for matching to the load and yet the current flow on the case is very small. It is very interesting to note that the analysis presented in Ref. 49 provided the essential design concept for developing antennas for PDC handsets and other small mobile terminals presently used.

Figure 58. Base-station antenna setup for determining spacing. (From [1] with permission from Wiley.)

Figure 59. SINR characteristics with respect to antenna spacing d . (From [1] with permission from Wiley.)

From the 1980s to present, downsizing of mobile terminals has made remarkable progress and, accordingly, antenna size, except for monopole elements, has accordingly decreased. The downsizing was advantageous for users; however, it posed a serious problem for antenna designers, as the antenna design should be such that antenna performance should remain unchanged, even though the antenna size becomes more compact. Fortunately, this problem has not been widely experienced, as antenna performance was not as significantly degraded as was expected. There was the assistance of the conducting materials existing in the equipment, which contributed to radiation as part of the radiator. The typical conducting material in the equipment is a rectangular shielding plate or box, where RF and other circuits are included. Usually a built-in antenna element is placed on this plate or box, and it acts as a ground plane (GPL). As a GPL performs as a part of radiator, when a small antenna element is placed on it and induces current on it, the antenna size is equivalently increased, and hence antenna performance is enhanced. Antenna gain and bandwidth may be increased, although this depends on the size of GPL and the type of antenna. A typical example of GPL performance can be observed in PDC handsets, where a PIFA is used as a built-in antenna. A bandwidth of $\leq 17\%$ can be achieved, although that of a PIFA in free space is ordinarily only

Figure 60. Radiation patterns with and without interference. (From [1] with permission from Wiley.)

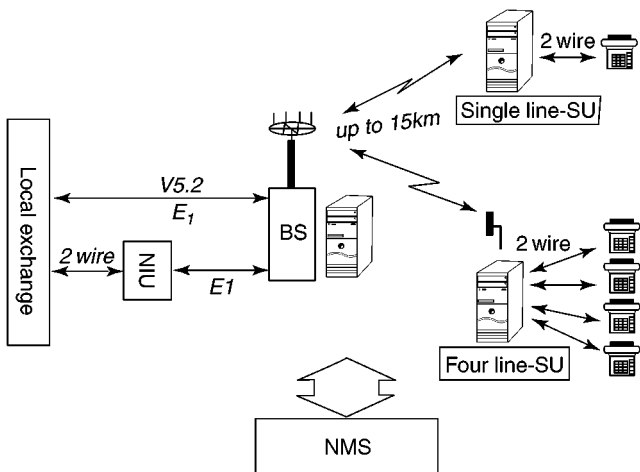

Figure 61. System concept of PHS WLL. (From [41] with permission from IEEE.)

1–2%. A gain increase of several decibels is also observed. It is interesting to note that the GPL had been used as part of the radiator without any conscious effort; that is, it was not intentionally applied in the design of small handset antennas.

Effective use of a GPL can be seen in another case, where the radiation mode is increased with the help of current on the GPL. Modal increase in is one of the most significant concepts for developing a small antenna. By introducing multimode into a small antenna system, enhanced antenna performance may be expected, so that a practically useful small antenna may be realized. This concept was applied to a pager antenna system, where a small rectangular loop antenna was used [50], and a dipole mode was produced in addition to the loop mode. Figure 66 shows the antenna model, where a coaxial cable is

Figure 62. Monopole antenna placed on the top of small portable equipment. (From [47] with permission from IEEE.)

Figure 63. Model of portable equipment with a monopole: (a) equivalent expression; (b) monopole on the ground plane; (c) equivalent dipole. (From [47] with permission from IEEE.)

directly connected to the loop input terminal without using a balun. The direct connection of a balanced system (the loop terminal) to an unbalanced line (a coaxial cable) is not common; however, the connection was intentionally done in order to produce the dipole mode in the antenna system. By this means, unbalanced currents are produced on the terminals and then flow into both the ground parts (GPL) of the printed-circuit board (PCB) and the surface of the loop element. These unbalanced currents lead to produce a dipole mode (Fig. 67a) in addition to the loop mode (Fig. 67b). Then, the radiation pattern, which is actually the receiving pattern, is almost omnidirectional as a result of the combined patterns of the loop and the dipole, with a 90° phase difference. In addition, combination of both the dipole and the loop modes produces receiving patterns that allow the pager to have appreciable sensitivity in various situations, for example, with the pager unit laid down, or placed so as to stand erect on a desk. This concept—the use of a dual mode, similar to the loop and dipole—is very useful for creating small antennas. The dual mode may be a combination of electric and magnetic modes, or inductive and capacitive modes, and so on. It can be applied in designing antennas for any other small antenna terminals.

There are both advantages and disadvantages in utilizing current on the GPL inside mobile terminals. The advantage is the enhancement of antenna performance.

Figure 64. An asymmetric dipole consisting of a monopole and portable equipment. (From [47] with permission from IEEE.)

Figure 65. Equivalent models of antenna shown in Fig. 64: (a) equivalent expression with a thin, long monopole and a thick, short monopole, standing on the ground plane and (b) their equivalent expression with dipoles, taking out the ground plane. (From [47] with permission from IEEE.)

On the contrary, the disadvantage is the possible degradation of antenna performance due to the effect of adjacent materials, including the human body. In fact, more than 6 dB gain degradation has been observed in the talk position of mobile phones, mainly due to the effect of a user's hand. A hand holding a handset varies the currents on the GPL, and thus the impedance and frequency, so that antenna gain and efficiency deteriorate. The human head, when the handset is at talk position, also varies antenna performance in the same way as does the hand. Antenna gain is also decreased by the influence of the hand and the head, which both absorb radiation power.

With the increase in current distribution on the GPL inside the handsets, the radiation toward the human head may increase, and so would the SAR (specific absorption rate). To reduce the undesired radiation toward the human head and thus the SAR value in the head, the appropriate selection of antenna type, the method of feeding it, and the place and method of mounting the antenna element on the equipment should all be seriously considered. Thus, fur-

Figure 66. Schematic expression of a pager antenna system. (From [47] with permission from IEEE.)

Figure 67. Equivalent expression of a pager antenna system; (a) dipole mode; (b) loop mode. (From [47] with permission from IEEE.)

ther consideration in designing the handheld phone antenna is needed in order to improve the SAR problem and antenna performance at the same time.

Use of an internal antenna, replacing a monopole, which has long been used in mobile terminals, is a trend in today's mobile terminals. Possible antenna characteristics desired for the latest mobile terminals are to have

1. A magnetic current as a radiating source
2. Balance
3. Two modes (e.g., two polarization components)

For item 1 the objective is to create a built-in antenna by making an antenna small and of low profile, or flush-mounted. A magnetic current source, such as a loop or slot, is effectively used by being placed on the GPL such that the source current is parallel to the GPL. With this structure, the EM field produced in front of the GPL is doubled by the additional field due to the image of the source current. As a result, antenna gain is doubled, compared with an antenna system in free space, yet the antenna is small and of low profile. By adequate balancing (item 2), the currents on the GPL, generated by the antenna element, can be reduced, so that the human body effect can be mitigated. In practice, a loop, a normal-mode helical dipole, a meanderline dipole, and any other type of antenna having a balanced structure, so that no unbalanced current flow is generated on the GPL, can be used for this purpose. As for item 3, it has been shown that an antenna having two modes such as a dipole and a loop can contribute to enhance antenna performance so that antenna size is minimized. In other aspects, an antenna having two polarizations components, such as vertical and horizontal polarizations, can, to some extent, reduce multipath fading [51]. An L-shaped loop [52] can be used as one of the candidates for this purpose.

Now, by combining any one or all of items 1, 2, and 3 with the conventional design concept, an advanced antenna system can be developed. Item 3 indicates that the GPL is not purposely utilized for enhancing antenna performance, but rather is separate from the antenna system. This is then an advanced concept that should be applied

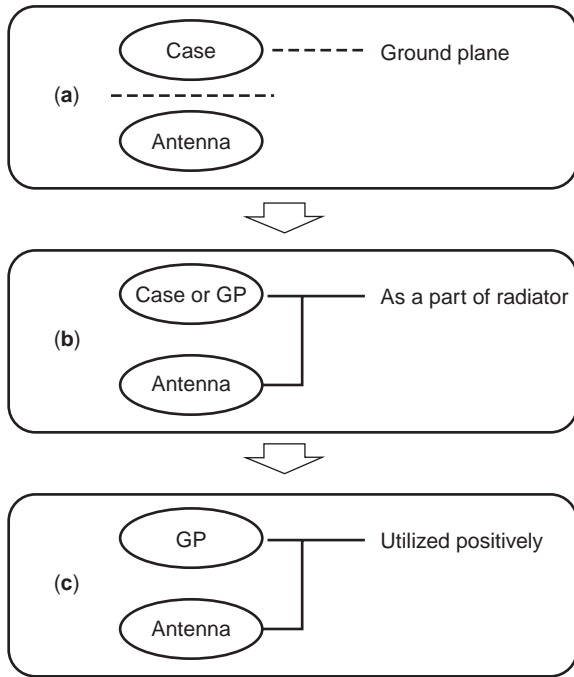

Figure 68. Three stages in development of antenna design concept. (From [47] with permission from IEEE.)

for designing an antenna, which should be developed further.

The design concept explained above is depicted in Fig. 68, where the steps are as follows:

- First stage*—use of a quarter-wavelength monopole and its image
- Second stage*—combined design of a monopole and the equipment case (metal) as a radiator
- Third stage*—utilization of GPL to enhance performance of a built-in small antenna
- Fourth stage*—separation of GPL from the antenna system

The next stage will be design of antenna with a concept in which the device, function, or software is integrated into an antenna system so that sophisticated functions such as adaptive control and signal processing can be achieved. Applying the concept of an integrated antenna system (IAS) is a promising way to realize such antennas. Unification of a device into an antenna structure will bring a new antenna having enhanced performance, or improved characteristics. Integration of functions or software into the antenna structure may also create a new antenna system that performs with intelligence. Figure 69 illustrates this concept.

6.3. Typical Antenna Elements Used for Mobile Terminals

Typical antenna elements used for small mobile terminals include MP (monopole), NMHA (normal-mode helical antenna), PIFA (planar inverted-F antenna), ceramic chip, meanderline, and MSA (microstrip antenna). A majority of PDC mobile terminals employ an MP element and a

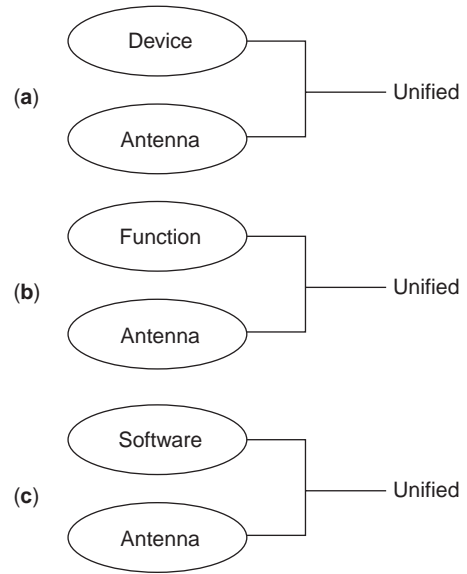

Figure 69. Advanced concept of antenna design. (From [47] with permission from IEEE.)

built-in PIFA as a pair element of diversity antenna (Fig. 70). An NMHA element placed on the top of an MP element was formerly used as an extension of the MP element in order to reduce the length of the MP; however, the design concept has been modified to employ an NMHA element as the replacement of the MP, when the MP element is retracted into the handset unit. An NMHA element has been used as the main antenna of PHS mobile terminals, since the operating frequency is 1.5 GHz, so that the antenna length can be short enough to be directly mounted on the unit body.

6.3.1. Monopole. Monopole is the most simple, thin, lightweight, low-cost, and hence useful as an antenna element for small mobile terminals. Hence it has long been

Figure 70. Antenna systems in PDC. (From [1] with permission from Wiley.)

Figure 71. Gain of a monopole with respect to the length of housing. (From [1] with permission from Wiley.)

used as typical antenna element for small mobile terminals.

Antenna performance depends on not only antenna element but also the dimensions of the ground plane, on which the antenna element is mounted. Figure 71 illustrates MP gain with respect to the length of housing when mounted on a rectangular conducting box [53]. The dimensions of the box are shown in the figure. Current distributions on the antenna element and the surface of the box are shown in Fig. 72, for (a) a case where a $\frac{1}{4}\lambda$ MP is used (a) and a case where a $\frac{1}{2}\lambda$ dipole is fed at its bottom (b) [54]. Amplitude of the current distributions is shown by hatched lines. The current distributions are obtained by using a wire grid model, in which the method of moments is applied. When the element length S is $\frac{3}{8}\lambda$ or $\frac{5}{8}\lambda$, current flows are observed to be relatively small as shown in Fig. 73, and yet input impedance characteristics are adequate to match the load impedance as shown in Fig. 74 [55].

6.3.2. Normal-Mode Helical Antenna (NMHA). In order to keep the antenna small, a traveling-wave structure is utilized, and NMHA is a typical example of this design. NMHA is a helical antenna that radiates in the direction normal to the helical axis, and the radiation patterns are essentially the same as that of a short dipole (Fig. 75). The dimensions of the helix are usually much smaller than the operating wavelength; the length of an individual turn is a small fraction of a wavelength λ , and the axial length is also much less than $\frac{1}{4}\lambda$. With this structure, a NMHA is

equivalently expressed by an array of small loops and short monopoles (Fig. 76) [56]. Inductive impedance is increased by the array of loops and compensates the capacitive impedance of short monopoles. As a consequence, the helical structure can be arranged to have self-resonance property, although the antenna length (in the axial direction) is considerably shorter than that of a conventional resonant-monopole or dipole antenna. In this way the antenna efficiency can be improved and extension of the antenna length may lead to increased bandwidth. The NMHA has been used in modern mobile phones worldwide.

The antenna model shown in Fig. 77 is considered [57]. The impedance characteristics of an antenna with dimensions of helical diameter $D_h = 0.018\lambda$, pitch $P = 0.006\lambda$, and wire diameter $2a = 0.0002\lambda$ are shown in Fig. 78, where the number of turns M_T used as a parameter. Figure 79 shows the radiation efficiency with respect to the pitch P . Figure 80 illustrates the relationships between D_h and P . Figure 80a shows the parameter used for the number of turns M_T , while Fig. 80b shows the radiation resistance R at resonance.

6.3.3. Meanderline Antenna. The meanderline antenna also has the traveling-wave structure, which enables reduction of the antenna length. It has a periodical array structure of alternative square patterns as shown in Fig. 81. With this pattern, the extended wire can be made much longer than the initial antenna (dipole)

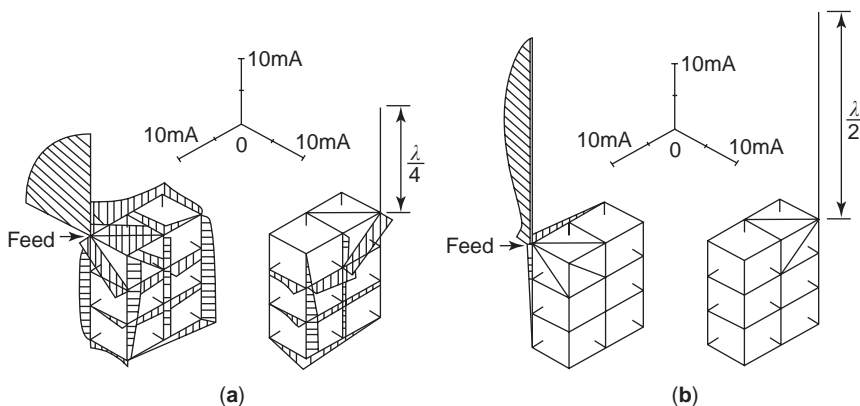

Figure 72. Current distributions on the antenna element and the surface of the rectangular conducting box: (a) a bottom-fed $\frac{1}{4}\lambda$ MP; (b) a bottom-fed $\frac{1}{2}\lambda$ dipole. (From [49] with permission from IEICE.)

Figure 79. Radiation efficiency ρ versus number of turns MT . (From [50] with permission from Research Studies Press.)

length, so that the self-resonance can be attained. The resonance frequency is then lower and radiation resistance is higher than that of a dipole of the same length. This in turn implies that the antenna is effectively made small.

In this section a meanderline dipole antenna, such as that shown in Fig. 81, where dimensional parameters are given, is considered [58]. Figure 82 shows the equivalent expression of the antenna, which consists of a series connection of short-circuited two-wire transmission lines (a) and a monopole (b). Using this model, design parameters can be found. At first, a relationship between the resonance frequency f_0 and the wire diameter b /pitch p is obtained as shown in Fig. 83. Here the planar line of width b is replaced equivalently by a wire of diameter d . When the resonance frequency f_0 is given, the number of turns N can be determined with prior knowledge of the wire radius b and the antenna width w using Fig. 84. As the antenna length becomes shorter, the radiation resistance R_{rad} decreases. The ratio of R_{rad} of a meanderline antenna to that of a half-wave dipole is shown in Fig. 85 as a function of the antenna size reduction ratio R_e in comparison with a half-wave dipole. Figure 86 shows radiation efficiency η and number of turns N with respect to the length l of the antenna.

When a meanderline monopole antenna is placed on a finite ground plane ($59 \times 25.4 \text{ mm}^2$) as shown in Fig. 87 [59], variation of the input impedance with respect to the antenna length L_{ax} is as shown in Fig. 88. When the antenna length $L_{\text{a,x}}$ is 73 mm and the number of segments is

Figure 81. Meanderline antenna. (From [58] with permission from IEICE.)

48, resonance occurs at two frequencies, 0.95 and 2.39 GHz (two-band operation), and the resonance impedance is about 25Ω at these two frequencies. Figure 89 shows the first resonance frequency f_0 versus antenna length L_{ax} . The empirical equation is derived as

$$f_0 = 22.69 L_{\text{ax}}^{-0.7392} \quad (5)$$

when $e_1 = e_2 = 3 \text{ mm}$, the substrate thickness t_s and width W_s are 3.17 mm and 11 mm, respectively, and the size of the ground plane is $59 \times 29.4 \text{ mm}^2$.

6.3.4. Inverted-F Antenna (IFA). The IFA shown in Fig. 90 can be treated in the same way as the antenna shown in Fig. 91a with its image. The IFA shown in Fig. 91a is equivalently decomposed into two parts: an ILA with its image (b) and two 2-wire short-circuited-transmission lines (c). The two-wire transmission lines compensate capacitive impedance of the ILA and at the same time step up the input impedance so that matching to the 50- Ω load is made feasible. The input impedance of IFA is expressed by

$$Z_{\text{in}} = 4Z_a \cap 2Z_b \quad (6)$$

where Z_a denotes the input impedance of the antenna shown in Fig. 91b, Z_b is the impedance of the short-circuited two-wire transmission line with length h and width S , and \cap expresses the parallel combination of impedances.

The input impedance of an IFA can be adjusted by selecting S and h , appropriately. An example is shown in Fig. 92 [60].

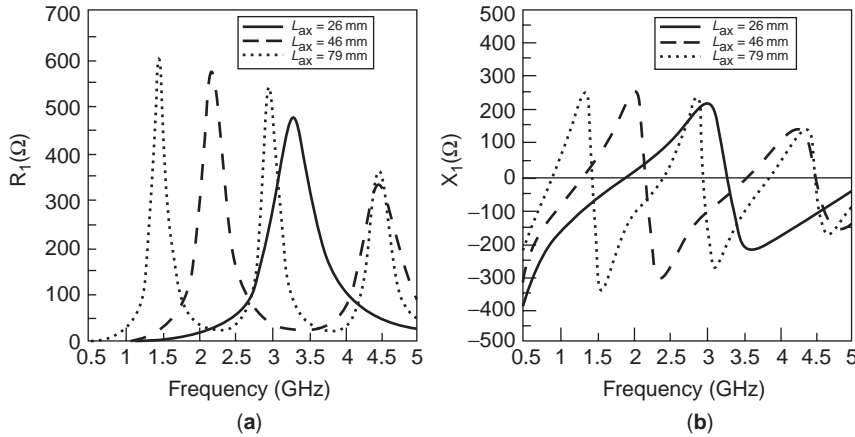

Figure 88. Variation of input impedance of a meanderline antenna versus antenna length. (From [59] with permission from CRC.)

6.3.5. Planar Inverted-F Antenna (PIFA). The planar inverted-F antenna is apparently a modification of the IFA with replacement of the IFA’s linear horizontal element with a planar element. However, the PIFA differs from the IFA in its radiation principle. The PIFA’s source of radiation is the magnetic current on the peripheral aperture of the planar element, whereas that of IFA is the electric currents on the linear F-shaped vertical and horizontal elements. In addition, the peripheral aperture of the PIFA measures about a half-wavelength, whereas that of the IFA is about a quarter-wavelength.

Study of the PIFA structure has initially started with a half-wave slot placed on the side of a rectangular conducting body as shown in Fig. 93a. The slot is fed at a point near a short-circuited end in order to attain adequate impedance to match the load impedance. The idea was born in the process of development of handset antennas. The basic concept was to develop a small, low-profile antenna suitable for handset units. In order to ensure a low-profile or flush-mount structure, use of a magnetic current as a

source of radiation was considered. The slot antenna satisfies this requirement. Meanwhile, the microstrip antenna (MSA) had been known as a useful planar antenna, having a small and low-profile structure. Then an attempt was made to place that slot antenna on a ground plane to form a planar structure such as an MSA (Fig. 93b), and the performance was confirmed to be satisfactory for handset use. Finally, the antenna configuration was formulated to achieve the structure illustrated in Fig. 93c, in which the short-circuited part is reduced to decrease the antenna size. In a PIFA, the peripheral aperture of a half-wavelength contributes to radiation, whereas in MSA a patch end aperture of about a quarter-wavelength contributes to radiation.

In fact, an attempt was initially made to increase the bandwidth of a linear IFA by replacing the linear horizontal element with a planar element; however, this was not successful, as the bandwidth increase obtained was only 1–2%, unless otherwise increasing the height.

An example of the input impedance ($R + jX$) of a similar antenna model is shown in Fig. 94a [61]. The equivalent circuit of this antenna model is shown in Fig. 94b. It is interesting to note that in the equivalent circuit there is a reactance jX_a . The bandwidth enhancement of an antenna system, composed of a PIFA element placed on the handset unit, may attribute to this reactance. This reactance has constant impedance over a bandwidth much wider than that of the antenna system.

There are many variations of the PIFA element in practice. In fact, some PIFA elements can hardly be identified as PIFA components because the modified antenna structure differs entirely from the original structure.

6.3.6. Ceramic Chip Antenna. The ceramic chip antenna is a small ceramic bulk antenna in appearance, but is

Figure 89. The first resonance frequency of a meanderline antenna versus antenna length. (From [59] with permission from CRC.)

Figure 90. Inverted-F antenna.

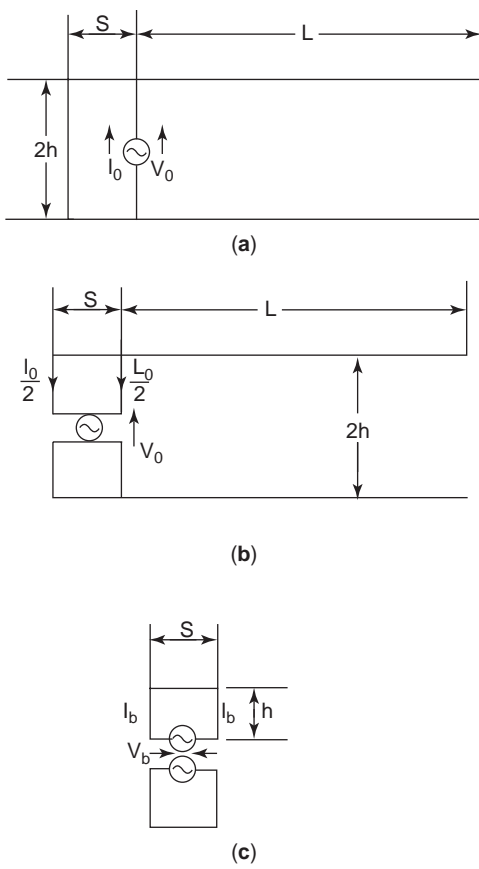

Figure 91. Equivalent expressions: (a) antenna model with its image element; (b) an IFA with its image; (c) two 2-wire transmission lines.

composed of an antenna element encapsulated by the ceramic material of high relative permeability. The antenna element is printed on the ceramic substrate and encapsulated by the ceramic material, which usually has a high

relative permeability of ≥ 20 . As a typical element, the meanderline, inverted-F, normal-mode helix, or other planar pattern is used. Use of plate ceramic, on which the antenna element is printed, is typical; however, there is another type—a small but bulky substrate that is structured with multi-layered very thin ceramic sheet, in which the antenna element is encapsulated. The antenna elements printed on the top and bottom surfaces of the ceramic substrate are connected by via wires.

One of the smallest ceramic chip antennas is 1.6 mm wide, 3.2 mm long, and 1.3 mm high as depicted in Fig. 95. This may be the world's smallest antenna at present; Fig. 96 illustrates an exploded view of the antenna structure. The thin ceramic substrate is composed of multilayered thin ceramic sheets. The antenna element used is a normal-mode helix, which is formed in the substrate by connecting printed patterns on the top- and bottom-layer via wires. This antenna has been used for small mobile terminals, in which the antenna is placed on a corner of the ground plane (GPL) as shown in Fig. 97. Usually a small part of the ground plane beneath the antenna element is taken out in order to avoid excessive loss due to the GPL. However, the antenna needs the help of the GPL; in other words, this antenna actually excites the GPL so that the small antenna and the GPL work as a combined antenna system. Thus the antenna performance depends on the size of the GPL, and how and where the antenna element is placed on the GPL.

Some examples of practical applications of small ceramic chip antenna are shown in Fig. 98, in which antenna mounting, operating frequency, antenna performance such as gain, bandwidth, and radiation patterns are illustrated.

In this type of antenna the resonant frequency can be controlled by the antennas flexible structure, and reasonably high gain and wide bandwidth may be realized, in addition to very small size and very light weight. Typically, this antenna has a gain of -5 to $+10$ dBi and a bandwidth of ~ 100 MHz in 5-GHz regions.

6.4. Antennas for Small Mobile Terminals

6.4.1. Handset Antennas. The handset antenna used for the PDC system is an example that employs a monopole (MP), a normal-mode helical antenna (NMHA), and a planar inverted-F antenna (PIFA), as shown in Fig. 99 [62].

Figure 99. Antennas for a PDC handset. (From [63] with permission from IEICE.)

The NMHA element is placed on top of the MP. The MP element and the NMHA element are separated electrically. In the transmitting/receiving mode, the MP element is extracted outside the handset case and fed at the bottom. The NMHA is not active in this situation; only the MP element is operational. In the receiving mode, as the MP element is retracted inside the handset case and its bottom is disconnected from the feed terminals, only the NMHA acts as an antenna. In Fig. 99a, the MP element

Figure 100. A meanderline helix used for small mobile terminals. (From [63] with permission from IEICE.)

Figure 101. Current distributions on an antenna element and the unit: (a) $L_W \frac{1}{4}\lambda$ and L_Z 125 mm; (b) $L_W 0.54\lambda$ and L_Z 125 mm; (c) $L_W \frac{1}{4}\lambda$ and L_Z 83 mm. (From [1] and [64] with permission from Wiley and IEICE, respectively.)

is extracted from the unit and in Fig. 99b, it is retracted inside the unit.

The typical length of the MP element is either $\frac{3}{8}\lambda$ or $\frac{5}{8}\lambda$, because with these lengths, relatively small current flows on the handset unit and yet a better input impedance to match the load impedance is achieved than with $\frac{1}{2}\lambda$ and other lengths (Fig. 74) [55].

The typical length (extended) of the NMHA is about $\frac{1}{4}\lambda$. Lengths other than $\frac{1}{4}\lambda$ may be used if, for instance, a particular input impedance is specified. The gain of this type of antenna is generally about -0.5 dBd peak and about -9 dBd average in the horizontal plane, when the length is about $\frac{1}{4}\lambda$; however, this varies depending on the length of the handset unit.

A meanderline helix, shown in Fig. 100, has been used in some mobile terminals instead of NMHA [63].

Figure 102. Antenna model used for the analysis: (a) dimensions and (b) wire grid model. (From [1] and [58] with permission from Wiley and IEICE, respectively.)

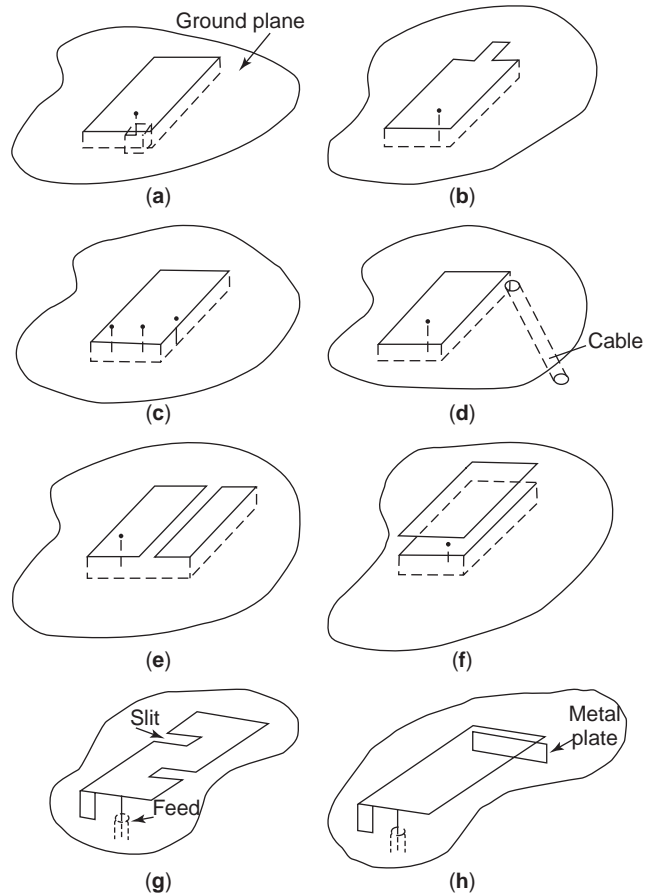

Figure 103. Configurations of planar element to achieve wide bandwidth or multiband operation. (From [1] and [55] with permission from Wiley and Denshi Sohgo Publishing Co., Japan, respectively.)

A PIFA element, a built-in antenna, is placed on the ground plane, which is actually a shielding plate for the RF circuits in the handset unit. The PIFA is employed as a pair of the diversity elements with the MP element. The PIFA is an antenna of rather narrow bandwidth, representing 1–2% in the relative bandwidth in free space. However, when it is mounted on a finite ground plane, the bandwidth usually increases. In practice, the bandwidth of an antenna system, which uses a built-in PIFA element in a handset unit, can be designed to have bandwidth wider than that of the whole-spectrum bandwidth of the PDC system. This is attributed to the handset unit,

Figure 104. Switching circuit for dual-frequency resonance. (From [1] and [55] with permission from Wiley and Denshi Sohgo Publishing Co., Japan, respectively.)

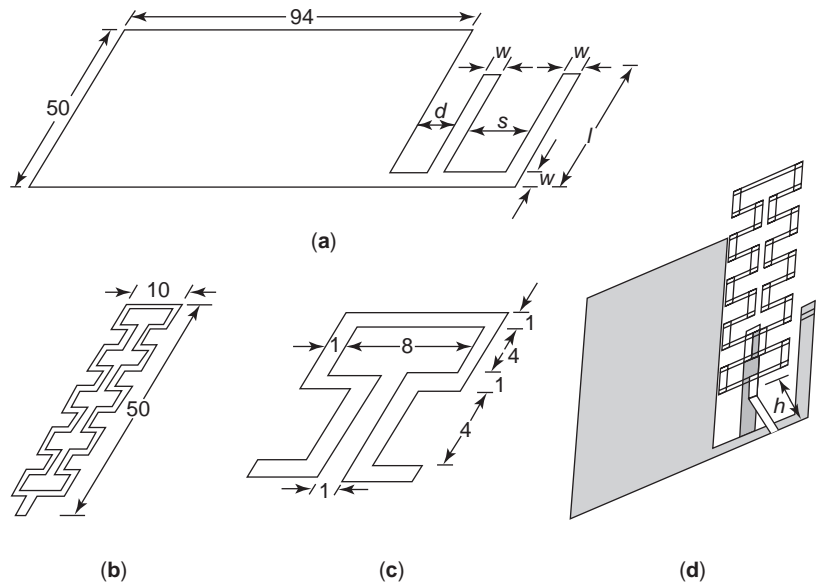

Figure 105. Antenna and printed circuit board (PCB): (a) PCB and parasitic metal strips (layer 1); (b) antenna geometry (layer 2); (c) detail of antenna geometry; (d) antenna height h from PCB. (From [67] with permission from IEEE.)

which acts as a part of the radiator, due to the current flow excited by the PIFA element.

Consequently, the impedance of the antenna system, which consists of an antenna element and the handset unit, is varied by the effect of the handset unit. Figure 101 illustrates an example of the current distributions on an antenna model [64] composed of an MP element, a PIFA element, and the handset unit. Figure 102 shows the antenna model used for the analysis and the dimensions. In the analysis the handset unit is simulated by a rectangular conducting box and modeled with wire grids, and the frequency is 900 MHz [64]. Figure 101 shows the current distributions for cases where (a) the length L_W of the MP = 83 mm ($\lambda/4$) and the length L_Z of the handset unit = 125 mm, (b) $L_W = 180$ mm (0.54λ) and $L_Z = 125$ mm, and (c)

$L_W = 83$ mm ($\lambda/4$) and $L_Z = 83$ mm. The PIFA, measuring 60×35 mm and placed at a distance 12 mm away apart from the handset unit surface, is assumed to be the same in all cases. Amplitudes of the current distributions are illustrated on each wire of the wire grid. The method of moment is applied to obtain these distributions. It has been shown that with an MP element of $\lambda/4$, much current flow on the handset unit is observed, while with that of 0.54λ (nearly a half-wavelength) almost no current flow is observed. This is a very important factor in designing handset antennas.

One of the more recent trends in mobile communications is for multimode handsets, which can operate for such frequency bands as 800 MHz (AMPS), 900 MHz (GSM, PDC), 1.5 GHz (PDC, GPS), 1.9 and 2 GHz (GSM, IMT-2000), 2.4 GHz (Bluetooth), and 5 GHz (WLAN, ITS). Thus, multifrequency antennas are desired. In the PDC system, for example, two bands are used; the lower bands are 810–828 MHz and 940–958 MHz, respectively, for receiving and transmitting, and the higher bands are 1477–1501 MHz and 1429–1453 MHz, respectively, for receiving and transmitting. In IMT-2000, 2-GHz bands are used. In order to design antennas that can operate at multifrequency bands, various techniques are used. The simplest technique is to increase the antenna length so that the resonance occurs at multiple-frequency bands. There are several methods for increasing antenna length; such as using a traveling-wave structure, loading impedance for multiple resonance, and arranging a matching circuit for multifrequency operation. For planar elements, some methods are shown in Fig. 103 [65], where part (a) shows a matching circuit, part (b) uses a small additional piece, part (c) uses additional pins, part (d) uses a cable as a reactance, part (e) shows the addition of a parallel parasitic element, part (f) shows the addition of a stacked element, part (g) uses slits on the planar element, and part (h) shows the addition of a loading element. When the bandwidth required is too wide to be covered by a matching

circuit, a switching circuit is used. An example of such a switching circuit is given in Fig. 104 [66], showing (a) a varactor circuit and (b) VSWRs for two frequencies. A MEMS (microelectronic switching) device can be used for this purpose.

Figure 105 shows an example of a triple-band antenna that uses a driven meanderline element and two coupled parasitic elements. The antenna operates effectively in the AMPS 800 (824–894 MHz), GSM 900 (880–960 MHz), and GSM 1900 (1850–1990 GHz) systems with a VSWR of <math><2.5</math>. The VSWR characteristics are shown in Fig. 106 [67].

Figure 107 shows another example of a multiband antenna composed of two branch elements fed by a short element [68]. The arms have different lengths; one arm is a quarter-wavelength at the lower-frequency region (e.g., GSM 900), while the other has a quarter-wavelength at the higher-frequency region (e.g., DCS 1800 and PCS 190). To shorten the wavelength, the arms can be structured in meanderline, spi-

Figure 115. Radiation pattern of a handset antenna system: (a) in free space; (b) at talk position. (From [1] and [71] with permission from Wiley and IEICE, respectively.)

ral line, or other shapes. Figure 108 depicts the calculated return loss, which shows a dual-band operation.

Figure 109 illustrates a dual-band antenna modified from a PIFA by employing planar meanderline as the radiating element and folded to reduce the antenna size [69]. Return loss characteristics are illustrated in Fig. 110. Two-band operation at 900 and 1800 MHz is achieved with a small volume of $24 \times 10 \times 7.2 \text{ mm}^3$.

Figure 111 illustrates the basic structure of an H-shaped slot antenna that operates at two frequency bands: 2.4 and 5.2 GHz [70]. The basic principle of this antenna originates from an asymmetrically excited slot, on which two magnetic current flows that contribute to radiation in two bands are produced as shown in Fig. 112. By decomposing these two currents, a slot consisting of additional slots at the both right and left ends (Fig. 113), can be constituted and an H-shape antenna is created. VSWR characteristics are shown in Fig. 114. This antenna is designed for application to the Bluetooth (2.4 GHz) and the Wireless LAN systems (5.2 GHz).

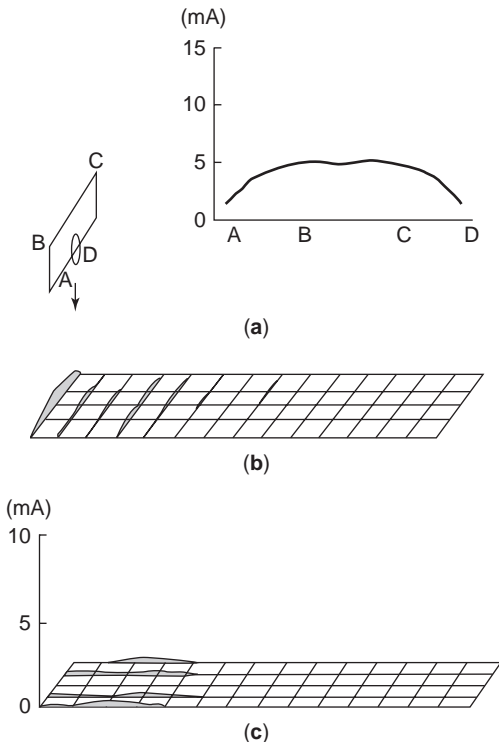

Figure 118. Current distribution in a balanced antenna system (similar to configuration in Fig. 117). (From [1] and [71] with permission from Wiley and IEICE, respectively.)

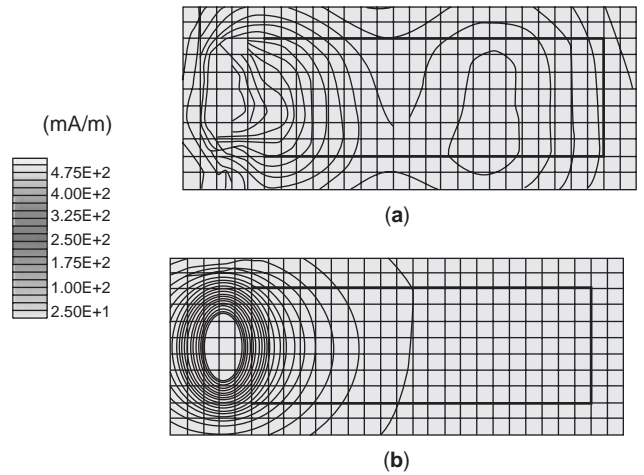

Figure 119. Measured current distributions of loop antenna system: (a) unbalanced system; (b) balanced system. (From [1] and [71] with permission from Wiley and IEICE, respectively.)

Antenna performance of a handset usually degrades at the talk position, due mainly to the effect of the human body such as the operator’s hand and head. The major reason for the degradation is the variation in the current flow on the handset unit. A typical example of distorted radiation patterns caused by the body effect is shown in Fig. 115, with the handset placed in free space and (b) at talk position.

Because the currents on the handset unit are produced by the excitation of the built-in PIFA, its variation is caused mainly by the body effects, the degradation of antenna performance may be avoided by decreasing such current flow. The reduction of such current flow can be realized by means of an antenna system that has balanced terminals and is fed with a balanced line [70]. An example that uses a loop antenna placed on a ground plane and fed with a two-wire line is shown in Fig. 116; Fig. 116a shows the feed with unbalanced line and Fig. 116b, with a balanced line. Figure 117 shows current distributions in an unbalanced structure: (a) on the antenna element, (b) on the ground plane (the y axis), and (c) on the ground plane (the x axis). Figure 118 shows similar current distributions in a balanced structure for comparison with the unbalanced structure. Figure 119 illustrates magnetic field distributions on the surface of the antenna system that correspond to current distributions. Figure 119a shows the distributions in the unbalanced structure and Fig. 119b, in the balanced structure.

Figure 120. Configuration of one-wavelength (1λ) U-shaped dipole antenna (after [72]).

Figure 121. Radiation patterns: (a) in free space; (b) at talk position (after [72]).

It can be seen in Fig. 119 that a significant reduction in current flow can be realized using the balanced antenna structure. The antenna element is not necessarily a loop for this purpose, but any other element such as NMHA or meanderline, can be used, whenever the input terminals are balanced and fed with a balanced line. One should be careful if an antenna system has very asymmetric structure, even when the terminals have balanced structure and are fed with a balanced line. With the asymmetric structure, there may be some difficulty in achieving a truly electrically balanced structure, and thus some unbalanced currents flow at the terminals.

Practical application of a balanced-type antenna is seen in a latest handset. Figure 120 depicts a model of a U-shaped dipole and its dimensions [71]. The antenna has a balanced mode and is fed with a balanced line through a balun. The radiation performance of the antenna is shown in Fig. 121, where radiation patterns in free space and at talk position are shown. The antenna is located on top of the handset as shown in Fig. 122.

6.4.2. Diversity Antenna. It is very common to use two antenna elements in the diversity system. There has been an exception in a type of PDC handset, where a single antenna element is devised to perform diversity function

Figure 122. U-shaped antenna mounted on top of handset (after [72]).

[72]. An antenna is applied to a clam-shell type handset (Fig. 123), which consists of two parts, one of which flips to open and the other, to close the unit. Each of these two parts has circuitry on it, and some radiation currents flow on the ground plane of both parts. Thus they can be used as a radiator component as well as the antenna element. In order to achieve diversity function, the two parts are electrically separated, and two impedance components Z_1 and Z_2 are located between the two parts. This configuration is simplified in Fig. 124, where part (a) illustrates location of impedances and (b) expresses switching of impedances Z_1 and Z_2 for the diversity performance. Since the radiation pattern can be varied by changing the value of impedance, for instance, from Z_1 to Z_2 , pattern diversity can be achieved. Changing the impedance value contributes to variation in phase of the current flowing on the ground plane so that additional lower correlation coefficients can be obtained.

6.4.3. Antennas for PHS Terminals. The PHS (personal handy-phone system) has been used in Japan as an extension of the indoor use of cordless phones to outdoor applications. The communication areas are limited to small

Figure 123. Handset to which a single-antenna-element diversity system is applied.

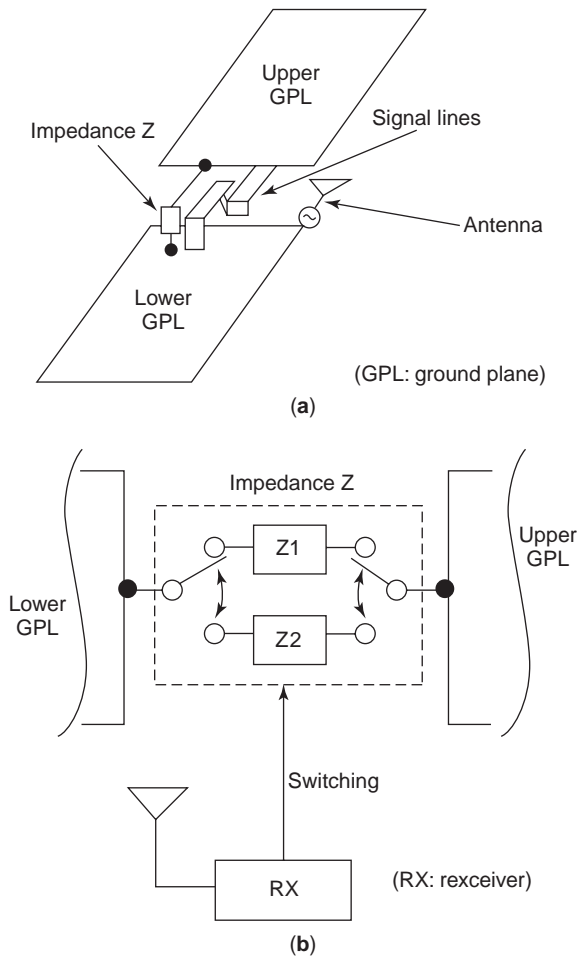

Figure 124. Diversity system using a single antenna element: (a) schematic expression; (b) circuitry to function diversity. (From [73] with permission from IEICE.)

zones, such as several hundred meters in diameter. The transmitter power of the mobile terminals is kept as low as 10 mW. The frequency band is 1895–1918 MHz. It should

Figure 125. A chip antenna mounted at a corner of ground plane in a PHS unit. (Courtesy of Murata Mfg. Co., Japan.)

Figure 126. Radiation patterns: (a) x - y plane; (b) y - z plane; (c) x - z plane; (d) geometry. (Courtesy of Murata Mfg. Co., Japan.)

be noted that a faster data transmission can be handled by the PHS than by the PDC.

PHS mobile terminals use a single-antenna element, which is typically an MP, an NMHA, or a small chip antenna. Because the operating frequency is higher and the bandwidth is narrower than those in the PDC system, a smaller antenna element can be used. Then antenna design is easier than that in the PDC systems. The MP element has a structure similar to that in the PDC, but the length of the PDC is shorter than that of the PHS. An example of the inside view of a PHS is shown in Fig. 125, where mountings of both a chip antenna and an NMHA are shown. Figure 126 shows the radiation patterns. The gain is evaluated to be about -2 to -4 dBd at maximum and -4 to -7 dBd on average, depending on the plane measured.

APERTURE ANTENNAS

1. INTRODUCTION

Aperture antennas are most commonly used at microwave and the millimeter-wave frequencies. There are a large number of antenna types for which the radiated electromagnetic fields can be considered to emanate from a physical aperture. Antennas that fall into this category include reflector antennas, lenses, and horn antennas. The geometry of the aperture may be square, rectangular, circular, elliptical, or virtually any other shape. The term “aperture antenna” usually has more to do with the method used to analyze the antenna than the actual form of the antenna. For instance, array antennas viewed as a continuous field function bounded by a conducting screen can be considered to be an aperture antenna. This would encompass so-called planar (flat-plate) waveguide and microstrip arrays.

Aperture antennas are very popular for aerospace applications because they can be flush-mounted onto the spacecraft or aircraft surface. Their aperture opening can be covered with an electromagnetic (dielectric) window material that is transparent to the RF energy to protect the antenna from the environmental conditions [1]. This is known as a *radome*, and it is implemented so as not to disturb the aerodynamic profile of the vehicle, which is of special importance to high-speed aircraft or missiles.

In order to evaluate the distant (far-field) radiation patterns, it is necessary to know the surface currents that flow on the radiating surfaces of the antenna aperture. In many instances, these current distributions may not be known exactly and only approximate or experimental measurements can provide estimates. A technique based on the equivalence principle allows one to make reasonable approximations to the electromagnetic fields on, or in the vicinity of, the physical antenna aperture structure, which can then be used to compute far field antenna radiation patterns.

Field equivalence, first introduced by Schelkunoff [2], is a principle by which the actual sources on an antenna aperture are replaced by equivalent sources on an external closed surface that is physically outside the antenna aperture. The fictitious sources are said to be *equivalent* within a region because they produce the same fields within that region. Another key concept is Huygens’ principle [3], which states that the equivalent source at each point on the external surface is a source of a spherical wave. The secondary wavefront can be constructed as the envelope of these secondary spherical waves [4].

Using these principles, the electrical and/or magnetic fields in the equivalent aperture region can be determined with these straightforward, but approximate, methods. The fields elsewhere are assumed to be zero. In most applications, the closed surface is selected so that most of it coincides with the conducting parts of the physical antenna aperture structure. This is preferred because the

Alpharetta, Georgia

1. INTRODUCTION

Aperture antennas are most commonly used at microwave and the millimeter-wave frequencies. There are a large number of antenna types for which the radiated electromagnetic fields can be considered to emanate from a physical aperture. Antennas that fall into this category include reflector antennas, lenses, and horn antennas. The geometry of the aperture may be square, rectangular, circular, elliptical, or virtually any other shape. The term “aperture antenna” usually has more to do with the method used to analyze the antenna than the actual form of the antenna. For instance, array antennas viewed as a continuous field function bounded by a conducting screen can be considered to be an aperture antenna. This would encompass so-called planar (flat-plate) waveguide and microstrip arrays.

Aperture antennas are very popular for aerospace applications because they can be flush-mounted onto the spacecraft or aircraft surface. Their aperture opening can be covered with an electromagnetic (dielectric) window material that is transparent to the RF energy to protect the antenna from the environmental conditions [1]. This is known as a *radome*, and it is implemented so as not to disturb the aerodynamic profile of the vehicle, which is of special importance to high-speed aircraft or missiles.

In order to evaluate the distant (far-field) radiation patterns, it is necessary to know the surface currents that flow on the radiating surfaces of the antenna aperture. In many instances, these current distributions may not be known exactly and only approximate or experimental measurements can provide estimates. A technique based on the equivalence principle allows one to make reasonable approximations to the electromagnetic fields on, or in the vicinity of, the physical antenna aperture structure, which can then be used to compute far field antenna radiation patterns.

Field equivalence, first introduced by Schelkunoff [2], is a principle by which the actual sources on an antenna aperture are replaced by equivalent sources on an external closed surface that is physically outside the antenna aperture. The fictitious sources are said to be *equivalent* within a region because they produce the same fields within that region. Another key concept is Huygens’ principle [3], which states that the equivalent source at each point on the external surface is a source of a spherical wave. The secondary wavefront can be constructed as the envelope of these secondary spherical waves [4].

Using these principles, the electrical and/or magnetic fields in the equivalent aperture region can be determined with these straightforward, but approximate, methods. The fields elsewhere are assumed to be zero. In most applications, the closed surface is selected so that most of it coincides with the conducting parts of the physical antenna aperture structure. This is preferred because the

disappearance of the tangential electrical components over the conducting parts of the surface reduces the physical limits of integration. The formula to compute the fields radiated by the equivalent sources is exact, but it requires integration over the closed surface. The degree of accuracy depends on the knowledge of the tangential components of the electromagnetic fields over the closed surface.

Aperture techniques are especially useful for parabolic reflector antennas, where the aperture plane can be defined immediately in front of the reflector. Parabolic reflectors are usually electrically large. More surprisingly, aperture techniques can also be successfully applied to small-aperture waveguide horn antennas. However, for very small horn antennas with an aperture dimension of less than approximately one wavelength, the assumption of zero fields outside the aperture fails unless the horn is completely surrounded by a planar conducting flange [5]. In this section, the mathematical formulas will be developed to analyze the radiation characteristics of aperture antennas. Emphasis will be given to the rectangular and circular configurations because they are the most commonly used geometries. Because of mathematical complexities, the results will be restricted to the far-field region.

One of the most useful concepts is the far-field radiation pattern that can be obtained as a Fourier transform of the field distribution over the equivalent aperture, and vice versa. Fourier transform theory is extremely important to the analysis and synthesis of aperture antennas. Obtaining analytical solutions for many simple aperture distributions in order to design aperture antennas is useful. More complex aperture distributions, which do not lend themselves to analytical solutions, can be solved numerically. The increased capabilities of the personal computer (PC) have resulted in its acceptance as a conventional tool for the antenna designers. The Fourier transform integral is generally well behaved and does not present any fundamental computational problems.

Considering the use of the Fourier transform, first consider rectangular apertures in which one aperture dimension is large in wavelengths and the other is small in terms of wavelengths. This type of aperture is approximated as a line source and is treated with a one-dimensional Fourier transform [6]. For many kinds of rectangular aperture antennas such as horns, the aperture distributions in the two principal-plane dimensions are independent. These types of distributions are said to be separable. The total radiation pattern is the product of the pattern functions obtained from the one-dimensional Fourier transforms, which corresponds to the two principal-plane distributions.

If the rectangular aperture distribution cannot be separated, the directivity pattern is found in a similar manner to the line-source distribution, except that the aperture field is integrated over two dimensions rather than one dimension [7]. This double Fourier transform can also be applied to circular apertures.

For all aperture distributions, the following observations are made [8]:

1. A uniform amplitude distribution yields the maximum directivity (where nonuniform edge-enhanced

distributions for supergain are considered impractical), but at high sidelobe levels.

2. Tapering the amplitude at the center, from a maximum to a smaller value at the edges, will reduce the sidelobe levels compared with the uniform illumination, but it results in a larger (mainlobe) beamwidth and less directivity.
3. An inverse-taper distribution (amplitude depression at the center) results in a smaller (mainlobe) beamwidth but increases the sidelobe level and reduces the directivity when compared with the uniform illuminated case.
4. Depending on the aperture size in wavelengths and the phase errors, there is a frequency (or wavelength) for which the gain peaks, falling to smaller values as the frequency is either raised or lowered.

Finally, we consider aperture efficiencies. The *aperture efficiency* is defined as the ratio of the effective aperture area to the physical aperture area. The *beam efficiency* is defined as the ratio of the power in the mainlobe to the total radiated power. The maximum aperture efficiency occurs for a uniform aperture distribution, but maximum beam efficiency occurs for a highly tapered distribution. The aperture phase errors are the primary limitation of the efficiency of an antenna.

2. HUYGENS' PRINCIPLE

The principle proposed by Christian Huygens (1629–1695) is of fundamental importance to the development of wave theory [3]. Huygens' principle states that "Each point on a primary wavefront serves as the source of spherical secondary wavelets that advance with a speed and frequency equal to those of the primary wave. The primary wavefront at some time later is the envelope of all these wavelets" [9]. This is illustrated in Fig. 1 for spherical and

Figure 1. Spherical (a) planar and (b) wavefronts constructed with Huygens secondary waves.

Figure 2. Diffraction of waves through a slit based on the Huygens principle.

plane waves modeled as a construction of Huygens' secondary waves. Actually, the intensities of the secondary spherical wavelets are not uniform in all directions but vary continuously from a maximum in the direction of wave propagation to a minimum of zero in the backward direction. As a result, there is no backward-propagating wavefront. The Huygens source approximation is based on the assumption that the magnetic and electric fields are related as a plane wave in the aperture region.

The situation shown in Fig. 2, shows an infinite electromagnetic plane wave incident on an infinite flat sheet that is opaque to the waves. This sheet has an opening that is very small in terms of wavelengths. Accordingly, the outgoing wave corresponds to a spherical wavefront propagating from a point source. That is, when an incoming wave comes against a barrier with a small opening, all except one of the effective Huygens point sources are blocked, and the energy coming through the opening behaves as a single point source. In addition, the outgoing wave emerges in all directions, instead of just passing straight through the slit.

On the other hand, consider an infinite plane electromagnetic wave incident on an infinite opaque sheet shown in Fig. 3 that has a larger opening of dimension a . The

Figure 3. Plane wave incident on an opaque sheet with a slot of width a .

field everywhere to the right of the sheet is the result of the section of the wave that passes through this opening. If a is large in terms of wavelengths, the field distribution across the slot is assumed, as a first approximation, to be uniform. The total electromagnetic field at any point to the right of the opening is obtained by integrating the contributions from an array of Huygens sources distributed over the length a . We calculate the electric field at point P on a reference plane located at a distance R_0 from this opening by evaluating the integration of these Huygens sources [10]:

$$E = \int E_0 \frac{e^{-jkr}}{r} dy \quad (1)$$

For points near to the array, the integral does not simplify but can be reduced to the form of Fresnel integrals.

The actual evaluation of this integral is best achieved on a PC computer, which reduces the integral to a summation of N Huygens sources

$$E = \sum_{i=1}^N \frac{e^{-jkr_i}}{r_i} \quad (2)$$

where r_i is the distance from the i th source to point P . The field variation near the slot opening that is obtained in this way is commonly called a *Fresnel diffraction pattern* [4].

For example, let us consider the case in which the slot length a is 5 cm and the wavelength is 1.5 cm (corresponding to 20 GHz.) We can use Eq. (2) to compute the field along a straight line parallel to the slot. The field variation for $R_0 = 2.5$ cm shown in Fig. 4. For this case, R_0 is well within the near field (the so-called Fresnel region.) As we continue to increase R_0 , the shape of the field variation along this line continues to vary with increasing R_0 until we reach the far-field or Fraunhofer region (see the trends in Figs. 4b–4d). Once we have entered the Fraunhofer region, the pattern becomes invariant to range R_0 . For the distance to be in the far field, the following relationship must be met

$$R_0 \geq \frac{2a^2}{\lambda} \quad (3)$$

where a is the width of the slot and λ is the wavelength. Thus, the larger the aperture or the shorter the wavelength, the greater will be the distance at which the pattern must be measured if we wish to avoid the effects of Fresnel diffraction.

Huygens' principle is not without limitations as it neglects the vector nature of the electromagnetic field space. It also neglects the effect of the currents that flow at the slot edges. However, if the aperture is sufficiently large and we consider only directions roughly normal to the aperture, the scalar theory of Huygens' principle gives very satisfactory results.

Geometric optics (GO) techniques are commonly applied in reflector antennas to establish the fields in the reflector aperture plane. This procedure, referred to as

Figure 4. Electromagnetic field versus distance along the Y axis, with $R_0 = 2.5$ (a), 5(b), 15(c), and 20(d) cm.

the *aperture field method*, is employed as an alternative to the so-called induced-current method, which is based on an approximation for the electric current distribution on the reflector surface. The fields in the aperture plane can be thought of as an ensemble of Huygens sources. The radiation pattern can be computed via a numerical summation of these sources.

3. EQUIVALENCE PRINCIPLE

The ability to determine electromagnetic waves radiated fields via field equivalence principles is a useful concept, and the development can be traced by to Schelkunoff [2]. The equivalence principle often makes an exact solution easier to obtain or suggests approximate methods that are of value in simplifying antenna problems. Field equivalence principles are treated at length in the literature, and we will not consider the many variants here. The book by Collin and Zucker [11] is a useful source of reference. The basic concept is illustrated in Fig. 5, where the electromagnetic source region is enclosed by a surface S that is referred to as a *Huygens surface*.

In essence, Huygens' principle and the equivalence theorem shows how to replace actual sources by a set of equivalent sources spread over the surface S [12]. The equivalence principle is developed by considering a radiating source, electrically represented by current densities J_1 and M_1 . Assume that the source radiates fields E_1 and H_1 everywhere. We would like to develop a method that will yield the fields outside the closed surface. To accomplish this, a closed surface S is shown by the dashed lines that enclose the current densities J_1 and M_1 . The volume inside S is denoted by V . The primary task is to replace the original problem (Fig. 5a) by an equivalent one that will yield the same fields E_1 and H_1 (Fig. 5b). The formulation of the problem can be greatly facilitated if the closed surface is judiciously chosen so that the fields over most of—if not the entire—surface are known a priori.

The original sources J_1 and M_1 are removed, and we assume that there exists a field E, H inside V . For this field to exist within V , it must satisfy the boundary conditions on the tangential electric and magnetic field components on surface S . Thus on the imaginary surface S , there must exist equivalent sources [13]:

$$J_s = nx(H_1 - H) \tag{4}$$

$$M_s = -nx(E_1 - E) \tag{5}$$

These equivalent sources radiate into an unbounded space. The current densities are said to be equivalent

Figure 5. Equivalence principle with a closed Huygens surface S enclosing sources: (a) original problem; (b) equivalent problem.

only outside region V , because they produce the original field (E_1, H_1) . A field E or H , different from the original, may result within V .

The sources for electromagnetic fields are always electrical currents. However, the electrical current distribution is usually unknown. In certain structures, it may be a complicated function, particularly for slots, horns, reflectors, and lenses. With these types of radiators, the theoretical work is seldom based on the primary current distributions. Rather, the results are obtained with the aid of what is known as *aperture theory* [14]. This theory is based on the fact that an electromagnetic field in a source-free, closed region is completely determined by the values of tangential E or tangential H fields on the surface of the closed region. For exterior regions, the boundary condition at infinity may be employed to close the region. This is exemplified by the following case.

Without changing the E and H fields external to S , the electromagnetic source region can be replaced by a zero-field region with approximate distributions of electric and magnetic currents (J_s and M_s) on the Huygens surface. This example is overly restrictive and we could specify any field within S with a suitable adjustment. However, the zero-internal-field approach is particularly useful when the tangential electric fields over a surface enclosing the antenna are known or can be approximated. In this case, the surface currents can be obtained directly from the tangential fields, and the external field can be determined.

Assuming zero internal fields, we can consider the electromagnetic sources inside S to be removed, and the radiated fields outside S are then determined from the electric-magnetic surface current distributions alone. This offers significant advantages when the closed surface is defined as a *two-hemisphere region*, with all sources contained on only one side of the plane. If either the electric or magnetic field arising from these sources can be determined over the planar Huygens surface S , then the radiated fields on the far side of the plane can be calculated. The introduction of an infinite conducting sheet just inside of the Huygens surface here will not complicate the calculations of the radiated fields in the other half-space [15]. This infinite plane model is useful for antennas the radiation of which is directed into the right hemisphere (Fig. 6), and has found wide application in dealing with aperture antennas. For instance, if the antenna is a rectangular horn, it is assumed that the horn transitions into an infinite flange. All tangential fields outside the rectangular boundary along the infinite Huygens surface are taken to be zero.

When the limitations of the half-space model are acceptable, it offers the important advantage that either the electrical or magnetic currents need to be specified. However, knowledge of both is not required. It must be emphasized that any of the methods described before will produce exact results over the Huygens surface. In the analysis of electromagnetic problems, often it is easier to form equivalent problems that will yield the same solution only within a region of interest.

The steps that must be used to form an equivalent problem and solve an aperture antenna problem are as follows:

Figure 6. Some apertures yielding the same electromagnetic fields to the right side of the Huygens surface S : (a) horn; (b) parabola; (c) lens.

1. Select an imaginary surface that encloses the actual sources (the aperture). The surface must be judiciously chosen so that the tangential components of the electric field and/or the magnetic field are known, exactly or approximately, over its entire span. Ideally, this surface flat plane extending to infinity.
2. Over the imaginary surface S , form equivalent current densities J_s and M_s , assuming that the E and H fields within S are not zero.
3. Finally, solve the equivalent-aperture problem.

4. RECTANGULAR APERTURES

There are many kinds of antennas for which the radiated electromagnetic fields emanate from a physical aperture. This general class of antennas provides a very convenient basis for analysis that permits a number of well-established mathematical techniques to be applied and results in expressions for the distant radiation fields.

Horn and parabolic reflectors can be analyzed as aperture antennas. Incident fields are replaced by equivalent electric and magnetic currents. With use of vector potentials, the far fields are found as a superposition of each source. Generally, one can assume that the incident field is a propagating free-space wave, the electric and magnetic fields of which are proportional to each other. This will give the Huygens source approximation and allow us to use integrals of the electric field in the aperture plane. Each point in the aperture is considered as a source of radiation.

The first step involved in the analysis of aperture antennas is to calculate the electromagnetic fields over the aperture due to the sources on the rearward side of the infinite plane and to use these field distributions as the basis for the prediction of the distance fields on the forward half-space. The electromagnetic fields in the aperture plane cannot be determined exactly, but approximation distributions can be found by many different methods, which are dependent on the antenna. One can

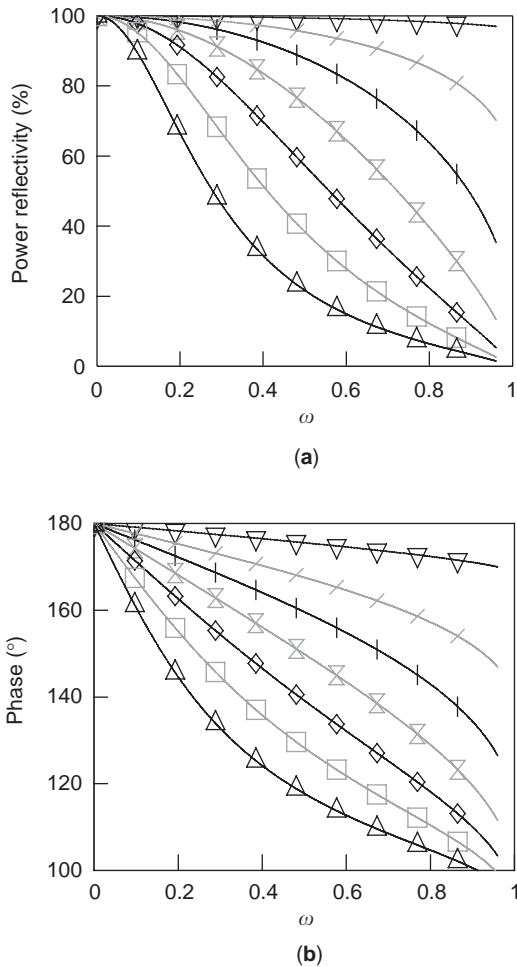

Figure 7. Coordinate system used to analyze a linear aperture of length L_w .

find the far-field radiation pattern for various distributions by, for instance, a Fourier transform relation.

Consider a line source of length L_w using the coordinate system illustrated in Fig. 7. Assume that the source is positioned in a ground plane of infinite extent. This model is simple and yet the analysis gives results that demonstrate the main features of the one-dimensional aperture. The line-source distribution does show a practical realization, namely, in a long one-dimensional geometry that has sufficient elements to enable it to be approximated by a continuous distribution. The applicable transform is [7,16]

$$E(\theta) = \int_{-\infty}^{\infty} E(x)e^{jkx \sin \theta} dx \tag{6}$$

and the inverse transform is

$$E(x) = \int_{-\infty}^{\infty} E(\sin \theta)e^{-jkx \sin \theta} d(\sin \theta) \tag{7}$$

where $k = 2\pi/\lambda$. For real values of θ , $-1 \leq \sin \theta \leq 1$, the distribution represents radiated power, while outside this region it represents reactive or stored power [17]. The field distribution $E(\sin \theta)$, or an angular spectrum, refers to a

distribution of plane waves. The angular spectrum finite aperture is the same as in the far-field pattern, $E(\theta)$. Now for a finite aperture, the Fourier integral representation [Eq. (6)] may be rewritten as [8] follows:

$$E(\theta) = \int_{-L_w/2}^{L_w/2} E(x)e^{jk \sin \theta} dx \tag{8}$$

For example, consider a so-called uniform distribution in which the amplitude is constant over the aperture region $-L_w/2 \leq x \leq L_w/2$:

$$E(x) = \frac{1}{L_w} \tag{9}$$

$E(x) = 0$ outside this region. The radiation pattern can be found by incorporating this into Eq. (8):

$$E(\theta) = \frac{1}{L_w} \int_{-L_w/2}^{L_w/2} e^{j2\pi x/\lambda \sin \theta} dx \tag{10}$$

We complete this straightforward integration and get the final result:

$$E(\theta) = \frac{\sin \frac{\pi L_w \sin \theta}{\lambda}}{\frac{\pi L_w \sin \theta}{\lambda}} \tag{11}$$

This $\sin(x)/x$ distribution is very important in antenna theory and is the basis for many practical antenna designs. It results in the narrowest radiation pattern beamwidth of any other distribution, but on the other hand has the highest first sidelobe level of -13.2 dB.

Another popular continuous aperture distribution is the cosine raised to a power n distribution. For all $-L_w/2 \leq x \leq L_w/2$, let

$$E(x) = \cos^n \frac{\pi x}{L_w} \tag{12}$$

and $E(x) = 0$ for all x outside this region. This popular distribution is illustrated in Fig. 8 for $n = 1, 2, 3$. To make a relative comparison of the two types of line-source

Figure 8. Some popular aperture distributions.

distribution discussed, we must first normalize the distributions to ensure that the total radiated power is the same relative to the uniform case. To do this, we multiply the radiation pattern expressions by the normalization constant:

$$C_p = \frac{1}{\int_{-L_w/2}^{L_w/2} E^2(x) dx} \quad (13)$$

To demonstrate, we computed the antenna radiation pattern for a one-meter-long line-source distribution for uniform, cosine, and cosine² distributions. For an assumed wavelength of 3 cm, the resulting antenna radiation patterns are shown in Fig. 9. These data indicate that the more heavily tapered the illumination, the greater the decrease in sidelobe levels, but this occurs for a penalty in reduced mainlobe directivity.

Many distributions actually obtained in practice can be approximated by one of the simpler forms or by a combi-

nation of simple forms. For example, a common linear aperture distribution is the cosine on a pedestal p :

$$E(x) = p + (1 - p) \cos \frac{\pi x}{L_w} \quad (14)$$

where $0 \leq p \leq 1$. This is a combination of a uniform plus a cosine-type distribution. The so-called triangular distribution is of interest

$$E(x) = 1 + \frac{x}{L_w/2} \quad (15)$$

for $-L_w/2 \leq x \leq 0$, and

$$E(x) = 1 - \frac{x}{L_w/2} \quad (16)$$

for $0 \leq x \leq L_w/2$.

In practice, the rectangular aperture is a common microwave antenna shape. Because of its configuration, the rectangular coordinate system shown in Fig. 10 is the

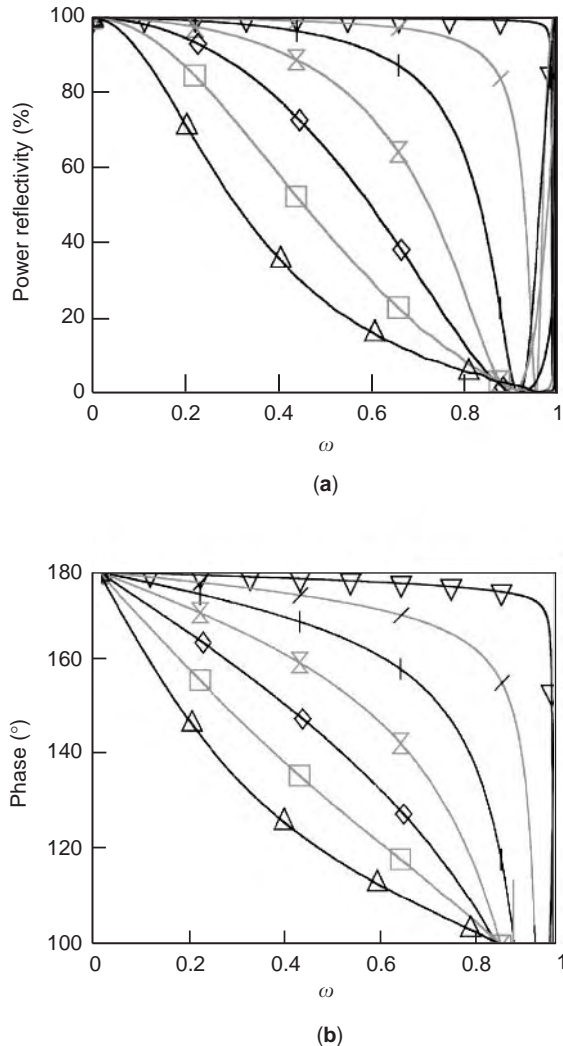

Figure 9. Radiation patterns of line sources for three different aperture distributions ($L_w = 1$ m, $\lambda = 3$ cm).

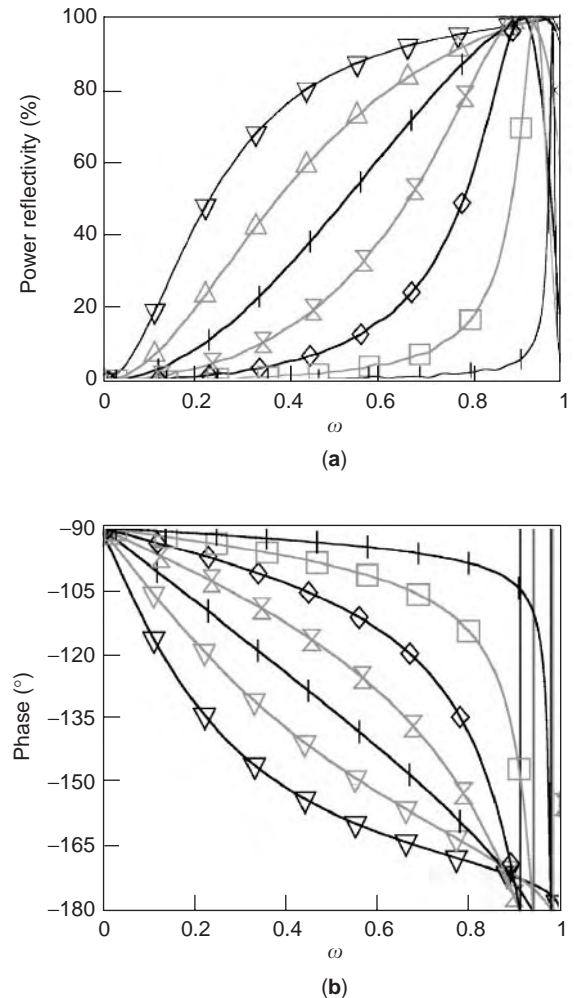

Figure 10. Coordinate system used to analyze rectangular aperture of dimensions $A_w B_w$.

most convenient system in which to express the electromagnetic fields at the aperture. Here, the aperture lies in the x - y plane and has a defined tangential aperture distribution $E(x,y)$. In keeping with the equivalence principle, we shall assume that the x - y plane is a closed surface that extends from $-\infty$ to $+\infty$ in the x - y plane. Outside the rectangular aperture boundaries we shall assume that the field distribution is zero for all points on the infinite surface. The task is then to find the fields radiated by the aperture; specifically, the pattern mainlobe beamwidths, the first sidelobe levels, and the directivity. Also shown in the figure is the superposition of a standard spherical coordinate system that will allow us to define a radiation pattern in terms of the two angle coordinates θ, ϕ .

Assuming a rectangular aperture of dimension A_w in the x plane and B_w in the y plane, the radiation pattern may then be obtained from the integral [18]

$$E(\theta, \phi) = \int_{-B_w/2}^{B_w/2} \int_{-A_w/2}^{A_w/2} E(x,y) e^{j(k_x x + k_y y)} dx dy \quad (17)$$

in which the directional wavenumbers are given by

$$k_x = k \sin \theta \cos \phi$$

$$k_y = k \sin \theta \sin \phi$$

These are also known as the x and y components of the propagation vector k [19].

For many types of antennas such as the rectangular horn antenna, the x and y functions are separable and may be expressed in the following form:

$$E(x,y) = E(x)E(y) \quad (18)$$

For these distributions, the pattern in the principal x - z plane can be determined from the line-source distribution $E(x)$ while the pattern in the y - z plane can be determined from the line-source distribution $E(y)$. We can illustrate this by assuming that both $E(x)$ and $E(y)$ are uniform distributions in which $E(x) = 1/A_w$ and $E(y) = 1/B_w$. We enter these into the Fourier transform relationship of Eq. (17) to get the following result:

$$E(\theta, \phi) = \frac{\sin \frac{k_x A_w}{2}}{\frac{k_x A_w}{2}} \frac{\sin \frac{k_y B_w}{2}}{\frac{k_y B_w}{2}} \quad (19)$$

From this pattern, we conclude that the principal plane radiation patterns of separable rectangular distributions correspond to the respective line-source distributions.

Next, we have applied this to an aperture size of $A_w = 75$ cm in the x dimension and $B_w = 125$ cm in the y dimension, an operating wavelength of 3 cm, and for simple cosine distributions in each plane. The results are plotted in Fig. 11, where it should be pointed out that $\phi = 0^\circ$ corresponds to the principal-plane radiation pattern in the x - z plane, $\phi = 90^\circ$ is the principal-plane pattern in the y - z plane, and $\phi = 45^\circ$ corresponds to the principal-plane

Figure 11. Radiation patterns for a rectangular aperture ($A_w = 75$ cm, $B_w = 125$ cm, $\lambda = 3$ cm).

pattern in the intercardinal plane. For nonseparable distributions, the integration of Eq. (17) is best carried out on a PC computer using numerical methods.

To generalize, we have applied a computer code to compute the secondary radiation patterns produced by uniform cosine raised to power n , cosine on a pedestal p , and triangular rectangular aperture distributions. The results shown in Table 1 compare the gain, mainlobe beamwidth, and the first sidelobe levels for each. All gain levels are compared with the uniform illumination case, and total radiated power is assumed in each case.

A uniform line-source or rectangular aperture distribution produces the highest directivity. However, the first sidelobe is only about -13.2 dB down. The results also show that the first sidelobe levels for a cosine illuminated aperture are -23 dB down but at a penalty of -0.91 dB in reduction of directivity compared to the uniform illuminated case. Other distributions have even lower first sidelobe levels but even greater reduction in directivity compared to the uniform illuminated case. Thus, aperture distributions used in practice must be a tradeoff or compromise between the desired directivity (or gain) and first sidelobe level.

5. CIRCULAR APERTURES

Circular aperture shape antennas form the largest single class of aperture antennas. For instance, the circular parabolic reflector is used extensively in satcom (satellite communications), terrestrial telecommunications, and radar applications.

The coordinate system used to analyze the radiation from a circular aperture of diameter D_w is the spherical coordinate system shown in Fig. 12, where the aperture lies in the x - y plane and radiation can be described in terms of the spherical coordinate components θ and ϕ . The radiation pattern from a circular aperture can be calculated by applying Huygens' principle in much the same way as we did for rectangular apertures. The simplest form of a circular aperture distribution is one in which the field does not vary with ϕ , that is, one that is rotationally

symmetric. This is not always true in practice; however, we will assume that to be the case here in order to demonstrate the methodology of analyzing circular apertures.

As was the case with rectangular apertures, a Fourier transform relationship exists between the antenna distribution and the far-field radiation pattern. For a circular symmetric aperture distribution, the radiation pattern can be written in normalized form [6]

$$E(u) = \frac{1}{\pi^3} \int_0^{2\pi} \int_0^\pi E(p) e^{jpu \cos(\phi - \phi')} p dp d\phi' \quad (20)$$

Figure 12. Coordinate system used to analyze a circular aperture of diameter D_w .

where

$$u = \frac{D_w \sin \theta}{\lambda}$$

and the normalized radius is

$$p = \frac{2\pi r}{D_w}$$

For a uniformly illuminated circular aperture, the normalized radiation pattern is expressed in terms of a first-order Bessel function

$$E(u) = \frac{2J_1(\pi u)}{\pi u} \quad (21)$$

which, in turn, can be expressed as

$$E(\theta) = \frac{2J_1 \frac{\pi D_w \sin \theta}{\lambda}}{\frac{\pi D_w \sin \theta}{\lambda}} \quad (22)$$

The uniformly illuminated circular aperture radiation pattern has a first sidelobe level of -17.6 dB compared with -13.2 dB for the uniformly illuminated rectangular aperture or line source. Other types of circular aperture distributions include the cosine raised to a power n

$$E(r) = \cos^n \frac{\pi r}{D_w} \quad (23)$$

where $0 \leq r \leq D_w/2$.

The so-called cosine on a pedestal p distribution is defined here as

$$E(r) = p + (1 - p) \cos \frac{\pi r}{D_w} \quad (24)$$

and the parabolic raised to a power n distribution is [15]

$$E(r) = \left[1 - \left(\frac{r}{D_w/2} \right)^2 \right]^n \quad (25)$$

To analyze the various circular aperture distributions, we can utilize a PC computer using numerical methods to perform the aperture integration of Eq. (20). To demonstrate the behavior of various distributions discussed, a computer code was applied to compute the secondary pattern characteristic produced by a uniform cosine raised to a power n , cosine on a pedestal p , and parabolic raised to power n distributions. The results shown in Table 2 compare the gain, beamwidth, and the first sidelobe levels of each. All gain levels are compared with the uniform illumination case.

6. BEAM EFFICIENCY

This discussion considers the effect of the aperture field distribution on the beam and aperture efficiencies. For many applications, the fraction of the total radiated energy that is in the main (null-to-null) antenna beam is important. This quantity, called the *beam efficiency* [20], can be used to judge the ability of the antenna to discriminate between signals received through its mainlobe and those through the minor lobes.

Before we delve into this subject, it is helpful to review some fundamentals. The mainbeam consists of the solid angle

$$\Omega_m = \theta_{hp} \phi_{hp} \quad (26)$$

where θ_{hp} and ϕ_{hp} are the half-power beamwidths of the mainlobes in the two principal planes, with minor lobes neglected. The total-beam solid angle Ω_a consists of the mainbeam solid angle plus the minor-lobe solid angle. Furthermore, the ratio of the mainbeam solid angle to the total-beam solid angle defines a property called the *beam efficiency* η_b :

$$\eta_b = \frac{\Omega_m}{\Omega_a} \quad (27)$$

In terms of the radiated intensity $E(\theta, \varphi)$ of a pencil beam with boresight at $(\theta = 0, \varphi = 0)$, the beam efficiency can be defined by [13]

$$\eta_b = \frac{\int_{-\theta_n/2}^{\theta_n/2} \int_{-\phi_n/2}^{\phi_n/2} E(\theta, \phi) E(\theta, \phi)^* \sin \theta d\phi d\theta}{\int_0^\pi \int_0^{2\pi} E(\theta, \phi) E(\theta, \phi)^* \sin \theta d\phi d\theta} \quad (28)$$

where θ_n and ϕ_n are the null-to-null beamwidths in the two principal planes. Also, $E(\theta, \varphi)^*$ denotes the conjugate of $E(\theta, \varphi)$.

The directivity of the aperture antenna can be expressed as

$$D = \frac{4\pi}{\Omega_a} = \frac{4\pi A_p}{\lambda^2} \quad (29)$$

where A_p is the physical area of the aperture. The *aperture efficiency* is defined as the ratio of the effective aperture area A_e to the physical aperture area, or

$$\eta_a = \frac{A_e}{A_p} \quad (30)$$

so that the ratio of the aperture and beam efficiencies is [8]

$$\frac{\eta_a}{\eta_m} = \frac{A_e \Omega_a}{A_p \Omega_m} \quad (31)$$

where Ω_m is the mainbeam solid angle and Ω_a is the total-beam solid angle, both of which are measured in steradians (sr). It is important to recognize, then, that the beam efficiency and aperture efficiency are related to each other.

In general, the aperture and beam efficiencies must be multiplied by a gain degradation factor due to phase errors within the aperture given by [21]

$$\eta_{pe} = e^{-(2\pi\delta/\lambda)^2} \quad (32)$$

where δ is the RMS phase error over the aperture. It is assumed that the correlation intervals of the deviations are greater than the wavelength. The controlling effect of tapers on the beam and aperture efficiencies tends to decrease them as the phase error increases. The efficiencies are also reduced by the presence of other phase errors.

The curves in Fig. 13 show that the beam efficiency tends to increase with an increase in taper but the aperture efficiency decreases. Maximum aperture efficiency occurs for a uniform aperture distribution, but maximum beam efficiency occurs for a highly tapered distribution. In most cases a taper is used that is intermediate between the two extremes.

7. APERTURE SYNTHESIS

To demonstrate the principles in aperture synthesis, consider a one-dimensional line source of length L_w . Earlier, in Eqs. (6) and (7), a Fourier transform pair was defined

Figure 13. Form of beam and aperture efficiencies for an aperture as a function of taper.

relating the aperture distribution of a line source with the far-field radiation pattern. In the synthesis process, we wish to determine an aperture distribution that will result in a desired radiation that is not necessarily a symmetric beam; for instance, let us determine the well-known $\text{csc}^2\theta$ (cosecant² θ)-shaped beam used in a ground-mapping radar. In order to do this, we first express the illumination function as a sum of N uniform distributions that have relative weights c_m and a relative linear aperture phase function ϕ_m . This may be expressed mathematically as follows:

$$E(x) = \sum_{m=1}^N c_m e^{j\phi_m x} \quad (33)$$

The Fourier transform of this aperture distribution gives us an expression for the far-field radiation pattern:

$$E(\theta) = \int_{-L_w/2}^{L_w/2} \sum_{m=1}^N c_m e^{j(k \sin \theta + \phi_m)x} dx \quad (34)$$

which may be expressed in the form

$$E(\theta) = \sum_{m=1}^N c_m \frac{\sin\left((k \sin \theta + \phi_m) \frac{L_w}{2}\right)}{(k \sin \theta + \phi_m) \frac{L_w}{2}} \quad (35)$$

Thus, each coefficient c_m is responsible for a $(\sin x)/x$ type of beam, and there are N different beams. The coefficients may be obtained manually by estimating the number of independent beams and their relative magnitudes and positions in angle space needed to approximate the desired radiation pattern. The results may be extended by the reader to a two-dimensional aperture.

The preceding equations form the basis for Woodward's aperture synthesis technique [6,28], which quantifies the aperture illumination required to produce a given beam shape that is desired. Another antenna synthesis method

called the virtual array synthesis method was more recently published by Vaskelainen [22]. In this method, the geometry of the virtual array is chosen so that there will be a suitable synthesis method for that geometry, and the synthesis of the virtual array can be done accurately. The excitation values for the virtual array are transformed into the excitation values of the actual array geometry. Matrix operations are simple and large arrays can easily be synthesized. Further information on antenna pattern synthesis techniques is given in Refs. 23–27.

8. MODERN FULL-WAVE METHODS [29]

Some aperture antennas can be addressed with analysis approaches known as *full-wave methods*. The application of such methods has rapidly expanded with the explosion of high-power PC computers.

Analysis methods are called “full-wave” when they start with the fundamental equations of electromagnetics and discretize them such that they can be reduced to linear matrix equations suitable for solving by a computer. The advantage is that there are no approximations in principle, only the size of the discrete interval, which is usually between 10 and 20 intervals per wavelength. There are three primary full-wave methods used in electromagnetics: the finite-element method (FEM) [30–33], the method of moments (MoM) [34–36], and the finite-difference time-domain (FDTD) method [37,38]. The MoM discretizes Maxwell’s wave equations in their integral form, the finite-difference method (FDM) discretizes the equations in the differential form, and the FEM method discretizes the equations after casting them in a variational form. All three techniques have been applied to aperture antenna analysis [39–41].

The MoM method finds natural application to antennas because it is based on surfaces and currents, whereas the other two methods are based on volumes and fields. This means that for MoM, only the antenna aperture surface structure must be discretized and solved, whereas for FEM and FDTD, all volumes of interest must be discretized. For antenna radiation, the far field would require an inordinate amount of space were it not for the recent development of absorbing boundary conditions. These boundary conditions approximate the radiation conditions of infinite distance in the space very near the radiating structure.

The MoM works by solving for currents on all surfaces in the presence of a source current or field. The radiated field is then obtained by integration of these currents in much the same way as it was obtained in the physical optics (PO) approaches. Thus, the MoM can be applied to any aperture antenna that the PO technique can be applied to, unless the problem is too large for the available computer resources. Ensemble [42] is a commercially available software package that is a 2.5D (two and one-half-dimensional) MoM program used primarily for patch antennas or antennas that can be modeled as layers of dielectrics and conductors. If the top layer is a conductor with radiating holes, the holes are aperture antennas, which this program is designed to analyze.

There is another full-wave commercial software package that is widely used for aperture antenna problems: the high-frequency structure simulator (HFSS) [43]. This is a 3D FEM software package with extensive modeling and automatic meshing capability. It is best for horn antennas or other kinds of antennas formed by apertures in various nonlayered structures. The latest version uses the “perfectly matched layer” type of absorbing boundary conditions.

In practice, full-wave methods cannot be directly applied to high-gain aperture antennas such as reflectors or lenses without difficulties because these structures are usually many wavelengths in size, requiring a large amount of computational resources. Often, however, if there is symmetry in the problem that can be exploited, the number of unknowns for which to solve can be greatly reduced. For instance, a high-gain reflector antenna that has circular symmetry allows for body-of-revolution (BoR) symmetry [44,45] simplifications in the modeling. Similarly, a large lens requires a computer program with dielectric capability [46] in addition to BoR symmetry modeling.

1. INTRODUCTION

Since the early nineteenth century, Fourier analysis has played an important role in almost all branches of science and engineering and in some areas of social science as well. In this method a function is transformed from one domain to another where many characteristics of the function are revealed. One usually refers to this transform

domain as the *spectral, frequency, or wavenumber* domain, while the original domain is referred to as *time or spatial domain*. In many applications, combined time–frequency analysis of a signal provides useful information about the physical phenomena; information that could not be extracted by either the time-domain or the frequency-domain analyses. For instance, in applications to identification and classification of targets based on the analysis of radar echo, time-domain scattering center analysis [1,2] provides information about the local features of the scatterer since these features appear as short timepulses. Frequency-domain analysis of radar echo using the singularity expansion method [3,4] provides information about the global features of the target. The combined time–frequency analysis can provide additional information, such as the dispersive nature of the target [5,6] and the dispersive nature of propagation in a transmission line [7].

Another area of interest to the electromagnetics community concerns solving boundary value problems arising from scattering and propagation of electromagnetic waves. Two of the main properties of wavelets vis-à-vis boundary value problems are their hierarchical nature and the vanishing moments properties. Because of their hierarchical (multiresolution) nature, wavelets at different resolutions (scales) are interrelated, a property that makes them suitable candidates for multigrid-type methods for solving partial-differential equations. On the other hand, the vanishing-moment property, causing wavelets, when integrated against a function of certain order, to render the integral zero, is attractive in sparsifying a dense matrix generated by an integral equation.

In applications to discrete datasets, wavelets may be considered as basis functions generated by dilations and translations of a single function. Analogous to Fourier analysis, there are wavelet series (WS) and integral wavelet transforms (IWTs). In wavelet analysis, WS and IWT are intimately related. The IWT of a finite-energy function on the real line evaluated at certain points in the timescale domain gives the coefficients for its wavelet series representation. No such relation exists between Fourier series and Fourier transform, which are applied to different classes of functions; the former is applied to finite-energy periodic functions, whereas the latter is applied to functions that have finite energy over the real line. Furthermore, Fourier analysis is global in the sense that each frequency (time) component of the function is influenced by all the time (frequency) components of the function. On the other hand, wavelet analysis is a local analysis. This local nature of wavelet analysis makes it suitable for time–frequency analysis of signals.

Wavelet techniques enable us to divide a complicated function into several simpler ones and study them separately. This property, along with fast wavelet algorithms that are comparable in efficiency to fast Fourier transform algorithms, makes these techniques very attractive in analysis and synthesis problems.

In this article we discuss some wavelet applications to electromagnetic problems. The organization of this article

is as follows. In the next section we give an overview of wavelet theory. Sections 3 to 6 deal with solution of integral equations arising from electromagnetic scattering and transmission-line problems. Differential equations, especially the multiresolution time-domain method, are considered in Section 7. Readers may refer to the literature [5–7] for time-frequency analysis of electromagnetic data.

2. WAVELET PRELIMINARIES

In this section we briefly describe the basics of wavelet theory to facilitate subsequent discussion on its application. More details on the topic may be found in the literature [8–16].

2.1. Multiresolution Analysis

As pointed out before, multiresolution analysis (MRA) plays an important role in the application of wavelets to boundary value problems. In order to achieve MRA we must have a finite-energy function (square integrable on the real line) $\phi(x) \in L^2(\mathbb{R})$, called a *scaling function*, that generates a nested sequence of subspaces

$$\{0\} \leftarrow \cdots \subset V_{-1} \subset V_0 \subset V_1 \subset \cdots \rightarrow L^2 \tag{1}$$

and satisfies the dilation (refinement) equation, namely

$$\phi(x) = \sum_k p_k \phi(2x - k) \tag{2}$$

with $\{p_k\}$ belonging to the set of square summable biinfinite sequences. The number 2 in (2) signifies “octave levels.” In fact, this number could be any rational number, but we will discuss only octave levels or scales. From (2) we see that the function $\phi(x)$ is obtained as a linear combination of a scaled and translated version of itself, and hence the term *scaling function*.

The subspaces V_j are generated by $\phi_{j,k}(x) := 2^{j/2} \phi(2^j x - k)$; $j, k \in \mathbb{Z}$, where $\mathbb{Z} := \{\dots, -1, 0, 1, \dots\}$. For each scale j , since $V_j \subset V_{j+1}$, there exists a complementary subspace W_j of V_j in V_{j+1} . This subspace W_j , called “wavelet subspace,” is generated by $\psi_{j,k}(x) := 2^{j/2} \psi(2^j x - k)$, where $\psi \in L^2$ is called the “wavelet.” From the discussion above, these results follow easily:

$$\begin{cases} V_{j_1} \cup W_{j_1} = V_{j_2} & j_2 = j_1 + 1 \\ V_{j_1} \cap V_{j_2} = V_{j_2} & j_1 > j_2 \\ W_{j_1} \cap W_{j_2} = \{0\} & j_1 \neq j_2 \\ V_{j_1} \cap W_{j_2} = \{0\} & j_1 \leq j_2 \end{cases} \tag{3}$$

The scaling function ϕ exhibits lowpass filter characteristics in the sense that $\hat{\phi}(0) = 1$, where a hat over the function denotes its Fourier transform. On the other hand, the wavelet function ψ exhibits bandpass filter characteristic in the sense that $\hat{\psi}(0) = 0$. Later in the article, we will see some examples of wavelets and scaling functions.

2.2. Properties of Wavelets

Some of the important properties that we will discuss in this article are given below:

- *Vanishing moment*—a wavelet is said to have a vanishing moment of order m if

$$\int_{-\infty}^{\infty} x^p \psi(x) dx = 0; \quad p = 0, \dots, m-1 \quad (4)$$

All wavelets must satisfy this condition for $p=0$.

- *Orthonormality*—the wavelets $\{\psi_{j,k}\}$ form an orthonormal basis if

$$\langle \psi_{j,k}, \psi_{l,m} \rangle = \delta_{j,l} \delta_{k,m}; \quad \text{for all } j, k, l, m \in \mathbb{Z} \quad (5)$$

where $\delta_{p,q}$ is the Krönercker delta defined in the usual way as

$$\delta_{p,q} = \begin{cases} 1 & p=q \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

The inner product $\langle f_1, f_2 \rangle$ of two square integrable functions f_1 and f_2 is defined as

$$\langle f_1, f_2 \rangle := \int_{-\infty}^{\infty} f_1(x) f_2^*(x) dx$$

with $f_2^*(x)$, representing the complex conjugation of f_2 .

- *Semiorthogonality*—The wavelets $\{\psi_{j,k}\}$ form a semiorthogonal basis if

$$\langle \psi_{j,k}, \psi_{l,m} \rangle = 0; \quad j \neq l; \quad \text{for all } j, k, l, m \in \mathbb{Z} \quad (7)$$

2.3. Wavelet Transform Algorithm

Given a function $f(x) \in L^2$, the decomposition into various scales begins by mapping the function into a sufficiently high-resolution subspace V_M :

$$L^2 \ni f(x) \mapsto f_M = \sum_k a_{M,k} \phi(2^M x - k) \in V_M \quad (8)$$

Now since

$$\begin{aligned} V_M &= W_{M-1} + V_{M-1} \\ &= W_{M-1} + W_{M-2} + V_{M-2} \\ &= \sum_{n=1}^N W_{M-n} + V_{M-N}, \end{aligned} \quad (9)$$

we can write

$$f_M(x) = \sum_{n=1}^N g_{M-n}(x) + f_{M-N}(x) \quad (10)$$

where $f_{M-N}(x)$ is the coarsest approximation of $f_M(x)$ and

$$f_j(x) = \sum_k a_{j,k} \phi(2^j x - k) \in V_j \quad (11)$$

$$g_j(x) = \sum_k w_{j,k} \psi(2^j x - k) \in W_j \quad (12)$$

If the scaling functions and wavelets are orthonormal, it is easy to obtain the coefficients $\{a_{j,k}\}$ and $\{w_{j,k}\}$. However for the semiorthogonal case, we need a dual scaling function ($\tilde{\phi}$) and dual wavelet ($\tilde{\psi}$). Dual wavelets satisfy the ‘‘biorthogonality condition’’:

$$\langle \psi_{j,k}, \tilde{\psi}_{l,m} \rangle = \delta_{j,l} \cdot \delta_{k,m}, \quad j, k, l, m \in \mathbb{Z} \quad (13)$$

For the semiorthogonal case, both ψ and $\tilde{\psi}$ belong to the same space W_j for an appropriate j ; likewise ϕ and $\tilde{\phi}$ belong to V_j . One difficulty with semiorthogonal wavelets is that their duals do not have compact support. We can achieve compact support for both $\tilde{\phi}$ and $\tilde{\psi}$ if we forgo the orthogonality requirement that $V_j \perp W_j$. In such a case we get ‘‘biorthogonal wavelets’’ [17] and two MRAs, $\{V_j\}$ and $\{\tilde{V}_j\}$. In this article we will discuss application of orthonormal and semiorthogonal wavelets only.

3. INTEGRAL EQUATIONS

Integral equations appear frequently in practice, particularly the first-kind integral equations [18] in inverse problems. These equations can be represented as

$$L_K f = \int_a^b f(x') K(x, x') dx' = g(x) \quad (14)$$

where $f(x)$ is an unknown function, $K(x, x')$ is the known kernel that might be the system impulse response or Green’s function, and $g(x)$ is the known response function.

3.1. Electromagnetic Scattering

Consider the problem of electromagnetic scattering by an infinitely long metallic cylinder, as shown in Fig. 1. For such a problem, electric surface current J_{sz} is related to the incident electric field via an integral equation

$$j\omega\mu_0 \int_C J_{sz}(l') G(l, l') dl' = E_z^i(l) \quad (15)$$

where

$$G(l, l') = \frac{1}{4j} H_0^{(2)}(k_0 |\rho(l) - \rho(l')|) \quad (16)$$

with the wavenumber $k_0 = 2\pi/\lambda_0$. The electric field E_z^i is the z component of the incident electric field and $H_0^{(2)}$ is the second-kind Hankel function of order 0, and λ_0 is the wavelength in free space. Here, the contour of integration has been parameterized with respect to the chord length.

Figure 1. Cross section of an infinitely long metallic cylinder illuminated by a TM plane wave.

The field component E_z^i can be expressed as

$$E_z^i(l) = E_0 \exp[jk_0(x(l) \cos \phi_i + y(l) \sin \phi_i)] \quad (17)$$

where ϕ_i is the angle of incidence.

Scattering from a thin perfectly conducting strip, as shown in Fig. 2a, gives rise to an equation similar to (15). For this case, we have

$$\int_{-h}^h J_{sy}(z') G(z, z') dz' = E_y^i(z) \quad (18)$$

where $G(z, z')$ is as given by (16).

As a final example of the scattering problem, consider scattering from a thin wire as shown in Fig. 2b. Here the current on the wire and the incident field are related to each other as

$$\int_{-l}^l I(z') K_w(z, z') dz' = -E^i(z) \quad (19)$$

where the kernel K_w is given by

$$K_w(z, z') = \frac{1}{4\pi j \omega \epsilon_0} \frac{\exp(-jk_0 R)}{R^5} \times [(1 + jk_0 R) \times (2R^2 - 3a^2) + k_0^2 a^2 R^2] \quad (20)$$

$$E^i(z) = E_0 \sin \theta \exp(jk_0 z \cos \theta) \quad (21)$$

This kernel is obtained by interchanging integration and differentiation in the integrodifferential form of Pocklington's equation and using the reduced kernel distance $R = [a^2 + (z - z')^2]^{1/2}$, where a is the radius of the wire [19].

All the equations described thus far have the form of a first-kind integral equation, namely

$$\int_a^b f(x') K(x, x') dx' = g(x) \quad (22)$$

Figure 2. (a) A thin half-wavelength-long metallic strip illuminated by a TM wave; (b) a thin wire of length $l/2$ and thickness $l/1000$ illuminated by a plane wave.

where f is the unknown function and the kernel K and the functions g are known. Here the objective is to reconstruct the function f from a set of known data (possibly measured) g . The kernel K may be regarded as the impulse response function of the system.

Although we discuss the solution technique for first-kind integral equations only, the method can be extended to second-kind equations [20,21] and higher-dimensional integral equations [22].

3.2. Transmission-Line Discontinuity

As an example of electromagnetic propagation in a transmission line, consider the problem of characterizing one discontinuity of a coplanar waveguide, shown in Fig. 3. The problem can be formulated by separating the configuration of Fig. 3a into two parts with the help of the equivalence principle [23], according to which the slot regions can be replaced by equivalent surface magnetic

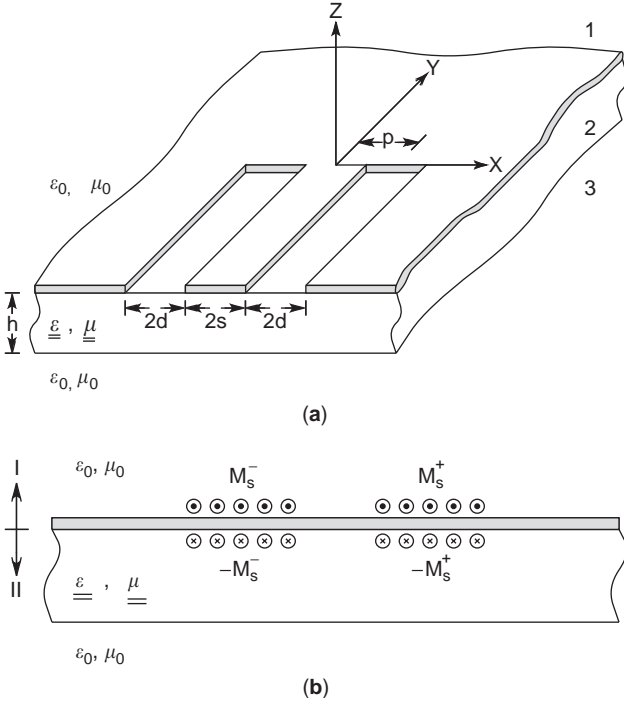

Figure 3. (a) Short-circuited coplanar waveguide with uniaxial substrate; (b) equivalent problem.

current, namely

$$\mathbf{M}_s(\mathbf{r}) = \mathbf{E}(\mathbf{r}) \times \hat{\mathbf{z}}; \quad \mathbf{r} \in \mathcal{D} := \mathcal{D}^+ \cup \mathcal{D}^- \quad (23)$$

where $\mathcal{D}^+ := \{x, y, z \mid x \in (s, s + 2d), y \in (-\infty, 0], z = 0\}$, and $\mathcal{D}^- := \{x, y, z \mid x \in (-s, -s - 2d), y \in (-\infty, 0], z = 0\}$. Then we can write the magnetic field integral equation by enforcing the boundary condition

$$\hat{\mathbf{z}} \times \mathbf{H}(\mathbf{r}) = 0; \quad \mathbf{r} \in \mathcal{D} \quad (24)$$

with $\mathbf{H}(\mathbf{r}) = \mathbf{H}_1(\mathbf{r}) - \mathbf{H}_2(\mathbf{r})$. The magnetic field is given by

$$\begin{aligned} \mathbf{H}(\mathbf{r}) &= \int_{\mathcal{D}^+} \underline{\mathbf{G}}^{HM}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{M}_s^+(\mathbf{r}') d\mathbf{r}' \\ &+ \int_{\mathcal{D}^-} \underline{\mathbf{G}}^{HM}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{M}_s^-(\mathbf{r}') d\mathbf{r}' \end{aligned} \quad (25)$$

$$\underline{\mathbf{G}}^{HM}(\mathbf{r}, \mathbf{r}') = \underline{\mathbf{G}}^{HM,I}(\mathbf{r}, \mathbf{r}') + \underline{\mathbf{G}}^{HM,II}(\mathbf{r}, \mathbf{r}') \quad (26)$$

where the superscripts I and II denote two half-spaces (see Fig. 3b). Details on solving discontinuity problem using wavelets in spectral domain may be found in Ref. 22.

4. MATRIX EQUATION GENERATION

In this section, we will attempt to solve integral equations discussed in the last section. The first step in solving any integral or differential equation is to convert these into a matrix equation to be solved for the unknown coefficients.

The goal is to transform Eq. (14) into a matrix equation

$$\mathbf{Z}i = v \quad (27)$$

where \mathbf{Z} is a two-dimensional matrix, sometimes referred to as the *impedance matrix*, i is the column vector of unknown coefficients to represent f , and v is another column vector related to g . Computation time depends largely on the way we obtain and solve (27). In the following section we describe conventional and wavelet basis functions that are used to represent the unknown function.

4.1. Conventional Basis Functions

The unknown function $f(x)$ can be written as

$$f(x) = \sum_n i_n b_n(x) \quad (28)$$

where $\{b_n\}$ form a complete set of basis functions. These bases may be “global” (entire-domain), extending the entire length $[a, b]$ or be “local” (subdomain), covering only a small segment of the interval, or a combination of both. Some of the commonly used subdomain basis functions are shown in Fig. 4.

For an exact representation of $f(x)$, we may need an infinite number of terms in the series presented above. However, in practice, a finite number of terms suffice for a given acceptable error. Substituting the series representation of $f(x)$ into the original equation (14), we get

$$\sum_{n=1}^N i_n L_K b_n \approx g \quad (29)$$

For the present discussion we will assume N to be large enough that this representation is exact. Now by taking the inner product of (29) with a set of *weighting functions* or *testing functions* $\{t_m; m = 1, \dots, M\}$, we get a set of linear equations

$$\sum_{n=1}^N i_n \langle t_m, L_K b_n \rangle = \langle t_m, g \rangle; \quad m = 1, \dots, M \quad (30)$$

Figure 4. Typical subdomain basis functions: (a) piecewise constant, (b) piecewise linear, (c) piecewise cosine, and (d) piecewise sine functions.

which can be written in the matrix form as

$$[Z_{mn}][i_n] = [v_m] \tag{31}$$

where

$$Z_{mn} = \langle t_m, L_K b_n \rangle; \quad m = 1, \dots, M; \quad n = 1, \dots, N$$

$$v_m = \langle t_m, g \rangle; \quad m = 1, \dots, M$$

The solution of the matrix equation gives the coefficients $\{i_n\}$ and thereby the solution of the integral equations. Two main choices of the testing functions are (1) $t_m(x) = \delta(x - x_m)$, where x_m is a discretization point in the domain; and (2) $t_m(x) = b_m(x)$. In the former case the method is called *point matching*, whereas the latter method is known as the *Galerkin method*. The method so described and those to be discussed in the following sections are generally referred to as “method of moments” (MoM) [24]. We will call MoM with conventional bases as “conventional MoM” and the method with wavelet bases, “wavelet MoM.” Observe that the operator L_K in the preceding paragraphs could be any linear operator—differential as well as integral.

4.2. Wavelet Bases

Conventional bases (local or global), when applied directly to the integral equations, generally lead to a dense (fully populated) matrix Z . As a result, the inversion and the final solution of such a system of linear equations are very time-consuming. In later sections it will be clear why conventional bases give a dense matrix while wavelet bases produce sparse matrices. Observe that conventional MoM is a single-level approximation of the unknown function in the sense that the domain of the function (e.g., $[a, b]$), is discretized only once, even if we use nonuniform discretization of the domain. Wavelet MoM as we will discuss, on the other hand, is inherently multi-level in nature.

Beylkin et al. [25] first proposed the use of wavelets in sparsifying an integral equation. Alpert et al. [20] used “waveletlike” basis functions to solve second-kind integral equations. In electrical engineering, wavelets have been used to solve integral equations arising from electromagnetic scattering and transmission-line problems [22,26–40]. In what follows we briefly describe four different ways in which wavelets have been used in solving integral equations.

4.2.1. Use of Fast Wavelet Algorithm. In this method, the impedance matrix Z is obtained via the conventional method of moments using basis functions such as triangular functions, and then wavelets are used to transform this matrix into a sparse matrix [26,27]. Consider a matrix W formed by wavelets. This matrix consists of the decomposition and reconstruction sequences and their translates. We have not discussed these sequences here, but

readers may find these sequences in any standard book on wavelets [e.g., 8–16].

Transformation of cite original MoM impedance matrix into the new wavelet basis is obtained as

$$WZW^T \cdot (W^T)^{-1}i = Wv \tag{32}$$

which can be written as

$$Z_w \cdot i_w = v_w \tag{33}$$

where W^T represents the transpose of the matrix W . The new set of wavelet-transformed linear equations are

$$Z_w = WZW^T \tag{34}$$

$$i_w = (W^T)^{-1}i \tag{35}$$

$$v_w = Wv \tag{36}$$

The solution vector i is then given by

$$i = W^T(WZW^T)^{-1}Wv \tag{37}$$

For orthonormal wavelets $W^T = W^{-1}$ and the transformation (32) is “unitary similar.” It has been shown [26,27] that the impedance matrix Z_w is sparse, which reduces the inversion time significantly. Discrete wavelet transform (DWT) algorithms can be used to obtain Z_w . Readers may find the details of discrete wavelet transform (octave scale transform) in any standard book on wavelets. In some applications it may be necessary to compute the wavelet transform at nonoctave scales. Readers are referred to the literature [7,41,42] for details on such algorithms.

4.2.2. Direct Application of Wavelets. In another method of applying wavelets to integral equations, wavelets are directly applied; that is, first the unknown function is represented as a superposition of wavelets at several levels (scales) along with the scaling function at the lowest level, prior to using Galerkin’s method described before.

In terms of wavelets and scaling functions we can write the unknown function f in (14) as

$$f(x) = \sum_{j=j_0}^{j_n} \sum_{k=K_1}^{K(j)} w_{j,k} \psi_{j,k}(x) + \sum_{k=K_1}^{K(j_0)} a_{j_0,k} \phi_{j_0,k}(x) \tag{38}$$

where we have used the multiscale property (10).

It should be pointed out here that the wavelets $\{\psi_{j,k}\}$ by themselves form a complete set; therefore, the unknown function could be expanded entirely in terms of the wavelets. However, to retain only a finite number of terms in the expansion, the scaling function part of (38) must be included. In other words, $\{\psi_{j,k}\}$, because of their bandpass

filter characteristics, extract successively lower and lower frequency components of the unknown function with decreasing values of the scale parameter j , while $\phi_{j_0,k}$, because of its lowpass filter characteristics, retains the lowest frequency components or the coarsest approximation of the original function.

In Eq. (38), the choice of j_0 is restricted by the order of the wavelet, while the choice of j_u is governed by the physics of the problem. In applications involving electromagnetic scattering, as a “rule of thumb” the highest scale, j_u , should be chosen such that $1/2^{j_u+1}$ does not exceed $0.1\lambda_0$, where λ_0 is the operative wavelength.

When (38) is substituted in (14), and the resultant equation is tested with the same set of expansion functions, we get a set of linear equations

$$\begin{bmatrix} [Z_{\phi,\phi}] & [Z_{\phi,\psi}] \\ [Z_{\psi,\phi}] & [Z_{\psi,\psi}] \end{bmatrix} \begin{bmatrix} [a_{j_0,k}]_k \\ [w_{j,n}]_{j,n} \end{bmatrix} = \begin{bmatrix} \langle v, \phi_{j_0,k'} \rangle_{k'} \\ \langle v, \psi_{j',k'} \rangle_{j',k'} \end{bmatrix} \quad (39)$$

where the ψ term of the expansion function and the ϕ term of the testing function give rise to the $[Z_{\phi,\psi}]$ portion of the matrix Z . A similar interpretation holds for $[Z_{\phi,\phi}]$, $[Z_{\psi,\phi}]$, and $[Z_{\psi,\psi}]$.

By carefully observing the nature of the submatrices, we can explain the “denseness” of the conventional MoM and the “sparseness” of the wavelet MoM. Unlike wavelets, the scaling functions discussed in this article do not possess the vanishing moments properties. Consequently, for two pulse or triangular functions ϕ_1 and ϕ_2 (usual bases for the conventional MoM and suitable candidates for the scaling functions), even though $\langle \phi_1, \phi_2 \rangle = 0$ for nonoverlapping support, $\langle \phi_1, L_K \phi_2 \rangle$ is not very small since $L_k \phi_2$ is not small. On the other hand, as is clear from the vanishing-moment property (4) of a wavelet of order m , the integral vanishes if the function against which the wavelet is being integrated behaves as a polynomial of a certain order “locally.” Away from the singular points the kernel has a polynomial behavior locally. Consequently, integrals such as $(L_K \psi_{j,n})$ and the inner products involving wavelets are very small for nonoverlapping support.

Because of its “total positivity” property [11, pp. 207–209], the scaling function has a “smoothing” or “variation diminishing” effect on a function against which it is integrated. The smoothing effect can be understood as follows. If we convolve two pulse functions, both of which are discontinuous but totally positive, the resultant function is a linear B -spline (triangular function) that is continuous. Likewise, if we convolve two linear B -splines, we get a cubic B -spline that is twice continuously differentiable. Analogous to these, the function $L_K \phi_{j_0,k}$ is smoother than the kernel K itself. Furthermore, because of the MRA properties that give

$$\langle \phi_{j,k}, \psi_{j',l} \rangle = 0, \quad j \leq j' \quad (40)$$

the integrals $\langle \phi_{j_0,k'}, (L_K \psi_{j,n}) \rangle$ and $\langle \psi_{j',n'}, (L_K \phi_{j_0,k}) \rangle$ are quite small.

The $[Z_{\phi,\phi}]$ portion of the matrix, although diagonally dominant, usually does not have entries that are very

small compared to the diagonal entries. In conventional MoM case, all the elements of the matrix are of the form $\langle \phi_{j,k'}, (L_K \phi_{j,k}) \rangle$. Consequently, we cannot, threshold such a matrix in order to sparsify it. In wavelet MoM case, the entries of $[Z_{\phi,\phi}]$ occupy a very small portion (5×5 for linear and 11×11 for cubic spline cases) of the matrix, while the rest contain entries whose magnitudes are very small compared to the largest, entry; hence a significant number of entries can be set to zero without affecting the solution appreciably.

4.2.3. Wavelets in Spectral Domain. In the previous section, we have used wavelets in the space domain. The local support and vanishing-moment properties of wavelet bases were used to obtain a sparse matrix representation of an integral equation. In some applications, particularly in spectral-domain methods in electromagnetics, wavelets in the spectral domain may be quite useful. Whenever we have a problem in which the unknown function is expanded in terms of the basis function in the space (time) domain while the numerical computation takes place in the spectral (frequency) domain, we should look at the space–spectral window product in order to determine the efficiency of using a particular basis function. According to the “uncertainty principle,” the space–spectral window product of a square integrable function cannot be less than 0.5; the lowest value is possible only for functions of Gaussian class. Because of the nearly optimal space–spectral window product of the cubic spline and the corresponding semiorthogonal wavelet, the improper integrals appearing in many spectral-domain formulations of integral equations can be evaluated efficiently. This is due to the fact that higher-order wavelets generally have faster decay in the spectral domain. The spectral-domain wavelets have been used to solve the transmission-line discontinuity problem [22].

4.2.4. Wavelet Packets. The discrete wavelet packet (DWP) similarity transformation has been used to obtain a higher degree of sparsification of the matrix than is achievable using the standard wavelets [38]. It has also been shown that the DWP method gives faster matrix-vector multiplication than do some of the fast multipole methods.

In the standard wavelet decomposition process, first we map the given function to a sufficiently high-resolution subspace (V_M) and obtain the approximation coefficients $\{a_{M,k}\}$ (see Section 2). The approximation coefficients $\{a_{M-1,k}\}$ and wavelet coefficients $\{w_{M-1,k}\}$ are computed from $\{a_{M,k}\}$. This process continues; that is, the coefficients for the next-lower level $M-2$ are obtained from $\{a_{M-1,k}\}$, and so on. Observe that in this scheme, only approximation coefficients $\{a_{j,k}\}$ are processed at any scale j ; the wavelet coefficients are merely the outputs and remain untouched. In a wavelet packet, the wavelet coefficients are also processed, which, heuristically, should result in a higher degree of sparsity since in this scheme, the frequency bands are further divided compared with the standard decomposition scheme.

4.3. Intervallic Wavelets

Wavelets on the real line have been used to solve integral equations arising from electromagnetic scattering and waveguiding problems. The difficulty with using wavelets on the entire real line is that the boundary conditions need to be enforced explicitly. Some of the scaling functions and wavelets must be placed outside the domain of integration. Furthermore, because of truncation at the boundary, the vanishing-moment property is not satisfied near the boundary. Also, in signal processing uses of these wavelets lead to undesirable jumps near the boundaries. We can avoid this difficulty by periodizing the scaling function as [10, Sect. 9.3]

$$\phi_{j,k}^p := \sum_l \phi_{j,k}(x+l) \tag{41}$$

where the superscript “p” implies periodic case. Periodic wavelets are obtained in a similar way. It is easy to show that if $\hat{\phi}(2\pi k) = \delta_{k,0}$, which is generally true for the scaling functions, then $\sum_k \phi(x-k) \equiv 1$. If we apply the last relation, which is also known as the “partition of unity” to (41), we can show that $\{\phi_{0,0}^p\} \cup \{\psi_{j,k}^p; j \in \mathbb{Z}^+ := \{0, 1, 2, \dots\}, k = 0, \dots, 2^j - 1\}$ generates $L^2([0,1])$.

Periodic wavelets have been used in other studies [35–37]. However, as mentioned elsewhere [10, Sect. 10.7], unless the function that is being approximated by the periodized scaling functions and wavelets has the same values at the boundaries, we still have “edge” problems at the boundaries. To circumvent these difficulties, wavelets, constructed especially for a bounded interval, have been introduced in [40]. Details on intervallic wavelets may be found in the literature [40,43–45]. Most of the time, we are interested in knowing the formulas for these wavelets rather than delving into the mathematical rigor of their construction. These formulas may be found in the literature [16,40].

Wavelets on a bounded interval satisfy all the properties of regular wavelets that are defined on entire real line; the only difference is that in the former case, there are a few special wavelets near the boundaries. Wavelets and scaling functions whose support lies completely inside the interval have properties that are exactly same as those of regular wavelets. As an example consider semiorthogonal wavelets of order m . For this case the scaling functions (B -splines of order m) have support $[0, m]$, whereas the corresponding wavelet extends the interval $[0, 2m - 1]$. If we normalize the domain of the unknown function from $[a, b]$ to $[0, 1]$ then there will be 2^j segments at any scale j (discretization step = 2^{-j}). Consequently, in order to have at least one complete inner wavelet, the following condition must be satisfied:

$$2^j \geq 2m - 1 \tag{42}$$

For j satisfying this condition, there are $m - 1$ boundary scaling functions and wavelets at 0 and 1, and $2^j - m + 1$ inner scaling functions and $2^j - 2m + 2$ inner wavelets. Figure 5 shows all the scaling functions and wavelets for $m = 2$ at the scale $j = 2$. All the scaling functions for $m = 4$

and $j = 3$ are shown in Fig. 6a, while Fig. 6b gives only the corresponding boundary wavelets near $x = 0$ and one inner wavelet. The rest of the inner wavelets can be obtained by simply translating the first one whereas the boundary wavelets near $x = 1$ are the mirror images of ones near $x = 0$.

5. NUMERICAL RESULTS

In this section we present some numerical examples for applications of wavelets to time–frequency analysis and integral equations. The purpose of these results is to give readers an idea of how wavelets can be applied. These examples can certainly be solved by other methods more efficiently, but they help understand wavelet approach in a simpler way.

Because of page limitations, we present only one example from electromagnetic scattering problems, the one for a cylindrical geometry. Numerical results for strip and wire problems can be found in Ref. 31. Results for spectral-domain applications of wavelets to transmission-line discontinuity problems may be found in Ref. 22. For more applications of wavelets to electromagnetic problems, readers may refer to Ref. 39.

The matrix equation (39) is solved for a circular cylindrical surface [40]. The surface current distribution is computed using linear and cubic spline wavelets. The wavelet MoM results are compared with the conventional MoM results. To obtain the conventional MoM results, we have used triangular functions for both expanding the unknown current distribution and testing the resultant equation. The conventional MoM results have been verified with a series solution [23]. The results of the conventional MoM and the wavelet MoM agree very well.

We want to show how “thresholding” affects the final solution. By “thresholding,” we mean setting those elements of the matrix to zero that are smaller (in magnitude) than some positive number δ ($0 \leq \delta < 1$), called the threshold parameter, times the largest element of the matrix.

Let z_{\max} and z_{\min} be the largest and the smallest elements of the matrix in (39). For a fixed value of the threshold parameter δ , define percent relative error (ϵ_δ) as [40]

$$\epsilon_\delta := \frac{\|f_0 - f_\delta\|_2}{\|f_0\|_2} \times 100 \tag{43}$$

and percent sparsity (S_δ) as

$$S_\delta := \frac{N_0 - N_\delta}{N_0} \times 100 \tag{44}$$

where f_δ represents the solution obtained from (39) when the elements whose magnitudes are smaller than δz_{\max} have been set to zero. Similarly, N_δ is the total number of elements left after thresholding. Clearly, $f_0(x) = f(x)$ and $N_0 = N^2$, where N is the number of unknowns.

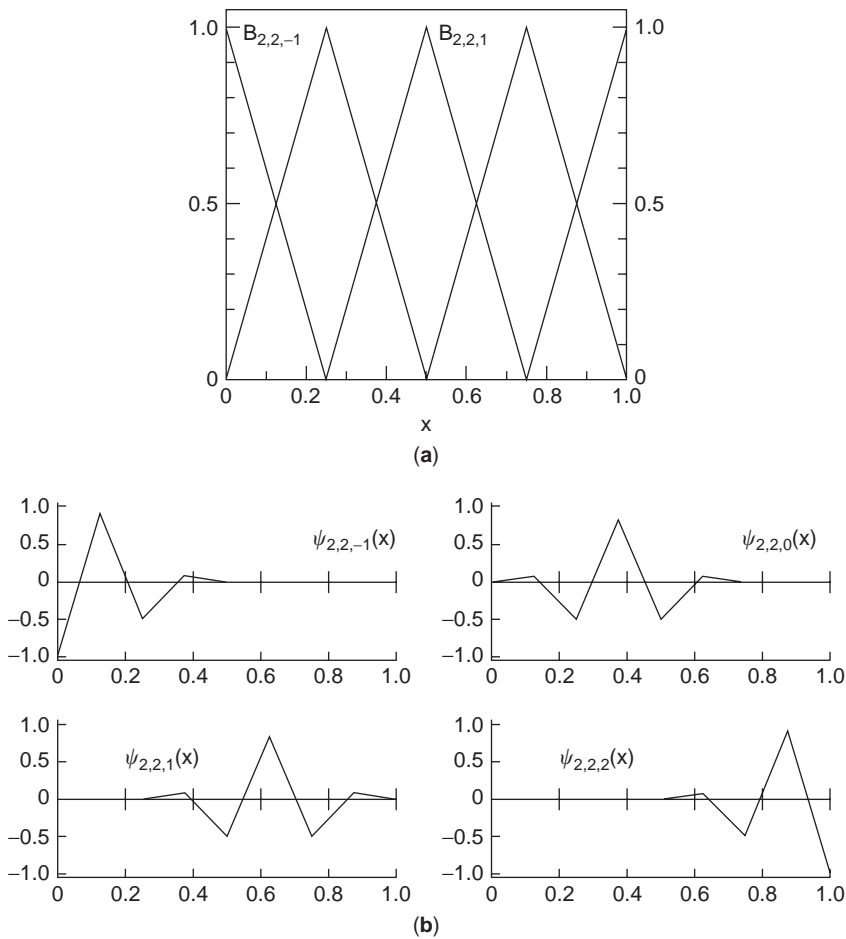

Figure 5. (a) Linear spline ($m=2$) scaling functions on $[0,1]$; (b) linear spline wavelets on $[0,1]$. The subscripts indicate the order of spline (m), scale (j), and the position (k), respectively [40].

Table 1 gives an idea of the relative magnitudes of the largest and the smallest elements in the matrix for conventional and wavelet MoM. As is expected, because of their higher vanishing moment property, cubic spline wavelets give the higher ratio, z_{\max}/z_{\min} .

The matrix elements with $\delta=0.0002$ for the linear spline case are shown in Fig. 7. Figures 8 and 9 give an idea of the pointwise error in the solution for linear and cubic spline cases for different values of threshold parameter.

It is worth pointing out here that regardless of the size of the matrix, only 5×5 in the case of the linear spline and 11×11 in the case of the cubic splines remain unaffected by thresholding; a significant number of the remaining elements can be set to zero without causing much error in the solution.

6. SEMIORTHOGONAL VERSUS ORTHOGONAL WAVELETS

Both semiorthogonal and orthogonal wavelets have been used for solving integral equations. A comparative study of their advantages and disadvantages has been reported [31]. The orthonormal wavelet transformation, because of its unitary similar property, preserves the condition

number (κ) of the original impedance matrix Z ; semiorthogonal wavelets do not. Consequently, the transformed matrix equation may require more iterations to converge to the desired solution. Some preliminary results comparing the condition number of matrices for different cases are given in Table 2 (where ON = orthonormal and SO = semiorthogonal).

In applying wavelets directly to solve integral equations, one of the most attractive features of semiorthogonal wavelets is that closed-form expressions are available for such wavelets [16,40]. Few of the continuous ON wavelets can be written in closed form.

One thing to be kept in mind is that, unlike signal processing applications where one usually deals with a discretized signal and decomposition and reconstruction sequences, here in the boundary value problem we often have to compute the wavelet and scaling function values at any given point. For a strip/thin-wire case, a comparison of the computation time and sparsity is summarized in Tables 3 and 4 [31].

Semiorthogonal wavelets are symmetric and hence have generalized linear phase [11, pp. 160–174], an important factor in function reconstruction. It is well known [10, Sect. 8.1] that symmetric or antisymmetric, real-valued, continuous, and compactly supported ON scaling functions and wavelets do not exist. Finally, in using

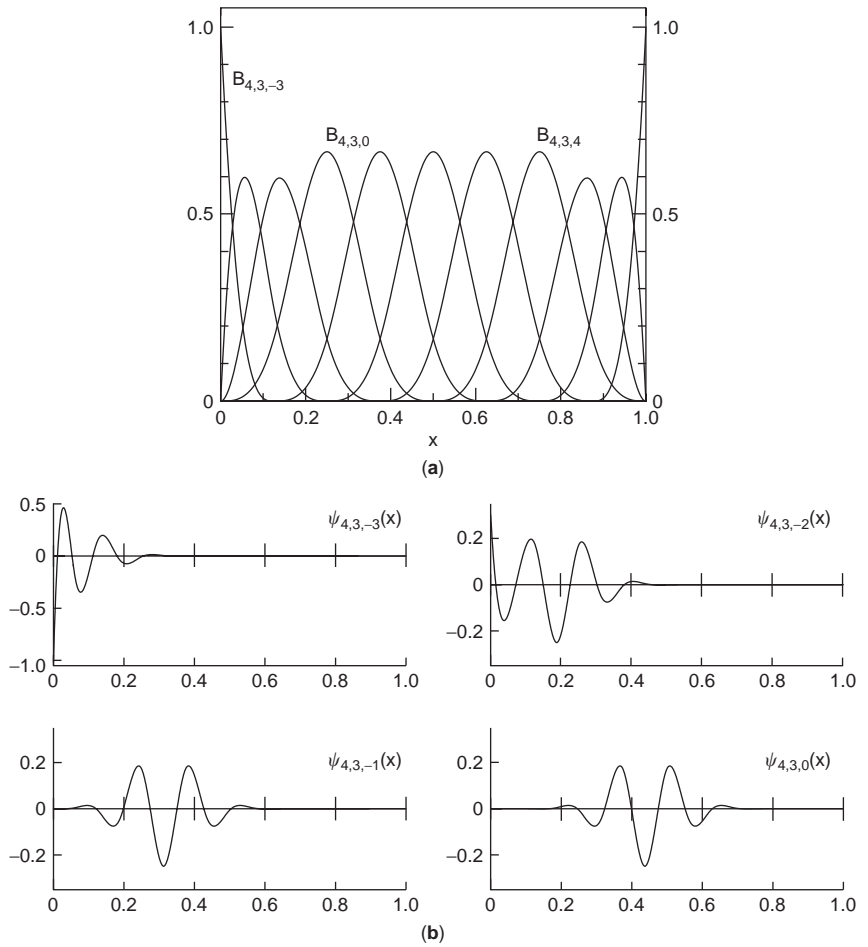

Figure 6. (a) Cubic spline ($m = 4$) scaling functions on $[0,1]$; (b) cubic spline wavelets on $[0,1]$. The subscripts indicate the order of spline (m), scale (j), and the position (k), respectively [40].

wavelets to solve spectral domain problems, as discussed before, we need to look at the time–frequency window product of the basis. Semiorthogonal wavelets approach the optimal value of the time–frequency product, which is 0.5, very fast. For instance, this value for the cubic spline wavelet is 0.505. It has been shown [46] that this product approaches to ∞ with the increase in smoothness of ON wavelets.

7. DIFFERENTIAL EQUATIONS

An ordinary differential equation (ODE) can be represented as

$$Lf(x) = g(x); \quad x \in [0, 1] \tag{45}$$

Table 1. Relative Magnitudes of Largest and Smallest Elements of Matrix for Conventional and Wavelet MoM ($\alpha = 0.1\lambda_0$)

	Conventional MoM	Wavelet MoM ($m = 2$)	Wavelet MoM ($m = 4$)
Z_{\max}	5.377	0.750	0.216
Z_{\min}	1.682	7.684×10^{-8}	8.585×10^{-13}
Ratio	3.400	9.761×10^6	2.516×10^{11}

Source: Ref. 40.

with

$$L = \sum_{j=0}^m a_j(x) \frac{d^j}{dx^j} \tag{46}$$

and some appropriate boundary conditions. If the coefficients $\{a_j\}$ are independent of x , then the solution can be obtained via a Fourier method. However, in the ODE case, with nonconstant coefficients, and in PDEs, we generally use finite-element or finite-difference-type methods.

7.1. Multigrid Method

In the traditional finite-element method (FEM), local bases are used to represent the unknown function and the solution is obtained by Galerkin’s method, similar to the approach described in previous sections. For the differential operator, we get sparse and banded stiffness matrices that are generally solved using iterative techniques, such as the Jacobi method.

One disadvantage of conventional FEM is that the condition number (κ) of the stiffness matrix grows as $O(h^{-2})$, where h is the discretization step. As a result, the convergence of the iterative technique becomes slow and the solution becomes sensitive to small perturbations in the matrix elements. If we study how the error

Figure 7. A typical grayscale plot of the matrix elements obtained using linear wavelet MoM. The darker color represents larger magnitude. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

decreases with iteration in iterative techniques, such as the Jacobi method, we find that the error decreases rapidly for the first few iterations. After that, the rate at which the error decreases slows down [47, pp. 18–21]. Such methods are also called “high-frequency methods” since these iterative procedures have a “smoothing” effect on the high-frequency portion of the error. Once this portion is eliminated, convergence becomes quite slow. After the first few iterations, if we could rediscritize the domain with coarser grids and thereby go to lower

Figure 8. The magnitude of surface current distribution computed using linear ($m = 2$) spline wavelet MoM for different values of the threshold parameter δ [40].

Figure 9. The magnitude of surface current distribution computed using cubic ($m = 4$) spline wavelet MoM for different values of the threshold parameter δ [40].

frequency, the convergence rate would be accelerated. This leads us to a multigrid-type method.

Multigrid or hierarchical methods have been proposed to overcome the difficulties associated with the conventional method [47–63]. In this technique one performs a few iterations of the smoothing method (Jacobi type), and then the intermediate solution and the operator are projected to a coarse grid. The problem is then solved at the coarse grid, and by interpolation one goes back to the finer grids. By going back and forth between finer and coarser grids, the convergence can be accelerated. It has been shown for elliptic PDEs, that for wavelet-based multilevel methods, the condition number is independent of discretization step [i.e., $\kappa = O(1)$] [58]. The multigrid method is too involved to discuss in this article. Readers are encouraged to look at the references provided at the end of this article.

Multiresolution aspects of wavelets have also been applied in evolution equations [62,63]. In evolution problems, the space and time discretizations are interrelated to gain a stable numerical scheme. The timestep must be determined from the smallest space discretization. This makes the computation quite complex. A spacetime adaptive method has been introduced [63] where wavelets have been used to adjust the spacetime discretization steps locally.

7.2. Multiresolution Time-Domain (MRTD) Method

The explosive growth in wireless communications (3G Cellular Systems, 802.11 WLANs) has spawned a great deal of research in electronic packaging for high-performance devices. Silicon-embedded components, ultracompact efficient antenna technology, and micromachining technology are critical to meet the cost and performance requirements for a higher level of multifunction integration in the development of wireless transceivers, since they can

considerably reduce the MMIC real estate and the amount of needed discrete elements. In addition, advances in device processing are enabling the creation of increasingly compact microwave circuits. These circuits incorporate a high degree of functionality through the combination of many microwave components in close proximity. These advanced devices often utilize geometries with high aspect ratios, small feature size, and moving parts. These characteristics, which are necessary to the operation of these devices, often lead to difficulties in predicting performance. The simulation of these complex devices requires the use of extremely small elements or cells, which can tax many simulation tools beyond their limits. This has led to the use of a combination of methods, such as full-wave simulation and microwave circuit simulation, or, if higher accuracy is required, the use of a parallel full-wave simulator on specialized hardware. For the modeling of all of these wireless elements, time-domain full-wave techniques demonstrate numerous advantages since they are robust and easy to program, and they can use wideband excitations that allow for one simulation to cover the entire frequency band of interest and can be easily parallelized on relatively inexpensive hardware, making it possible to simulate large structures.

The FDTD [67,70] method is one of the most mature and versatile time-domain numerical techniques and has been used for a wide variety of structures. The use of variable gridding along with effective parallelization approaches allows fine details of large structures to be modeled. Curves and diagonal elements can be modeled using stair stepping. In addition, a wide variety of FDTD enhancements make possible the modeling of small gaps, multielectric/membrane configurations and resonating passives. Macroscopic results, such as *S* parameters and impedances, can be determined by probing and comparing voltages and currents at different points in the structure. The multiresolution time-domain technique (MRTD)

Table 3. Comparison of CPU Time (in seconds) per Matrix Element for Spline, Semiorthogonal, and Orthonormal Basis Function [31]

	Wire	Plate

[62,65] is an adaptive generalization of the FDTD technique that is based on the principles of multiresolution analysis and makes use of wavelets to alleviate the computational burdens of FDTD for complex or large structures, such as multilayer packages or MEMS, where the position of the boundaries is time changing and the membrane thickness is much smaller than any other detail in the transverse direction. The MRTD technique allows the cell resolution to vary with both time and position. The wavelets can be used to represent higher levels of detail along with higher-frequency content. As fields propagate through the structure, the resolution can be varied to allow for the rapidly changing fields.

The multiresolution time-domain (MRTD) technique uses a wavelet discretization of Maxwell's equations to provide a time- and space-adaptive electromagnetic modeling scheme. The advantage of this method is that it can use much larger cells than similar methods [64], such as finite-difference time-domain (FDTD). The number of basis functions used in each cell can be varied as a function of space and time [71]. In this way, grids of complex structures can use high-resolution cells in areas of large field variation and lower-resolution cells elsewhere. The multiresolution time-domain technique draws its name from the application of multiresolution principles to Maxwell's equations. In the application of the method, the electric and magnetic fields are expanded into a scaling and wavelet functions and then inserted into Maxwell's equations. The method of moments is then applied to these equations. This leads to a time marching scheme much like the finite-difference time-domain technique. The advantage of this technique over other methods is that wavelets can be added or subtracted during to the simulation at any point in the grid. In this way the grid can react to both complex geometry and rapid changes in the field as it propagates through the grid. The choice of wavelet basis functions determines the characteristics of the MRTD scheme. The Battle-Lemarie [72,73], the Daubechies [10], and other wavelet basis (e.g., biorthogonal wavelets [17,68,74]) have been successfully applied and demonstrated significant savings in memory and execution time requirements by one and two orders of magnitude, respectively [75–79] with respect to the FDTD technique. The stability and dispersion performance of entire-domain (e.g., Battle-Lemarie) MRTD schemes has been investigated for different stencil sizes and for zero-resolution wavelets [80]. Analytical expressions for the maximum stable timestep have been derived. Larger

stencils decrease the numerical phase error, making it significantly lower than FDTD for low and medium discretizations. Stencil sizes greater than 10 offer a smaller phase error than does FDTD even for discretizations close to 50 cells per wavelength. The enhancement of wavelets further improves the dispersion performance for discretizations close to the Nyquist limit (23 cells per wavelength) making it comparable to that of much denser grids (10–15 cells per wavelength), although it decreases the value of the maximum timestep guaranteeing the stability of the scheme. The finite-domain Haar basis functions (Fig. 10) provide a convenient tool for the transition from FDTD to MRTD due to their compact support, and to their similarity with the FDTD pulse basis, thus providing an effective demonstration tool for this section. In order to create an efficient scheme, Wavelet systems are usually chosen to create sparse discretizations of the modeled equations. The multiresolution time-domain (MRTD) [62] technique makes possible the application of wavelet decomposition principles to the space discretization of Maxwell's equa-

tions. The practical outcome of this application is a time-space-adaptive grid. This grid is very useful because the resolution can be customized to match a given structure using a minimum number of grid points. Through careful application of thresholding [64], this effect can be enhanced by allowing the resolution to be changed based on the requirements of representing the waveform as a function of time. The use of wavelets, however, is not without a price and the application of localized effects becomes difficult.

The quantities that are found directly in MRTD are the values of the wavelet/scaling coefficients; the field values must be reconstructed by summing all coefficients that overlap at any given point. Because all wavelet coefficients cover multiple grid locations, the application of effects at individual points in the grid is challenging. Changing the values of wavelet coefficients to alter the field values at one point effects the values at many other points. Careless coefficient modification can lead to nonphysical field values and unstable algorithms.

The Haar wavelet family is in many ways one of the simplest; however, it has many properties that make its application to practical structures favorable [64]. Most importantly, it is finite-domain and when reconstructed leads to finite areas of constant field value (equivalent gridpoints [66]). Using this property, it is possible to apply pointwise effects in the MRTD grid when an arbitrary level of Haar wavelets is used.

This section discusses the fundamentals of the MRTD derivation and techniques that can be used for the intracell modeling of PECs and dielectric interfaces with Haar MRTD to apply PEC effects at individual equivalent gridpoints. These techniques use wavelet reconstruction/decomposition to apply pointwise effects in the MRTD grid and makes possible the use of the MRTD timespace-adaptive grid for complex structures. Using this method, large, sparse cells can be used in homogeneous areas surrounding high-resolution structures while high-resolution grids can be used to represent fine features. Various examples from large-scale MEMS, packaging, antenna and interconnecting structures demonstrate the potentials of MRTD technique for system-level analysis, design, and optimization.

7.2.1. Fundamentals of MRTD. To clearly present the MRTD method, a brief derivation of 2D Haar MRTD is presented, as well as a partial listing of the properties of

Figure 10. Haar scaling function ϕ and wavelet ψ_0 .

Haar wavelet expansions. The extension to 3D and other basis functions is straightforward.

7.2.1.1. Haar Basis Functions. Haar basis functions are based on pulses in space. The Haar scaling function ϕ , as well as the Haar mother wavelet ψ_0 , are presented in Fig. 10. The scaling function is simply a pulse function over a given domain. The wavelet function is based on the scaling function, and consists of two pulses, each of half the domain of the scaling function and of the opposite magnitude. The inner product of either function with itself is 1, while the inner product of the two functions is 0 [65].

The Haar wavelets of higher resolution levels are based on the mother wavelet. For each level of resolution the number of wavelets is doubled while the domain of each is halved. The magnitude of each function is modified so that the inner product of each wavelet function with itself is one. The inner product of any wavelet coefficient with any other wavelet coefficient, at any resolution level, or with the scaling function, is 0 [65]. Figure 11 presents the wavelet coefficients for wavelet resolution levels 1 and 2. We assume that the maximum used wavelet resolution is r_{\max} .

The reconstruction of the wavelets yields some interesting properties. When the coefficients of the expansion are summed to determine field values, the function appears as a pulsetrain. The pulses have the domain of half of the highest resolution wavelet. Furthermore, these

pulses overlap the constant valued sections of the highest-resolution wavelets. A linear combination of the wavelet and scaling functions has as many degrees of freedom as the number of coefficients used. There are $2^{r_{\max} + 1}$ functions used per level, and any finite real value can be represented at the center of each half of the r_{\max} level wavelets.

The effect of the variable grid when it is used to represent electromagnetic fields can be easily seen. If the field value can be approximated as constant across the half-domain of the highest-resolution wavelet, there is no need for increasing resolution. If the field has more rapid variation, each increase in resolution doubles the effective resolution of the cell. High-resolution cells can be used to represent rapid field variation (such as impressed currents and discontinuity effects) while low-resolution cells can be used elsewhere.

7.2.1.2. Haar MRTD Derivation. The equations

$$\frac{dE_x}{dt} = \frac{1}{\epsilon} \frac{dH_z}{dy} \tag{47}$$

$$\frac{dE_y}{dt} = -\frac{1}{\epsilon} \frac{dH_z}{dx} \tag{48}$$

$$\frac{dH_z}{dt} = \frac{1}{\mu} \left[\frac{dE_x}{dy} - \frac{dE_y}{dx} \right] \tag{49}$$

represent the 2D TE_z mode of Maxwell's equations for source-free, lossless, isotropic media. These functions will be used to demonstrate the expansion of Maxwell's equations in this article as a compromise between completeness and space requirements. The expansion of the E_x field in (47) in terms of Haar scaling and wavelet functions is

$$\begin{aligned} E_x(x,y) = & \sum_{n,i,j} h_n(t) \left[{}_n E_{i,j}^{x,\phi\phi} \phi_i(x)\phi_j(y) \right. \\ & + \sum_{r=0}^{r_{\max}} \sum_{p=0}^{2^r-1} {}_n E_{i,j,r,p}^{x,\psi\psi} \psi_{i,p}^r(x)\phi_j(y) \\ & + \sum_{r=0}^{r_{\max}} \sum_{p=0}^{2^r-1} {}_n E_{i,j,r,p}^{x,\phi\psi} \phi_i(x)\psi_{j,p}^r(y) \\ & \left. + \sum_{r=0}^{r_{\max}} \sum_{p=0}^{2^r-1} \sum_{s=0}^{r_{\max}} \sum_{q=0}^{2^s-1} {}_n E_{i,j,r,p}^{x,\psi\psi} \psi_{i,p}^r(x)\psi_{j,q}^s(y) \right] \end{aligned} \tag{50}$$

where ${}_n E_{i,j}^{x,\phi\phi}$ is the coefficient corresponding to scaling function in x and y that represents the electric field in the i, j cell at timestep n . $\psi_{j,p}^r$ denotes a wavelet of resolution r at the p position $[(p - 0.5)/2^r]$ of the j cell. Other coefficients have similar definition. The time dependence is assumed to be constant for each timestep using the pulse $h_n(t)$, although efforts have been published where wavelets have been used in the time domain as well [77].

In a 2D expansion wavelets and scaling functions are used in both the x and y directions. The terms in (50) represent the products of the basis functions in both

Figure 11. Haar wavelets at resolutions 1 and 2.

Figure 12. 2D Haar coefficients for $r_{\max} = 0$.

directions. For each of these products, one coefficient results. The four groups of coefficients represent the scaling x /scaling y , wavelet x /scaling y , scaling x /wavelet y , and wavelet x /wavelet y coefficients. There are $2^{2(r_{\max} + 1)}$ wavelets for a maximum resolution r_{\max} . For a maximum resolution level $r_{\max} = 0$, the four coefficients in 2D [one for each product term in (50)] are presented in Fig. 12.

When the E and H -field expansions are inserted into (47)–(49), the method of moments can be applied to determine update equations for each of the wavelet/scaling coefficients [65]. It has been shown [65,66] that the offset between the E and H fields in this expansion yields the best dispersion properties and locates the equivalent gridpoints in the same pattern as in the FDTD Yee cell [67]. In the 2D case, as in the 1D case presented above, the equivalent gridpoints are at the center of the constant valued sections of the highest-resolution wavelets. In Fig. 12 these are the locations of the + and – in the $\psi_x \psi_y$ function.

The update equations for this case are

$$\begin{aligned} n\mathbf{E}_{i,j}^x &= n-1\mathbf{E}_{i,j}^x + \frac{\Delta t}{\epsilon\Delta y} (\mathbf{U}_{E_{x1} n-1} \mathbf{H}_{i,j}^z \\ &+ \mathbf{U}_{E_{x2} n-1} \mathbf{H}_{i,j-1}^z) \end{aligned} \quad (51)$$

$$\begin{aligned} n\mathbf{E}_{i,j}^y &= n-1\mathbf{E}_{i,j}^y + \frac{\Delta t}{\epsilon\Delta x} (\mathbf{U}_{E_{y1} n-1} \mathbf{H}_{i,j}^z \\ &+ \mathbf{U}_{E_{y2} n-1} \mathbf{H}_{i-1,j}^z) \end{aligned} \quad (52)$$

$$\begin{aligned} n\mathbf{H}_{i,j}^z &= n-1\mathbf{H}_{i,j}^z + \frac{\Delta t}{\mu} \left[\frac{1}{\Delta y} (\mathbf{U}_{H_{E_{x1} n-1}} \mathbf{E}_{i,j}^x \right. \\ &+ \mathbf{U}_{H_{E_{x2} n-1}} \mathbf{E}_{i,j+1}^x) - \frac{1}{\Delta x} (\mathbf{U}_{H_{E_{y1} n-1}} \mathbf{E}_{i,j}^y \\ &\left. + \mathbf{U}_{H_{E_{y2} n-1}} \mathbf{E}_{i+1,j}^y) \right] \end{aligned} \quad (53)$$

These equations are written in a matrix form similar to that used in Ref. 65, where, for example, each $n\mathbf{E}_{i,j}^x$ is the vector of the scaling and wavelet coefficients that represent the electric field in the i, j cell at timestep n . The \mathbf{U} matrices are the results of the inner products from the method of moments. Equations (51)–(53) form an explicit set of equations that can be used in a time marching scheme similar to the FDTD method [67]. The resolution can be varied on a cell-by-cell basis, and can also be changed as a function of time [64]. The timestep for this method

$$\Delta t = \frac{1}{c \sqrt{\left(\frac{2^{r_{\max}} + 1}{\Delta x}\right)^2 + \left(\frac{2^{r_{\max}} + 1}{\Delta y}\right)^2}} \quad (54)$$

is the same as FDTD for a cell spacing equal to the equivalent gridpoint spacing [64,65].

7.2.2. Subcell Modeling in MRTD. The method presented in the previous section allows a timespace-variable grid to be used to model Maxwell equations. While not presented, it is possible to continuously vary the dielectric constant continuously through a cell [68,79]. Using this method, arbitrary structures consisting of only dielectrics can be modeled efficiently. However, the addition of PEC structures adds difficulties. A novel technique has been introduced that allows for the intracell modeling of multiple PEC's [81] using MRTD grids, a development that would eliminate one of the major roadblocks in the minimization of memory requirements using this type of adaptive simulator.

The PEC boundary condition requires that electric fields tangential to PECs be set to zero. In (51)–(53) update equations are presented that allow the determination of wavelet/scaling coefficients at a future timestep based on the wavelet/scaling coefficients of the surrounding fields at previous timesteps. If the PEC structure is the size of an MRTD cell, all the scaling/wavelet coefficients can be zeroed to apply the boundary condition. If the PEC structure is smaller than the cell, however, the scaling/wavelet coefficients must be modified such that the field values at non-PEC locations are unchanged while the field values at PEC locations are zeroed.

One way to determine the seating/wavelet coefficients that zero selected fields while leaving other fields unchanged is to use the reconstruction matrix. For example, the $n\mathbf{E}_{i,j}^x$ matrices in (51)–(53) can be transformed into field values by multiplying with a matrix that represents the summation of the fields at the appropriate equivalent gridpoints. In this case

$$\mathbf{E}_R = \mathbf{R}\mathbf{E}_W \quad (55)$$

where \mathbf{E}_R is the reconstructed fields, \mathbf{E}_W is the wavelet coefficients, and \mathbf{R} is the reconstruction matrix. It was previously noted that there are as many independent points that can be reconstructed in \mathbf{E}_R as there are coefficients in \mathbf{E}_W . Thus, \mathbf{R} is square. For the case of

Figure 13. Coordinates for reconstructed fields.

$r_{\max} = 0$, and (55) can be expanded as

$$\begin{bmatrix} \mathbf{E}_{1,1} \\ \mathbf{E}_{1,2} \\ \mathbf{E}_{2,1} \\ \mathbf{E}_{2,1} \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{bmatrix} \begin{bmatrix} {}_n\mathbf{E}_{i,j}^{x,\phi\phi} \\ {}_n\mathbf{E}_{i,j}^{x,\psi\phi} \\ {}_n\mathbf{E}_{i,j}^{x,\phi\psi} \\ {}_n\mathbf{E}_{i,j}^{x,\psi\psi} \end{bmatrix} \quad (56)$$

if the coordinates for the reconstructed fields are given as in Fig. 13.

Just as \mathbf{R} can be used to reconstruct the field coefficients from their scaling/wavelet values, \mathbf{R}^{-1} can be used to decompose the field values to scaling/wavelet coefficients. Thus, the application of a PEC boundary condition to an individual equivalent gridpoint can be accomplished by reconstructing the fields, zeroing the fields tangential to PECs, and then decomposing back to scaling/wavelet coefficients. However, a more efficient method results when the reconstruction/decomposition matrices are applied directly to the MRTD update equations.

By using the reconstruction/decomposition matrices directly on (51)–(53) a pointwise update equation results. For example, multiplying (51) by \mathbf{R} , using $\mathbf{H}_{i,j}^z = \mathbf{R}^{-1}\mathbf{R}\mathbf{H}_{i,j}^z$, and defining $\mathbf{U} = \mathbf{R}\mathbf{U}\mathbf{R}^{-1}$ yield

$$\begin{aligned} \mathbf{R}_n\mathbf{E}_{i,j}^x &= \mathbf{R}_{n-1}\mathbf{E}_{i,j}^x + \frac{\Delta t}{\epsilon\Delta y} (\mathbf{U}'_{E_{x1}}\mathbf{R}_{n-1}\mathbf{H}_{i,j}^z \\ &+ \mathbf{U}'_{E_{x2}}\mathbf{R}_{n-1}\mathbf{H}_{i,j-1}^z) \end{aligned} \quad (57)$$

which gives an update on the electric field points in terms of the magnetic field points.

Using this equation, it is possible to zero the field points that are tangential to PECs by multiplying with a matrix \mathbf{I}_p , which is the identity matrix with zeros in the rows corresponding to PEC locations. As (57) is an update equation, and the initial values of all fields are 0, multiplying the electric field vectors in (57) with \mathbf{I}_p is redundant.

The new update equation with PEC locations zeroed is

$$\begin{aligned} \mathbf{R}_n\mathbf{E}_{i,j}^x &= \mathbf{R}_{n-1}\mathbf{E}_{i,j}^x + \frac{\Delta t}{\epsilon\Delta y} (\mathbf{I}_p\mathbf{U}'_{E_{x1}}\mathbf{R}_{n-1}\mathbf{H}_{i,j}^z \\ &+ \mathbf{I}_p\mathbf{U}'_{E_{x2}}\mathbf{R}_{n-1}\mathbf{H}_{i,j-1}^z) \end{aligned} \quad (58)$$

By multiplying (58) with \mathbf{R}^{-1} and defining $\mathbf{U}^p = \mathbf{R}^{-1}\mathbf{I}_p\mathbf{U}\mathbf{R}$, the PEC MRTD update equation is

$$\begin{aligned} {}_n\mathbf{E}_{i,j}^x &= {}_{n-1}\mathbf{E}_{i,j}^x + \frac{\Delta t}{\epsilon\Delta y} (\mathbf{U}_{E_{x1}}^p {}_{n-1}\mathbf{H}_{i,j}^z \\ &+ \mathbf{U}_{E_{x2}}^p {}_{n-1}\mathbf{H}_{i,j-1}^z) \end{aligned} \quad (59)$$

This equation is the same as (51) except for the use of the \mathbf{U}_p matrices. Thus, it is possible to implement subcell PEC modeling in MRTD while changing only the inner product matrices. This method adds no increase in computational overhead, and simply requires the additional memory to store the \mathbf{U} matrices.

7.2.3. Examples. To test the method, a PEC screen in a 2D parallel-plate waveguide was simulated. An expanded view of the grid surrounding the screen is presented in Fig. 14. The areas where the PEC is applied are shaded. A maximum wavelet resolution of 2 was used. In this simulation, the voltage at the output of the screen was probed. When compared to the results of an FDTD simulation of the same structure (Fig. 15), the maximum difference in magnitude is shown on the order of 10–12% of the peak field value. This is within the numerical accuracy of Matlab [69], which was used for the simulations, showing that the techniques are identical.

7.2.3.1. CPW–Microstrip Transition. The CPW–microstrip transition simulated is shown in Fig. 16. The loss of this transition can be optimized over a wide frequency range with the use of FDTD and design curves for various packaging specifications can be derived. The plot in Fig. 17 shows S_{21} of this transition for a variety of lengths of the

Figure 14. Grid used to represent PEC screen.

Figure 15. Difference between FDTD and MRTD results.

central straight section from 10 to 20 GHz. This data was obtained using time-domain voltage probes at the input (V_1) and output (V_2) of the transition, converting them to frequency domain through the use of a discrete Fourier transform and identifying the reflected voltage through the use of a reference input voltage (V_{ref}) derived by the simulation of a through CPW line [64]. In addition, the use of the full-wave FDTD, which provides the values of all electromagnetic components throughout the geometry, offers a more intuitive visualization of the circuit. For example, in the transition the electric fields have to change smoothly from a coplanar waveguide mode to a microstrip mode, in order to minimize the local reflections. Thus, in the design process it is desirable to identify where this transition takes place and optimize the tapering. Figure 16 is a plot of total electric field for a transverse cross section of the transition. It can be seen that at the position of this cross section, the field is mostly in a CPW mode, although a microstrip mode has started developing below and at the edges of the signal line there. The relative amplitudes of the E field could provide an intuitive design rule for the spacing between the CPW ground and signal line, so as not to suppress the microstrip mode.

7.2.3.2. Microstrip-Line Coupling. Embedded transmission lines are commonly used in multilayer packages, where

Figure 16. CPW–microstrip transition; E -field distribution.

Figure 17. S_{21} for various central linewidths. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the use of noncontinuous grounds could lead to increased crosstalk effects. In this article, the FDTD technique is used for the estimation of the coupling of the finite-ground microstrip lines of Fig. 18 [66]. The results for different line spacing and for a ground connecting via (optimized design) presented in Fig. 19 have been obtained by combining two simulations, an even/odd-mode excitation. In addition, to reduce the unwanted crosstalk, the electric and the magnetic field distributions have been calculated and plotted along a transverse cross section. It is apparent that most of the coupling is through the magnetic field lines, leading to the design conclusion that attempts to reduce the coupling should focus on magnetic shielding.

7.2.3.3. MEMS Capacitive Switch. One example of a MEMS structure that benefits from simulation in MRTD [67] is the MEMS capacitive switch shown in Fig. 20. The gap between the plates in the switch is $\frac{1}{175}$ th of the substrate thickness. The simulation of this device in FDTD is tedious and slow because of the large number of cells that must be used in order to accurately represent the very small gap and substrate.

In MRTD, the number of cells can be reduced by using the built-in adaptive gridding capability of the method. In addition, further efficiencies can be obtained in large

Figure 18. Embedded finite-ground microstrip lines.

simulations featuring this structure by allowing fewer cells to be used when the electric field variation near the cell is low.

7.2.3.4. LTCC Antenna Development. A via-fed stacked cavity-backed patch antenna has been designed (based on a 10-layer LTCC process) for IEEE 802.11a 5.8 GHz band [68] as shown in Fig. 21. The heights of the lower and upper patches (400 mils, 400 mils) are respectively 8 mils (2 LTCC GL550 layers) and 32 mils.

The input impedance and radiation characteristics of the stacked-patch antenna are shown in Figs. 22 and 23 respectively. The 10-dB return loss bandwidth of the antenna is about 4.

7.2.4. Concluding Remarks. The multiresolution time domain (MRTD) is a wavelet-based extension of FDTD. It demonstrates a very high efficiency in the calculation of the scattering parameters as well as its the estimation of the packaging effects and of the parasitic crosstalk between neighboring geometries. In addition, its inherent capability of global electromagnetic field calculation as well as MRTD’s multi-PEC cell allows for the identifica-

Figure 20. MEMS switch feeding capacitive stub.

tion of “hotspots” of high field concentration and for the derivation of physically driven solutions for improvement of the overall system-on-package efficiency. The time/space-adaptive grid of MRTD allows it to be used to model finely detailed structures. Areas of the grid containing small features can use increased resolution, while homogenous areas can use low resolution. It is important to note that this technique can be used to model structures with continuous dielectric variations, and thus composite cells, that is, those with multiple PEC and dielectric regions per cell, can be modeled. Furthermore, the pointwise expansion of MRTD equations can be used in the future to model other subcell components, such as lumped elements and equivalent circuits.

APPLIED NUMERICAL ELECTROMAGNETIC ANALYSIS FOR PLANAR HIGH-FREQUENCY CIRCUITS

JAMES C. RAUTIO
Sonnnet Software, Inc.
Phoenix, New York

1. INTRODUCTION

Both commercial and military wireless applications push limits for size and performance. In the 1970s troops had to make educated guesses about the battlefield situation. Today, frontline troops can have a real-time display showing where every one is, even including the enemy. Cell-phones of the 1980s were the size of a book. Today, they have greater coverage and are so small that they get lost in a pocket. Technology drives these advances. A critical part of this technology is electromagnetic (EM) analysis.

Wireless technology achieves these dramatic advances by shifting functionality from printed circuit boards (PCB) and discrete components (e.g., inductors, capacitors, resistors, transistors) to monolithic integrated circuits. These radiofrequency integrated circuits (RFICs) can be on silicon (Si) or gallium arsenide (GaAs). Another choice, midway between RFIC and PCB, is low-temperature cofired ceramic (LTCC). For example, if you were to open your cellphone, you would see a tiny piece of ceramic connected to the antenna. That little piece of ceramic is an LTCC circuit that replaces a PCB and numerous discrete elements formerly occupying a volume almost as large as your entire modern cellphone.

Other portions of your cellphone might include Si RFICs. Formerly restricted to digital/computer applications, silicon integrated circuits can now be used to shrink entire PCB assemblies down to the size of a few grains of sand. For example, silicon RFICs are widely used for radiofrequency identification (RFID) tags. Costing pennies and the size of a credit card, RFID tags use an embedded Si RFIC to transmit information whenever they receive an appropriate radio signal. You might use this when you buy gasoline or pay a toll. Demanding military applications, where high frequency and high power are important, can make use of the superior, but more expensive, GaAs.

Figure 1 shows a photomicrograph of a GaAs MMIC (monolithic microwave integrated circuit) wafer. During the design phase it is common to place multiple designs on a single GaAs wafer. The circuit in the center is a two-stage 1.2–3.2-GHz 1-W GaAs amplifier with 20 dB small-signal gain. It was fabricated on a 75- μm -thick wafer and is 2.98 mm on each side. Electromagnetic analysis is absolutely critical in achieving success on first fabrication for circuits like this.

In all of these applications, it is important to squeeze every gram of performance out of the selected technology, and to do that with the smallest possible size and the shortest possible design and fabrication time.

The high-frequency design process widely used prior to the 1990s began with an approximate design, then the

Figure 1. During the design phase, multiple circuits are usually placed on a single GaAs wafer. Here, in the center of this photomicrograph, is a two-stage 1.2–3.2-GHz 1-W GaAs MMIC amplifier with 20 dB small-signal gain. (Image courtesy of M/A-COM, Inc., A Tyco Electronics Company.)

circuit was built. The technology to complete a design with one fabrication simply did not exist. Thus, after building the circuit using these early design approaches, measurements would invariably show that its performance did not meet requirements. For example, an amplifier might not have enough gain, or a filter might be set for the wrong frequency. This was fully expected.

After the initial failure, the designer would review exactly how the circuit failed to meet expectations and then incrementally tune the circuit (a process called “tweaking”), or possibly redesign and refabricate the circuit with the hope that it would perform better the second time around. This redesign–refabricate cycle might be exercised half a dozen times before the desired performance was achieved.

Then, in the 1980s, high-frequency designers started making RF circuits on silicon and gallium arsenide. Now, instead of a few days for fabrication, GaAs RFICs required 3–6 months for fabrication and the cost for fabrication was around \$50,000 each time. Tweaking a circuit was no longer possible. Five or six redesign–refabricate iterations were too expensive and took far too long. This is where the technology of numerical electromagnetics found its first widespread application.

2. APPLICATION EXAMPLE

Prior to the advent of RFICs, components like inductors were literally a simple coil of wire. The approximate inductance was calculated using simple formulas. Then with the inductor in the circuit, it could be tweaked, if desired, to the exact inductance by bending the wire or tuning a small ferrite slug.

Figure 2 shows a spiral inductor on silicon. The venerable coil of wire has been flattened into a spiral so that it can be placed on the flat surface of a silicon IC. This results in several non-inductor-like characteristics. First, recall that the magnetic field in the old coil of wire is just

Figure 2. An 8.25-turn spiral inductor on silicon has thick conductors that must be modeled with two sheets of conductor to accurately include the skin effect and current crowding on inductance and loss.

like that of the classical bar magnet, with all the magnetic field going through the center of the coil and then loosely spreading around the outside and finding its way back to the other end.

In a spiral inductor, some of the returning magnetic field pushes back through in between the spiral turns. The magnetic field that penetrates the plane of the spiral pushes and pulls the current in the spiral turns, the result is called “current crowding.” This increases the already high resistive loss of the tiny conductors in the inductor. In addition, while the spiral inductor is on top of the silicon substrate, there may be a conducting ground plane on the bottom side of the silicon. There is extra capacitance to this ground plane that can be significant. Making things more difficult, the semiconducting silicon substrate itself allows current to flow, further modifying this extra capacitance and increasing loss.

Note that this inductor is actually modeled as two thin sheets very close to each other. This is because the thickness of the metal is about the same as the gap between the spiral turns. In this case, both sheets are needed for the highest accuracy at high frequency because the current actually flows close to the surface of the metal (“skin effect”). Since there are two sheets of skin effect current in the actual inductor (one flowing on top of the thick metal, the other on the bottom), two sheets of current are used to model the inductor. So, while it initially looks like just one inductor, we actually have two very tightly coupled inductors, one directly on top of the other, and that is the way it is analyzed. This simple inductor is not so simple.

The Z axis is magnified for the inductor of Fig. 2, the metal thickness is $2.8\ \mu\text{m}$, and the gap between lines is $3.2\ \mu\text{m}$. No vias connecting the edges of the sheets, and no additional sheets are used as they are not needed. Testing to see if edge vias or additional sheets are needed is easily done by simply adding them, reanalyzing, and comparing the results. Typically we find that this simple two-sheet model is sufficient when the gap is on the order of the thickness, as we have here.

Figure 3. Measured (thin lines) versus calculated (thick lines) inductance and Q for the spiral inductor of Fig. 2.

Measured versus calculated data for this inductor are shown in Fig. 3. The quality factor (Q) is related to resistive loss; higher Q indicates lower loss. These results are typical of the kind of agreement usually seen with EM analysis. With this kind of capability, the high-frequency designer can now modify the design on the computer to achieve exactly the desired response, and then build the circuit once. Once a rare event, achieving complete success on the first fabrication for even the most complicated circuits is now common.

Figure 4 shows the current distribution on the inductor. First notice that there is high current on the edges. This edge concentration of current is characteristic of planar circuits and causes increased loss. Inclusion of this high edge current requires use of a very small subsection size. If a large subsection size is used, the high edge current cannot be included in the analysis and the loss is underestimated.

Note also that the high edge current is present on only one edge of some of the interior turns of the inductor. This

Figure 4. High current on the edges of planar conductors significantly increases loss. The effect of current crowding causes current to switch from side to side, further increasing loss. Current on the bottom side of the thick metal is shown.

is the current crowding referred to above, where the inductor magnetic field penetrating the plane of the inductor pushes and pulls the current on the spiral turns to one edge or the other. This additionally increases loss and if not included in the analysis, results in an optimistic estimate of loss. Current distribution visualization is an important diagnostic tool.

This spiral analysis uses a new type of meshing, “conformal meshing,” which allows accurate and fast analysis. This spiral was analyzed in 5 min 9 s per frequency on a 3-GHz Pentium. Conformal meshing is discussed in detail below.

3. CIRCUIT THEORY ANALYSIS OF RFICS

Prior to the 1980s, most RF design was based on approximate circuit theory. The performance of any electrical circuit can be described in terms of voltage [measured in volts (V)] and current [amperes (A)] at a specified frequency [hertz (Hz)]. For example, a wall outlet might be described as providing 115 V at up to 15 A at 60 Hz.

This is true for RF circuits, only the frequency is much higher. For example, the radio signal going to the antenna of your cellphone might be 1 V at 20 mA at 900 MHz. This is a different voltage, different current, and different frequency, but basically the same idea.

The interplay between voltage and current (assuming a single fixed frequency) are mathematically described in terms of Ohm’s law, Kirchhoff’s current law, and Kirchhoff’s voltage law. We won’t detail these laws here, other than to point out that they are easily implemented in a computer. This was done just as soon as computers started to become widely available in the 1970s.

With the combination of computers and circuit theory, RF designers could quickly analyze their proposed designs consisting of inductors, capacitors, resistors, and transistors. This worked well, up to a point. At higher frequencies, the inductor was no longer just an inductor. Capacitance and resistance become important as well. In addition, there might be unwanted coupling between two different inductors. All this was not too much of a problem, because the designers could build their circuit, then tweak the design with a soldering iron, screwdriver, and pliers to achieve the desired performance.

Then, in the 1980s, circuits started getting smaller. Si and GaAs RFICs generated substantial interest. In the 1990s LTCC (with a dozen or more layers in one tiny ceramic block) saw development. As things became smaller and packed more closely together, tweaking a circuit simply was not possible. Effects that circuit theory did not include, such as stray coupling, became important. When a design did not work the first time, it was a complete refabrication. Designers could not wait years for the completion of multiple redesign–refabricate iterations.

4. ELECTROMAGNETIC ANALYSIS

In the 1980s, with the introduction of the IBM PC, serious computer power became available on the desktop at reasonable cost. Although initially starting with a clock

rate under 4 MHz, the PC became steadily faster achieving multi-GHz clock rates with the turn of the century. It was the advent of fast inexpensive desktop computing that allowed the next step in RFIC design to take place.

Clearly, something more precise than circuit theory with its volts and amperes was required. This turned out to be electromagnetics, which describes circuits in terms of electric field and magnetic field. We are all familiar with the static (i.e., unchanging) electric field surrounding the head of a longhaired youngster touching a Van de Graph generator. We are also familiar with the static magnetic field surrounding a bar magnet.

The interplay between electric field and magnetic field is governed by Maxwell’s equations. For a description of Maxwell’s equations appropriate for the college-bound high school senior, see Ref. 1. Maxwell’s equations deal with more than just static electric and magnetic fields. They completely describe how changing (i.e., dynamic) electric and magnetic fields behave. For a quick explanation, Maxwell’s equations state that a changing electric field generates a magnetic field. It also works in reverse; a changing magnetic field generates an electric field.

Remember that cellphone transmitting a signal at 900 MHz? Its signal, which consists of changing electric and magnetic fields interwoven together and each completely dependent on the other for their existence, changes direction and then back again 900 million times a second. How they do this and what happens as a result is completely covered by Maxwell’s equations.

The mathematical details are discussed later in this article; and while the top-level concepts are relatively simple, the detailed math is complicated. To appreciate the complexity, note that both the electric and magnetic fields are vector fields. In other words, any computer analysis must determine both the direction and magnitude for both electric and magnetic fields everywhere in the circuit being analyzed. This is not a trivial problem.

Additionally, if the analysis is for a specific frequency (i.e., a frequency-domain analysis), the phase of each field at each point in the circuit must be determined. In an alternative approach, the EM analysis generates signals at all frequencies simultaneously. This is EM analysis in the time domain, and now the magnitudes and directions of both fields must be determined as a function of time everywhere in the circuit.

4.1. Volume Meshing EM Analysis

There is tremendous complexity within Maxwell’s equations. This means that there is also a huge diversity in methods of solution. Four general approaches have seen wide application in high-frequency design. All the approaches rely on meshing the high-frequency circuit into many small subsections. Maxwell’s equations are then applied to find the electric and magnetic fields for each subsection in the entire mesh.

The most general class of techniques relies on meshing the entire volume of the problem. The approach called “finite elements” meshes the entire volume into small tetrahedral cells. A technique known as finite-difference time domain (FDTD), or a related technique known as

finite integration technique (FIT), meshes the entire volume into tiny rectangular cells. For both techniques, when a more accurate solution is required; simply use more and smaller cells or tetrahedra.

Of course, a finer mesh means the analysis time increases. As with all EM analyses, analysis time can easily exceed tens of hours. The analysis time is strongly related to the number of cells or subsections. Thus, there is a practical upper limit on the complexity of the circuit that can be analyzed using electromagnetics. Where this upper limit occurs depends on the specific EM analysis used and the type of circuit being analyzed.

The different EM analysis techniques all have their relative advantages and disadvantages. This is important to understand as using an EM analysis on an inappropriate type of problem can result in analysis times 10–1000 times longer, if indeed the problem can be done at all.

Volume meshers are ideal for 3D arbitrary structures that can have any shape and structure whatsoever. A classic example is a cellphone held close to a human head (Fig. 5).

A disadvantage of meshing a problem using tetrahedra is that linear current flow is not well represented. This is easily seen by viewing a finite-element current distribution. The current distribution can lack the smoothness that is characteristic of a true current distribution. In addition, the high current that is naturally present at any sharp metal edges can be indistinct, if present at all.

Fortunately, the response of a circuit is not strongly dependent on the exact current distribution. Thus, useful data can easily result even if the current distribution is not exactly calculated. However, an extremely high accuracy solution might be elusive.

The finite-element method works in the frequency domain. In other words, the analysis assumes that there is a signal at only one specific frequency at any one time. In order to obtain data at 100 frequencies, 100 analyses must be performed. There are interpolation approaches that can provide a spectrally rich dataset after completing a full analysis at fewer frequencies as discussed below.

Figure 5. Volume meshing tools excel for 3D arbitrary geometries. Problems of critical importance can be solved easily.

FDTD and FIT are time-domain approaches that assume that all frequencies are present in the circuit at the same time. This is done by exciting the circuit with an impulse (actually a narrow Gaussian pulse, to avoid numerical problems). The impulse contains energy at all frequencies, and the circuit response is analyzed as a function of time. After the time impulse response is calculated, it is transformed to the frequency domain. In this way, a spectrally rich dataset is generated at all frequencies present in the original impulse input without need for interpolation.

The advantage of a time-domain analysis is that the circuit response at all frequencies is determined in a single analysis. The disadvantage is that the analysis can handle an impulse input on only one port (i.e., input or output terminal/connector) at a time. Thus, in order to completely characterize a circuit with, say, 15 ports, 15 complete time-domain analyses are required. The finite-element approach also suffers from this same problem.

While both finite-element and the time-domain analyses can, and are, used for planar circuit analysis, they are usually much slower than tools specifically designed for planar analysis. Thus, volume meshing tools should typically be used for planar circuits only when a specialized planar tool is not available, or if there is an important nonplanar aspect to the circuit. In addition, the volume meshing tools can be used to double-check the results of a planar tool, assuming that the circuit is not too complicated.

4.2. Surface Meshing EM Analysis

Silicon and GaAs RFICs, and LTCC circuits are all planar circuits. In general, use of a volume meshing tool to analyze these, and other planar circuits, is inappropriate. Both faster analysis times and higher accuracy are realized by using EM tools made specifically for planar circuits. Such tools take advantage of the fact that these kinds of circuits are mostly planar (with short vias connecting circuit on different layers) and embedded in layered dielectric. In addition, each layer of dielectric must be uniform within itself, with the possible exception of very small volumes (e.g., a small hole in a layer of dielectric). These specializations allow these tools to subsection only the surface of the metal in the circuit. This is far more efficient and accurate than subsectioning the entire volume of a planar circuit.

There are two basic kinds of surface meshing planar EM tools: (1) those intended for unshielded circuit analysis and (2) those used for shielded circuit analysis (i.e., a circuit contained in a conducting box). In both cases, the circuit metal (and only the circuit metal) is meshed into a set of small subsections. As with the volume meshers, smaller subsections mean higher accuracy, but at the cost of increased analysis time. And also as with the volume meshers, at some point the number of subsections increases the analysis time to tens of hours, setting an upper limit to the level of circuit complexity that can be analyzed. Exactly where this upper level is can vary widely depending on the type of circuit and specific tool

being used. No single tool is superior for all planar circuits.

Both types of surface meshing approaches first calculate the coupling between every possible pair of subsections, namely, put current on one subsection and calculate the voltage induced in another subsection. If there are 100 subsections, then the calculated pairwise coupling is stored in a 100×100 matrix. The analysis then inverts the 100×100 matrix to yield the current distribution and total circuit response. Since this is a frequency-domain analysis, this process must be repeated at each frequency of interest. The principal difference between unshielded and shielded analysis is the means by which they calculate the coupling between subsections. Unshielded EM analysis calculates the subsection-to-subsection coupling by means of numerical integration. For shielded analysis, the coupling is calculated by using the fast Fourier transform (FFT). Each approach has advantages and disadvantages.

The advantage of the unshielded/numerical integration approach is that the subsections can be of any shape, size, or orientation (e.g., triangle or rectangle, or even polygon). This is because the numerical integration takes place over the area of the subsection. Since numerical integration is easily performed over any desired area, any desired size subsection can be used. The disadvantage of the unshielded analysis is that the numerical integration introduces numerical integration error. Special care must be taken to avoid numerical integration error in the vicinity of poles, which result from surface waves present in unbounded media. Depending on the specific circuit, design requirements, mesh, and frequency of analysis, the numerical integration error may or may not be important. Fortunately, this is typically of concern only when high accuracy is required.

Shielded analyses use a 2D FFT (fast Fourier transform) to calculate the coupling. Recall that in digital signal processing, a time signal must first be uniformly time-sampled prior to using the FFT. The same is true with FFT-based EM analysis, except that the planar surface of the circuit substrate is first uniformly space-sampled in two dimensions. This means that the shielded/FFT based analysis starts with a fine uniform underlying FFT mesh. The FFT mesh can easily be 1024×1024 cells, so the individual cell size can be about the same size as a pixel on a computer screen. Nevertheless, the principal disadvantage of shielded/FFT analysis is that, like a picture on a computer screen, the circuit outline is first pixilated so that its edges follow the fine FFT mesh.

The FFT also brings the shielded analysis its principal advantage. Because there is no numerical integration, there is no numerical integration error. The coupling between each pair of subsections is calculated to full numerical precision. Thus, the accuracy and dynamic range of shielded/FFT EM analysis is the highest that can be obtained. The accuracy of shielded EM analysis is quantitatively explored below.

Generally, if high accuracy or the effect of a shielding box might be important, a shielded/FFT analysis should be used. If accuracy is not of the highest importance or the effect of shielding sidewalls cannot be allowed, then an

unshielded analysis can be used. There are additional considerations in selecting the appropriate analysis technique for a given problem, too numerous to discuss here. Ideally, a high-frequency planar circuit designer will have access to both shielded and unshielded tools and will be able to use each as appropriate. The tradeoff between the two is very much like the tradeoff between analog cell-phones (unshielded/numerical integration) and digital cellphones (shielded/FFT). Many of the same issues arise.

5. COMPANION MODELING

The usual EM-based high-frequency design flow is

1. Design the circuit using circuit theory, optimize to meet all requirements.
2. Lay out the circuit.
3. Analyze the circuit using EM.
4. If the circuit meets requirements, build the circuit.
5. Otherwise, change (i.e., “tweak”) the layout in hopes of improving performance.
6. Return to step 3 and see if the changes worked.

This design process can be performed manually, or with the use of automated optimization algorithms. Automated optimization algorithms that drive an EM analysis should be used only if the design already yields nearly the desired response due to the typically long time required for high-accuracy EM analysis. This design flow represents a huge advance over that of the 1980s, when a fabrication rather than EM analysis, was used in step 3. This greatly increased the time and expense to design completion.

A modification of the abovementioned approach, called “companion modeling” [2], can substantially further reduce the time and expense. This process adds structure to the tweaking step, step 5, in the design flow:

- 5a. Determine a mapping between the critical parameters of the circuit theory model and the layout. For example, associate the length of a transmission line in the circuit theory model with a specific dimension in the layout. This process is called “space mapping” [3].
- 5b. Optimize the circuit theory model to match the EM analysis results.
- 5c. Note the changes in the critical parameters of the circuit theory model. Reverse those changes in the layout. For example, if the optimized circuit theory transmission line became $10\mu\text{m}$ shorter, then lengthen that transmission line (in the layout) by $10\mu\text{m}$.

Step 5b is counterintuitive. The circuit theory result meets all requirements. The initial EM analysis does not. So the high-frequency designer instinctively wants to optimize the layout (using EM analysis) to match the circuit theory. The problem is that any EM-based optimization is very slow. Unless the result is close, this will be a long and possibly never-ending process. Instead, step 5b optimizes the desired circuit theory result to match the not-so-good

EM result. Now the optimization loop uses the much faster circuit theory. With proper selection of critical parameters, an answer is obtained quickly. Then proceeding to step 5c, if a decrease of $10\ \mu\text{m}$ in a transmission-line length changes the good circuit theory response so as to match the not-so-good EM result, we reason that an increase of $10\ \mu\text{m}$ should make the not-so-good EM result nearly match the desired circuit theory response. Just reverse the changes, and the layout can be quickly tweaked into the desired response. The entire loop usually needs to be performed only 2 or 3 times before it is exited at step 4.

Although companion modeling (a special case of a general technique known as *space mapping*) is not presently widely known, the power of this approach means that it is likely to become, in some form, the primary design flow approach for EM-based high-frequency design.

6. DIVIDE-AND-CONQUER ANALYSIS STRATEGY

No matter what approach is used to solve a problem, for some problem size, the time required becomes too large to obtain a solution in a reasonable length of time. This can happen easily when using EM analysis tools. Analysis times of days or even weeks can be easily seen. Problems that are too large for computer memory or take too long to analyze still need a solution of some kind.

Divide-and-conquer strategies are useful in many of these situations. Figure 6 shows a typical parallel-coupled line bandpass filter. While this filter is still easily analyzed as one complete filter, it serves to illustrate the divide-and-conquer strategy.

This filter is divided into eight subcircuits. Now, rather than analyzing the entire filter at once, each of the eight subcircuits is analyzed separately. Because the EM analysis time is typically proportional to the number of subsections cubed, performing eight small analyses is much faster than performing one large analysis.

After the eight subcircuits are analyzed, they are all connected together by circuit theory nodal analysis and the S parameters of the two-port filter result. In modern EM analysis software, this entire process is automatic once the user has specified the circuit subdivisions. A disadvantage of this approach is that coupling between the different sections is not included. Such coupling occurs

only between line segments that are not perpendicular to the dividing line. Thus, one should not specify any horizontal circuit dividing lines for this particular circuit as such lines are parallel to the filter's coupled lines. The coupling between resonators is critical to the filter performance and must be included. Thus, all dividing lines in this filter are perpendicular to the coupled lines of the filter.

With the circuit divided as shown, coupling between nonadjacent resonators is not included. If such coupling is important, as is the case with elliptic function filters, then this approach should not be used in a manner that causes such coupling to be eliminated from the analysis.

Extremely precise de-embedding of tightly coupled ports is required for success of this approach, as described in Section 11. If there is any port discontinuity left in any of the subcircuit ports, that remaining port discontinuity is inserted in the center of the resonators of the complete circuit. This disrupts the filter response.

Manual modification of the automatically generated netlist (which is used by circuit theory to connect all eight subcircuits together) allows an even faster analysis. Note that subcircuit S_8 is identical to subcircuit S_1 (with a rotation). Thus, switching subcircuit S_8 references to subcircuit S_1 with appropriate attention to node numbering can eliminate all references in the netlist to subcircuit S_8 .

By noting other symmetries, only four of the eight subcircuits need to be analyzed electromagnetically. This modification further cuts the analysis time by half. Measured, and calculated results are shown in Fig. 7.

7. ERROR EVALUATION

Accuracy is the primary reason in using EM analysis. If accuracy is not an issue, then the high-frequency designer should use circuit theory, which is much faster. Accuracy directly impacts whether success on first fabrication is achieved. Because of the critical importance of success on first fabrication, the issue of accuracy cannot be left to chance. All handwaving, subjective, nonquantitative claims of "high accuracy" should be ignored if such statements are made in the absence of hard quantitative data.

Because EM analysis always has some degree of error, success on first fabrication cannot be guaranteed. In a complicated circuit, there are many sources of error. Often

Figure 6. A parallel-coupled line bandpass filter is divided into eight smaller sections for much more rapid analysis.

Figure 7. Measured versus calculated data show visually identical results nearly everywhere validating the divide-and-conquer approach for this filter.

these errors average out, so there is no problem. However, sometimes the errors add together in the same direction, sometimes by chance, and sometimes causally. When the errors add together, the result is a design failure. There is always a risk of failure. The successful high-frequency designer works aggressively to minimize that risk. In that way, rather than getting, say, 5 out of 10 designs to succeed on first fabrication, the knowledgeable designer sees 9 out of 10 designs succeed. The competitive advantage is substantial.

An attitude sometimes seen among high-frequency designers is that several percent error is not a problem. This can be true, depending on the circuit and on the requirements. Several percent error in the transmission-line characteristic impedance for a branchline coupler is not likely to be a problem. Several percent error in the velocity of propagation for a 5% bandwidth filter will require at least one additional fabrication. The informed designer will know when to, and when not to strive to realize absolute minimum analysis error.

A widely held, and usually untested, belief is that as long as the subsection size is small with respect to the wavelength, then EM analysis error is small. This is incorrect. In fact, subsection size must be small with respect to how rapidly (as a function of position) the current distribution changes. Thus, as described below, subsection width must be small with respect to linewidth in addition to being small with respect to wavelength. Specific quantitative knowledge of EM analysis error is critical to the design engineer's success.

The most common approach to accuracy validation involves the widespread "good agreement between measured and calculated" (GABMAC) plot, examples of which are shown in Figs. 3 and 7. While certainly important as a final reality check, the GABMAC plot is of little value for quantitative determination of analysis error as differences can be additionally due to measurement and fabrication error. Determining the magnitude of the analysis error by itself in such tests is nearly impossible.

Each of the following tests are easily performed on any EM analysis. Intended to supplement, not replace, the

usual GABMAC test, these tests use simple circuits that are easily analyzed on any EM tool and allow precise quantitative evaluation of analysis error.

7.1. The Stripline Standard

Exact theoretical solutions are known for a small set of planar problems. Such problems allow the precise evaluation of analysis error. Any and all differences between calculated data and the exact answer is analysis error.

Stripline is one such problem that has an exact solution and has been used to precisely evaluate the error of EM analysis [4]. For example, as applied to a shielded planar EM analysis, the following empirically determined upper bounds are found for analysis error

$$e_{z0} \leq \frac{16}{N_W} \quad (1)$$

$$e_V \leq 2 \left(\frac{16}{N_L} \right)^2 \quad (2)$$

where

e_{z0} = percent error in characteristic impedance

e_V = percent error in velocity of propagation

N_W = number of cells across width of line

N_L = number of cells per wavelength along length of line

These upper bounds are met nearly in equality for most of their range.

Figure 8 shows a performance plot where analysis error is plotted versus analysis time on a 3-GHz Pentium. For each data point, N_W is doubled. N_L is held constant at 1024 cells per wavelength. N_W is taken up to 1024, and although larger values can be evaluated, a larger value of N_L would be required in order to continue to see convergence. Even as it is, the error convergence starts to slow down for large N_W . It is important to note that the convergence to the exact correct answer is smooth, the error decreasing by about half each time N_W is doubled.

When the convergence is smooth, Richardson extrapolation [5,6] can be used to arrive at a nearly exact answer

Figure 8. A performance plot shows the precise analysis error versus analysis time for an exactly known zero-thickness lossless stripline. Note the logarithmic scale on both axes.

based on two lower accuracy results. For this dataset, Richardson extrapolation converges to 0.002% error, one order of magnitude better. Note that this performance plot can be viewed as a lower bound (i.e., best possible speed/accuracy performance) for a given EM analysis. Most practical circuits are more complicated. If one were able to generate a performance plot for a more complicated circuit, the analysis time would be longer, moving the performance curve to the right. In addition, there would be more sources of error, thus moving the performance curve up. Thus the stripline standard performance plot represents a kind of starting line for the race to analyze a circuit both as quickly and as accurately as possible.

For metal-insulator-metal (MIM) capacitors [7], common on RFICs, the following upper bounds are also nearly met in equality over most of their range:

$$e \cong \frac{5.12}{1/N_A + 1/N_B} \quad (3)$$

where

e = percent capacitance error
 N_A = number of cells among capacitor length
 N_B = number of cells across capacitor length

These equations may be used to evaluate and simply subtract the error from a single EM analysis of an MIM capacitor. In fact, the analysis error of the MIM capacitor is so well behaved that an EM analysis can be used to directly determine the amount of capacitance due to fringing field, usually a very small amount.

7.2. The Zero-Length Coupled Line

Another approach is to use a coupled pair of microstrip lines. There is no exact solution for such a structure; however, there is a degenerate case that is of interest for error evaluation: the zero-length coupled line.

No EM analysis can analyze a zero-length coupled line directly. Rather, they must analyze a finite length of line and then de-embed to zero length. The exact answer is simply that all reflection coefficients and all coupled transmission coefficients must be zero, or $-\infty$ dB. Because all EM analyses have error, something other than $-\infty$ dB results. This result is the noise floor of the analysis.

Figure 9 shows that the noise floor for a shielded planar analysis is around -130 dB. Generally analysis results should not be trusted down to any more than 20 dB above the noise floor. The noise floor for this specific EM analysis has been found to range between -100 and -180 dB, depending on the circuit and mesh size used.

7.3. The Thick Stripline Benchmark

Another benchmark is thick stripline [8]. The characteristic impedance is known for the selected geometry (Fig. 10) to better than $\pm 0.0006\%$. This upper bound on the error is estimated by using the thick stripline equations for the line of Fig. 10, except that the thickness set to zero. That answer is then compared with the known exact

Figure 9. The exact value of S_{11} , S_{21} , and S_{41} of a zero-length coupled line should be $-\infty$ dB. The calculated values, plotted here, show that the analysis numerical noise floor is below -120 dB.

solution for zero-thickness stripline. It is at zero thickness that the thick stripline equations have maximum error; thus the difference at zero thickness is an upper bound on the thick stripline equation error when using nonzero thickness. In addition, when the zero-thickness result is compared to the result with thickness, as in Fig. 10, it is found that the characteristic impedance changes by 25% between the two cases.

Thus, we have a structure whose correct answer is known very precisely and that is also strongly dependent on the parameter of interest: thickness. This is ideal for a benchmark. Thickness is modeled in a planar analysis with multiple sheets [9]. As the number of sheets increase, and as N_W increases, the result should converge to the exact answer, as seen in Fig. 11. Note once more that the smooth convergence, with the error decreasing by about half each time, allows a Richardson extrapolation [5,6] to provide a nearly exact answer.

The error convergence has been shown to be good for this specific shielded EM analysis; a similar convergence test can be performed to quantify the expected error due to thickness for an actual design situation. In practice, it has been found that multisheet models for thickness are needed when either the width of the line, or the gap

Figure 10. An extremely thick stripline is used to test the multisheet model for accuracy.

Figure 11. As the number of zero-thickness sheets used to represent this very thick stripline increases, S_{11} converges to the exact answer.

between lines, is on the order of or less than the thickness of the lines. In some RFIC situations, this can be common.

Extreme cases of thickness are becoming common as decreasing loss becomes important in RFIC design. For example, a $6\ \mu\text{m}$ metal thickness combined with a $2\ \mu\text{m}$ gap between lines would require perhaps half a dozen sheets for accurate analysis at high frequency. In this case, it is possible to simulate coupling between such closely spaced thick lines by using the two-sheet model and modifying the permittivity and permeability of nearby dielectric to compensate for the coupling that is otherwise underestimated by the two-sheet model.

8. ELECTROMAGNETIC INTERPOLATION

When using a frequency-domain analysis, which includes all the planar approaches described above, a complete analysis must be performed at each frequency. If data at 100 frequencies are required, then 100 complete analyses must be performed.

In order to reduce the number of analyses required, interpolation can be used. Substantial work in this area has been accomplished since the mid-1990s, with spectacular results. A recent (at time of writing) publication in this area, including an extensive bibliography, is Ref. 10. Here, we briefly describe only a simple approach to give an idea of what can be done.

8.1. Linear Interpolation

In high school, we are introduced to linear interpolation, where we are given two data points: (x_0, y_0) and (x_1, y_1) . We then calculate the coefficients a and b of the equation

$$y = ax + b \quad (4)$$

that passes through the two points. We can then perform an interpolation by using this equation to calculate y for

all desired values of x . While simple algebra is all that is required, the solution of this problem can also be cast in the form of a 2×2 matrix. The solution for a and b is obtained by inverting the matrix. For EM analysis, x is the frequency and y is the calculated data (usually S , Y , or Z parameters), which is complex (real and imaginary, or magnitude and angle).

8.2. Cubic Spline Interpolation

At the next level, we have the cubic spline. The process is identical to that above, except that it uses an equation that is a bit more complicated:

$$y = a_3x^3 + a_2x^2 + a_1x + a_0 \quad (5)$$

Now there are four unknown a coefficients; thus we require four data points and we invert a 4×4 matrix to solve for the four coefficients. Once that task is done, we may evaluate the equation for any and all values of x (frequency) that we desire and realize many data points after having only calculated data at four frequencies.

8.3. Padé Rational Polynomial Interpolation

The cubic spline has problems for interpolating high-frequency data. For example, if impedance or admittance is being interpolated, y might need to go to infinity (i.e., a pole). At a given frequency (x), and with finite coefficients, the result of a cubic spline cannot go to infinity. This suggests that we use a ratio of two polynomials, for example

$$y = \frac{a_3x^3 + a_2x^2 + a_1x + a_0}{b_2x^2 + b_1x + 1} \quad (6)$$

where, we have four unknown coefficients in the numerator (providing for three “zeros” in the resulting function and setting the amplitude of y at $x = 0$) and two unknown coefficients in the denominator (providing for two poles in the resulting function). With a total of six unknowns, we now require six data points. In a manner similar to that seen for the cubic spline, with six data points, we can write six linear equations (by multiplying both sides by the denominator polynomial), resulting in a 6×6 matrix. Solution of the matrix yields the six unknown coefficients.

The total number of terms both numerator and denominator must be less than or equal to the total number of data points taken. However, their distribution between numerator and denominator is arbitrary. More recent research has been directed toward finding a distribution that is optimum in some way for a given set of data.

This ratio of two polynomials is known as a *Padé rational polynomial*. By noting the similarity to the Laplace transform of a lumped circuit, we note that, given a sufficient number of terms, the Padé rational polynomial can exactly represent an arbitrary lumped circuit. However, it cannot exactly represent a distributed circuit. Thus, for high-frequency circuits, the Padé rational polynomial is generally bandlimited.

8.4. Applied Interpolation Issues

As typically applied to EM analysis, at least two analyses are initially performed. This yields two data points. Then several interpolations are formed, either with different numbers of data points, or with a different distribution of coefficients between numerator and denominator. The differences between these different interpolations (all based on the same data) are treated as an estimate of the interpolation error. While the true interpolation error can be as much as 20 dB greater than the estimate, the estimated error does tend to correctly show the frequency at which the true error is highest. The next data point is then taken at this highest error frequency. The iterative algorithm proceeds until the maximum estimated error is below a user-selected threshold.

Early application of the Padé rational polynomial to high-frequency EM analysis was limited in bandwidth, dynamic range, and occasional failure to converge. However, more recent results now provide a much more robust implementation. Basically, in addition to the actual high-frequency circuit data at each frequency, the interpolation can also make use of the tremendous amount of information contained within the method-of-moments (MoM) matrix used by the EM analysis, for example, frequency derivative information.

The advanced techniques can easily interpolate over a $1000 \times$ bandwidth (e.g., from 0.1 to 100 GHz) with analysis at 15–20 frequencies, or over a small bandwidth with analysis at only four or five frequencies, no matter how complex the response (see Fig. 12).

Even so, today's interpolation algorithms do still exhibit failure modes of which the informed designer should be aware. In one failure mode, the interpolation fails when an attempt is made to interpolate data that are below the analysis noise floor. The noise floor depends strongly on the specific EM technique, specific circuit, specific meshing, and specific frequency. Observed noise floors range from 40 to over 180 dB down for the different types of planar analyses. Special caution should be exercised

Figure 12. Only four frequencies were analyzed for this six-resonator filter: the start, stop, and the two arrowed frequencies. All the remaining data are interpolated. The interpolated data are visually identical to those from a full calculation.

whenever interpolation is invoked on data that approach to within 20 dB of the noise floor.

The second failure mode is seen in shielded analysis. Early algorithms could fail with only one box resonance. Modern algorithms are more robust, providing accurate data even with large numbers of box resonances; however, the number of data points required for convergence can be excessive. Thus, even though the resulting data are still accurate, analysis time can become excessive.

9. CONFORMAL MESHING

As described above, one advantage of the unshielded EM analysis is that the required numerical integration can be performed over any arbitrary subsection as desired. In practice, arbitrary size, shape, and orientation rectangles and triangles are used. More advanced techniques additionally include arbitrary polygons.

Shielded analyses use the FFT to calculate the coupling between subsections. While the FFT provides unsurpassed accuracy and dynamic range, it requires a fine underlying uniform FFT mesh. These tiny FFT mesh cells are joined together into larger rectangular subsections.

In order to increase speed, both shielded and unshielded analyses try to maximize use of large subsections. Large subsections substantially reduce the size of the matrix, thus speeding the analysis. However, large subsections also decrease analysis accuracy, especially when the subsections are so large that the natural high edge current is not allowed to form.

The arbitrary triangles of the unshielded analysis are a distinct advantage in analyzing arbitrary smoothly curving circuits. A few triangles can easily form a piecewise linear representation of a curving edge, especially when the error introduced by ignoring the high edge current is acceptable. However, when high edge current must be included, a large number of narrow rectangular subsections must be inserted on the conductor edges, rapidly increasing the subsection count and analysis time.

Merging the small FFT cells of the shielded analysis can be severely limited by curving geometries. Even the largest rectangular subsections must still be small, thus limiting the reduction in the number of subsections. As a small compensation, the high accuracy yielded by the small subsections is still seen. To alleviate this bottleneck, conformal meshing [11] was developed. The tiny FFT cells are still present, so the accuracy and dynamic range provided by the FFT remains uncompromised. However, instead of merging the cells into larger rectangular subsections, the cells are merged into large subsections that both cover the entire width of a transmission line and curve to follow arbitrary curving edges. In this way, a subsection count reduction of 100 times or more can be achieved. Since matrix solve time increases with the subsection count cubed, a $100 \times$ reduction in subsection count realizes a $1,000,000 \times$ faster analysis.

Normally large subsections that cover the entire width of a transmission line result in decreased accuracy because high edge current is not allowed. This is not the case with conformal mesh because the mesh automatically

Figure 13. Conformal meshing allows analysis of this four-way power splitter including the critical high edge current in 19 s per frequency on a 3-GHz Pentium.

includes the high edge current in the conformal subsections. Thus we simultaneously achieve two seemingly contradictory goals: the fast analysis of a few large subsections and the accurate analysis of many small subsections.

Figures 2–4, presented and discussed above, show a circular 8.25-turn spiral inductor that was analyzed using conformal meshing. No other form of meshing and no other technique of analysis has yet been found to successfully analyze this inductor, including the effect of conductor thickness and high edge current. While one other approach was found to be able to complete an analysis, the result was overwhelmed with numerical noise due to the large problem size. Using conformal meshing, the inductor requires 5 min 9 s per frequency on a 3-GHz Pentium. Six frequencies were analyzed and interpolated to provide the plotted data.

Figure 13 shows a four-way power splitter analyzed using conformal meshing. Note that the high edge current is well represented, even though the analysis required only 19 s per frequency on a 3-GHz Pentium.

Conformal meshing marks a major advance in the size of problem for which numerical EM analysis can achieve fast and accurate results.

10. SHIELDED ELECTROMAGNETIC ANALYSIS THEORY

Because of the complexity of Maxwell's equations, there are innumerable methods of solution, each approach having advantages and disadvantages for a given type of problem. In this section, we describe one approach to the analysis of planar circuits in a shielded environment using the method of moments [12]. This particular solution is detailed in Refs. 13 and 14.

For the geometry of Fig. 14, we can treat the perfectly conducting sidewalls as a rectangular waveguide propagating in the z direction. The rectangular waveguide TE (transverse electric) and TM (transverse magnetic) modes in each dielectric region form a complete orthogonal basis for any source-free field. We sum all the TE and TM modes (over the composite summation index i) in each region so as to match tangential electric fields at the interface

between the two regions ($z = h$)

$$\mathbf{E}_t^{(1)} = \sum_i V_i \frac{\sin(k_{iz}^{(1)} z)}{\sin(k_{iz}^{(1)} h)} \mathbf{e}_i \quad (7)$$

$$\mathbf{H}_t^{(1)} = \sum_i V_i Y_i^{(1)} \frac{\cos(k_{iz}^{(1)} z)}{\sin(k_{iz}^{(1)} h)} \mathbf{h}_i \quad (8)$$

$$\mathbf{E}_t^{(0)} = \sum_i V_i \frac{\sin(k_{iz}^{(0)} (c - z))}{\sin(k_{iz}^{(0)} (c - h))} \mathbf{e}_i \quad (9)$$

$$\mathbf{H}_t^{(0)} = \sum_i V_i Y_i^{(0)} \frac{\cos(k_{iz}^{(0)} (c - z))}{\sin(k_{iz}^{(0)} (c - h))} \mathbf{h}_i \quad (10)$$

where

$$Y_{i,TE}^{(p)} = -jk_{iz}^{(p)} / \omega\mu_p$$

$$Y_{i,TM}^{(p)} = -j\omega\epsilon_p / k_{iz}^{(p)}$$

$$k_{i,z}^{(p)} = (k_p^2 - k_x^2 - k_y^2)^{1/2}$$

$$k_p = \omega(\mu_p\epsilon_p)^{1/2}$$

Figure 14. Shielded electromagnetic analysis views the conducting sidewalls of the shielding box as rectangular waveguide. The fields for each layer are written as a sum of waveguide modes.

$$\begin{aligned}
 k_x &= m\pi/a \\
 k_y &= n\pi/b \\
 \mathbf{e}_{i,\text{TE}} &= N_1 g_1 \mathbf{u}_x - N_2 g_2 \mathbf{u}_y \\
 \mathbf{e}_{i,\text{TM}} &= N_2 g_1 \mathbf{u}_x - N_1 g_2 \mathbf{u}_y \\
 \mathbf{h}_I &= \mathbf{u}_z \times \mathbf{e}_i \\
 g_1 &= \cos(k_x x) \sin(k_y y) \\
 g_2 &= \sin(k_x x) \cos(k_y y) \\
 N_1 &= (2/ab)^{1/2}, \quad m=0, \quad n \neq 0 \\
 N_1 &= 0, \quad m \neq 0, \quad n=0 \\
 N_1 &= 2(n/b)(ab/(n^2 a^2 + m^2 b^2))^{1/2}, \quad m \neq 0, \quad n \neq 0 \\
 N_2 &= 0, \quad m=0, \quad n \neq 0 \\
 N_2 &= (2/ab)^{1/2}, \quad m \neq 0, \quad n=0 \\
 N_2 &= 2(m/a)(ab/(n^2 a^2 + m^2 b^2))^{1/2}, \quad m \neq 0, \quad n \neq 0
 \end{aligned}$$

The modal admittances are those of the standing-wave modes, which differ from the more usual traveling-wave modes by the imaginary factor j . The amplitude of the i th mode (V_i) is determined as described below.

Note that the equations above, and this entire approach, maintain full validity for any degree of lossy or conductive substrates. The only change required is that the characteristic impedances and wavenumbers presented above become complex.

10.1. Calculating the Coupling between Subsections

The central problem is to determine the voltage on one subsection (the “field” subsection) caused by current on another subsection (the “source” subsection). It is this pairwise coupling that fills the moment matrix for every possible source–field pair of subsections.

In order to proceed, we must first assume a specific current distribution for the source subsection. We use the “rooftop” current distribution [15] (Fig. 15). In Fig. 15, the height indicates the current density over the rectangular area of the subsection. Several rooftops are overlapped to yield a piecewise linear approximation to the current in the direction of current flow (Fig. 16). Rooftops are placed side by side to yield a stepwise approximation to the actual current distribution in the direction transverse to current flow.

A given area must be subsectioned twice, once for x -directed current and a second time for y -directed current. Figure 17 shows how the x - and y -directed subsections overlap. Note that the centers of the x -directed and y -directed rooftops must be offset. This offset is required in order to allow current to flow from one rooftop to the next.

Figure 15. The vertical direction represents the current density on a rectangular subsection. Current is flowing in the x direction. This is called a “rooftop” basis function.

Figure 16. The total current from the sum of two overlapping rooftop basis functions yields a piecewise linear approximation to the current in the direction of the current flow.

We now evaluate the V_i so that the discontinuity in tangential H field at $z = h$ equals the rooftop current at the source subsection. With \mathbf{J}_s representing the rooftop current distribution centered on the source subsection at (x_0, y_0) , we have

$$V_i = -Z_i \iint \mathbf{J}_s(x, y, x_0, y_0) \cdot \mathbf{e}_i(x, y) dx dy \quad (11)$$

$$Z_i^{-1} = Y_i^{(0)} \text{ctn}[k_{iz}^{(0)}(c - h)] - Y_i^{(1)} \text{ctn}[k_{iz}^{(1)}h] \quad (12)$$

Note that Z_i is just the impedance of the topcover and ground plane transformed by the intervening rectangular waveguide to the surface of the substrate (at $z = h$) and connected in parallel. Extension of this technique to multiple layers requires only the modification of Z_i .

When the full forms of the vector fields \mathbf{J}_s and \mathbf{e}_i are inserted above, the expression for V_i becomes complicated; however, it is simply the sine and cosine integrals. Analytic evaluation of the integrals is tedious but straightforward. The V_i are then used in Eqs. (7)–(10) to determine the tangential electric fields everywhere due to the subsection current distribution \mathbf{J}_s .

Within the framework of the method of moments, the \mathbf{J}_s (one for each subsection) represent “basis” or “expansion” functions. The total current on a circuit is a sum of all the \mathbf{J}_s . To complete the method of moments, we must select “testing” functions. Here, we choose a Galerkin technique, in that the testing functions are the same as the basis functions.

Now, given a specific source subsection with current \mathbf{J}_s impressed on it, we calculate the voltage on a specific field subsection by multiplying the tangential electric field by a rooftop testing function centered on the field subsection and integrating over the area of the field subsection. This integration is of the same form as Eq. (11). It is once more a tedious but straightforward sine and cosine integration that is performed analytically.

Figure 17. When a y -directed rooftop basis function overlaps half of an x -directed rooftop, current can flow around a corner. Note how the center of any x -directed rooftop must be offset from the center of any y -directed rooftop.

10.2. Solving the Moment Matrix

The process described above is repeated for every possible pair of source–field subsections. For N subsections, this fills an $N \times N$ impedance matrix, $\underline{\underline{Z}}$. The amplitude of the current density on each subsection is stored in the $N \times 1$ vector $\underline{\underline{J}}$ and the total voltage on each subsection is stored in the $N \times 1$ vector $\underline{\underline{V}}$. The resulting matrix equation is

$$\underline{\underline{V}} = \underline{\underline{Z}} \underline{\underline{J}} \quad (13)$$

Typically most of the numerical effort is in inverting the $\underline{\underline{Z}}$ matrix. This operation is of order N^3 . Values of N up to 30,000 can now be solved in about an hour on a 3-GHz Pentium. Prior to solving the matrix, we designate a few subsections as “port” subsections. Port subsections are subsections to which we plan to make outside circuit connections. After the matrix is solved, we have

$$\underline{\underline{J}} = \underline{\underline{Y}} \underline{\underline{V}} \quad (14)$$

In order to meet the boundary condition of zero voltage on a conductor, we set the voltage on all nonport subsections to zero. Once we do that, we see that we don’t even need to solve for most of the $\underline{\underline{Y}}$ matrix. If solving the matrix with LU (lower/upper) decomposition, we still must do the full decomposition. However, nearly the entire back solve step is no longer needed.

With the nonport subsection voltages set to zero, we only need the portions of the $\underline{\underline{Y}}$ matrix that deal exclusively with port subsections. If there are two port subsections, the result is a 2×2 matrix. After converting current density $\underline{\underline{J}}$ to current, and possibly changing signs (when circuit theory positively directed current is of direction opposite that of EM analysis positively directed current), this is actually the $\underline{\underline{Y}}$ matrix of the circuit and is the solution to the problem.

If the current distribution is required, additional back solve effort is applied, yielding a larger portion of the $\underline{\underline{Y}}$ matrix. For example, if there are N total subsections and two of these subsections represent ports, we need either a $2 \times N$ or a $N \times 2$ portion of the $\underline{\underline{Y}}$ matrix. Then we use Eq. (14) to calculate $\underline{\underline{J}}$ for any possible port excitations.

10.3. Application of the Fast Fourier Transform

The summation of Eqs. (7)–(10) over i is actually a two-dimensional summation over rectangular waveguide mode numbers m and n for all TE and TM rectangular waveguide modes. Performing this summation repeatedly is very slow. It is performed more efficiently by making a simple trigonometric modification.

Simplifying to one dimension for illustrative purposes, one form of the required summation for a source subsection located at x_0 and a field subsection located at x_1 is

$$S = \sum_{m=0}^M C_m \cos \frac{m\pi x_0}{M} \cos \frac{m\pi x_1}{M} \quad (15)$$

For the complete summation, the summation index m goes to infinity. However, if x_0 and x_1 are restricted to integers

in the range from 0 to M and we take advantage of the periodicity of the trigonometric functions, the entire summation may be performed over the indicated summation range by appropriate modification of the C_m .

This summation is starting to look like a Fourier cosine series, except for one problem. We have the product of two cosines, instead of one. This is easily remedied by rewriting the summation as the sum of two summations:

$$2S = \sum_{m=0}^M C_m \cos \frac{m\pi(x_0 + x_1)}{M} + \sum_{m=0}^M C_m \cos \frac{m\pi(x_0 - x_1)}{M} \quad (16)$$

Both summations are now a cosine series easily and rapidly summed by specialized FFT (fast Fourier transform) algorithms. In fact a single FFT cosine transform provides results for all possible values of $x_0 + x_1$ and $x_0 - x_1$ after taking into account the periodicity in M .

10.4. Improving Speed and Memory Requirements

For the actual two-dimensional summation (over all TE and TM waveguide mode numbers m and n), the 2D cosine transform is performed using a 2D FFT specialized for the cosine transform. Because the C_m depend on both the basis and testing functions, an additional 2D transform is required each time a different type of source or field subsection is used. For a single layer, typically three 2D FFTs are required, one each for x/x , y/y , and x/y coupling. Depending on the specific basis and testing functions, a sine transform may be required instead.

Multiple layers are accommodated by modification of Eq. (12). The modification is such that both extremely thin and extremely thick layers have no impact on accuracy or analysis time. This also changes the C_m in the summation above, so the FFTs must be repeated once more. This approach, when completely including all coupling between all layers, easily accommodates up to several hundred layers.

As mentioned above, all metal must be subsectioned twice, once for x -directed current, and a second time for y -directed current. Further, the center of all x -directed rooftops are offset with respect to the centers of the y -directed subsections. This offset is realized by restricting subsection center coordinates to either even or odd values. This means that the 2D FFTs need be performed for only half of the values of (x_0, y_0) and (x_1, y_1) . With further specialized modification, the size of the required FFTs is cut by half in both dimensions, resulting in a $4 \times$ speed increase.

Different basis and testing functions require only the modification of V_i in Eqs. (7)–(10). Other basis functions that have been implemented in shielded analysis include vias (for conducting current vertically through layers), and triangles [16]. Triangles are used to fill in the staircase that would otherwise exist when meshing with rectangular subsections. However, when comparing analysis results with and without the use of triangles, they are found to provide an advantage only when the transmission line is one or two rectangular subsections wide. If

there is symmetry along one centerline axis in the circuit, the FFTs need to include only half of the m or n modes, resulting in a further doubling of the FFT speed.

Unshielded analysis must also calculate coupling between subsections. In this case, it is worthwhile to store certain intermediate results that depend only on the dielectric geometry. In shielded analysis, the corresponding results are always calculated when needed. This is because the FFT-based calculation of these results is so fast that storing them for later use would actually slow down the analysis.

Matrix storage reduction is also possible. The most significant reduction is realized by noting that the \underline{Z} matrix is symmetric. It is relatively simple to organize LU decomposition so that storage is required for only half the matrix, cutting memory requirements by half.

Provided extremely low-frequency data are not required, all calculations can be performed in single precision, cutting storage requirements by half again. For both single and double precision, careful attention to avoiding loss of precision when dividing by the pivot element is critical. If there is potential loss of precision, then rows and columns must be pivoted. Rigorous testing for potential matrix solve problems requires running literally thousands of cases. Checking for success in only a few cases is certain to leave hidden problems.

Intel architecture computers utilize a specialized FPU (floating-point unit) that performs all calculations using 80 bits of precision. One way to minimize numerical precision problems is to leave the result of continuing calculations (e.g., dot products) and critical numbers (e.g., the pivot element) in the FPU, thus avoiding the precision loss caused by repeated truncation to single or double precision.

11. DE-EMBEDDING ELECTROMAGNETIC DATA

Whether derived from electromagnetic analysis or from measurement, high-frequency data must be properly “de-embedded” if accurate results are to be obtained. In the early days of high-frequency measurement, slotted-line techniques were used. With these approaches, a standing wave is measured on a length of transmission line (e.g., rectangular waveguide). Then, with knowledge of the transmission-line characteristic impedance, the standing-wave measurements can be converted into S -parameter data.

De-embedding approaches analogous to slotted-line measurements are in use today in planar EM analyses, primarily in unshielded environment analyses. While easily implemented, such slotted-line techniques are compromised by the necessity to independently determine the transmission line characteristic impedance. This is usually done by a separate 2D cross-sectional EM analysis. Two additional sources of error are thus introduced: (1) error inherent in the cross-sectional EM analysis and (2) error due to the determination of the characteristic impedance.

This second source of error is due to the fact that the characteristic impedance must be determined from linear

functionals of the cross-sectional fields. For example, voltage is determined by selecting a path from the line to ground and integrating the electric field over that path. While unique for lossless homogeneous media, results can range over 20% or more for typical inhomogeneous microstrip media, depending on which circuit parameters (power, current, or voltage) are calculated and which path integrals are taken. This uncertainty in the “correct” value of characteristic impedance translates directly into error in the final result.

11.1. Modern De-embedding Algorithms

For modern high-frequency measurements, a device under test (DUT) is placed in a test fixture. The test fixture is typically microstrip for connections to the DUT, and either coax or ground–signal–ground (GSG) probepads for connection to the measurement equipment. In order to characterize and remove the effect of the test fixture, a series of known standards are inserted at the location of the DUT and measured. Typical standards might include a short (circuit), open (circuit), load, and through. However, both slotted-line and many modern de-embedding approaches suffer from the fact that characteristic impedance must be independently determined. This is because these approaches cannot directly measure voltage at any point in the circuit.

In contrast, shielded EM analyses can determine both the voltage and current directly and unambiguously at ports. The shielded analyses use infinitesimal gap voltage sources at the edge of the substrate; a side view is shown in Fig. 18. Because the gap source is immediately adjacent to a perfect ground reference (the sidewall), the voltage is unique and precisely determined. With both port current and voltage known uniquely and unambiguously, the port input impedance is known as well.

11.2. De-embedding the Port Discontinuity

The problem with box sidewall ports is that the port input impedance also includes fringing fields excited by the port. The port fringing fields can be viewed as a port discontinuity including both series inductance and shunt capacitance. When loss is present, resistance and conductance may additionally be part of the port discontinuity. Now, the de-embedding problem becomes characterization of the port discontinuity.

Figure 18. The shielded electromagnetic analysis uses an infinitesimal gap voltage source to excite the circuit, shown here from the side.

Figure 19. The L length through line shown schematically includes the port discontinuities, shown here as pure shunt capacitance. The $2L$ length through has the same port discontinuity and twice the length of the transmission line.

For the most straightforward de-embedding approach, the port discontinuity is specialized to pure shunt admittance. This is realized in the EM analysis by forcing uniform voltage along the length of the gap. This disallows transverse current at the port, effectively short-circuiting out any series port inductance. That this assumption is correct is tested as part of the de-embedding process, as described below.

The de-embedding procedure [17] first analyzes two standards, an L length through and a $2L$ length through. A schematic of the L length through including port discontinuities is shown in Fig. 19. Alternatively, only a single $2L$ length through with an internal port at L from each box wall port may be analyzed. The data for the L length through is then obtained by exciting the $2L$ length box wall ports in an odd mode to determine Y parameters of the L length through.

To characterize the port discontinuity, first convert the data for the L and $2L$ length throughs to $ABCD$ cascading parameters. Then invert the $ABCD$ parameters for the $2L$ length through and pre- and postmultiply the result by the $ABCD$ parameters for the L length through. This leaves only a cascade of the port discontinuity with itself; this is called the *double-port discontinuity*.

If the $2L$ line includes a third internal port, as mentioned above, then data for a single-port discontinuity can be uniquely determined [18]. However, if the port discontinuity is specialized to a pure shunt admittance, then the single-port discontinuity can be determined only on the basis of the L and $2L$ length $ABCD$ parameters.

If the port discontinuity is a pure shunt admittance, then $A=D=1.0$ and $B=0.0$. This leaves the C (of the $ABCD$ parameters) equal to the double-port discontinuity shunt admittance. The single-port discontinuity is determined by simply dividing C by 2.

If these conditions on A , B , and D are not met, then either the port discontinuity is not a pure shunt admittance, or another failure mode (discussed later) has occurred. If the more general technique described in Ref. 18 is used, then this self-consistency check is not possible and de-embedding failure will not be detected until it is realized that the analysis calculated incorrect results; however, a general port discontinuity can be characterized.

Once the port discontinuity has been characterized, the DUT data are de-embedded by inverting the single-port discontinuity $ABCD$ matrix and pre- and postmultiplying the DUT $ABCD$ data.

This de-embedding approach is valid for both lossless and lossy situations, including metal loss, dielectric loss, and—under the restrictions noted below—radiation loss.

11.3. Determination of Characteristic Impedance

This de-embedding approach has absolutely no need for knowledge of the characteristic impedance of the transmission lines, as it deals directly only with the terminal (port) voltages and currents. However, additional information can be obtained by de-embedding the $ABCD$ parameters (in the same way the DUT was de-embedded) of the L length through. Then, by noting the $ABCD$ parameters for an ideal TEM through line of length L

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} = \begin{bmatrix} \cos(\beta L) & jZ_0 \sin(\beta L) \\ j\frac{\sin(\beta L)}{Z_0} & \cos(\beta L) \end{bmatrix} \quad (17)$$

we can then determine [19] the “TEM equivalent” characteristic impedance Z_0 and wavenumber β of the L length line by equating (17) with the calculated $ABCD$ parameters of the L length through. We emphasize that this determination of the characteristic impedance is not required in any way for the actual de-embedding process itself.

Once the de-embedded $ABCD$ parameters of the L length through have been obtained, they can be used (by inverting them and then pre- or postmultiplying (as desired) the DUT $ABCD$ parameters) to shift the reference plane of the DUT data into the box. This is sometimes done to remove the port connecting transmission lines.

11.4. De-embedding Failure Mechanisms

This de-embedding approach fails if the through standards allow propagation of more than one transmission-line mode. This is easily detected in the double-port discontinuity data as A , B , and D are different from the values stated above. In addition, the L length line must be long enough that the port fringing fields on each end do not interact with each other. A length of at least one substrate thickness, and preferably two, is usually all that is required. If this condition is not met, then once more, A , B , and D are different from the above-stated values.

An additional failure mechanism is sometimes exhibited when radiation is allowed. Shielded analyses approximate radiation by making the topcover resistive, usually 377Ω per square. The box conducting sidewalls form a rectangular waveguide. The topcover must be positioned far enough above the DUT that it is not involved in fringing fields (i.e., near field) of the DUT. Placing the topcover above the DUT by about the size of the DUT is usually sufficient.

A radiation related de-embedding failure mode is seen when the sidewalls of the box containing the L length through form a cutoff rectangular waveguide but the sidewalls of the $2L$ length through form a propagating waveguide. Thus, the L length through does not see radiation loss, but the $2L$ length through does. The error introduced is typically small because the radiation loss for a simple through line is typically small. However, careful

inspection of the S parameters of an otherwise lossless passive structure can in this case actually show a small gain. If high-accuracy S parameters including radiation loss are important, then one should take care to make sure that the box containing the L length through is large enough to allow propagation up to the topcover. This failure mode is not detected by inspection of A , B , and D as in other failure modes.

A final failure mechanism occurs if one of the standards excites a box resonance. This resonance appears in the de-embedded data and also causes the values of A , B , and D for the port discontinuity to differ from the values stated above.

For typical high-frequency applications, the port discontinuity capacitance is a few tenths of a picofarad. Occasionally, such a port discontinuity is unimportant for a specific application and de-embedding can be skipped.

11.5. De-embedding Multiple Coupled Ports

In the case of multiple coupled ports, A , B , and D of the $ABCD$ matrices above all become, themselves, matrices. For example, if there are two ports on one side of the box, both of which are to be de-embedded, the L and $2L$ length throughs each become a pair of coupled lines and each element of the $ABCD$ matrix becomes a 2×2 matrix.

The approach is fully valid, no matter how many ports and no matter how tightly coupled they are. Analyses with several hundred ports, as tightly coupled as desired, are easily performed. The very high accuracy of this de-embedding technique for tightly coupled ports is critical in the success of divide-and-conquer analysis strategies, as described above.

12. CONCLUSION

The field of applied high-frequency numerical electromagnetics began in the 1990s and has reached an advanced state of development. Today, numerical electromagnetics is considered a necessary part of nearly any high-frequency design. The designer can now complete numerous design iterations in days, or even in hours, that previously would have taken weeks or months. Once the design is complete, success on first fabrication is now regularly enjoyed.

Future advancements in this field are likely to be outside the realm of Maxwell's equations. Specifically, interoperability with design frameworks, faster computers, and a maturation of the generally accepted RF design cycle are all likely to see activity in the near future. Numerical electromagnetics promises to play an important role in the future of both commercial and military high-frequency design.

1. INTRODUCTION

An artificial magnetic conductor (AMC) [1,2] is a nearly lossless reactive surface, usually realized as a printed circuit board, that presents a reflection coefficient of the order of $+1$ to incident plane waves and simultaneously inhibits the propagation of surface waves across its surface over a prescribed band of frequencies (the so-called bandgap). Because of the in-phase reflection coefficient at the surface, the total tangential magnetic field is close to zero over its operational band, thus emulating the properties of a theoretical perfect magnetic conductor (PMC). However, whereas a true PMC would allow the grazing propagation of waves with vertical magnetic field over its surface while suppressing waves with vertical electric field, the AMC suppresses propagation of both types of waves. This combination of properties yields the following experimentally verified desirable features:

1. The radiation from a proximate, horizontal electric dipole (a wire antenna) is reflected in phase, augmenting the dipole's gain instead of canceling it, as would occur over a conventional conducting ground plane.
2. The input impedance of the dipole is increased.
3. The radiated power along the surface is dramatically reduced, leading to backlobe suppression and further increased broadside gain.

When properly designed, the AMC surface-wave bandgap will correspond to the same frequency band over which the AMC exhibits a high surface impedance, thus enabling realization of an efficient, electrically thin antenna structure. Because of features 1 and 2, the AMC is classified as a high-impedance surface. Because of feature 3, the AMC can also be classified as an artificially soft surface [3] since, for an arbitrary point source located at the center of the AMC, simultaneous cancellation of E_ϕ and H_ϕ over the surface corresponds to the suppression of radially propagating TE and TM surface waves. Because the suppression of surface waves occurs over a well-defined frequency range, the AMC is classified as an electromagnetic bandgap (EBG) structure. However, because this behavior

results from a texture with periodicity much smaller than the free-space wavelength and does not involve periodic structure resonances, the AMC is classified as a metamaterial or artificial magnetodielectric.

The latter definition is adopted here as the most appropriate. In Section 2 the artificial anisotropic magnetodielectric parameters of the AMC are derived from quasistatic analysis of its physical features. It is then shown that these parameters are sufficient to completely explain the features enumerated above. In particular it is demonstrated that the permittivity and permeability normal to the surface are the key parameters that control the surface-wave suppression properties of the AMC. The degree of control available to the engineer for designing an AMC, including its thickness, operational frequency, bandwidth of favorable reflection coefficient, and bandwidth of surface-wave suppression, is the subject of Section 3. Section 4 applies the results of Section 3 to develop a design approach for typical AMCs. Section 5 places the AMC in the context of earlier and later developments of other artificial magnetic conductors found in the literature. Finally, Section 6 highlights more recent successful applications of the AMC ranging from tunable antenna ground planes to applications as a suppressor of crosstalk between collocated antennas.

2. THE AMC AS A TWO-LAYER ARTIFICIAL UNIAXIAL ANISOTROPIC MAGNETODIELECTRIC

Figure 1 shows the original AMC embodiment, invented at UCLA in the late 1990s by Sievenpiper et al. [1,2]. It consists of an electrically thin, planar, periodic structure with vertical conductors (vias) that terminate on a periodic array of planar conductors [the frequency-selective surface (FSS)], above a conducting ground plane, that can be fabricated using low-cost printed circuit technologies.

The normal incidence reflection coefficient of this AMC surface can be derived immediately from its transmission-line representation. It turns out that for typical configurations the dielectric constant of the substrate is not a critical parameter because its thickness is so small that the electric field throughout its volume is nearly zero. The effect of the vias can likewise be ignored since for a normal incidence wave the electromagnetic fields are transverse to them and therefore are nearly invisible (or, stated another way, the transverse polarizability of thin metallic cylinders perpendicular to both E and H fields is negligible). Therefore, the groundplane is a short circuit in the transmission line of free space, above which, at a distance

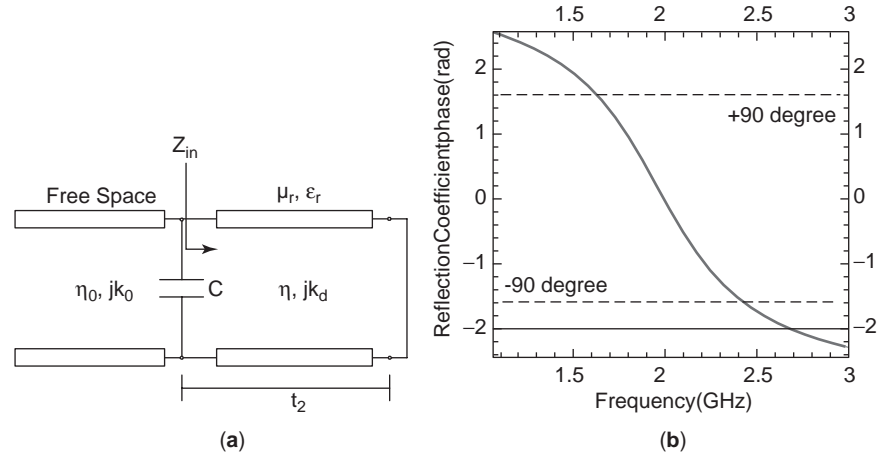

Figure 1. Sievenpiper high-impedance surface.

Figure 2. Transmission-line representation of the normal incidence reflection properties of the AMC (a) yields the typical reflection phase–frequency plot (b). In the example of (b) the center or resonance frequency is 2 GHz and the useful reflection coefficient band extends from 1.65 to 2.35 GHz.

t_2 , there is a large shunt capacitance. The value of the shunt capacitance is chosen to resonate the short circuit so that just above the capacitive sheet the short (circuit) is electrically a quarter-wavelength away at the design frequency. Clearly the phase angle of the reflection coefficient is 0° at this frequency and must vary from $+180^\circ$ at DC to -180° at the frequency where the short is electrically a half-wavelength away. The operational band of the AMC, from the standpoint of favorable reflection coefficient, is then defined as the frequency band bounded by the $+$ and -90° phase frequencies, since at those frequencies the radiation from the image of a horizontal electric dipole does not subtract from the source radiation. It is also the band of frequencies for which the wave impedance for plane wave incidence is greater than that of free space. Figure 2 illustrates these considerations.

The fractional bandwidth of a typical Sievenpiper AMC structure is defined by its normal incidence reflection properties using the transmission-line model. The impedance of the transmission line is the dielectric substrate's impedance for normally incident TEM waves η with its corresponding propagation constant $\beta = k_d$. The input impedance of the short(-circuit) transmission for normal incidence is

$$Z_{in} = j\eta \tan(k_d t_2) \quad (1a)$$

With the assumption of an electrically thin structure ($\tan(k_d t_2) = k_d t_2$), this impedance can be simplified as

$$Z_{in} = j\omega\mu_D\mu_0 t_2 = j\omega L \quad (1b)$$

Therefore, the transmission line can be replaced by its total series inductance L , which is then in series with the short circuit forming a tank LC circuit with the FSS capacitor, of resonant frequency $\omega_0 = (LC)^{-1/2}$. (It should be noted that the inductance involved here has nothing to do with the via rods; they are essentially transparent to a normally incident plane wave.)

The reflection coefficient of this simplified circuit tuned to resonate at a center frequency of ω_0 can be obtained

easily as a function of frequency:

$$\Gamma(\omega) = \frac{j\omega t_2 \mu_D \mu_0 - \eta_0 \left(1 - \left(\frac{\omega}{\omega_0}\right)^2\right)}{j\omega t_2 \mu_D \mu_0 + \eta_0 \left(1 - \left(\frac{\omega}{\omega_0}\right)^2\right)} \quad (2)$$

Defining f_{up} as the frequency at which the phase of the reflection coefficient of Eq. (2) crosses -90° , $\Gamma = -j_1$, and f_{low} the frequency at which it crosses $+90^\circ$, $\Gamma = j_1$, and substituting these two values of Γ into the equation, it is easy to show that for thin high-impedance surfaces, the bandwidth $BW = f_{up}/f_{low}$ is given by

$$\frac{BW - 1}{\sqrt{BW}} = \frac{\omega_{+90} - \omega_{-90}}{\omega_0} = 2\pi\mu_D \frac{t_2}{\lambda_0} \quad (3)$$

Thus, to support a 10% instantaneous bandwidth an AMC with purely dielectric, nonpermeable ($\mu_D = 1$) substrate need be only $\frac{1}{62}$ th of a wavelength thick. In applications requiring wide instantaneous bandwidth, for example, to accommodate an octave frequency range ($BW = 2$), the AMC thickness must be over a tenth of a free-space wavelength thick ($t_2 = 0.113 \lambda_0$). This thickness may be too large for some applications, and thus magnetically loaded AMCs ($\mu_D > 1$) have been designed. The limiting case of a Sievenpiper AMC is one whose thickness is a full $\lambda_0/4$, and whose FSS capacitance has gone to zero. The exact phase bandwidth for this thick case (maximum instantaneous bandwidth for an AMC) is 3–1 or 100% fractional bandwidth.

The transmission-line model of the reflection coefficient of the AMC just described illustrates the fact that the AMC derives its in-phase reflection coefficient property from a “quarter-wave ground plane” effect. This in itself is not a novel accomplishment since physically thin but electrically quarter-wave-thick ground-plane structures are trivial to construct using high-dielectric-constant materials. However, such structures are useless in practice for gain enhancement of antennas because the preferred mode of radiation of a horizontal dipole above a dielectrically clad ground plane is into the surface waves and not

Figure 3. Effective medium model and parameters for AMC.

into free space. The key to the usefulness of the AMC is therefore that its surface-wave suppression properties occur in the same band in which the reflection coefficient is in phase. This can be accomplished only by exploiting its anisotropic degrees of freedom.

In the following analysis we assume that the periodicity of the unit cells in the AMC is very small compared to the wavelength so that it can be modeled in terms of effective medium theory, treating the quasielectrostatic and quasimagnetostatic features separately. We also assume a square lattice, with equal periods in both the x and y directions. Because of the form of the AMC structure, we choose to separate the effective medium into two distinct layers. The “spacer” layer or “rodded medium” layer consists of a regular array of conducting vias connected to the conducting backplane. This is covered by a capacitive “FSS” layer, which consists of a regular array of metal patches. Although the FSS layer can be infinitely thin in theory, we assign it a finite (and somewhat arbitrary) thickness in the effective medium representation. Because of the symmetry of the structure, both layers can be modeled with uniaxial permittivity and permeability tensors. Figure 3 shows the effective media model layers and associated permittivity and permeability tensors.

2.1. Effective Medium Model for the Substrate

In order to derive the values for the elements of these tensors, first consider a medium consisting of an array of infinite rods. When an electric field exists throughout the whole space (such as in the low-frequency limit of a wave traveling through this “forest” of rods), symmetry considerations allow us to concentrate on one unit cell of the array. In the quasielectrostatic limit, that cell has PEC plates at $z=0$ and $z=h$ (arbitrary) and PMC walls all around, as in Fig. 4.

As Fig. 4 suggests, the actual shape of the PMC boundary of the unit cell cannot possibly be a significant factor in the quasistatic effective medium behavior of this

array, and so we take it to be a cylindrical boundary of equal cross-sectional area. If the array is immersed in free space, the only polarization vector is that inside the rods, and thus the only excess current in this space comes from the rod current $\partial P/\partial t$. Assuming that the rods are metal, this is purely a conduction current. It creates a circulating magnetic field inside the unit cell that starts at the surface of the rod and vanishes on the surrounding PMC surface (since H tangential to a PMC must vanish). Integration of the magnetic energy inside the unit cell and setting it equal to $\frac{1}{2} I^2 L$ yields

$$L = \frac{\mu h}{4\pi} \left[\ln\left(\frac{1}{\alpha}\right) + \alpha - 1 \right]; \quad \alpha = \frac{\pi a^2}{d^2} \quad (4)$$

where α is the ratio of the rod’s cross-sectional area, to the cross-sectional area of the unit cell.

The circuit describing the unit cell is then the capacitance of the cell $\epsilon_0 \epsilon_D A/h$ in parallel with the inductance. The effective capacitance of that circuit is

$$C_{\text{eff}}(\omega) = \frac{1}{j\omega} Y = \frac{1}{j\omega} \left(j\omega \frac{\epsilon_D \epsilon_0 A}{h} + \frac{1}{j\omega L} \right) \quad (5)$$

$$= \frac{\epsilon_D \epsilon_0 A}{h} - \frac{1}{\omega^2 L}$$

The effective permittivity is then the effective capacitance of that circuit divided by the capacitance of the empty unit cell:

$$\epsilon_{\text{eff}}(\omega) = \epsilon_D - \frac{1}{\omega^2 \epsilon_0 \frac{\mu A}{4\pi} \left[\ln\left(\frac{1}{\alpha}\right) + \alpha - 1 \right]} \quad (6)$$

Thus, at low frequencies it is negative, and it crosses zero at the so-called plasma frequency, defined as the frequency at which the unit cell resonates.

Figure 4. Equivalent unit cell for the rodded medium.

This medium was analyzed on the basis of its periodic structure properties by Brown [4], under the assumption of thin rods arrayed in a square lattice. His solution is obtained from solving the equation

$$\cos\left(\frac{2\pi l}{\lambda} n\right) = \cos\left(\frac{2\pi l}{\lambda}\right) + \frac{\lambda}{2l} \frac{\sin\left(\frac{2\pi l}{\lambda}\right)}{\ln\left(\frac{l}{2\pi\rho}\right) + F\left(\frac{d}{\lambda}\right)} \quad (7)$$

where l is the distance between rods, n is the effective refractive index referenced to the background in which the wavelength is measured, and the correction function F can be approximated by

$$F\left(\frac{d}{\lambda}\right) \approx 0.15 \left(\frac{d/\lambda}{0.5}\right)^2 \quad (8)$$

Setting $\epsilon_{\text{eff}}^{\text{Brown}}(\lambda) = n^2$, the results of Brown's model can be compared to the effective medium model. Figure 5 shows the comparison for rods of radius 0.18 mm, spaced 2.4 mm center to center in a Cartesian array. Note the close agreement. For rods that are not thin compared to the separation between them (breakdown of Brown's equation), the quasistatic analysis above continues to be self-consistent. However, for rod separations that are not a small fraction of the wavelength, Brown's equation correctly predicts the periodic structure scattering above the frequency where the effective permittivity crosses zero. The quasistatic model does not include this phenomenon. Therefore, in designing an AMC where the negative values of the normal permittivity are crucial, Eq. (6) and its derivation can be used. It has the advantage that it allows the designer to consider the effect of loading the vias with lumped elements such as series inductors, and evaluate the effect this would have on the effective med-

ium properties of the AMC. However, for predicting the AMC performance at frequencies where the normal permittivity of the substrate becomes positive, it is mandatory to use Brown's equation.
