RADIOWAVE PROPAGATION IN MULTIPATH CHANNELS

R. D. KOILPILLAI
Ericsson, Inc.

With the rapid growth in wireless communications, there is considerable interest in radiofrequency (RF) propagation and RF channel modeling in the 400 MHz–2 GHz

band, where multipath propagation is a characteristic property. The topic of RF signal propagation and the factors that affect the RF signals have been extensively studied since the late 1960s [1–3]. This article presents a comprehensive overview of the RF signal variations related to propagation in multipath fading channels. The diverse phenomena that cause signal variations are described via mathematical models. The different types of fading and their salient features are discussed in detail. The goal of this article is to provide a mathematical and an engineering-oriented treatment of multipath fading, thereby providing the reader with the necessary tools and the information to understand the different RF propagative issues and how they impact wireless communications.

The different propagative effects are classified in two major categories as shown in Fig. 1:

- Small-scale effects
- Large-scale effects

The small-scale effects are those caused by multipath propagation, the phenomenon by which the transmitted signal reaches the receiver via multiple paths. The received signal is a superposition of the different multipath signals, which add constructively or destructively, thereby producing signal fluctuations. The variations of the signal level are typically produced by movement over short distances (10–20 times the wavelength λ of the RF carrier) during which the mean signal level remains constant. The different types of fading and their mathematical characterization and modeling are discussed in the following sections.

On the other hand, large-scale effects are those caused by variations in the distance between transmitter and receiver, which are manifested in the form of path loss, and by environmental factors, such as terrain, which produce lognormal shadowing about the local mean signal level. These issues are also discussed in detail.

A schematic of a communication system is shown in Fig. 2. The term “channel” is used to imply different portions of the communication link. Two terms used in this article, namely, the propagative channel and the baseband channel need to be defined. The propagation channel is the physical medium that supports RF propagation between the transmitting and receiving antennas. This includes the objects that cause the multipath and time dispersion. This channel is time-varying. The baseband equivalent channel consists of a complex-valued baseband representation of the channel. If the nonlinearities in the IF/RF stages of both transmitter and receiver are neglected, then the baseband channel can also be represented by a linear, time-varying channel model, which includes the appropriate models for the propagation channel.

1. BASIC DEFINITIONS

1.1. Static Channels

The simplest type of communication channel is a static channel, in which the only signal impairment caused by

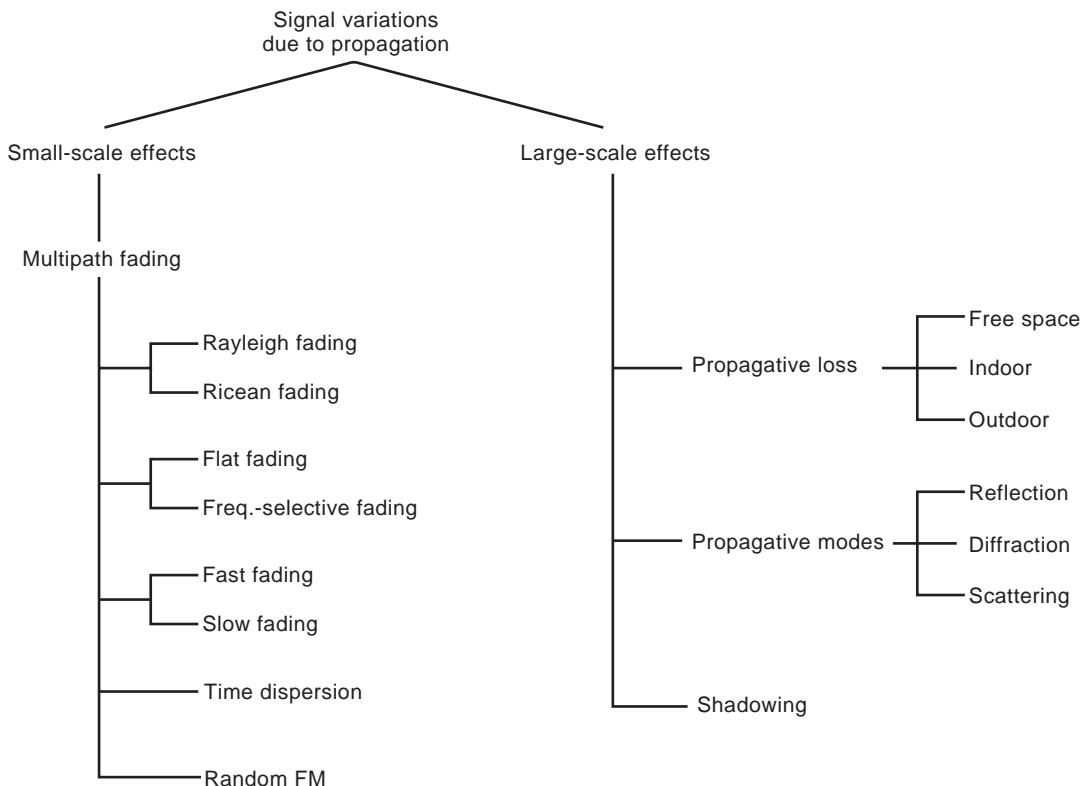

Figure 1. Classification of the small-scale effects and the large-scale effects that cause signal variability in an RF environment.

the channel is additive white Gaussian noise (AWGN). The noise is assumed to have a flat, power spectral density and is uncorrelated in time. These characteristics are typical of the thermal noise generated in communication equipment.

The AWGN channel is widely used to evaluate the performance of communication systems [4] (modulation, coding, etc.). In RF communications, a static environment is unlikely, except in a few situations when there is a dominant line-of-sight (LoS) component between the transmitter and receiver, and there is essentially no multipath, such as in microwave LoS links and in microcells. In practice, the AGWN channel serves the useful role of providing performance bounds for RF communication channels because the practical channels (typically Rayleigh and Ricean) always produce signal impairments more severe than the AGWN channel.

1.2. Fading Channels

Some of the commonly encountered communication channels, such as that encountered in wireline communications over telephone networks, can be characterized as AWGN channels that have a linear time-invariant (LTI) filter channel model. However, this representation does not apply to radio frequency (RF) channels because their transmission characteristics change with time and hence require statistical characterization using *linear, time-varying channel models*. Typically RF channels are characterized by the following time-varying phenomena:

1. Multipath propagation and signal fading
2. Multipath time dispersion
3. Doppler shift

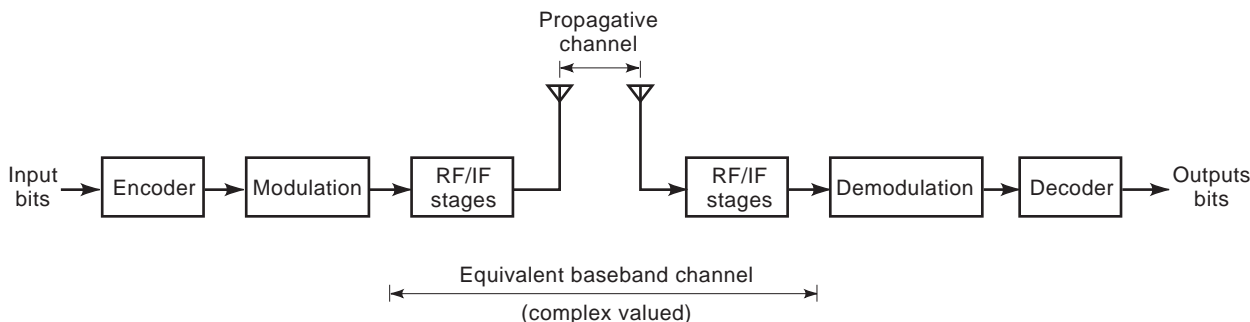

Figure 2. Definition of propagative channel and baseband channel.

4. Random frequency/phase modulation
5. Shadowing

In this article, these salient features of RF fading channels and their statistical characterization are described. Some examples of RF channels that fall in this category are

- Mobile cellular channels
- Mobile satellite channels
- Channels with ionospheric and tropospheric propagation

1.2.1. Multipath and Time Dispersion. *Multipath* is the phenomenon by which a transmitted signal reaches a receiver via multiple propagative paths, each of which has an associated propagative delay. For instance, in Fig. 3, the signal from the base station to the mobile station has three paths with propagative delays τ_1 , τ_2 , and τ_3 , respectively. One of them is the direct line-of-sight path between the transmitter and receiver (with delay τ_1). The other two paths (with delays τ_2 and τ_2) are caused by scatterers/reflectors. If a narrow pulse is transmitted in this channel (with $\tau_1 \neq \tau_2 \neq \tau_3$), then three copies of the pulse are received, as shown in Fig. 4. Channels exhibiting this property are called *time-dispersive*.

1.2.2. Doppler Spread. Another distinctive characteristic of radio channels is the time variation of the channel. This can be caused by mobility of transmitter or receiver or a change in the propagative environment (change in the scatterers). The received signal $x(t)$ in this time-varying multipath channel can be expressed as

$$x(t) = \sum_n \alpha_n(t) s[t - \tau_n(t)] \quad (1)$$

Figure 3. An example of multipath propagation due to multiple scatterers.

Figure 4. Effect of time dispersion due to multipath propagation.

where $s(t)$ is the modulated signal, $\alpha_n(t)$ and $\tau_n(t)$ are the attenuation factor and the propagative delay, respectively, for the signal received via the n th path. The modulated signal $s(t)$ is typically represented as [4]

$$s(t) = m(t) \cos[2\pi f_c t + \theta(t)] = \text{Re}[u(t)e^{j2\pi f_c t}] \quad (2)$$

with carrier frequency f_c , and $u(t) = m(t) \cos \theta(t) - jm(t) \sin \theta(t)$. Substituting Eq. (2) in Eq. (1), the signal received $x(t)$ is given by

$$x(t) = \text{Re} \left(\left\{ \sum_n \alpha_n(t) e^{-j2\pi f_c \tau_n(t)} u[t - \tau_n(t)] \right\} e^{j2\pi f_c t} \right) \quad (3)$$

The corresponding baseband (complex) signal $r(t)$ and the equivalent baseband channel $c(\tau; t)$ are given by

$$r(t) = \sum_n \alpha_n(t) e^{-j2\pi f_c \tau_n(t)} u[t - \tau_n(t)] \quad (4)$$

$$c(\tau; t) = \sum_n \alpha_n(t) e^{-j2\pi f_c \tau_n(t)} \delta[t - \tau_n(t)] \quad (5)$$

Consider the transmission of an unmodulated carrier $s(t) = A \cos 2\pi f_c t$. Then, using Eq. (4), with $u(t) = 1$, the received signal is given by

$$r(t) = \left[A \sum_n \alpha_n(t) e^{-j2\pi f_c \tau_n(t)} \right] \quad (6)$$

which also represents the response of the channel to a complex exponential $e^{j2\pi f_c t}$. Even though $s(t)$ is a monochromatic signal, the output of the channel $r(t)$ contains many different frequency components, which are generated as a result of the time variations of the channel response. The range of frequencies over which the spectrum of $r(t)$ is nonzero is called the *Doppler frequency*

spread (B_d) of the channel, which yields a measure that is directly proportional to the rate of variations of the channel response.

1.2.3. Signal Fading. In Eq. (5), $c(\tau;t)$ is the time-varying (complex-valued) channel impulse response (CIR) and is the discrete multipath channel model, wherein τ represents the time dispersion and t denotes the time index for the variations as a function of time. The CIR $c(\tau;t)$ can be viewed as the superposition of phasors, each with a time-varying gain/amplitude $\alpha_n(t)$ and a time-varying phase $\phi_n(t) = -2\pi f_c \tau_n(t)$. With random variations in $\alpha_n(t)$ and $\phi_n(t)$ (caused by the time-varying multipath), these phasors can add constructively or destructively. The *fading phenomenon*, which results in signal amplitude becoming very small, is caused by instantaneous destructive combining of the phasors. An important observation is that a small change in $\tau_n(t)$ produces a significant phase change (i.e., a 2π change occurs if $\tau_n(t)$ changes by $1/f_c$). Using the central-limit theorem, $r(t)$ can be modeled as a complex-valued Gaussian random process [4], which implies that $c(\tau;t)$ is also a complex-valued Gaussian random process in the t variable. This random amplitude variation is a fundamental characteristic of multipath channels, and hence its understanding is crucial to the use of these channels. In *Rayleigh fading* channels, $c(\tau;t)$ is modeled as zero-mean, and corresponds to the case when there are random variations in the scattering environment (usually caused by the movement of the transmitter or receiver) and there is no line-of-sight (LoS) path. In *Ricean fading* channels, $c(\tau;t)$ is nonzero mean because of the presence of a LoS component or because of fixed scatterers. Typically Rayleigh fading channels are encountered in all cellular and land-mobile radiocommunications, whereas Ricean fading channels are encountered in mobile satellite communications. A detailed characterization of these channels is presented in the subsequent sections.

In some cases, it is more suitable to have a continuous multipath model. In this case, the received signal $x(t)$ is given by

$$x(t) = \int_{-\infty}^{\infty} c(\tau;t)s(t-\tau) d\tau \quad (7)$$

which is similar to Eq. (1) with the summation replaced by an integral. This model is typically used in tropospheric scatter and ionospheric propagation. In the sequel, we focus on the discrete model for multipath channels, which is typical for most terrestrial RF channels.

1.2.4. Fading in a Mobile Communication Environment. If the transmitter and receiver were stationary and all the scatterers were fixed, then the signal fading variations, described in the previous section, would not be observed. In mobile communications (such as cellular), the receiver or transmitter is usually moving. So the scattering environment is constantly changing. A typical fading signal envelope (characterized by Rayleigh fading) for a mobile receiver using a carrier frequency $f_c = 1.9$ GHz and moving at 100 km/h, is shown in Fig. 5. It can be seen that

the signal envelope can vary as much as 40 dB (30 dB below and 10 dB above) relative to the rms value.

A spatial viewpoint of multipath fading is very useful. Consider a stationary transmitter and fixed scatterers. The signals from the scatterers can be visualized as forming a spatial standing wave pattern with peaks (points in space where the multipath signals add constructively) and troughs (where the signals add destructively). The spatial separation between troughs and peaks is roughly $\lambda/2$, where λ is the wavelength of the carrier. If a mobile receiver were to move through this spatial standing wave pattern, then it experiences the signal fading every time the receiver has moved by $\lambda/2$. In Fig. 5, the x axis is the time in seconds. As the receiver moves, it can experience multiple signal fades per second.

Example 1. Consider a mobile station moving at 100 km/h and communicating at a carrier frequency of 1.9 GHz. The corresponding wavelength $\lambda = 0.15$ m. Because the vehicle is moving at 100 km/h ($= 27.77$ m/s), the vehicle covers a distance corresponding to 176λ in 1 s. Hence, the envelope of signal received by the mobile can experience as many as 350 signal fades per second, as shown in Fig. 5. The extent of signal impairment depends on the extent of signal amplitude reduction, known as the *depth of the fade*. This is quantified via the level crossing rate and the duration of fades discussed in a subsequent section.

1.2.5. Shadowing. *Shadowing* is the term that refers to the long-term variations in the local mean of the received signal power at a distance d from the transmitter. These variations are typically caused by the terrain, buildings, foliage, and other obstructions in the signal path. If the instantaneous power of the signal received at the receiver is averaged to remove the effect of fast fading, the local mean signal level Ω' at that particular distance d from the transmitter is obtained. The local mean remains constant over a small distance (of the order of multiples of the wavelength of the RF carrier). The local mean Ω' is a

Figure 5. Typical envelope variations in Rayleigh fading at a vehicle speed of 100 km/h and carrier frequency 1.9 GHz. The RMS value of the signal envelope is 0 dB.

random variable because of the signal level variations caused by the terrain and other environmental factors. Through empirical studies, the RV Ω has been characterized by the log-normal distribution (see the next section) with a standard deviation in the typical range of 6–9 dB.

2. FADING DISTRIBUTIONS

The two most commonly encountered types of fading environments are

1. Rayleigh fading
2. Ricean fading

In this section, the statistical properties of Rayleigh and Ricean fading are described. This mathematical framework is very useful in providing tools for analyzing and simulating the performance of communications over fading channels and also for providing insight into the design of robust communication systems in a fading environment (see Ref. 16). Ricean fading covers a very broad spectrum of environments from static AWGN channels on the one end to Rayleigh fading channels on the other. So, it represents an entire family of fading channels. However, because Rayleigh channels are the most frequently encountered environment in wireless (mobile) communications, it forms an important class for study. Both Rayleigh and Ricean distributions refer to the statistics of the received signal's envelope.

3. RICE DISTRIBUTION

Let X and Y be two independent Gaussian random variables (RVs) with means m_1 and m_2 , respectively, and common variance σ^2 . Then the RV V , defined as $V \triangleq \sqrt{X^2 + Y^2}$, is distributed according to *Ricean distribution* [8], whose pdf is given by

$$f_V(v) = \begin{cases} \frac{v}{\sigma^2} I_0\left(\frac{sv}{\sigma^2}\right) e^{-(v^2 + s^2)/2\sigma^2} & v > 0 \\ 0 & v \leq 0 \end{cases} \quad (8)$$

where $s^2 = m_1^2 + m_2^2$ and I_0 is the zeroth-order modified Bessel function of the first kind given by

$$I_0(x) = \frac{1}{2\pi} \int_0^{2\pi} e^{x \cos u} du = \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{x \cos u} du \quad (9)$$

It can be verified that the RV $\hat{V} = V^2$ has a noncentral chi-square distribution whose noncentrality parameter is s^2 . The cdf of a Ricean RV V is given by (4)

$$F_V(v) = \Pr(v \leq V) = \int_0^v f_V(v) dv = 1 - Q\left(\frac{s}{\sigma}, \frac{v}{\sigma}\right) \quad (10)$$

where Q is the generalized Q function defined as

$$Q(a, b) = e^{-\frac{a^2 + b^2}{2}} \sum_{k=0}^{\infty} \left(\frac{a}{b}\right)^k I_k(ab), \quad b > a > 0$$

and $I_k(x)$ is the k th-order modified Bessel function of the first kind.

Ricean fading is typically encountered in environments where there is a dominant, nonfading signal component (i.e., a line-of-sight path between transmitter and receiver, and this causes the nonzero mean of X and Y). This is commonly true in mobile satellite channels. The signal received can be modeled as the superposition of the scattered multipath signals (with random angles of arrival) and the line-of-sight signal. The effects of the scattered signals depends on their strength relative to the strength of the nonfaded signal, which is characterized by the parameter called *Ricean factor* K , defined as $K \triangleq s^2/2\sigma^2$. It is quite common to specify the Rice factor in decibels, $K_{\text{dB}} \triangleq 10 \log_{10} K$ dB. As mentioned previously, the Ricean distribution spans a broad spectrum of fading environments, including the following special cases:

- $K \rightarrow 0$ ($\Rightarrow s^2 \sim 0$) \Rightarrow Rayleigh fading channel
- $K \gg 1$ ($\Rightarrow s^2 \gg \sigma^2$) \Rightarrow static channel (no fading)

A plot of the Ricean pdf for different values of the Ricean factor K is given in Fig. 6. As the value of K increases, the mean (and also the variance) of V increases. In practice, this implies that the LOS signal component is stronger relative to the scattered signal components, and as a result the magnitude of signal fades is reduced. Figure 7 shows segments of Rayleigh and Ricean fading for different values of K . For $K=10$, in Fig. 7 the fade depth is typically ≤ 10 dB, whereas for $K=1$, signal fades of up to 30 dB are observed.

3.1. Rayleigh Distribution

As shown in the preceding section, the Rayleigh distribution is a special case of the Rice distribution ($K \rightarrow 0$ dB). The Rayleigh distribution can also be derived independently from the central chi-square distribution, as shown herein. Let X and Y be two independent identically distributed (i.i.d.) zeromean Gaussian RVs with variance σ^2 .

Figure 6. Plot of the Rayleigh pdf and the Ricean pdf for different values of the Rice factor $K=1, 4$, and 10 .

Figure 7. Plot of a typical segment of Rayleigh and Ricean fading waveforms.

Then the RV V defined as $V \triangleq \sqrt{X^2 + Y^2}$, is distributed according to the *Rayleigh distribution*, whose pdf is given by

$$f_V(v) = \begin{cases} \frac{v}{\sigma^2} e^{-\frac{v^2}{2\sigma^2}} & v \geq 0 \\ 0 & v < 0 \end{cases} \quad (11)$$

A brief derivation of the pdf $f_V(v)$ is given in the Appendix. Equation (11) can be obtained from Eq. (8) by setting $s^2 = 0$. It can also be shown that the RV $\hat{V} = V^2$ has a central chi-square distribution. The cdf of V is given by

$$\begin{aligned} F_V(v) &= Pr(v \leq V) = \int_0^v f_V(v) dv \\ &= 1 - e^{-\frac{v^2}{2\sigma^2}}, v \geq 0 \end{aligned} \quad (12)$$

The mean and variance of V are given by

$$E[V] = \sqrt{\frac{\pi}{2}} \sigma$$

and

$$E[V^2] = 2\sigma^2$$

and the higher order moments of V can be obtained from the expression [4]

$$E[V^k] = (2\sigma^2)^{k/2} \Gamma\left(1 + \frac{k}{2}\right)$$

3.2. Nakagami Distribution

The Nakagami- m distribution [5] was designed to fit empirical data and in some cases provides a better match than Rayleigh or Rice distributions. Hence, it is frequently used to characterize the statistical fluctuations of signals transmitted over multipath fading channels. An RV V with *Nakagami- m distribution* has a pdf given by

$$f_V(v) = \frac{2}{\Gamma(m)} \left(\frac{m}{\Omega}\right)^m v^{2m-1} e^{-\frac{mv^2}{\Omega}}, m \geq \frac{1}{2} \quad (13)$$

where $\Omega = E[V^2]$, $\Gamma(m)$ is the gamma function, and the parameter m is called the fading figure, defined as

$$m \triangleq \frac{\Omega^2}{E[(V^2 - \Omega)^2]}, m \geq \frac{1}{2}$$

The following are special cases of the Nakagami- m distribution:

- $m = 1$; the Nakagami- m distribution reduces to the Rayleigh pdf.
- $m = 1/2$; $f_V(v)$ is the one-sided Gaussian pdf (more severe than Rayleigh fading).
- $m \rightarrow \infty$; it is a static channel (no fading).
- The Nakagami- m distribution also provides a close approximation of the Rice distribution with the following relationship between the Rice factor K and the

Nakagami parameter m :

$$m = \frac{(K+1)^2}{(2K+1)}$$

Because of its versatility in modeling a wide range of fading conditions and its analytical tractability, the Nakagami- m distribution is widely used.

3.3. Lognormal Distribution

The variations in the local mean of the signal power received in a fading environment is referred to as shadowing. These variations are caused by terrain and other environmental factors. Shadowing is characterized via the lognormal distribution, as defined herein. An RV Ω' is said to have a log-normal distribution if its pdf is given by

$$f(\Omega) = \frac{1}{2\pi\sigma_\Omega} e^{-(\Omega-\mu)^2/2\sigma_\Omega^2} \quad (14)$$

where

$$\Omega = 20 \log_{10} \Omega'$$

$$\mu = E[\Omega]$$

and

$$\sigma_\Omega^2 = E[\Omega^2] - \mu^2$$

4. CHARACTERIZATION OF RAYLEIGH FADING

Extensive measurements of the envelope variations of signals have been carried out in the 100–2000 MHz frequency band, which covers commercial cellular, public safety, and special mobile radio applications. The measured data confirm that the envelope of the received signal is Rayleigh distributed when measured over short distances ($\sim 10\lambda$ – 20λ) over which the mean signal level is constant. In this section, the key results of the mathematical model of Rayleigh fading channels and their characterization are presented. For a complete derivation of the results, the reader is referred to Refs. 1–3. Herein, the model proposed in Ref. 1 is considered.

4.1. Mathematical Model for Rayleigh Fading

In Fig. 8, the X – Y plane is assumed to be the horizontal ground plane. Consider a mobile receiver moving with velocity v along the X axis. The model [1] is that the signal received consists of a number of horizontally traveling plane waves each with random amplitude (but equal on average) and random angle of arrival. The phases of the waves are uniformly distributed in $[0, 2\pi]$ and are assumed to be statistically independent of the amplitudes.

Let the angle of the n th incoming wave be α_n with respect to the X -axis. We assume a fixed transmitter with a vertically polarized antenna and a mobile receiver with a whip/monopole antenna. The vehicular motion introduces

Figure 8. Reference figure for deriving the mathematical model for Rayleigh fading.

a Doppler shift given by

$$f_n = \frac{v}{\lambda} \cos \alpha_n (\text{Hz}) \quad (15)$$

where v is the velocity in m/s and λ is the wavelength (in meters) of the transmitted carrier signal. From Eq. (15), the maximum Doppler shift is given by $f_{n,\text{max}} = v/\lambda$ Hz.

The electric and magnetic field components received at the mobile receiver are E_z , H_x , and H_y respectively. Next, the expressions for E_z are derived. The superposition of the different waves is expressed as

$$E_z = E_0 \sum_{n=1}^N C_n \cos(2\pi f_c t + \theta_n) \quad (16)$$

where $\theta_n = 2\pi f_n t + \phi_n$, where f_c is the carrier frequency, f_n is the Doppler shift, $E_0 C_n$ is the amplitude of the n th wave, and ϕ_n are the random phase angles uniformly distributed in $[0, 2\pi]$. The C_n are normalized such that $(\sum_{n=1}^N C_n^2) = 1$, where $\langle \rangle$ indicates the ensemble average. For large N , using the central limit theorem, the field components E_z , H_x , and H_y can be approximated by Gaussian random processes. The following derivation assumes that the mean power of the signal is constant with time, which is typically the case as the mobile receiver traverses short distances (i.e., the shadowing is a constant). Equation (16) can be expressed as

$$E_z = T_c(t) \cos 2\pi f_c t - T_s(t) \sin 2\pi f_c t \quad (17)$$

where

$$T_c(t) = E_0 \sum_{n=1}^N C_n \cos(2\pi f_n t + \phi_n) \quad (18)$$

$$T_s(t) = E_0 \sum_{n=1}^N C_n \sin(2\pi f_n t + \phi_n)$$

Both $T_c(t)$ and $T_s(t)$ are Gaussian random processes. The corresponding RVs T_c and T_s have zero mean and equal variance given by

$$\langle T_c^2 \rangle = \langle T_s^2 \rangle = E_0^2/2$$

and the ensemble average is evaluated over α_n , ϕ_n , and C_n . The Gaussian RVs T_c and T_s are uncorrelated and hence independent. Their common variance is $E_0^2/2$. The envelope of E_z is given by

$$|E_z| = V \triangleq \sqrt{T_c^2 + T_s^2} \quad (19)$$

Using the results from the section on Rayleigh distribution, V is a Rayleigh distributed random variable, whose pdf is given by Eq. (11).

4.2. Power Spectrum of Rayleigh Fading

If the transmitted signal is a sinusoid of frequency f_c , the instantaneous frequency of the received signal arriving at angle α is given by [using Eq. (15)]

$$f(\alpha) = f_c + f_m \cos \alpha \quad (20)$$

where f_m is the maximum Doppler frequency. Hence

$$\cos \alpha = \left(\frac{f - f_c}{f_m} \right)$$

and

$$\sin \alpha = \sqrt{1 - \left(\frac{f - f_c}{f_m} \right)^2} \quad (21)$$

Assuming a large number of scatterers and that the mobile receiver has a vertical whip antenna, then the total incoming power is uniform as a function of the incident angle α . Using the derivation in Refs. 1 and 3, the power spectrum of the electric field is given by

$$S_{E_z}(f) = \begin{cases} \frac{3b}{2\pi f_m} \frac{1}{\sqrt{1 - \left(\frac{f - f_c}{f_m} \right)^2}}, & |f - f_c| \leq f_m \\ 0 & |f - f_c| > f_m \end{cases} \quad (22)$$

where b is a scale factor denoting the mean power received by an isotropic antenna. A normalized plot of the power spectrum is shown in Fig. 9. The peak of the power spectrum occurs at $\pm f_m$. The power spectra for the magnetic field components are given in Ref. 1.

4.3. Envelope Correlation for Rayleigh Fading

An important result obtained by using the power spectrum $S_{E_z}(f)$ is the envelope correlation $R_{TT}(\tau) = \langle T(t)T^*(t + \tau) \rangle$ where $T(t) = T_c(t) + jT_s(t)$ is the baseband representation of the E -field components given by Eq. (18) and the envelope correlation is expressed as a function of

Figure 9. Power spectrum of the received E -field in a Rayleigh fading environment.

the time separation τ . Using the Fourier relationship

$$\begin{aligned} R_{TT}(\tau) &= \int_{f_c - f_m}^{f_c + f_m} S_{E_z}(f) e^{-j2\pi(f - f_c)\tau} df \\ &= \int_{f_c - f_m}^{f_c + f_m} \frac{3b}{2\pi f_m} \frac{e^{j2\pi(f - f_c)t}}{\sqrt{1 - \left(\frac{f - f_c}{f_m} \right)^2}} df \end{aligned} \quad (23)$$

it can be shown that

$$\begin{aligned} R_{TT}(\tau) &= \langle T_c(t)T_c(t + \tau) \rangle + \langle T_s(t)T_s(t + \tau) \rangle \\ &= \int_{f_c - f_m}^{f_c + f_m} \frac{3b}{2\pi f_m} \frac{1}{\sqrt{1 - \left(\frac{f - f_c}{f_m} \right)^2}} \cos(2\pi(f - f_c)t) df \end{aligned} \quad (24)$$

From Ref. 20, we have the result

$$\int_0^1 \frac{1}{\sqrt{1 - x^2}} \cos(ax) dx = \pi/2 J_0(a)$$

where J_0 is the zeroth-order Bessel function of the first kind. Using this result, we obtain

$$R_{TT}(\tau) = 1.5b J_0(2\pi f_m \tau) \quad (25)$$

This shows that the envelope of a Rayleigh faded signal has a Bessel autocorrelation function, which plays an important part in designing effective error correcting coding and interleaving techniques for Rayleigh fading channels.

4.4. Rayleigh Fading Statistics

Two statistical properties that help characterize Rayleigh fading are

1. The level crossing rate (LCR)
2. The duration of fades

The derivation of these two parameters is based on the work of Rice [1,7,8].

4.4.1. Level Crossing Rate. The level crossing rate (LCR) is defined as the expected rate at which the Rayleigh fading envelope $V(t)$, normalized to the local rms signal level, crosses a specified level (V_{ref} in a positive direction. Figure 10 depicts a typical envelope variation that has three crossings of the level V_{ref} in the duration of T seconds. The LCR N_V , the number of level crossings per second is given by [1]

$$N_V = \int_0^\infty \dot{v}p(V, \dot{v}) d\dot{v} = \sqrt{2\pi}f_m\rho e^{-\rho^2} \tag{26}$$

where \dot{v} is the rate of change (the time derivative) of the envelope $V(t)$, $p(V, \dot{v})$ is the joint pdf of v and \dot{v} at a specified value of V , and $\rho = V/V_{\text{rms}}$ is the normalized value of the envelope. It can be verified that the peak value of N_V occurs at $\rho = -3$ dB.

Example 2. Consider a signal with carrier frequency of 1.9 GHz and a receiver moving at a velocity of 100 km/ph. The corresponding value of the Doppler frequency $f_m = 176$ Hz. At a normalized value of $\rho = 0$ dB, using Eq. (26), we obtain the value $N_V = 162$ crossings/s. Hence the LCR gives a characterization of the fluctuation rate of the signal envelope.

4.4.2. Duration of Fades. The duration of fades is the expected value of the time at which the signal level is below a specified value V_{ref} . In Fig. 10, consider a time interval T (seconds), and let τ_i be the duration of the i th fade below the level V_{ref} . Then

$$P[v \leq V] = \frac{1}{T} \sum_i \tau_i \tag{27}$$

Figure 10. A method to compute the level crossing rate and fade duration for Rayleigh fading.

Using the expression for the pdf of V , we have

$$P[v \leq V] = \int_0^V p(v) dv = 1 - e^{-\rho^2} \tag{28}$$

where $\rho = V/V_{\text{rms}}$. Using Eqs. (27) and (28), we obtain the expression for \bar{T}_{fade} , the average duration of a fade below $v = V$ (as given in Ref. 1)

$$\bar{T}_{\text{fade}} = \frac{1}{TN_V} \sum_i \tau_i = \frac{1}{\sqrt{2\pi}} \frac{[e^{\rho^2} - 1]}{\rho f_m} \tag{29}$$

Example 2Cont. Consider the same example as in the preceding section. For the same parameters, using Eq. (29), the average duration of a fade 20 dB below the RMS value of the envelope $\rho = 1.43$ ms.

4.4.3. Observations Based on Fading Statistics.

- $N_V \propto f_m$ and $\bar{T}_{\text{fade}} \propto 1/f_m$
- At low Doppler frequency, the LCR is low, and hence the duration of fades is long. This observation is helpful in choosing diversity and error correction schemes over fading channels.
- The value of \bar{T}_{fade} yields an estimate of the number of symbols that may be lost because of a fade (burstiness of errors caused by fading).

In particular, if a mobile communication system is designed with a specified fade margin, then the performance of the receiver can be estimated by using the parameters f_m , ρ , and \bar{T}_{fade} to relate the instantaneous signal-to-noise ratio (SNR) to the instantaneous bit error rate (BER).

4.4.4. Random Frequency/Phase Modulation. The baseband representation of the E -field components, as given in Eq. (18), can be expressed as

$$T(t) = T_c(t) + jT_s(t) = A(t)e^{j\phi(t)} \tag{30}$$

where $T_c(t)$ is the in-phase component and $T_s(t)$ is the quadrature component. The effect of the multipath fading channel is represented by $T(t)$, which is a complex-valued, multiplicative scaling of the transmitted signal. The time-varying nature of $T_c(t)$ and $T_s(t)$ manifests itself as a random phase modulation of $\theta(t)$. In FM receivers, the effect of $T(t)$ produces a baseband noise component, which can be evaluated [1]. The baseband noise is characterized by the frequency deviation it produces. It is interesting to note that the frequency deviation (and hence, the rms value of the baseband noise) depends on the depth of the fade. As the signal envelope V experiences deep fades, the frequency deviation of the random FM increases proportionally. The effect of $T(t)$ can also be viewed as random phase rotation given by $\arctan [T_s(t)/T_c(t)]$. Hence, multipath fading causes impairments of the received signal that have the characteristics of random FM and random phase shifts.

5. SIMULATION OF RAYLEIGH FADING

In the preceding sections, the power spectrum and the envelope correlation of a Rayleigh faded signal have been discussed. Using these results, two methods are obtained for generating Rayleigh fading:

1. the stochastic filtered noise approach [9,10]
2. the Jakes method (deterministic) [1]

Both methods are easily modified to generate Ricean fading. Let $T(t) = T_c(t) + jT_s(t)$ be the complex baseband representation of Rayleigh fading. The main requirements on T_c and T_s for generating Rayleigh fading are that

- They have a Gaussian pdf.
- They be zero mean and have equal variance (typically normalized to 0.5, such that the variance of $T(t)$ is unity.
- T_c and T_s must be uncorrelated.
- The autocorrelation of $T(t)$ must satisfy the condition in Eq. (25); This condition also implies that the power spectrum closely approximates Eq. (22).

5.1. Filtered Noise Approach

The method for implementing the stochastic filtered noise approach is shown in Fig. 11. The steps are as follows:

1. Generate two independent Gaussian (white) noise sources.
2. Each of the sequence of random variables (samples of the noise) is filtered by a baseband Doppler filter whose frequency response is given by $\sqrt{S_{E_z}(f)}$.
3. The output of the Doppler filters yields the in-phase and quadrature components of the Rayleigh fading signal.

It can be verified that the output signal $T_c + jT_s$ has a Rayleigh envelope with the time correlation specified by the maximum Doppler frequency f_m . The filtering in step 2 can be done in the frequency domain via FFT. The steps for using the FFT for the filtering are outlined in Ref. 9.

5.2. Jakes' Method

In this section, the Jakes (deterministic) approach for generating Rayleigh fading is discussed (Fig. 12). The main advantage of this method over the stochastic

method is that segments of time-correlated fading can be generated without having to generate the fading in between the desired segments, as is typically the case when simulating the performance of time-division multiple-access (TDMA) signals.

The details of the model (Fig. 12) are as follows:

- There are N_0 oscillators with frequencies given by

$$f_n = f_m \cos\left(\frac{2\pi n}{N}\right), \quad n = 1, 2, \dots, N_0 \quad (31)$$

and one oscillator with frequency f_m , where f_m is the maximum Doppler frequency. The total number of oscillators is $(N_0 + 1)$, where $N_0 = \frac{1}{2}(N/2 - 1)$. The parameter N is chosen such that T_c and T_s are Gaussian and the power spectrum of $T(t) = T_c(t) + jT_s(t)$ closely approximates the condition in Eq. (22). In Ref. 1, it is shown that a good approximation is obtained for $N > 34$ ($\Rightarrow N_0 \geq 8$).

- In Fig. 12, the phases α and $\beta_n, n = 1, 2, \dots, N_0$ are chosen such that the probability distribution of the resultant phase ($\arg[T(t)]$) is close to a uniform distribution in $[0, 2\pi]$. These phases are introduced by the respective multipliers $2 \cos \beta_n$ and $2 \sin \beta_n$. The uniform distribution of $\arg[T(t)]$ is ensured if

$$\langle T_c^2 \rangle = \langle T_s^2 \rangle$$

and

$$\langle T_c T_s \rangle = 0 \quad (32)$$

Choices of values that satisfy Eq. (32) are

$$\alpha = 0$$

$$\beta_n = \frac{\pi n}{N_0 + 1}$$

$$\text{Scale 1} = \frac{1}{\sqrt{2N_0}}$$

$$\text{Scale 2} = \frac{1}{\sqrt{2(N_0 + 1)}}$$

Other choices are also possible:

- The oscillator phases ϕ_n in Fig. 12 are randomly chosen in the range $[0, 2\pi]$. The purpose of ϕ_n is to provide

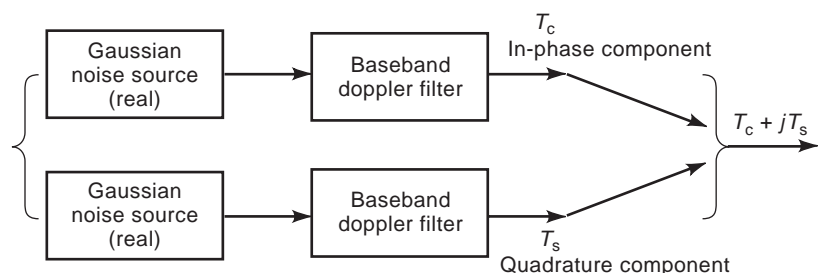

Figure 11. Stochastic filtered noise method for generating Rayleigh fading.

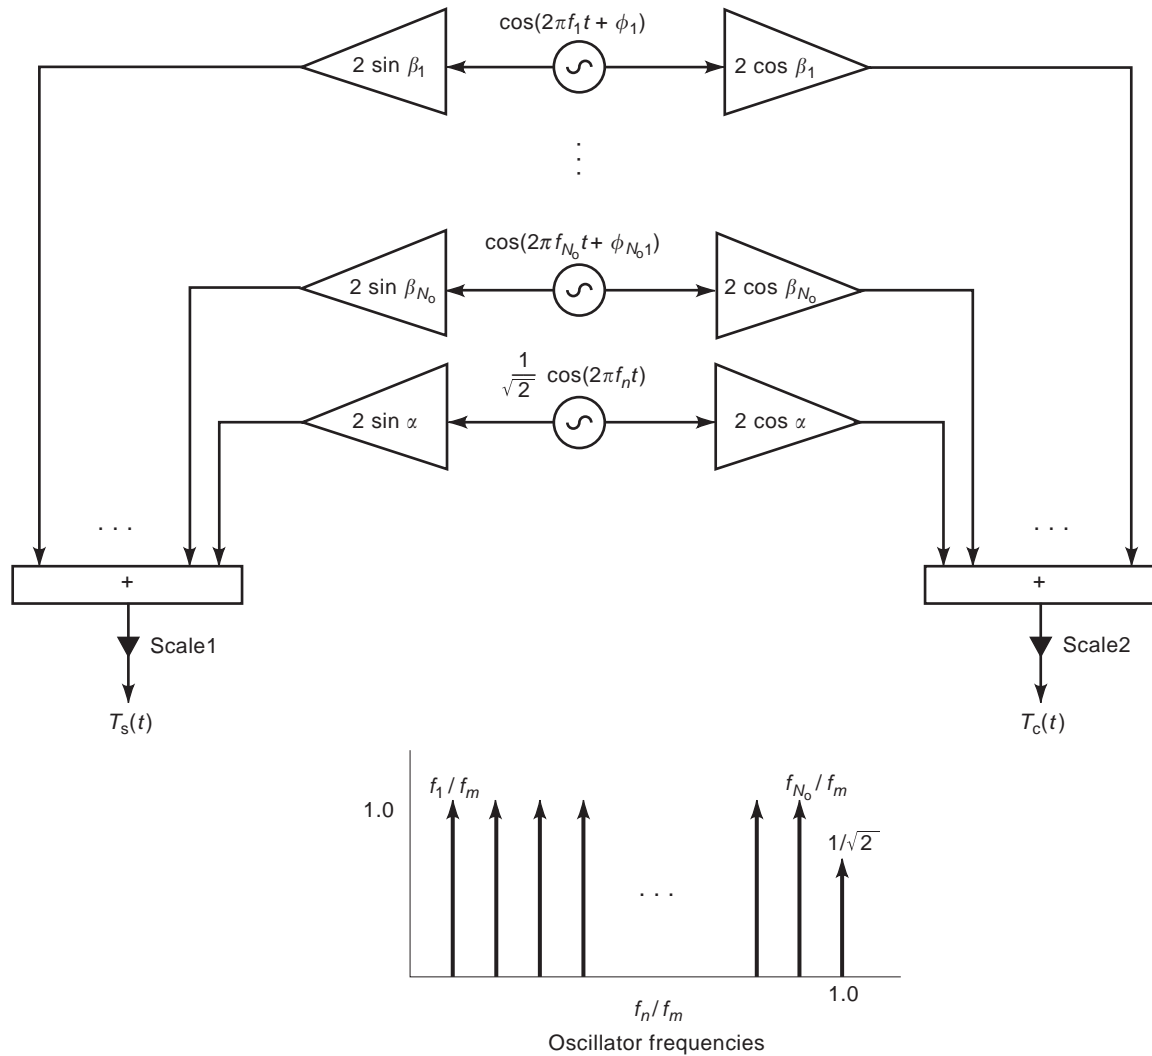

Figure 12. Jakes' method for generating Rayleigh fading.

a means of randomly initializing the fading waveform generator. They do not affect the statistical properties of $T_c(t)$ and $T_s(t)$.

5.3. Generating Multiple Uncorrelated Fading Waveforms

In many practical applications, it is necessary to generate multiple uncorrelated Rayleigh fading waveforms. In Ref. 1, a method of modifying Fig. 12 to generate multiple uncorrelated fading is mentioned. However, it has been observed [11] that the method in Ref. 1 produces waveforms with nonzero correlation when more than two waveforms are generated. An attractive and computationally efficient alternative is presented in [11] based on the Walsh-Hadamard transform. Using this method, the multiple fading waveforms are guaranteed to be uncorrelated.

6. CHARACTERIZATION OF MULTIPATH CHANNELS

Consider the equivalent, complex-valued, lowpass impulse response of a time-varying multipath channel $c(\tau;t)$ as

given by Eq. (5), where $c(\tau;t)$ is a zero-mean, complex-valued Gaussian random process in the variable t . Assume that $c(\tau;t)$ is wide-sense stationary (WSS). Then the autocorrelation of $c(\tau;t)$ is given by

$$\phi_c(\tau_1, \tau_2; \Delta t) = \frac{1}{2} E[c(\tau_1; t)c^*(\tau_2; t + \Delta t)] \tag{33}$$

Assuming uncorrelated scattering, that is, that the scattering/multipath signal at delay τ_1 given by $c(\tau_1;t)$ is uncorrelated to the signal at delay τ_2 given by $c(\tau_2;t)$; hence

$$\phi_c(\tau_1, \tau_2; \Delta t) = \phi_c(\tau_1; \Delta t)\delta(\tau_1 - \tau_2) \tag{34}$$

When $\Delta t = 0$, $\phi_c(\tau, 0) = \phi_c(\tau)$, which is called the *multipath intensity profile*, or the *power-delay profile*. There are different experimental methods for measuring the power-delay profile of a channel such as direct pulse measurement, spread spectrum sliding correlator measurement, and frequency-domain channel sounding [10]. A typical power-delay profile is given in Fig. 14. The range of τ over which

Figure 13. A typical power-delay profile and the method of sampling the power delay profile to generate a tapped-delay-line model.

$\phi_c(\tau)$ is nonzero is called the *multipath spread* of the channel τ_m .

6.1. Time Parameters

6.1.1. Time-Dispersion Parameters. The mean excess delay, RMS delay spread, and the excess delay spread are channel parameters that are obtained from the power-delay profile $\phi_c(\tau)$:

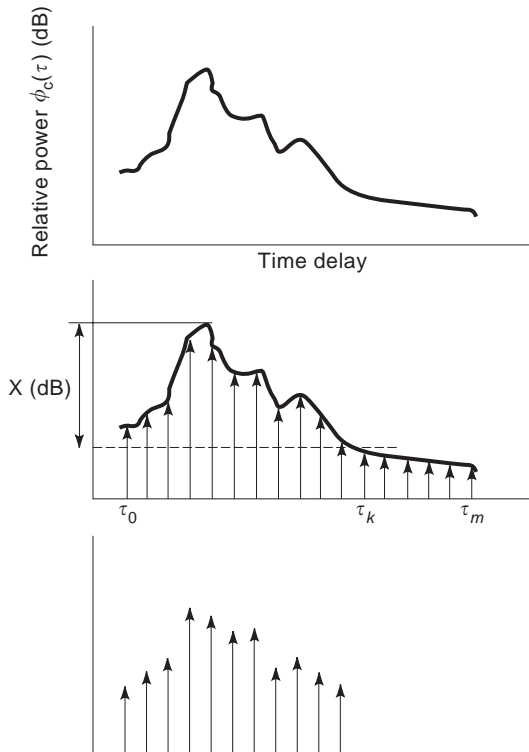

Figure 14. Classification of multipath fading channels.

- The *mean excess delay* of the power-delay profile is given by

$$\bar{\tau} = \frac{\sum_k \phi_c(\tau_k) \tau_k}{\sum_k \phi_c(\tau_k)} \quad (35)$$

- where $\phi_c(\tau_k)$ is the strength of the multipath component with delay τ_k (obtained from the power-delay profile). Typically the τ_k are measured relative to the first arriving multipath signal.
- The *RMS delay spread* is defined as $\sigma_\tau = \sqrt{\tau^2 - (\bar{\tau})^2}$, where τ^2 is given by

$$\tau^2 = \frac{\sum_k \phi_c(\tau_k) \tau_k^2}{\sum_k \phi_c(\tau_k)} \quad (36)$$

- Suppose that τ_0 is the first arriving multipath and τ_K is the delay beyond which the power drops below X dB of the maximum strength multipath component, then, $(\tau_K - \tau_0)$ is called the maximum excess delay (X dB).

In practice, the value of $\bar{\tau}$, τ^2 and σ_τ depend on the value of the threshold for detecting the presence of a signal component.

6.1.2. Coherence Bandwidth. The coherence bandwidth B_c is an important parameter in time-dispersive channels. B_c can be viewed as the range of frequencies over which there is a strong envelope correlation. There is, however, more than one formal definition of B_c . In Ref. 4, the coherence bandwidth is defined as the reciprocal of the multipath spread of the channel τ_m :

$$B_c \approx \frac{1}{\tau_m} \quad (37)$$

A more widely used engineering definition of B_c is given in Refs. 1, 7, 10, and 12. Wherein the coherence bandwidth is defined as the bandwidth over which the frequency correlation is > 0.5 . In Ref. 12 it is shown that to satisfy this condition,

$$B_c \approx \frac{1}{2\pi\sigma_\tau} \approx \frac{1}{6\sigma_\tau} \quad (38)$$

where σ_τ is the rms delay spread given by Eq. (36). Another interpretation of B_c is as follows. If two sinusoids with frequency separation $> B_c$ are transmitted through this channel, then they are affected differently. For modulated signals, if B_c is smaller than the BW of the signal (W), then the channel is said to be *frequency-selective*. If B_c is greater than the BW of the signal, the channel is said to be *frequency-nonselective*.

6.1.3. Coherence Time. The RMS delay spread (σ_τ) and the coherence BW (B_c) describe the time-dispersive nature of the channel. Analogously, the Doppler spread (B_D) and

the coherence time (T_c) describe the time-varying nature of the channel in a local area (small-scale region). The Doppler spread B_D , is defined as the range of frequencies over which the Doppler spectrum is nonzero. In Ref. 4, the coherence time is defined as

$$T_c \approx \frac{1}{B_D} \quad (39)$$

Coherence time is a measure of the length of time over which the channel impulse response is essentially constant. Alternatively, the coherence time can be viewed as the length of time over which two received signals have a strong potential for envelope correlation. Just as coherence BW has a statistical definition, coherence time T_c can be defined [12] as the time over which the time correlation function is ≥ 0.5 . In Ref. 12 it is shown that

$$T_c \approx \frac{9}{16\pi f_m} \quad (40)$$

where f_m is the maximum Doppler frequency.

6.2. Channel Classification

Multipath fading channels are classified on the basis of the way the channel appears to the transmitted signal. The coherence bandwidth B_c and the coherence time T_c , two of the main properties that influence the effect of the channel on the transmitted signal, are classified as follows:

- If the BW of the transmitted signal (W) is smaller than the coherence BW (B_c), then the fading channel appears as *frequency-nonselective* or *frequency flat*. This implies that all the frequencies of the transmitted signal experience the same channel effects. If $W = B_c$, then it is classified as a frequency-selective fading channel.
- If the duration of the received waveform [a symbol duration (T_s) for digital transmission] is less than the coherence time, then the channel is said to be *time flat*. Otherwise, it is classified as time-selective.

Based on these definitions, we have the classification depicted in Fig. 13.

6.3. A Tapped-Delay-Line Channel Model

In addition to providing channel information such as the RMS delay spread, the power-delay profile $\phi_c(\tau)$, also provides a means for modeling the channel using a tapped-delay-line (FIR) model. From Eq. (5), $\alpha_n(t)$ is the amplitude/gain coefficient for a path arriving with delay $\tau_n(t)$. A typical power-delay profile is shown in Fig. 14, which in the second figure, is uniformly sampled into equal delay bins. In general, the different bins contain a number of received signals (corresponding to different paths) whose times of arrival lie within the particular delay bin. These signals are represented by an impulse at the center of each delay bin that has an amplitude with the appropriate

statistical distribution (Rayleigh, Ricean, etc.). In deriving this model, two assumptions are made:

- There are sufficient number of rays clustered together in each delay bin.
- The statistical distribution of the envelope is known.

The rate of sampling the power-delay profile is affected by the time resolution desired and also the bandwidth of the transmitted signal. The next step after sampling the power-delay profile is to use a threshold (say, X dB below the peak of the power-delay profile), and using the threshold to truncate those samples below the threshold. This model can be implemented by using a tapped-delay line or FIR model, thereby allowing us to model arbitrary channel.

7. LARGE-SCALE EFFECTS

Understanding and characterizing the effects of the RF propagative channel are essential to designing RF communication systems. A wide range of channel conditions are encountered in RF communications, all the way from LOS channels to severely obstructed channels. Further, the channel may also be time-varying. Hence modeling is based on statistical and experimental information. This has continued to be an area of extensive research and measurement, since the early 1970s [1,7,10,16–20]. In this section, the two main components of signal variability due to the large-scale effects of RF propagation, namely, path loss and shadowing, are discussed.

7.1. Radio Signal Propagation

The salient features of RF propagation are briefly described in this section. For a detailed treatment of this subject, the reader is referred to Refs. 7 and 10. The three basic propagative mechanisms, illustrated in Fig. 15, are reflection, diffraction, and scattering. Together, these three modes enable us to estimate the signal level received by a transmitter for a given RF propagative channel.

Figure 15. The different modes of RF signal propagation, reflection, diffraction, and scattering.

- *Reflection.* This occurs when a radiowave propagating in one medium is incident on another medium that has different electrical properties and a part of the energy is reflected back into the first medium, depending on the specific electrical properties of the second medium. If the second medium is a perfect conductor, all of the incident energy is reflected. If the second medium is a dielectric, then the energy is only partially reflected. The reflection coefficient is a function of the medium's properties, the signal frequency, and the angle of incidence. Reflections of RF signals typically occur from objects in the propagative path whose size is larger than the wavelength (λ) of the RF carrier, such as buildings and walls. In the case of cellular/PCS signals at 1.9 GHz, the wavelength $\lambda = 15 \text{ cm} \approx 6 \text{ in.}$ Hence, a variety of objects act as reflectors. Signals are also reflected from the ground. A model commonly used to characterize RF channels is the two-ray ground reflection model [10].
- *Diffraction.* This can be viewed as the “bending” of RF signals around an obstruction, as shown in Fig. 15. Diffraction occurs when the obstruction between the transmitter and receiver has sharp edges. As explained by Huygen's principle, when a wavefront impinges on an obstruction, then secondary wavelets are produced, which give rise to bending of waves around the obstruction. The field strength of the diffracted wave in the shadowed region is the vector sum of the electric field components of the secondary wavelets. The knife-edge diffraction model [10] can be used to characterize the diffraction caused by a single object, such as building in the path of an RF signal.
- *Scattering.* This occurs when the RF signal is incident on a surface that has a certain degree of “roughness” [7,10]. Scattering in an RF channel is commonly caused by objects, such as buildings. The *critical height* $h_c = \lambda/8 \sin \theta_i$, where θ_i is the angle of incidence. This implies that the maximum to minimum level of the surface must be greater than h_c .

7.2. Propagative Path-Loss Models

7.2.1. Free-Space Propagative Loss. When there is a LoS path between the transmitter and receiver, the free-space propagation model can be used to predict the signal strength. Such conditions occur in some satellite and terrestrial microwave communication links. Suppose that the distance between the transmitter and receiver is d meters, where d is in the far field. Then the free-space model (based on the Friis formula) gives

$$P_r(d) = \frac{P_t G_t G_r \lambda^2}{(4\pi)^2 L} \frac{1}{d^2} \quad (41)$$

where P_t and P_r are the transmitting and receiving power, respectively, with transmitting antenna gain G_t , receiving antenna gain G_r , and λ is the wavelength of the carrier. The term L represents the losses in the system ($L \geq 1$). The path loss L_p is the difference between the transmitting and

receiving power values expressed in decibels:

$$L_p(\text{dB}) = 10 \log_{10} \frac{P_t}{P_r} = 10 \log_{10} \left[\frac{(4\pi)^2 L}{P_t G_t G_r \lambda^2} \right] + 20 \log d \quad (42)$$

As the signal propagative distance d increases, the received power decreases at 20 dB/decade, as seen from Eq. (42). Another commonly used method to compute the signal power received $P_r(d)$ is by measuring it relative to the received power $P_r(d_0)$ at a reference point (distance d_0 from the transmitter) as given by

$$P_r(d) = P_r(d_0) \left(\frac{d_0}{d} \right)^2, \quad d \geq d_0 \quad (43)$$

7.2.2. Outdoor Propagative Loss. In dealing with non-LoS environments, which is typical of most RF communication links, such as cellular/PCS, we need appropriate models for computing the propagative path loss (because the criteria for free-space propagation are not met). This topic has been very extensively studied. Detailed information can be found in Refs. 7, 10, 12, and 16. Computation path loss is of particular interest to communication systems designers. Because the actual RF communication environments encountered in practice are so numerous, a unified theoretical/analytical framework for estimating path loss is not feasible. Most system designers resort to empirical approaches and semianalytical methods, which have been validated by experimental/measured data, to estimate the path loss. The work of Okamura and Hata [13] is very widely used for path loss estimation. Okamura's work is based purely on measured data, and Hata provided the empirical model to fit that data. The advantage of using empirical models and curve fitting to measured data is that it accounts for both known and unknown sources of path loss. On the other hand, the disadvantage is that the validity of the empirical model, derived from a set of data, is not guaranteed for a different environment.

Let d be the distance between the transmitter and receiver. Both theoretical and measurement-based models show that the average path loss $[L_p(d)]$ increases directly proportional to d^n , where n is called the path-loss exponent. Typically $n \geq 2$, as summarized in the Table 1. By contrast, in free space, $N=2$. The path loss $L_p(d)$ is given by

$$L_p(d) \propto d^n \quad (44)$$

$$L_p(d) = L_p(d_0) + 10n \log_{10} \left(\frac{d}{d_0} \right) \quad (45)$$

Table 1. Path-Loss Exponents for Different Environments

Environment	Path-Loss Exponent n
Free space	2
Urban cellular	2.7–4.0
In-building (non-LoS)	3.0–6.0
Shadowed urban cellular	4.0–6.0

The reference point d_0 is chosen such that $L_p(d_0)$ can be computed using the free-space path-loss model.

7.2.3. Hata and COST-231 Models. This is one of the most widely used models for estimating path loss in RF communication channels. Based on extensive measured data, Okamura generated sets of curves that characterize the median attenuation (50th percentile) $L_{p,50}$, for a wide range of environments [range of carrier frequency (f_c), effective height of transmitting antenna ($h_{t,\text{eff}}$), and distance d from transmitter]. Hata [12] provided an empirical formulation from Okamura's data, which shows good agreement (between the model and the measured data) for $f_c \leq 1.5$ GHz. An extension of Hata's model for frequencies up to 2 GHz is provided in Ref. 14. The Hata model and COST-231 models are given below:

Hata model:

$$L_{p,50} = 69.55 + 26.16 \log_{10} f_c - 13.82 \log_{10} h_{t,\text{eff}} - a(h_{r,\text{eff}}) + (44.9 - 6.55 \log_{10} h_{t,\text{eff}}) \log_{10} d \quad (46)$$

COST-231 model:

$$L_{p,50} = 46.3 + 33.9 \log_{10} f_c - 13.82 \log_{10} h_{t,\text{eff}} - a(h_{r,\text{eff}}) + (44.9 - 6.55 \log_{10} h_{t,\text{eff}}) \log_{10} d + C_M \quad (47)$$

where $h_{r,\text{eff}}$ is the effective height of the receiving antenna, $a(h_{r,\text{eff}})$, is a correction factor based on $h_{r,\text{eff}}$, and C_M is a correction factor based on the propagative environment. The details regarding $a(h_{r,\text{eff}})$, and C_M are provided in Ref. 10. The range of values for which the Hata and COST-231 models are valid are summarized in Table 2.

The Hata model has a correction factor for rural environments. In general, the Hata model and the COST-231 model provide an example of the path loss computation in a outdoor, non-LOS environment. A variation, called the COST231-Walfish-Ikegami model can be used for transmitting antennas above or below rooftops and is accurate for $d > 20$ m. A number of models similar to these discussed in this section are also used in practice. So, the choice of path-loss models must take into account all aspects of the propagative environment, including transmission frequency, distance of transmission, polarization, antenna heights, surface refractivity, terrain irregularity, foliage, climate, ground conductivity, and ground dielectric constant [10].

Table 2. Range of Validity of Hata and COST-231 Models

Parameter	Range of Validity	
	Hata	COST-231
Carrier frequency f_c	150–1500 MHz	1500–2000 MHz
Effective transmit height $h_{t,\text{eff}}$	30–200 m	30–200 m
Effective receive height $h_{r,\text{eff}}$	1–10 m	1–10 m
Distance d from transmitter	≥ 1 km	1–20 km
Correction factors	$a(h_{r,\text{eff}})$	$a(h_{r,\text{eff}}), C_M$

7.2.4. Indoor Propagative Loss. An increasing number of wireless communications applications are designed for indoor environments. Hence, there is considerable interest in indoor propagation and in models for it. Although the characteristics of indoor propagation vary slowly (quasi-static behavior [15]) as compared with outdoor propagation, a key difference is that propagation within a building is strongly influenced by a number of factors, such as building type, layout, construction material (amount of metal used), types of partitions, and height and placement of antennas. As a result, the variability in signal propagation and hence the path loss is quite significant. The model best suited for characterizing path loss in indoor propagation is similar to that for lognormal shadowing. The path loss at a distance d from the transmitter is given by

$$L_p(d) = \left[L_p(d_0) + 10n \log_{10} \left(\frac{d}{d_0} \right) + \Omega \right] (\text{dB}) \quad (48)$$

where Ω is a normal RV with standard deviation σ and n is the path loss exponent. It was reported in Ref. 15 that the typical range of n is 3–4. A comprehensive list of the typical values of n and σ for a variety of indoor environments is provided in Ref. 10.

7.3. Shadowing

As discussed earlier, shadowing is caused by terrain and other environmental factors, such as foliage. The effect of shadowing causes the variations in the mean of the received signal. Let $\hat{L}_p(d)$ denote the path loss (including the effect of shadowing) at a specified distance from the transmitter. Based on extensive measurements, it has been verified that $\hat{L}_p(d)$ can be characterized as a random variable with a lognormal distribution about the mean value. When expressed in dB, the RV perturbing the local mean value of the path loss is a normal RV, as given by

$$\hat{L}_p(d) = [L_p(d) + \Omega] (\text{dB}) \quad (49)$$

where $L_p(d)$ is given by one of the path-loss models in the preceding section and Ω is a normal RV with standard deviation σ . The RV Ω is obtained from the lognormal RV Ω' , whose pdf is given earlier. Equation (49) describes the path loss for a specified value of d but with different values of shadowing/obstructions between the transmitter and receiver. In practice, the path loss exponent n and the standard deviation σ , are used to characterize any environment. In most cases, n and σ can be calculated from measurements.

7.4. A Practical Design Model

The goal of this section is to provide a framework for combining the various results in this article relating to small-scale signal variations and large-scale signal variations into a set of relevant parameters that may be used by communication systems designers for link budget calculations. The components of the different effects and their impact on the link budget are shown pictorially in Fig. 16.

Predicting the expected mean received signal power is an important step in designing a communication link and

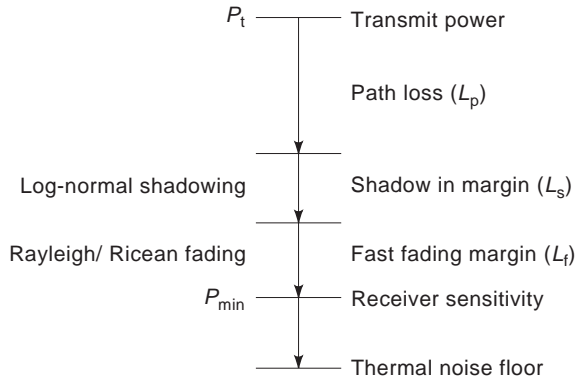

Figure 16. Different components of link budget—propagative loss, shadowing margin, and fading margin.

in estimating the coverage area for a specific transmitter. In Fig. 16, P_t is the transmitted signal power and P_{\min} is the minimum signal strength that must be received for the receiver to operate satisfactorily, that is, the signal strength to produce the minimum carrier-to-noise ratio (C/N) needed for acceptable communications. This is called *receiver sensitivity* and is expressed in dBm. There are three margins, one for each of the following practical effects:

- Propagative path loss
- Small-scale effects—fading margin
- Large-scale effects—shadowing margin

In the previous section, the methods of determining the path loss L_p for different environments were presented. The large-scale effect due to shadowing is modeled as a lognormal random variable. Hence, a shadowing margin L_s must be included in the link budget (Fig. 16). The small-scale effects, characterized by Rayleigh/Ricean fading, cause significant amplitude variations. Hence a fading margin L_f is also included in the link budget. From Fig. 16, the total transmitted power is given by

$$P_t = P_{\min} + L_f + L_s + L_p \quad (50)$$

The path loss L_p is deterministic (based on the distance between the transmitter and receiver), whereas the fading and shadowing are probabilistic. The amount of margin must be judiciously chosen so that the net margin is minimized but still meets the minimum signal strength requirements. If the amount of losses exceeds the margin of a communication system, then an *outage* occurs, which implies that the communication link cannot be used until the channel conditions improve. This summarizes the tradeoffs that must be handled by the designers of communication systems.

8. CONCLUSION

A comprehensive overview of the RF signal variations related to propagation in multipath fading channels has been presented. The diverse phenomena that cause signal

variations are described via mathematical models. The different types of fading and their salient features are discussed in detail. This article provides a mathematical and an engineering-oriented treatment of multipath fading, thereby providing the reader with the necessary tools and the information to understand the different RF propagative issues and the way they affect wireless communication.

9. APPENDIX: DERIVATION OF RAYLEIGH PDF

Let X and Y be two independent identically distributed (i.i.d.) zero-mean Gaussian RVs with variance σ^2 . Because X and Y are independent, their joint pdf is the product of their marginal pdf's:

$$F_{X,Y}(x,y) = \frac{1}{2\pi\sigma^2} e^{-\frac{x^2+y^2}{2\sigma^2}} \quad (A.1)$$

Using a change of variables, $V \triangleq \sqrt{X^2 + Y^2}$ and $\phi \triangleq \tan^{-1}(Y/X)$, the joint pdf $f_{V,\Theta}(v, \theta)$ is given by

$$F_{V,\Theta}(v, \theta) = \frac{f_{X,Y}(x,y)}{|\det \mathbf{J}(x,y)|} = \frac{v}{2\pi\sigma^2} e^{-\frac{v^2}{2\sigma^2}} \quad (A.2)$$

where $\mathbf{J}(x,y)$ is the Jacobian matrix for the transformation of variables. From Eq. (A.2), we obtain the marginal pdf of V and Θ as

$$f_{\Theta}(\theta) = \int_0^{\infty} f_{V,\Theta}(v, \theta) dv = \frac{1}{2\pi} \quad (A.3)$$

$$f_V(v) = \begin{cases} \frac{v}{\sigma^2} e^{-\frac{v^2}{2\sigma^2}} & v \geq 0 \\ 0 & v < 0 \end{cases} \quad (A.4)$$

Hence, Θ is uniformly distributed, and V is Rayleigh distributed.

RECONFIGURABLE ANTENNAS

JENNIFER T. BERNHARD
 University of Illinois at
 Urbana—Champaign
 Urbana, Illinois

1. INTRODUCTION

The idea of antenna reconfiguration is not a recent one. Indeed, it is already more than two decades old (as of 2004). However, we are coming into an era where new functionality in antennas is not a novelty but rather a requirement to enable future communication and sensing systems. For instance, current planar phased-array technology is fundamentally limited in both scan angle and frequency bandwidth as a result of the limitations of the individual array elements. As another example, simple single antennas deployed on portable wireless data devices are usually minimally functional and limit noise immunity, battery life, and, ultimately, data throughput. Both of these cases illustrate the fact that limited antenna functionality could have a significant impact on performance of high-speed communication links in the future. One approach to expand system capability to meet new challenges is to develop reconfigurable antennas and apertures. Ideally, new communication systems can then

leverage this broad antenna functionality to take advantage of emerging techniques in wideband microwave circuits and signal processing, resulting in more efficient, secure, and cost-effective high-performance communication and sensing systems.

1.1. What Constitutes Reconfigurability?

Reconfigurability, when used in the context of antennas, is the capacity to change an individual radiator's fundamental operating characteristics through electrical, mechanical, or other means. Under this definition, then, the traditional phasing of signals between elements in an array to achieve beamforming and beamsteering does not make the antenna "reconfigurable," since the antenna's basic operating characteristics remain unchanged in this case [1,2].

Ideally, reconfigurable antennas should be able to alter their fundamental characteristics—their operating frequencies, impedance bandwidths, polarizations, and radiation patterns—independently to accommodate changing operating requirements (see ANTENNA PARAMETERS and ANTENNA THEORY articles for details on these fundamental characteristics). However, the development of these antennas poses significant challenges to both antenna and system designers. These challenges lie not only in obtaining the desired levels of antenna functionality but also in integrating this functionality into complete systems to arrive at efficient and cost-effective solutions. As in many cases of technology development, the majority of the system cost will come not from the antenna but the surrounding technologies that enable reconfigurability.

1.2. Overview

The goal of this article is to provide examples of the kinds of reconfigurable antennas that have been developed to date, in the hope that these examples may provide a foundation for new innovations in the future. While the reference list (Bibliography and Further Reading Sections) is extensive, it is by no means exhaustive. Rather, the selections chosen for discussion represent a cross section of the current state of the art. A firm grounding in basic antenna theory and design, found in the ANTENNA THEORY article, is desirable to understand fully all of the reconfigurable antennas' behaviors, capabilities, and shortcomings.

1.3. Organization

The sections are organized according to antenna capabilities rather than according their method of reconfigurability. Section 2 discusses frequency/bandwidth reconfigurable antennas, Section 3 describes polarization reconfigurable antennas, and Section 4 presents single-antenna elements with radiation pattern reconfigurability. In many cases, reconfigurable antennas possess more than one property that can change, but not independently. This happens, for example, when changes in operating frequency are coupled with changes in radiation patterns that cannot be avoided. In these cases, this behavior coupling is noted and the antennas are grouped according to their dominant characteristics. In contrast, Section 5

addresses radiating apertures that can change in more than one operating dimension in controlled, independent ways—that is, changes in the fundamental operating characteristics are largely decoupled. Section 6 offers a discussion of some supporting technologies that must be fully realized before reconfigurable antennas can proliferate. These technologies include reliable, mass-manufacturable RF MEMS switches, noninterfering switch and control bias networks, and expanded signal processing and feedback algorithms that exploit this new antenna functionality. Finally, Section 7 outlines the significant impact that reconfigurable antennas may have on future communication systems.

2. FREQUENCY RECONFIGURABILITY

Frequency reconfigurability is by far the area of antenna reconfigurability that has seen the most development to date. In many cases, changes in the operating frequency of an antenna have been referred to as “tuning,” since many changes to the antenna’s physical or electrical configuration produce relatively small variations within a frequency band around the antenna’s nominal operating point. These kinds of tuning techniques are most often applied to “resonant” antennas. Resonant antennas typically possess dimensions comparable to a half-wavelength (or integer multiples thereof) at the operating frequency. They also have commensurately narrow impedance bandwidths defined by the frequencies where the antenna’s input voltage standing-wave ratio (VSWR) is less than 2 (or a value of S_{11} less than -9.6 dB). Resonant antennas usually have impedance bandwidths less than 10%, and more commonly 1–2%. Therefore, for these antennas, tuning is most often achieved by discrete or continuous changes to their electrical lengths.

The following subsections are organized according to the degree to which the operating frequency and/or the impedance bandwidth of the antenna can be reconfigured.

2.1. Continuous Frequency Reconfigurability

The development of the first frequency-tunable antennas gained attention through a groundbreaking paper in 1982 [3]. In this work, wideband operation of a resonant, inherently narrowband structure, the rectangular microstrip patch antenna, was achieved using varactors (variable-capacitance devices) to vary the structure’s effective electrical length and, as a result, its operating frequency. Researchers have since applied the concept to frequency tuning for other microstrip, wire, and slot antennas [e.g., 4–11], including some that use ferrite substrate material [6] and substrates with embedded frequency-selective surfaces [11] and others that use optically variable capacitors or other optical tuning means [8,9].

Larger but continuous frequency shifts have been achieved with physical rather than electrical changes in antenna structure. One of these was first demonstrated in 1998, where a piezoelectric actuator system was employed to vary the spacing between a microstrip antenna and a parasitic radiator to change the operating frequency of the

Figure 1. Mechanically actuated reconfigurable microstrip antenna with a parasitic radiator for continuous frequency tuning [14] (© IEEE 2001).

antenna [12–14]. A photograph of the prototype antenna is presented in Fig. 1. While normally possessing a very narrow impedance bandwidth (1%), controlled movement of the parasitic element, which changed the spacing s , delivered an effective bandwidth of about 9% as shown in Fig. 2. The bandwidth and gain of the structure also changed as a function of parasitic element spacing, but these changes were directly coupled to the changes in operating frequency.

Continuous frequency changes have also been demonstrated in a magnetically actuated out-of-plane microstrip antenna [15] that uses a micromachining process called *plastic deformation magnetic assembly* (PDMA) [16]. In this work, a microstrip antenna designed for operation around 26 GHz was covered with a thin layer of magnetic material and released from the substrate. Application of an external DC magnetic field causes plastic deformation of the antenna at the boundary point where it is attached to the microstrip feedline, resulting in a patch positioned at an angle over the substrate. A photograph of one prototype is given in Fig. 3. Small changes of the angle at which the structure resides results in changes in operating frequency that preserve radiation characteristics,

Figure 2. Measured return loss data versus frequency over a range of values of parasitic element spacing s [14] (© IEEE 2001).

Figure 3. Photograph of a magnetically actuated out-of-plane frequency reconfigurable microstrip antenna [15] (© 2003 IEEE).

while larger angles result in frequency shifts accompanied by significant changes in the antenna’s radiation pattern. In particular, as the elevation angle between the patch and the horizontal substrate increases beyond 45°, the antenna’s radiation is more characteristic of a horn antenna, and changes toward the pattern of a monopole antenna as the angle approaches 90° [15].

2.2. Switched Multiple-Frequency Reconfiguration

Another approach to frequency reconfiguration is the use of switched connections that result in operation at two or more discrete frequency bands. Typically, the switching in these designs is enabled with diodes, FET switches, or proposed RF MEMS devices.

Using solid-state devices, one group has investigated the switchable operation of radiating slots [17]. In this approach, control of bias across a number of PIN diode switches changes the resonant frequency of a radiating slot structure by changing its apparent electrical length [17]. The structure, depicted in Fig. 4, has four switches (S1-S4) placed in positions along the slot to produce operating bands with a VSWR less than 2:1 in four separate bands. The researchers found that it was critical to strongly reverse bias switches in the OFF state to ensure appropriate impedance matching in the four bands [17]. Measured results demonstrate the discrete operating bands between 550 and 900 MHz (Fig. 5) and also indicate that the radiation characteristics of the antenna are essentially independent of the tuning [17].

While this approach to tuning works well as lower frequencies, the losses and parasitics inherent in solid-state switches limit their use as the frequency of operation increases. For operation at higher frequencies, a number of researchers have proposed the use of RF MEMS switches rather than diodes or FETs to achieve apparent changes in an antenna’s length or size. For instance, researchers have demonstrated a patch antenna integrated with RF MEMS actuators, shown in Fig. 6 [18]. These actuators are used to create capacitances at the edges of the patch that change the apparent electrical length of the patch. Exper-

Figure 4. Planar reconfigurable VHF slot antenna with microstrip feedline after [17]; all units are in millimeters and switch positions are denoted with S1-S4 (© IEEE 2001).

imental results, provided in Fig. 7, indicate that this configuration shifts the operating frequency by about 1.6% (from 25 to 24.6 GHz) without significant changes in any other operating parameter. In other examples, Gupta et al. proposed the use of switches to change the electrical length of rectangular slot ring antennas [19], Ali and Wahid proposed switched lengths in a Yagi antenna [20], Weedon et al. proposed a two-dimensional grid of switchable patches to form large or small microstrip radiators [21,22], and Vinoy and Varadan proposed switched fractal antennas [23]. In prototype tests using ideal short and open circuits, all of these antennas succeed in maintaining radiating properties while switching their operating frequencies. Interestingly, an analysis of a two-dimensional array of filamentary microstrip dipoles interconnected by lossy MEMS switches indicates that the array-antenna

Figure 5. Measured return loss of the reconfigurable VHF slot antenna for various switch states [17] (© 2001 IEEE).

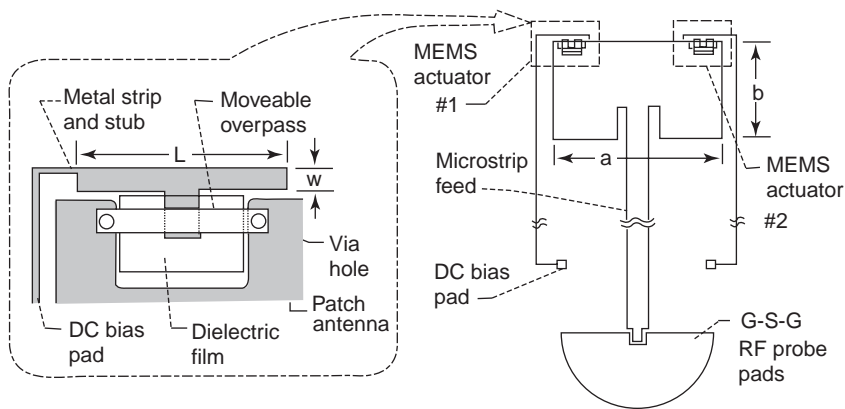

Figure 6. Frequency reconfigurable patch antenna element with two independent MEMS actuators, $L = 580 \mu\text{m}$, $W = 50 \mu\text{m}$, $a = 2600 \mu\text{m}$, $b = 1500 \mu\text{m}$ [18] (© IEEE 2001).

gain and the aperture efficiency remain much higher with frequency than in an array of fixed dipoles [2].

Another approach to switched-frequency reconfigurability is to combine a number of different antennas designed for different frequencies in a single structure and then use switches or other mechanisms to control the operating frequency. One example of this approach is a stacked reconfigurable antenna [24,25]. In this structure, two relatively broad frequency bands (each with approximately 40% bandwidth relative to their nominal operating frequencies) are alternately achieved in the 2–4 and 8–10 GHz frequency bands. The basic antenna structure

consists of a microstrip bowtie with a mixed dielectric substrate. Polarization variability at each feedpoint is supported by orthogonal placement of two balanced bowtie elements that can be driven to produce linear, elliptical, or circular polarization. Array operation in the lower band requires that the upper-band elements be disconnected via switches below the ground plane. In this stacked configuration, the upper-band elements act as floating parasitic elements for the lower-band elements, slightly broadening the impedance bandwidth. Operation of the upper-band elements requires that the lower-band elements be grounded via switches. In this configuration, the lower-band elements act as the ground plane for the upper-band elements [24,25].

Another example of a multiple-antenna-switched system is the reconfigurable leaky-wave/patch microstrip aperture [26]. This radiating system can operate over a range of frequencies and is shown in Fig. 8. The leaky-wave structures operating between 8 and 10 GHz are arrayed so that they provide high gain and moderate bandwidth and can be frequency-scanned about the elevation angle with gain up to 12 dB [26]. Figure 9 demonstrates the effect of frequency scanning in the leaky-mode array. Additionally, the ends of each of several leaky-wave apertures can be segmented into several smaller patch antenna apertures operating at discrete frequencies between 4 and 8 GHz through activation of switched connections.

Figure 7. Measured return loss demonstrating switched frequency reconfigurability with integrated MEMS actuators [18] (© IEEE 2001).

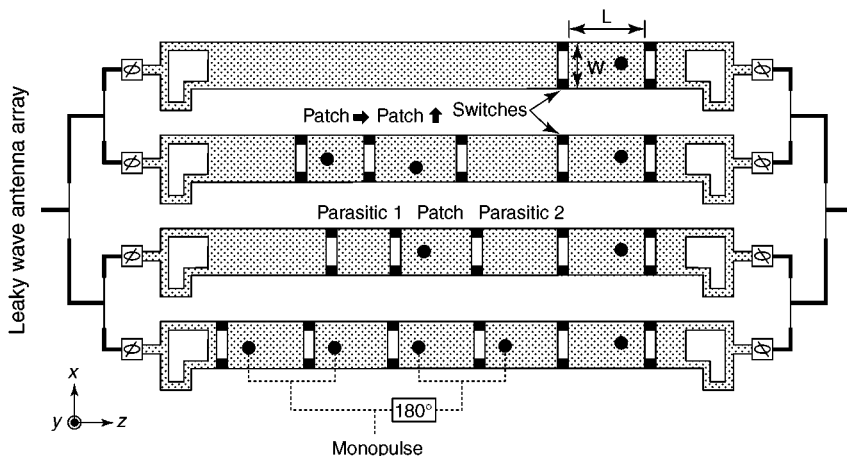

Figure 8. Schematic of reconfigurable leaky-wave/patch aperture array [26] (© IEEE 2002).

Figure 9. Measured frequency scanning using the leaky-wave structure of the reconfigurable array [26] (© IEEE 2002).

The patch antennas provide broadside radiation pattern coverage and moderate gain [26].

3. POLARIZATION RECONFIGURABILITY

Several antennas have also been developed that have reconfigurable polarization characteristics. From a design standpoint, this kind of reconfigurability can be more difficult to achieve than frequency reconfigurability, since the structure of the antenna has to change in ways that alter the way current flows on the antenna without affecting the operating frequency. Polarization reconfiguration could be useful for achieving more reliable wireless connections by adjusting to changing environmental

conditions, in effect, acting as a form of switched antenna diversity.

One example of such a polarization-agile antenna is the “patch antenna with switchable slots,” or PASS antenna [27]. The broader concept of the PASS has also been applied to achieve switched dual-band frequency reconfigurability as well [28]. In general, the PASS antenna consists of a microstrip antenna with one or more slots cut out of the copper patch, shown in Fig. 10 [27]. A switch (either solid-state or RF MEMS) is inserted in the center of the slot to control the behavior of currents on the patch. When the switch is open, currents must flow around the slot. When the switch is closed, the current can follow the shorter path created by the closed switch. Polarization reconfigurability is achieved by including two orthogonal slots on the surface of the patch. As demonstrated in the measurements provided in Fig. 11, alternate activation of the switches yields either right-hand or left-hand circular polarization. Others patch antennas with switchable circular polarization, using switches in the feed excitation slots rather than the surface of the patch, have also been proposed for active read/write microwave tagging systems [29].

Another polarization reconfigurable antenna, this one using a MEMS actuator, is shown in Fig. 12 [30]. In this design, the MEMS actuator is located within a simple microstrip patch antenna designed to support two orthogonal modes when excited in the corner. The actuator consists of a movable metal strip suspended over a metal stub. When the strip is suspended above the stub, the antenna has a circularly polarized radiation pattern (measurements shown in Fig. 13 [30]). Using electrostatic actuation, the metal strip can be lowered to create an antenna with dual linear polarization.

4. RADIATION PATTERN RECONFIGURABILITY

A diverse set of designs has emerged to date to deliver radiation pattern reconfigurability while maintaining other operating characteristics. This section is organized

Figure 10. Geometry of a patch antenna with switchable slots (PASS) for RHCP/LHCP diversity [27] (© IEEE 2002).

Figure 11. Measured axial ratio of the patch antenna with switchable slots in the xz plane [27] (© IEEE 2002).

Figure 12. Polarization reconfigurable patch antenna element with integrated MEMS actuator, with $a = 1500 \mu\text{m}$, $b = 1492 \mu\text{m}$; inset shows photomicrograph of the MEMS actuator [30] (© IEEE 2002).

according to basic antenna type, since the mechanism for radiation pattern configuration relies heavily on specific antenna design.

4.1. Pattern Reconfigurable Microstrip Antennas

The ability to change radiation patterns on microstrip antennas while maintaining operating frequency is one of the most challenging areas of antenna reconfigurability. This is because the significant changes in the antenna structure necessary to produce changes in radiation characteristics are usually closely coupled to the input impedance of the antenna. Manipulation of an antenna's radiation pattern can be used to avoid intentional or non-intentional jamming sources, to act as a switched pattern diversity system, and to direct signals only toward intended users [31].

One research group has developed radiation reconfigurable microstrip antennas that maintain their

frequency and bandwidth characteristics [31]. The basic antenna structure consists of a single-turn square spiral antenna, shown in Fig. 14, which exhibits a broadside radiation pattern in its fundamental state. To enable reconfiguration, the antenna is equipped with two switches (either solid-state or RF MEMS) – one between the spiral and ground (shown on the left of Fig. 14) and a second that opens a small gap in the spiral arm (shown on the right of Fig. 14). When both switches are activated, this

Figure 13. Measured circularly polarized radiation patterns of a MEMS-actuated polarization reconfigurable antenna [30] (© IEEE 2002).

Figure 14. Radiation pattern and frequency reconfigurable square spiral microstrip antenna showing switch placements necessary for reconfiguration [31] (© IEEE 2003).

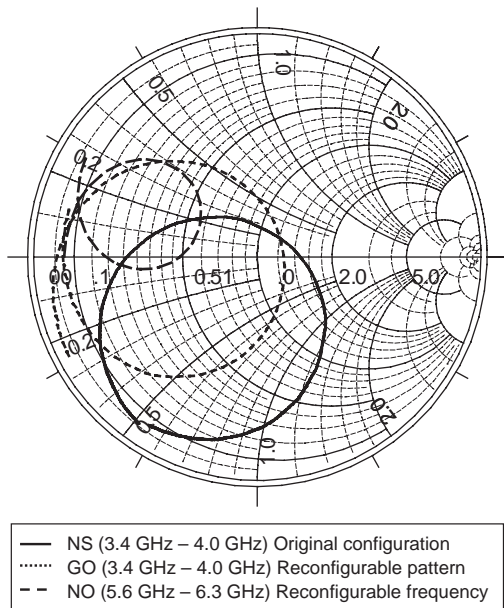

Figure 15. Measured input impedance of the original configuration (NS), the reconfigured radiation pattern (GO), and the reconfigured frequency (NO) [31] (© IEEE 2003).

configuration (called GO) maintains a shared 2:1 VSWR bandwidth of 50 MHz with the original configuration (called NS) operating at 3.7 GHz (see Fig. 15) while providing a 45° tilt from broadside in radiation pattern (Fig. 16). Additionally, with activation of only the second switch, the NO configuration provides a broadside radiation pattern at a higher operating frequency of 6.0 GHz [31]. This antenna and its variations are being considered for implementation in phased arrays [32] as well as implemented as a single element on portable computers to improve data communication link reliability and noise immunity [33].

4.2. Pattern Reconfigurable Reflector Antennas

Clarricoats and his colleagues were some of the first to demonstrate radiation pattern reconfigurability with aperture antennas by actively changing the structure of a mesh reflector [34,35]. Initially, changes in the reflector shape were achieved by manually adjusting each meshed region of interest [34]. Later, the process of reconfiguration was achieved by implementing computer-controlled stepper motors to pull strings attached to specific points on the reflector mesh [35].

A related, but more compact and accurate approach to reflector antenna pattern reconfigurability changes the shape of the subreflector in satellite applications [36]. The main reflector of this system has a fixed shape. The subreflector is made with a thin flexible material such that it deforms by movement of a set of piezoelectric linear point actuators attached on its back surface. When the subreflector is deformed, the electromagnetic field illuminating the main reflector can be changed, leading to a different far-field radiation pattern. During the design process, actuation points are successively added to the structure by

using an iterative electromagnetic finite-element algorithm to determine where the errors between the desired and actual subreflector shape is greatest [36].

Changes in reflector behavior have also been demonstrated using high-impedance surfaces (see the FREQUENCY-SELECTIVE SURFACES article for more information) [37,38]. High-impedance surfaces are created using a lattice of small resonant elements. This lattice produces high surface impedance near the resonant frequency of the elements, creating, in effect, an artificial ground plane. By inserting varactors between the resonant elements, the resonant frequency is tuned and the phase of a signal reflected from the surface is changed. Electronic control of the applied voltage across the varactors in the surface then allows reconfigurable beamshaping and beamsteering [37,38].

4.3. Pattern Reconfigurable Horn-Related Structures

A MEMS planar antenna was developed in 1999 that also uses mechanical changes in antenna structure to achieve reconfigurable radiation patterns [39]. Shown in Fig. 17, the basic antenna consists of a coplanar strip transmission line feed into a planar vee-shaped structure. Rotational hinges fixed to the substrate material hold the interior points of each arm in place. Each arm of the vee is movable by pulling or pushing by MEMS actuators, resulting in lateral movement of the arms. This lateral movement is then used to change the antenna's beam direction and/or the beamshape. Operating at 17.5 GHz, this antenna achieved *E*-plane beamsteering by rotating both arms by the same angle while maintaining a vee angle of 75° . Measured results shown in Fig. 18 show directional shifts of 30° and 48° for 30° and 45° positions of the vee, respectively [39]. Additionally, by moving the arms in opposite directions to change the vee angle, the antenna's beamshape could be changed as depicted in measured results provided in Fig. 19 [39].

Another group has implemented a flared planar dipole antenna with a tuned high-impedance surface to achieve beamsteering in the elevation plane [40]. The horizontally polarized antenna couples energy into leaky transverse waves on a tunable textured ground plane, shown in Fig. 20. The mechanically tunable surface, shown in more detail in Fig. 21, consists of a high-impedance ground plane and a tuning layer [40]. The tangential wavevector of the leaky waves is changed according to the change created in the surface resonant frequency by moving the tuning layer relative to the ground plane. Measured results on this design, shown in Fig. 22, indicate that beamsteering of at least 45° is possible [40].

4.4. Pattern Reconfigurable Array Structures

Other novel approaches to beamsteering have been developed by a research group at Texas A&M University [41]. Rather than employing conventional ferrite or solid-state phase shifters, these techniques steer beams through perturbations in propagation constants in a number of different transmission-line and antenna configurations. One of these is a movable grating antenna array fed by a dielectric image line (waveguide) that operates at

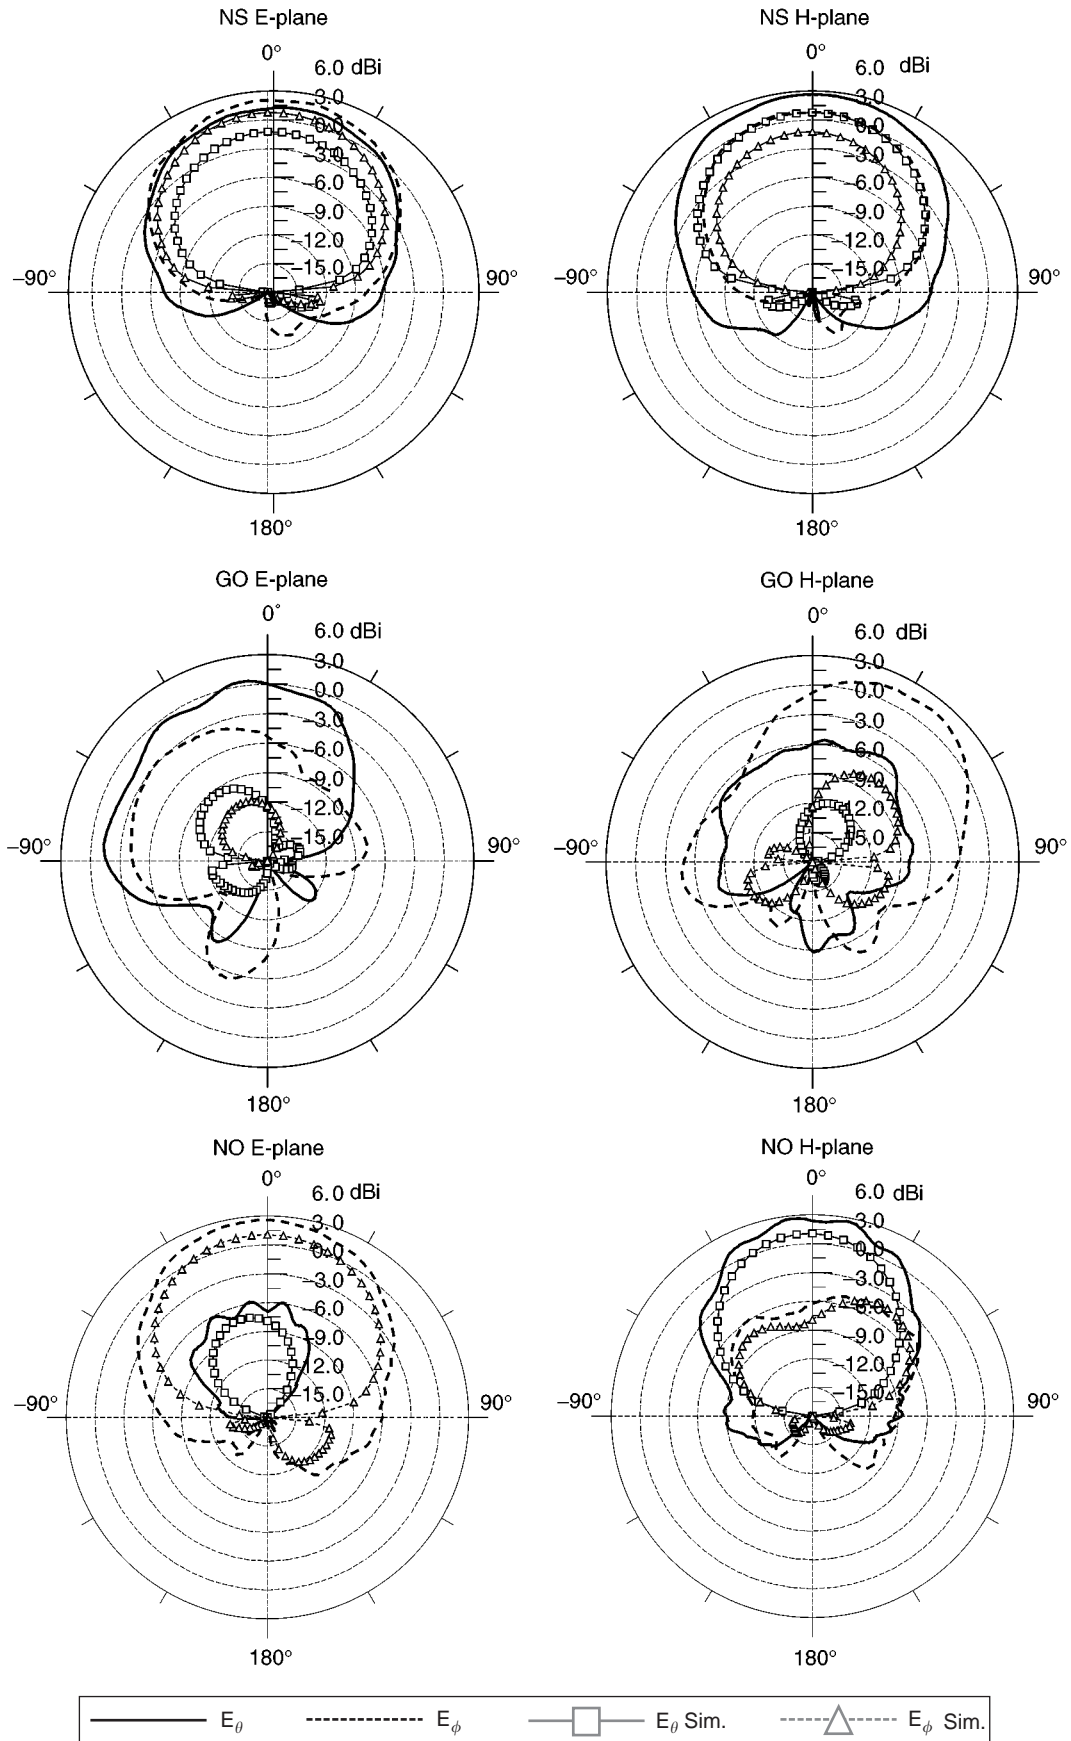

Figure 16. Measured and simulated gain (dBi) in the E plane (xz plane) and H plane (yz plane) for the three configurations of the antenna shown in Fig. 14 [31] (© IEEE 2003).

Figure 17. Concept (a) and cross section (b) of a MEMS reconfigurable vee antenna [39] (© IEEE 1999).

millimeter-wave frequencies, shown in Fig. 23 [41]. This leaky-wave antenna is essentially a dielectric waveguide with periodically placed conducting strips that form a grating above it. The widths of the strips on a thin, movable grating film placed over the dielectric image line are designed to gradually perturb the propagation constant along the line. Physical shifts of the grating film change the apparent grating spacings and result in a scanned beam [41]. In general, the antenna produces a fan-shaped beam, illustrated in Figs. 24 and 25, which is highly directional in one plane but very broad in the other. As indicated in Fig. 26, scan angles of up to 53° have been demonstrated with this design at 35 GHz, with lower scan angles achievable over an operating band between 30 and 40 GHz [41].

Figure 19. Measured and theoretical *E*-plane patterns (in halves) for 90° and 120° vee antennas [39] (© IEEE 1999).

5. RECONFIGURABLE APERTURES

Instead of reconfiguring a specific antenna, the two reconfigurable apertures discussed here take a unique

Figure 20. A reconfigurable antenna using horizontally polarized flared notch that couples energy into leaky modes on a tunable impedance surface; by tuning the surface resonant frequency (using a mechanically tunable surface impedance) with respect to the excitation frequency, the radiated beam is steered in the elevation plane [40] (© IEEE 2002).

Figure 21. A detailed diagram of a mechanically tunable impedance surface created using two printed-circuit boards: a high-impedance ground plane and a separate tuning layer; the resonant frequency of the surface is tuned through movement of the tuning layer across the stationary high-impedance surface, which varies the capacitance between overlapping plates [40] (© IEEE 2002).

approach—creating whatever antenna is necessary to achieve specific frequency, bandwidth, polarization, and radiation characteristics. The first is an antenna that uses hundreds or thousands of FET or other switches to connect small nonresonant conductive pads that create a large antenna aperture [42]. A conceptual drawing of the aperture is provided in Fig. 27. To achieve any specified performance goal, a genetic search algorithm determines the combination of switch states across the aperture. For each pass through the genetic algorithm, a finite-difference time-domain electromagnetic simulation is used to evaluate candidate designs. In general, narrowband configurations achieve more gain than do wideband configurations, and high-frequency operation degrades as a result of the pad density and the solid-state switch capacitance [42].

Another antenna aperture concept, developed by researchers at the Sarnoff Corporation, uses semiconductor plasmas to form antenna structures [43]. Figure 28 highlights the difference between this approach and that of the previous aperture [42]. This “pixel” approach to a reconfigurable aperture relies on high-conductivity plasma islands that are formed and controlled by injected DC currents into high-resistivity silicon-based diode structures. A detailed description of the structure, including the plasma injection driver configuration, is shown in Fig. 29. While there are still many technical issues to be addressed with this design (including the challenge of creating the necessary carrier densities in the silicon), this approach possesses several unique and attractive features, one of which is that when turned off, the aperture possesses an extremely low radar cross section. In

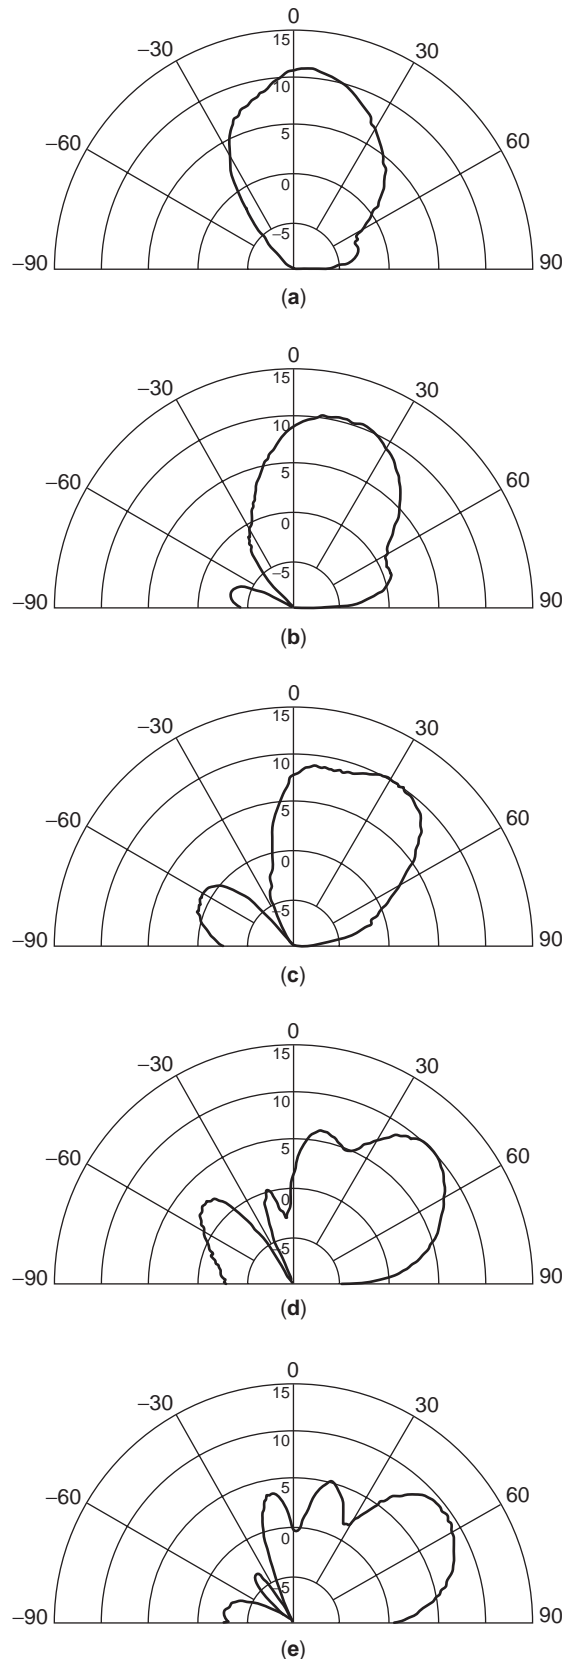

Figure 22. (a–e) Measured radiation patterns for five different positions of the tuning plate at a frequency of 2.5 GHz; each successive plot depicts a change in the relative position of the tuning plate by 63.5 μm [40] (© IEEE 2002).

Figure 23. A movable grating antenna array fed by a dielectric image line, capable of beam scanning at millimeter-wave frequencies [41] (© IEEE 2002).

addition to forming specific antenna structures, it can also be used to reconfigure holograms for holographic antennas that promise to deliver performance comparable to traditional phased arrays without the need for expensive phase shifters [43].

6. ENABLING RECONFIGURABILITY

While research and development of reconfigurable antenna and aperture designs has seen tremendous growth since the 1990s, their deployment in real applications

Figure 24. *xz*-plane co- and cross-polarization patterns at 35 GHz for a grating spacing of 7.8 mm [41] (© IEEE 2002).

Figure 25. *yz*-plane co- and cross-polarization patterns at 35 GHz for a grating spacing of 7.8 mm [41] (© IEEE 2002).

will take much longer. This is due to the fact that there are several technological barriers that must be overcome to make reconfigurability both practical and affordable. The first issue is the device that makes the antenna reconfigurable, whether it is electrical, magnetic, or mechanical. While there have been continual advances in the development of RF MEMS switches and other devices, they still suffer from a number of drawbacks that prevent their deployment in actual systems. Some of these include power-handling capability, response time, high-frequency behavior, and packaging/integration strategies. While these drawbacks will be addressed in the near future, antenna designers must wait or develop reconfigurable structures in the meantime that use more mature

Figure 26. Measured and calculated beam scanning capabilities along the θ direction at 30, 35, and 40 GHz [41] (© IEEE 2002).

technologies. (Interested readers are referred to the Further Reading list as well as the MICROELECTROMECHANICAL DEVICES article for a more complete picture of the evolution and the state of the art of enabling RF MEMS.)

The second issue is the actuation of the devices. Most reconfigurable antenna designers will acknowledge that the greatest engineering challenge for these antennas lies not in the design of the antenna but rather in the physical control infrastructure for the devices [42]. This barrier is particularly acute for reconfigurable designs that rely on hundreds or thousands of switches. A popular choice for overcoming this situation is some kind of optical signaling

Figure 28. Reconfigurable dipoles made of (a) metal strips connected/isolated using MEMS or pin switches or (b) plasma islands activated or deactivated to establish conductive antennas [43] (© IEEE 2003).

Figure 29. Depiction of a reconfigurable plasma grid structure: (a) grid structure is fabricated on top of the silicon wafer using silicon pin devices with an integrated feed, DC, and control circuitry; (b) cross section of the plasma grid structure showing the layer interconnection [43] (© IEEE 2003).

and control that does not interfere with normal antenna operation [9,42], but this approach will not work for all applications.

Finally, the most serious barrier to adoption of reconfigurable antennas may lie in the areas of signal processing and control. Without links back to system-level performance requirements and measures, antenna reconfigurability may be ignored or underutilized. It is imperative that members of the reconfigurable antenna community collaborate with researchers and developers in signal processing and control so that future systems can reach their full potential.

7. FUTURE OUTLOOK

New multifunction reconfigurable antennas have the potential to dramatically reduce the number and size of large array-based antenna systems, improve system efficiency, and decrease system cost and weight. They also have the potential to revolutionize the way we think about antennas, antenna systems, and their roles in national

defense, communications, and sensing. The age of the reconfigurable antenna is just beginning. With the requisite development of supporting technology and interactions with system designers, antenna reconfigurability promises to provide not only dramatic improvements in current system performance but also new degrees of freedom that will enable future systems with capabilities that previously were considered impossible.

RECTIFYING ANTENNAS (RECTENNAS)

1. INTRODUCTION

Rectifying antennas, commonly referred to as *rectennas*, are integral parts of microwave power transmission or wireless power transmission (WPT) systems. In WPT systems, RF power is transmitted from one location and captured at another location. The term *rectenna* consists of parts of the words “rectifier” and “antenna” since its function is to absorb incoming radio frequency (RF) energy and convert this energy to usable DC power.

Rectennas have been used in numerous space–space, ground–space, and ground–ground WPT demonstrations. However, these demonstrations have remained only studies into the feasibility of WPT. These “feasibility” studies and consequently many of the modern-day advances in rectenna technology have stemmed from Peter E. Glaser’s concept of space solar power (SSP) [1]. In an operational SSP system, a solar power satellite (SPS) would collect the sun’s solar power and convert it to microwave power. The satellite would then transmit the microwave energy to rectenna arrays positioned on Earth’s surface. These rectenna arrays, proposed to be several miles in diameter, would then capture the RF power and convert it to DC energy. Most of the world’s energy comes from the consumption of fossil fuels. These combustible fuels are limited resources that produce harmful byproducts when consumed. The idea of SSP providing readily available clean and continuous power for our future energy needs has generated widespread interest, especially in the United States and Japan.

Other advanced concepts for WPT include the ground–space application of powering aircraft and high-altitude platforms remotely using microwaves emitted from Earth’s surface. Several of the efforts in remotely powering aircraft are described in detail in Section 5. WPT can also be useful in several ground–ground applications including supplying power to remote locations such as islands where the infrastructure to generate power is either absent or not cost effective to build. However, the primary future use for WPT is seen in a myriad of space–space applications. These include supplying power to space

Figure 1. Schematic of the rectenna circuit.

colonies and space shuttles from nuclear powered satellites. This will enable space explorers to obtain the necessary power needed, at locations far from Earth, to further explore the depths of space.

2. RECTENNA OPERATION OVERVIEW

A schematic of the basic rectenna is illustrated in Fig. 1. A photo of an actual rectenna is shown in Fig. 2 to depict the corresponding rectenna components etched on a printed substrate. An antenna is used to capture the incident RF energy at frequency f . This energy is then passed through the harmonic rejection filter with minimal loss and on to the Schottky diode, where the RF energy is rectified to form DC power. The DC energy is then passed through the DC bypass filter to appear as the voltage V_D across the load resistor R_L . The remaining energies at the various harmonic frequencies $2f, 3f, \dots$ created from the Schottky diode's nonlinear process are reflected back to the diode by both the harmonic rejection filter and the DC bypass filter. This "trapping effect" results in additional mixing of the harmonic frequencies and ultimately in the generation of more DC power. The harmonic rejection filter also keeps

Figure 2. Photograph of a rectenna. A linear polarized dipole is used to absorb the incoming microwave energy. Copper strips (not seen) are etched on the substrate's backside between the dipole and the diode to form the harmonic rejection filter. A chip capacitor forms the DC bypass filter. The load resistor is not shown [2].

unwanted harmonic energy from reradiating into free space via the antenna. If allowed to reradiate, this harmonic energy could interfere with various electronic devices in close proximity to the rectenna that are operating in the same frequency band. In past designs, lowpass filters have been used to suppress the harmonic energy with very low loss. However, in more recent designs, bandstop filters have been used in order to provide much greater harmonic suppression while maintaining the low loss in the passband. In addition, the harmonic rejection filter is designed to match the real part of the diode's impedance to the antenna's input impedance Z_A . The DC bypass filter also serves two additional purposes: (1) it tunes out the reactance of the Schottky diode based on the DC bypass filter's position in the rectenna circuit, and (2) it blocks any RF signals from reaching the resistive load. This allows the DC voltage across the load resistor to be level with minimal amplitude versus time variation.

3. DESIGN THEORY

In designing a highly efficient rectenna, careful consideration must be given to choosing the proper diode, the type of transmission line to distribute the power between the rectenna's various components, the type of antenna, the spacing between the diode and the DC bypass filter (capacitor), and the resistance value of the load. The first component to consider is the nonlinear Schottky diode since the design of the other rectenna parts depends directly on the diode's performance.

The diode conversion efficiency (η_D) is key in determining the rectenna's performance and is based on the diode's equivalent circuit diagramed in Fig. 3. The diode efficiency is defined as the following ratio:

$$\eta_D = \frac{\text{DC output power}}{\text{RF power incident on diode}} \quad (1)$$

A diode model described by Yoo and Chang [3] is used to predict the Schottky diode's behavior. The model is a function of the diode's electrical parameters and the microwave circuit losses at the fundamental frequency of operation. Harmonic effects are not included because the

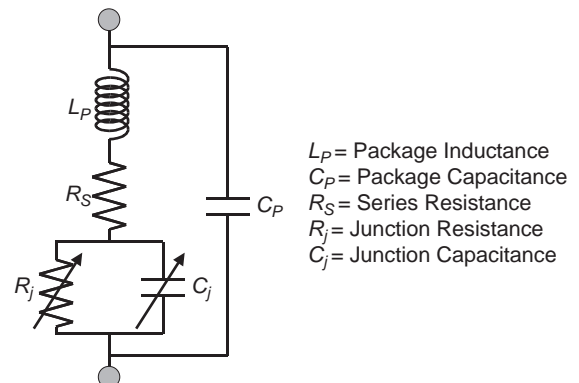

Figure 3. Schottky diode equivalent circuit.

major portion of the RF power is converted to DC, and the remaining RF power is considered to be predominantly at the fundamental frequency f . This also helps to keep the model simple. The package parasitics L_P and C_P are also neglected since, in most cases, where electrically small flip chip or beam lead diodes are used, their effects are negligible. The RF-to-DC conversion efficiency is described by [2,3]

$$\eta_D = \frac{1}{A+B} \quad (2)$$

where the low-frequency denominator asymptote is

$$A = 1 + \frac{R_L}{\pi R_S} \left(1 + \frac{V_{bi}}{V_D}\right)^2 \left[\theta_{on} \left(1 + \frac{1}{2 \cos^2 \theta_{on}}\right) - \frac{3}{2} \tan \theta_{on} \right] + \frac{R_L}{\pi R_S} \left(1 + \frac{V_{bi}}{V_D}\right) \frac{V_{bi}}{V_D} (\tan \theta_{on} - \theta_{on}) \quad (3)$$

and the high-frequency term is

$$B = \frac{R_S R_L C_j^2 \omega^2}{2\pi} \left(1 + \frac{V_{bi}}{V_D}\right) \left(\frac{\pi - \theta_{on}}{\cos^2 \theta_{on}} + \tan \theta_{on}\right) \quad (4)$$

where R_S is the diode's series resistance and ω is the angular frequency ($2\pi f$), V_{bi} is the forward-bias turnon voltage of the diode, and V_D is the self-bias voltage due to rectification across the terminals of the diode. The variable θ_{on} refers to the forward-bias turnon angle of the diode [3]. It is represented by

$$\tan \theta_{on} - \theta_{on} = \frac{\pi R_S}{R_L \left(1 + \frac{V_{bi}}{V_D}\right)} \quad (5)$$

Equation (5) is a transcendental equation and can be solved iteratively. The diode's abrupt junction capacitance C_j is

$$C_j = C_{j0} \sqrt{\frac{V_{bi}}{V_{bi} + |V_D|}} \quad (6)$$

where C_{j0} is the diode's zero bias junction capacitance. To keep the diode from exhibiting avalanche breakdown, the self-rectifying voltage V_D should be less than or equal to half of the breakdown voltage V_B . Given this limitation and Eqs. (2)–(6), selection of the proper diode can be based on its diode parameters R_S , V_{bi} , V_B , and C_{j0} . The diode voltage V_D should be chosen very close to $V_B/2$ for the best possible RF-to-DC conversion efficiency [4].

The diode's input impedance is defined as [2]

$$Z_D = \frac{\pi R_S}{D + jE} \quad (7)$$

where

$$D = \cos \theta_{on} \left(\frac{\theta_{on}}{\cos \theta_{on}} - \sin \theta_{on}\right) \quad (8)$$

and

$$E = \omega R_S C_j \left(\frac{\pi - \theta_{on}}{\cos \theta_{on}} + \sin \theta_{on}\right) \quad (9)$$

The real part of the diode's impedance from Eq. (7) is generally on the order of a couple hundred ohms. This resistance value determines the type of transmission line to use in order for the diode to achieve high RF-to-DC conversion efficiency. By choosing a transmission line with a characteristic impedance equal to the diode's real impedance, RF mismatch at the diode is eliminated. If mismatch is present, the RF-to-DC conversion efficiency suffers. A commonly used transmission line that can be designed to have characteristic impedances on the order of several hundred ohms is the coplanar stripline (CPS). CPS is composed of two parallel strips that, when constructed properly, can propagate energy from one location to another with very low loss.

The imaginary part of the diode impedance that results from Eq. (7) is tuned out using the length of transmission line between the diode and the DC bypass filter (chip capacitor). The capacitor acts electrically as a short to RF energy. Therefore, the combination of the capacitor and the length of transmission line between the diode and capacitor form a short-circuited tuning stub. The CPS has a topology that is readily suited to construct the short-circuited tuning stub. This tuning stub's length is adjusted by changing the capacitor's placement on the CPS. With the tuning stub counteracting the diode's reactance and the characteristic impedance of the CPS matching the real impedance of the diode, the RF energy that is incident on the diode will ideally see no reflection or mismatch across the terminals of the diode.

A technique described by Strassner and Chang [4] and shown in Fig. 4 utilizes a microstrip to CPS balun to determine the distance between the diode and the capacitor in conjunction with various source powers and load resistances. In addition, this technique provides a direct approach for experimentally determining the diode's RF-to-DC conversion efficiency versus the microwave power incident on the diode. In essence, this circuit provides a way to design the rectifier portion of the rectenna. Microwave energy is inputted into the microstrip line. The electromagnetic fields are then rotated in the transition region in order to match the microstrip line to the CPS. Once the energy strikes the diode, DC power is formed and passed to the load. The various harmonic energies strike the

Figure 4. Circuit designed for the direct determination of a diode's RF-to-DC conversion efficiency. The black traces are etched on the top of the substrate, and the gray area is etched on the backside of the substrate [4].

Figure 5. Rectenna measurement setup.

capacitor and are returned to the diode for further mixing. The distance between the capacitor and R_L can be arbitrary since only DC energy is propagated between the two. Likewise, the distance between the harmonic rejection filter and diode is arbitrary since both are matched to the characteristic impedance of the CPS. This direct measurement approach has the advantage over the model of including the effects of the higher order harmonics.

The final rectenna component is the *antenna*. The impedance Z_A looking into the terminals of the antenna must be purely real and must match the characteristic impedance of the transmission line that connects it to the harmonic rejection filter. Selection of the antenna is based on the necessary polarization, gain, and bandwidth as well as how the antenna is to be connected to the rest of rectenna circuitry. As far as printed rectennas are concerned, the ones that have achieved the highest efficiencies have used dipole antennas etched on thin substrates. These types of antennas are easily fed using CPS. A reflecting plane is normally placed approximately a $\lambda/4$ behind the dipole antenna in order to focus the antenna's energy in one direction. Since air acts as the dielectric between the dipole and the reflecting ground plane, the antenna can achieve close to 100% radiating efficiency. Having such a high radiation efficiency is key in achieving the best possible rectenna efficiency.

In many of the most recent designs where dipoles and CPS transmission lines are used, columns of parallel-cascaded rectennas are joined in series to produce large DC powers at the output of the array. In such cases, the rectennas on each column produce DC currents that are summed at the end of that column. Likewise, the DC voltages of each column are summed, resulting in the voltage V_A across the load resistor R_A . This array load resistor is defined by

$$R_A = R_L \frac{N_x}{N_y} \quad (10)$$

where N_x is the number of columns in the array, N_y is the number of rectennas in each column, and R_L is the optimal load resistance for each individual rectenna. The diodes are connected in parallel in each column, and the columns are connected in series.

Array spacing is governed both by the DC-pass filter placement and the effective areas of each individual

rectenna. The capacitors (DC-pass filters) not only optimize DC conversion but also isolate the array elements. Proper capacitor placement will enable each rectenna to capture energy with negligible reactance. Under this state of zero reactance, the array is perfectly matched.

4. FREE-SPACE MEASUREMENT

To obtain the rectenna's RF-to-DC conversion efficiency using the free-space measurement shown in Fig. 5, Eq. (1) or the diode efficiency is rewritten incorporating the Friis transmission equation as

$$\eta_D = \frac{\left(\frac{V_D^2}{R_L}\right)}{P_t G_t G_r \left(\frac{\lambda_0}{4\pi r}\right)^2} \quad (11)$$

where P_t and G_t are the transmitted power and transmitter gain, respectively, G_r is the gain of the rectenna's antenna, r is the distance between the transmitter and the rectenna, and λ_0 is the free-space wavelength at the fundamental frequency. The calculated free-space efficiency curves using Eqs. (2)–(6) should predict the directly measured diode efficiency using the balun circuit and the free-space measurement based on Eq. (11).

For determining a rectenna array's efficiency, in which multiple rectennas are combined together, the rectenna's antenna gain G_r in Eq. (11) is replaced by $4\pi A_e/(\lambda_0^2)$. The effective area of the array A_e is a physically measured quantity and corresponds to the rectenna array's total surface area exposed to the incident microwave energy. V_D is replaced by V_A , and R_L is replaced by R_A . V_A and R_A represent the array's output voltage and output load resistor, respectively.

The setup for obtaining the free-space measurement is presented in Fig. 5. In order to achieve uniform illumination across the rectenna array's surface, the transmitting horn antenna must be located far away from the rectenna array. However, this produces unwanted spillover effects where a significant portion of the transmitted energy misses the rectenna array's surface. To avoid these spillover effects, transmitting antennas are designed with low sidelobes and positioned close to rectenna array. At such

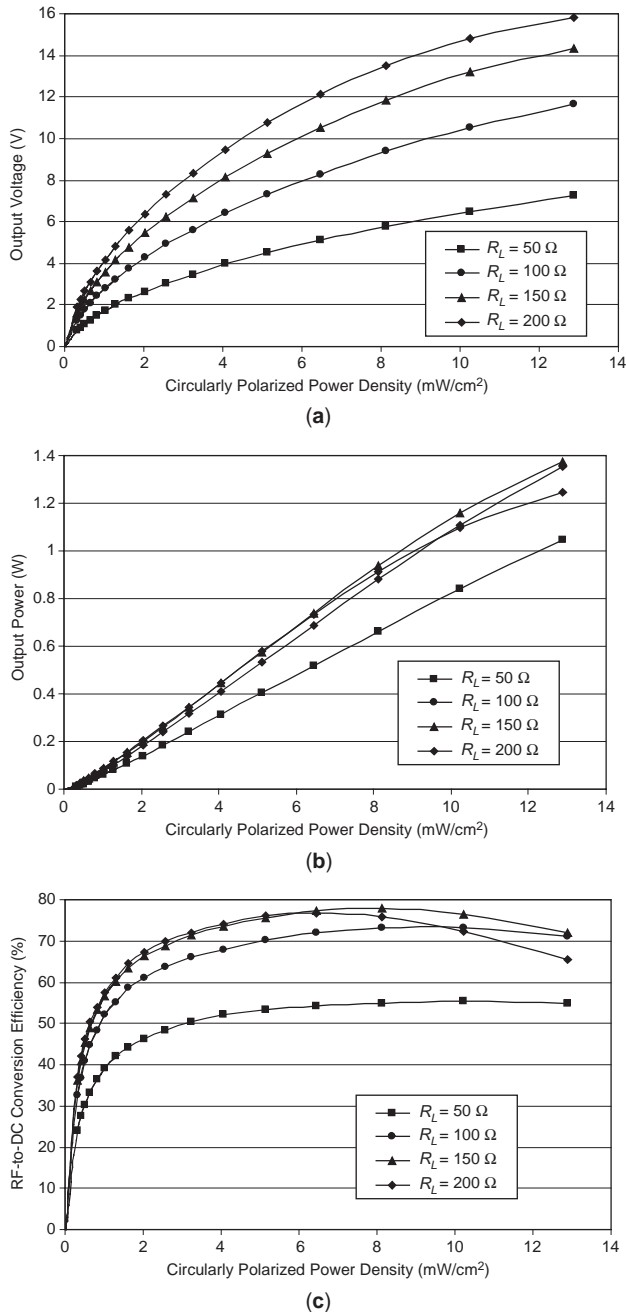

Figure 6. Rectenna array CP measured performance: (a) rectified voltage; (b) output power; (c) RF-to-DC conversion efficiency for various degrees of resistive loading.

close distances, the beamshape of the transmitting antenna’s gain is not constant over the rectenna array’s receiving aperture. Thus, each rectenna element in the array must be tuned specifically for its corresponding incident power density.

Typical plots of a rectenna array’s voltage across the load resistor, power at the load, and RF-to-DC conversion efficiency are shown in Fig. 6. These plots correspond to a 5.8 GHz circularly polarized rectenna designed by Strassner and Chang [5]. Figure 6a shows that as the load resistance R_L is increased, the voltage V_D will also increase.

Figure 7. State-of-the-art rectenna efficiencies. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

This occurs in order to keep the DC output power constant as a function of V_D^2/R_L . Figure 6b illustrates the constant power versus load. As the load resistance decreases to 100Ω , the DC output power will start to decrease. This degradation is due in part to the mismatch between the lower load resistances and the CPS characteristic impedance. The poor performance when $R_L = 100 \Omega$ is also noticeable in the RF-to-DC efficiency plot in Fig. 6c. The rectenna yields excellent RF-to-DC conversion efficiency over a wide range of load resistances and incident power density levels. The peak efficiency moves to lower power densities as the load resistance is increased.

The chart in Fig. 7 shows the best efficiencies that have been achieved since the early 1960s for the frequencies 2.45 GHz [6], 5.8 GHz [2], and 35 GHz [7]. The plot illustrates how the efficiency degrades as the operating frequency increases. Predicting the conversion efficiency of higher frequencies from measured data gathered at 2.45 GHz works reasonably well. This scaling prediction is based on the effective area differences at the various frequencies. During scaling, the antenna gain is held constant at 6.4 dB. This gain is typical for a linearly polarized dipole antenna located $\lambda/4$ over a ground plane. The main limitations on increasing the RF-to-DC conversion efficiency lie in the device physics of the Schottky diode.

5. HISTORY AND APPLICATIONS OF THE RECTENNA

The first recorded demonstration of WPT occurred in 1888 when Heinrich Hertz used parabolic reflectors and half-wavelength dipoles to transmit and receive microwave power at a frequency of 500 MHz [8]. To generate the microwave energy, the opposite halves of the dipoles were charged to a high voltage until an arc occurred across the gap. This arcing released capacitive stored energy setting up oscillations along the dipole. The dipole then radiated a portion of the oscillating energy in the form of microwaves. This accomplishment by Hertz was vital to the experimental validation of Maxwell’s equations with regards to electromagnetic energy propagating in free space. Hertz’ approach was strictly scientific. He knew that the lack of efficient and continuous source power in his design, coupled with the fact that no device existed that could convert

RF energy to DC power efficiently, prevented it from being useful in any practical sense.

The concept of efficient WPT began in 1898 at Colorado Springs, CO when Nikola Tesla used energy at a frequency of 150 kHz to successfully power 200 lightbulbs. The RF energy was generated from large oscillators, now referred to as “Tesla coils,” and propagated over a distance of 26 miles to the lightbulbs [9]. Even given this outstanding accomplishment for its time, many people remained skeptical of the ability of such technology to achieve profitability. In the 1920s and 1930s, Japanese [10] and U.S. researchers [11] considered the feasibility of WPT but again came up against technological limitations. The crucial development that ultimately enabled WPT to become a useful technology was the development of high-power, high-efficiency microwave tubes by the Raytheon Company, Waltham, MA in the 1950s [12].

On May 22, 1963, William C. Brown and others at the Spencer Laboratory of the Raytheon Company in Burlington, MA gave a demonstration of the first complete WPT system to a group of United States Air Force officials who had sponsored the development of the aforementioned high power microwave tubes [13]. In this demonstration, DC power was converted into 400 W of microwave power with an assumed efficiency of 50% at 2.45 GHz. This microwave energy was then fed to a horn that illuminated an ellipsoidal reflector 2.8 m in diameter. The reflector then bounced the microwave energy to the reflector’s focal point 7.4 m away where a diagonal horn was located to collect the reflected energy. The efficiency of the transmission and collection of the microwave energy between the two horns was 52%. After being collected by the diagonal horn, the microwave energy was converted back to DC using a thermionic diode with a very narrow gap between the cathode and anode at an efficiency of 50%. By multiplying the three efficiencies together, the overall DC-to-DC efficiency was found to be 13%.

Riding the success of Raytheon’s DC-to-DC conversion experiment, the United States Air Force expressed further interests in the ability of powering certain aircraft using WPT. On October 28, 1964 at Raytheon’s Spencer Laboratory, a public demonstration of the tethered microwave powered helicopter shown in Fig. 8 was given [14]. The demonstration was aired internationally on Walter Cronkite’s *CBS News Program* and proved that WPT could potentially be used to power communication or surveillance aircraft flying at high altitudes indefinitely. The helicopter experiment also introduced a new microwave device termed the “rectenna.” The rectennas used in the helicopter experiment consisted simply of packaged Schottky diodes connected end to end. The leads of the diodes formed the dipole antennas and the diode rectified the captured energy. During the experiment, the helicopter flew to an altitude of 18 m above the transmitter. The helicopter weighed 2.3 kg, had a rotor diameter of 1.76 m, and had an excess lift capability of 0.7 kg. It flew for 10 h at an altitude of 14.7 m. A magnetron was used to generate the necessary microwave energy at 2.45 GHz. The rectenna array’s area covered 0.37 m², and the DC output power of the rectenna array supplied to the electric motor was 270 W. The success of the tethered helicopter experiment

Figure 8. Air Force-Raytheon sponsored demonstration of microwave-powered helicopter was made to public media in October 1964.

prompted the Air Force to develop other tethered aircraft that could use microwave power to not only power the aircraft but also to change its pitch, yaw, roll, and position.

After a several-year lull in WPT, Brown gave a demonstration of the lightweight rectenna array to Werner von Braun and his staff at NASA MSFC in October 1968. The rectenna array had a power output: mass ratio of 1 kW/kg. This ratio represented an improvement of 3 over its predecessors. In the demonstration, a 3-ft parabolic antenna was illuminated with 200 W of microwave power at 2.45 GHz. The parabolic antenna reflected the energy to a rectenna array with an electric motor attached to a propeller to serve as the rectenna array’s load. When the rectenna array was placed in the beam from the parabolic antenna, the propeller spun impressively. Although the experiment was a simple one, it showed von Braun and his colleagues the merits of WPT. This in turn led to NASA funding WPT with the goal of improving the overall DC-to-DC efficiency.

In 1970 at NASA MSFC, Brown and his colleagues at Raytheon gained further support from NASA by demonstrating an overall DC-to-DC conversion of 26.6% [15]. For this experiment a new rectenna array design was developed that used four rectifying diodes in a bridge rectifier design. The system had a DC-to-microwave power efficiency of 65% and a radiated microwave power-to-DC conversion efficiency of 40.8%. This experiment also featured a “beam riding” capability in which a portion of the rectenna array’s output power was used to power a motor that kept the rectenna array in the beam of the transmitting antenna. The rectenna array was mounted on wheels to allow the movement of the array when the beam was steered. The array moved in an arc to maintain broadside orientation with the transmitting antenna’s beam.

Between 1970 and 1975, overall system efficiencies improved based on improvements in the pattern of the transmitting antenna. It had been discovered that if power were to be transmitted over long distances with any efficiency, a large transmitting antenna with negligible sidelobes would be needed. To meet this requirement, a dual-mode horn design was used to emit a Gaussian beam

with negligible sidelobes. Improvements in rectenna design also contributed to rises in overall efficiencies. Closer rectenna spacing in various patterns allowed for better collection of the power incident upon the rectenna array. Using the dual-mode horn, an efficiency of 60.2%, corresponding to the DC power at the rectenna array's output to the microwave power in the throat of the horn, was obtained. Had the dual band horn been available in the previous demonstrations in which reflector antennas were used, the efficiencies would have been about 1.5 times higher [8].

On March 4, 1975 at Raytheon, a demonstration of an overall DC-to-DC efficiency of $54.18\% \pm 0.94\%$ was given and certified by the Jet Propulsion Laboratory (JPL) Quality Assurance Department [16]. The certification was used to remove any doubts among the scientific and engineering communities. The demonstration was the culmination of a 5-year effort that had started in 1970 under the directorate of NASA MSFC and had focused on improving the overall DC-to-DC efficiency from 13% to 54%. The setup of the demonstration is shown in Fig. 9. A dual-mode horn emitted a Gaussian-shaped beam with negligible sidelobes at 2.446 GHz. Nearly all of the beam's energy was intercepted and absorbed by the rectenna array. The rectenna array then converted the microwave energy to DC power. The power density within the beam varies by a factor of 50 from the center of the beam to its edges, and the 199 rectenna array elements are matched in accordance to the power density of the beam at their corresponding positions. The breakdown of the 54.18% overall efficiency is 68.9% for the DC-to-microwave power conversion, 95% for the aperture-to-aperture transfer, and 82.4% for the beam collection and rectification. The DC output power was 495 W. The high rectenna efficiency is possible because of the gallium arsenide rectifier diodes used. These diodes are more efficient and can handle more power than their silicon predecessors.

In 1975, the transfer of microwave power to a rectenna array creating 30 kW of DC power at a distance of 1.54 km was demonstrated in the Mojave Desert at the JPL's Gold-

Figure 10. Demonstration of beamed power over one-mile distance at the JPL Goldstone facility in the Mojave Desert.

stone Facility [17]. The experiment set new records for WPT distance and the amount of power being transmitted. These new milestones proved the validity of WPT and its use in important applications. The demonstration setup is shown in Fig. 10. A high-powered klystron sends microwave energy at 2.388 GHz to the 25-m transmitting antenna seen in the foreground. This large antenna illuminates a 3.6×7.2 -m rectenna array located in the background a mile away. The rectenna array consists of 17 panels, each with 270 rectennas for a total of 4590 rectenna elements over the entire array. Of the microwave power intercepted by the rectenna array, 84% was converted into a DC power level of over 30 kW. Directly below the rectenna array is a bank of lights with two lights fed by each rectenna array panel. This rectenna array setup proved to be extremely robust surviving a lightning strike and years of use. The Goldstone demonstration was performed by Raytheon under contract from JPL.

After the Goldstone demonstration, attention shifted from the creation of full-WPT systems to improvements in rectenna design, especially with regard to RF-to-DC conversion efficiency and weight. The highest conversion efficiency was achieved by Brown at Raytheon in 1977 [18]. Brown used a GaAs-Pt Schottky barrier diode and aluminum bar dipole and transmission lines to achieve 90.6% conversion efficiency at 2.45 GHz and an input microwave power level of 8 W. In 1982, Brown and James Trimer developed the first printed thin-film rectenna. The printed rectenna operated at 2.45 GHz with 85% conversion efficiency. This rectenna was revolutionary in that it weighed 10 times less than any of its predecessors operating in the same frequency range [19]. Since the development of this rectenna, almost all rectennas have been printed using photolithographic etching techniques since they have the advantages of being lightweight and extremely easy to fabricate.

During the 1980s, the epicenter for WPT related research shifted from the United States to Japan. Japan saw SSP as a way to meet the energy needs of their nation given their limited natural resources and their ever-increasing reliance on nuclear energy. In 1983, Japan

Figure 9. An overall system efficiency of $54.18\% \pm 0.94\%$ was obtained at the Raytheon Company with the demonstration setup shown. The DC power output was 495 W, and the frequency was 2.446 GHz.

conducted their *microwave ionosphere nonlinear interaction* experiment (MINIX) rocket experiment [20]. It was the first WPT experiment in the ionosphere. In the experiment, 830 W was transmitted from one rocket to another rocket. In the MINIX experiment, Langmuir waves and electron cyclotron harmonic waves were observed and then modeled using nonlinear wave-particle interaction theory.

In 1980, a program to develop a long endurance high altitude platform called the *stationary high-altitude relay program* (SHARP) was proposed in Canada [21]. The platform was to be the first unmanned, fuelless, lightweight airplane that would be powered remotely by microwaves enabling it to stay afloat for long periods of time. On September 17, 1987, the $\frac{1}{8}$ -scale prototype SHARP with a wingspan of 4.5 m seen in Fig. 11 flew on beamed microwave power for 20 min at an altitude of 150 m. A microwave beam, consisting of 10 kW of source power at 2.45 GHz, was transmitted by a parabolic dish antenna with a 4.5 m diameter. Two 5-kW magnetrons generated the source power. The parabolic antenna tracked the airplane that flew inside a 50° cone. The power density at the airplane was 400 W/m^2 . The rectenna array was made to be dual-polarized by using two overlaid linear dipole rectenna arrays that were orthogonal to each other. The rectenna array used HP 2835 silicon Schottky diodes with a power-handling capability of 1 W and a RF-to-DC conversion efficiency of 70%. The rectenna received enough microwave energy to generate 150 W of DC power to the electric motor in order to lift and fly the 4.1-kg airplane.

In 1991, ARCO Power Technologies, Inc., Washington, DC, developed a rectenna element with 72% conversion efficiency at 35 GHz [22]. This frequency shift from the traditional 2.45 GHz to 35 GHz resulted in much smaller aperture areas. However, the components necessary for generating high power at 35 GHz are inefficient and expensive. Because of the disadvantages noted at 35 GHz, a new operating frequency or 5.8 GHz was investigated. The 5.8 GHz frequency has small component sizes and greater

transmission ranges than does the 2.45 GHz. In 1992, the first C-band rectenna yielded 80% conversion efficiency [23]. These efficiencies were measured in a waveguide simulator with an input power level of approximately 700 mW per element. This rectenna used a printed dipole that fed a quad bridge of silicon Schottky diodes.

A project similar to SHARP was one carried out in Japan in the early 1990s. The Japanese program, called *microwave lifted airplane experiment* (MILAX), involved team members from Kyoto University, Kobe University, Communications Research Laboratory, Nissan Motor Co. Ltd., Fuji Heavy Industries Ltd., and Toshiba Co. [24]. The MILAX fuel-free airplane is composed of balsa wood in order to keep its weight under 4 kg, and its wingspan was 2.5 m. The MILAX flew successfully for 40 s at an altitude of about 15 m covering a distance of 400 m over a straight course. The frequency used in the MILAX experiment was 2.411 GHz. The MILAX active phase array transmitter was composed of five-stage gallium arsenic (GaAs) semiconductor amplifiers, 4-bit digital phase shifters, and circular microstrip antennas. The transmitter was divided into 96 subarrays, each consisting of three antennas, one phase shifter, and one GaAs amplifier. Each subarray could supply 13 W of microwave output power, resulting in a total system radiation capability of 1.25 kW. The microwave power beam was radiated toward the MILAX airplane by an active phased-array antenna. At a distance of 15 m, the transmitter provided a power density of 200 W/m^2 . The transmitter was installed on the roof of an automobile as seen in Fig. 12. Six rectenna subarrays, each consisting of 20 rectennas, were installed on the bottom of the MILAX airplane. Each rectenna used a microstrip circular patch antenna to receive the incoming microwave energy. The circular patch antennas had the advantage of being nonresonant at the integer multiple harmonic frequencies of 2.411 GHz. This gave the circular patches the capability of suppressing the harmonic energy arising from the Schottky diodes from reradiation without additional harmonic suppression filters. However, these patch antennas had radiating efficiencies lower than those

Figure 11. Unmanned aircraft for the SHARP project.

Figure 12. Application of microwave power transmission to microwave-driven airplane (MILAX fuel-free flight experiment).

of dipole antennas. The diodes used are eight HP5082-2350 Schottky diodes in 2-series/4-parallel combination. The power handling capability for the rectenna array was 1 W per element, and the microwave-to-DC conversion efficiency was about 52%.

In 1993, Japan launched the International Space Year—microwave power transmission in space (ISY-METS) experiment to show WPT in space for the first time [25]. From a rocket, 800 W of 2.45 GHz microwave energy was transmitted using microstrip array antennas mounted on four deployed paddles. The rectenna array was placed on a second rocket to receive and convert the incoming microwave energy to DC power. The rectenna array was developed by McSpadden and Chang at Texas A&M University, College Station, TX. It used an orthogonally placed pair of three dipole antennas to achieve dual polarization. This orthogonal layout was similar to the one used in the SHARP project.

In the years 1995–1997, NASA conducted its “fresh-look study” to look at how recent technological advances could serve SSP with regard to United States interests. The study caused NASA to mobilize funding to research institutions, and one of their goals was improvements in rectenna capability. One such advancement occurred in 1998 when McSpadden and Chang developed a printed dipole rectenna, similar to the ones used in the ISY-METS experiment, that achieved 82% conversion efficiency at 5.8 GHz [2]. The rectenna used a MA/COM 40150-119 Schottky diode for rectification on a CPS layout and is shown in Fig. 2.

Since the late 1990s, researchers have looked into the designing of dual and circularly polarized (CP) rectennas, especially for SSP systems. Energy that is transmitted from space to Earth or vice versa undergoes Faraday rotation. This rotation detrimentally affects linearly polarized systems. However, dual and circularly polarized systems are not affected since the broadside alignment of the transmitting and receiving antennas can be arbitrary. Dual and circular polarization enables the receiving and/or transmitting antennas to be rotated without changing the rectenna’s output voltage.

In 2000, a group at JPL was able to operate a 50-V dual-polarized rectenna array composed of 9 patch antennas and 18 diodes to around 52% RF-to-DC conversion at 8.51 GHz [26]. The array was designed to produce high voltages (>50 V) in order to drive electrical actuators. Stacked patches, each with two slot-coupled feed points, were used to achieve the dual polarization.

In 2001, the University of Colorado, Boulder, CO published two novel rectenna arrays for power collection over large bandwidths [27]. Both of these arrays operated from 4.5 to 8 GHz and from 8.5 to 15 GHz. The first is a grid rectenna array, and the second is a spiral rectenna shown in Fig. 13. The grid array had a maximum conversion efficiency of 35% at 5.7 GHz for an incident power density of 7.78 mW/cm^2 of circular polarized energy. The spiral array used alternating RHCP and LHCP spirals to achieve a maximum conversion efficiency of 45% at 10.7 GHz for 1.56 mW/cm^2 . The lower efficiencies are due to the relatively low gain of the radiating elements since both arrays have radiators that are electrically large.

In 2002, a linearly polarized dual-frequency rectenna designed in a CPS layout and operating at both 2.45 and 5.8 GHz was developed by Suh and Chang at Texas A&M University [28]. To resonate at the two frequencies, slight modifications to the traditional dipole structure were made as shown in Fig. 14. The rectenna was placed 17 mm above a metal reflecting ground plane to focus the antennas’ energy in one direction. The rectenna used a MA/COM MA4E1317 Schottky diode and a chip capacitor to achieve 84.4% and 82.7% at 2.45 GHz and 5.8 GHz, respectively. A combination of CPS lowpass and bandstop filters were used to suppress higher-order harmonic energy from reradiating into free space.

In 1999 NASA started its SSP exploratory research and technology (SERT) study. In 2002, as a result of the study, Strassner and Chang developed the printed CP rectenna array shown in Fig. 15 [5]. The array provides 78% RF-to-DC conversion for an incident power density of 8 mW/cm^2

at 5.61 GHz. The rectenna uses a folded dipole antenna called a *dual rhombic loop antenna* (DRLA), which has the advantages of being circularly polarized, having higher gain than a traditional dipole antenna and being easily implemented into a CPS circuit. In comparison with a traditional dipole antenna, the DRLA's gain of 10.7 dBi gives it the advantage of reducing the number of rectenna elements necessary to cover the same receiving area over the array's surface. This reduction means fewer diodes and capacitors leading to great cost benefits especially in the case of large arrays. For low-power-density applications, a modified version of this array in which 4 DRLAs are tied to each diode (4×1) was demonstrated at the World Space Congress 2002 in Houston, TX. The demonstration featured an 18×4 array of these 4×1 DRLA rectennas with each individual 4×1 rectenna having a standalone RF-to-DC conversion efficiency of 82% [29].

6. CONCLUSIONS

All the aforementioned rectenna research has led to the acquisition of highly efficient RF-to-DC conversion capabilities. Not only have the antennas improved, but so too have the rectifying circuits. Improvements in the device physics of the Schottky diode and rectenna fabrication will enable better RF-to-DC conversion efficiencies. Only time will tell whether these improvements and advances in solar cell technology can lead to the development of a fully

operational SSP system. SSP will most likely be the primary driver for future rectenna research. A renewable energy source with no harmful byproducts promises to be one of the most important quests of the new millennium. Imagine Japan, a country with very few natural resources, as the new global supplier of energy. Finding a clean, renewable energy source should be a primary focus for the entire global community, and SSP, with rectennas as one of its core components, could be a solution to the problem.

REFLECTARRAY ANTENNA

JOHN HUANG
 Jet Propulsion Laboratory
 Pasadena, California

1. INTRODUCTION

The reflectarray antenna consists of a flat or slightly curved reflecting surface and an illuminating feed as

shown in Fig. 1. On the reflecting surface, there are many isolated elements (e.g., open-ended waveguides, printed patches, dipoles, or rings) without any power division transmission lines. The feed antenna illuminates these isolated elements, which are designed to scatter the incident field with electrical phases, which are required to form a planar phase front in the far-field distance. This operation is similar in concept to the use of a parabolic reflector that naturally reflects and forms a planar phase front when a feed is placed at its focal point. Thus the term “flat reflector” is sometimes used to describe the reflectarray, which utilizes technologies of both reflector and array. As shown in Fig. 2, there are several methods for reflectarray elements to achieve a planar phase front. For example, one is to use identical microstrip patches with different-length phase-delay lines attached to enable them to compensate for the phase delays over the different paths from the illuminating feed. Another method employs variable-size patches, dipoles, or rings to provide the elements with different scattering impedances and, thus, different phases to compensate for the different feed path delays. In the third method, for circular polarization only, the reflectarray has all identical circularly polarized elements but with different angular rotations to compensate for the feed pathlength differences.

To achieve low reflecting surface profile and low antenna mass, reflectarrays using printed microstrip elements have been developed. These reflectarrays combine some of the best features of the traditional parabolic reflector antenna and the microstrip array technology. Similar to a parabolic reflector, the reflectarray can achieve very good efficiency (>50%) for very large aperture since no power divider is needed and thus very little resistive insertion loss is encountered here. On the other hand, very similar to an array antenna, the reflectarray can have its main-beam designed to tilt at a large angle (>50°) from its broadside direction. Low-loss electronic phase shifters can be implanted into the elements for wide-angle electronic beam scanning. With this beam-scanning capability of the reflectarray, the complicated high-loss beamforming network and high-cost transmit/receive (T/R) amplifier modules of a conventional phased array are no longer needed. One significant advantage of the printed reflectarray is that, when a large aperture (e.g., 10-m) spacecraft antenna requires a deployment mechanism, the flat structure of the reflectarray allows a much simpler and more reliable folding or inflation mechanism than does the curved surface of a parabolic reflector. The flat reflecting surface of the reflectarray also lends itself for flush mounting onto an existing flat structure without adding significant mass and volume to the overall system structure. The reflectarray, which is in the form of a printed microstrip antenna, can be fabricated with a simple and low-cost etching process, especially when produced in large quantities. Another major feature of the reflectarray is that, with more than hundreds or thousands of elements in a general reflectarray having phase adjustment capability, it can achieve very accurate contour beamshape with a phase synthesis technique. With all these capabilities, there is one distinct disadvantage associated with the reflectarray antenna. This is its inherent narrow bandwidth, which

Figure 1. Configuration of a reflectarray antenna: three- (a) and two-dimensional (b) views.

generally cannot exceed much beyond 10%. This narrow-bandwidth behavior is discussed further in Section 4. Although the reflectarray has narrow bandwidth, due to its multitude of capabilities, the development, research, and application of the printed reflectarray antenna seem to be potentially boundless in the future.

2. REVIEW OF DEVELOPMENT HISTORY

The reflectarray antenna concept, shown in Fig. 1, was first demonstrated during the early 1960s [1]. Open-ended waveguide elements with variable-length waveguides were used to demonstrate the capability of achieving cophasal reradiated far-field beams. During this early time, since most wireless operations were done at relatively low microwave frequencies, the large-waveguide reflectarrays resulted in very bulky and heavy antennas. In addition, the efficiencies of these reflectarrays were not studied and optimized. More than 10 years later (in the mid-1970s), the very ingenious concept of “spiraphase” reflectarray was developed [2], where switching diodes were used in an eight-arm spiral or dipole element of a circularly polarized

reflectarray to electronically scan its mainbeam to large angles from the broadside direction. This is possible because, by angularly rotating a circularly polarized radiating element, its propagating electrical phase will also change by an appropriate amount proportional to the amount of rotation. However, because of the thick spiral cavity and large electronic components, the spiraphase reflectarray was still relatively bulky and heavy. Its aperture efficiency was still relatively poor. Thus, no continued development effort was followed. It should be noted here that, in order to ensure good efficiency for the reflectarray, the intricate relations between the element beamwidth, element spacing, and focal length/diameter (f/D) ratio must be well designed; otherwise, a large backscattered component field or a mismatched surface impedance would result.

Following the introduction of the printable microstrip antennas, the technologies of reflectarray and microstrip radiators were combined, and a typical configuration is illustrated in Fig. 3. Various printed microstrip reflectarray antennas were developed in the late 1980s and early 1990s for the purpose of achieving reduced antenna size

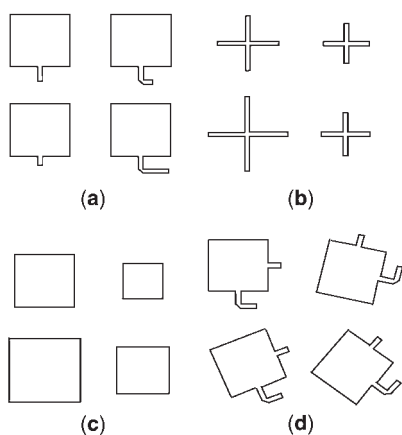

Figure 2. Various reflectarray elements: (a) identical patches with variable-length phase delay lines; (b) variable-size dipoles; (c) variable-size patches; (d) variable angular rotations.

Figure 3. Microstrip reflectarray with identical patches but different-length phase delay lines.

and mass. These printed reflectarrays came in various forms as shown in Fig. 2 and are all with flat low-profile and low-mass reflecting surfaces. The ones that used identical patch elements with different-length phase-delay lines [3–8] have elements similar to those shown in Fig. 2a. The phase-delay lines, having lengths in the order of half-wavelength long or less, are used to compensate for the phase differences of different pathlengths from the illuminating feed. The second approach, shown in Fig. 2b, used elements that are made of printed dipoles with variable dipole lengths [9]. Different dipole lengths will yield different scattering impedances, which then provide the different phases needed to compensate for the different pathlength delays. Similarly, microstrip patches with variable patch sizes [10], shown in Fig. 2c, were also developed. Circularly polarized microstrip patches with identical size but variable angular rotations [11,12], shown in Fig. 2d, were designed to form a cophasal far-field reflectarray beam. In addition to those shown in Fig. 2, several other reflectarray or equivalent developments during the 1990s are worth mentioning here. Printed variable-length dipole elements were used to form a frequency scanned grating-reflector antenna with an offset feed [13]. Printed annular rings of variable diameters arranged in Fresnel-zone configuration were also used to focus the beam [14]. In the 1996 Phased Array Conference, a 94-GHz monolithic reflectarray [15], using one-bit pin (positive–intrinsic–negative) diode phase shifters, was reported to achieve wide-angle ($\pm 45^\circ$) electronic beam scanning. In the same conference, a 35-GHz reflectarray, using waveguide/dielectric elements with 3-bit ferrite phase shifters [16], was also reported to achieve $\pm 25^\circ$ beam scanning. One technique proposed [11], although not yet developed, is worth mentioning here. By using the angular rotation technique with circularly polarized elements, miniature or micromachined motors could be placed under each element to achieve wide-angle beam scanning without the need of T/R modules and phase shifters. For application in the spacecraft area, a deployable and low-mass one-meter diameter inflatable reflectarray antenna [17] at the X-band frequency was developed. Another unique spacecraft application of the reflectarray was conceived [18] and developed [19] by using its many elements, with a numerical phase synthesis technique, to form a uniquely shaped contour beam. From all these developments, it can be seen that, at the end of twentieth century, reflectarray antenna technology has sufficiently matured and has had a variety of possible applications throughout the microwave and millimeter-wave spectra.

In early 2000, the development of reflectarray mushroomed, and several performance improvement techniques are worth mentioning here. One used multilayer stacked patches to improve the reflectarray bandwidth from a few percent to more than 10% [20]. As an extension to the 1-m X-band inflatable reflectarray mentioned above, a 3-m Ka-band inflatable reflectarray consisting of 200,000 elements was also developed [21], which is currently known as the “electrically largest reflectarray.” An amplifying reflectarray was developed [22] for each element of the reflectarray to amplify the transmitted signal and, thus, achieved very high overall radiated power. In

order to achieve good antenna efficiency, the most critical segment of the reflectarray design is its elements. The element performance was optimized by using the genetic algorithm (GA) method [23]. The reflectarray using sub-reflector and array feed configuration to achieve fine beam scanning was also studied [24]. To combat the shortcomings of narrow-bandwidth, dual-band multilayer reflectarrays using annular rings [25] and crossed dipoles [26] are also being developed. Another development that is worth mentioning here is a folded reflectarray configuration [27], where two reflecting surfaces are used to reduce the overall antenna profile due the feed height of a conventional reflectarray.

3. ANALYSIS AND DESIGN PROCEDURES

The design and analysis of a reflectarray can be separated into four essential steps, which are discussed separately below.

3.1. Element Characterization

The most important and critical segment of the reflectarray design is its element characterization. If the element design is not optimized, it will not scatter the signal from the feed effectively to form an efficient far-field beam. Its beamwidth must correlate correctly with the reflectarray's f/D ratio to accommodate all incident angles from the feed. Its phase change versus element change (patch size, delay line length, etc.) must be calibrated correctly. One very popular technique for calibrating the phase is to use the infinite-array approach [10,28] to include local mutual coupling effect due to surrounding elements. It is not feasible for the current computer technology to have a complete rigorous solution to include all the mutual coupling effect of all elements since the reflectarray generally consists of too many elements. The infinite array approach can be done by using the method-of-moment technique [10,28] or equivalently done by a finite-difference time-domain (FDTD) analysis on a unit cell of a single element [29]. Mathematical waveguide simulator, which simulates the infinite-array approach, can also be adapted by using the commercial software HFSS (high-frequency structure simulator; a finite-element technique) to achieve the element phase information. All these techniques are used to derive the phase change–element change curve, which is generally an “S”-shaped curve with nonlinear relationship as illustrated in Fig. 4. The antenna designer should minimize the slope at the center of the curve to ensure that the phase change will not be overly sensitive to the element change. If the curve is too steep, the element change or fabrication tolerance may become an issue, in particular at high microwave frequencies.

3.2. Required Phase Delay

The pathlengths from the feed to all elements are all different, and this variation leads to different phase delays. To compensate for these phase delays, the elements must have corresponding phase advancements designed in according to a unique “S” curve similar to that shown in

Figure 4. A typical “S” curve of a reflectarray element phase-change versus element-change.

Fig. 4. The following two equations give examples of how the compensating phase is calculated for each element of a reflectarray with a broadside-directed beam. The differential pathlength for each element is given as

$$\Delta L_{m,n} = L_{m,n} - L_{0,0} \quad (1)$$

where $L_{m,n}$ is the distance between the feed and the m th element, which can be obtained by using simple geometry. $L_{0,0}$ is the distance between the feed and a reference point on the reflectarray surface, such as the centerpoint. $\Delta L_{m,n}$ is thus the differential feed pathlength for the m th element. To achieve a collimated radiation, the phase advancement $\Delta\Phi_{mn}$ needed for the m th element is given by

$$\Delta\Phi_{mn} \text{ in degrees} = \left(\frac{\Delta L_{m,n}}{\lambda_0} - \text{integer of } \frac{\Delta L_{m,n}}{\lambda_0} \right) \times 360 \quad (2)$$

This equation indicates that the compensating phase can be repeated every 360° and the portion that is an integer multiple of a wavelength or 360° can be deleted.

3.3. Pattern Calculation

With all elements’ compensating phases known, the far-field radiation patterns can be calculated by the conventional array theory, where the radiation of all elements are summed together as follows. Consider a planar array consisting of $M \times N$ elements that are nonuniformly illuminated by a low-gain feed at position vector \vec{r}_f . Let the desired beam direction be specified by unit vector \hat{u}_0 . Then the far-field of the reflectarray in the \hat{u} direction will be of the form

$$E(\hat{u}) = \sum_{m=1}^M \sum_{n=1}^N F(\vec{r}_{mn} \cdot \vec{r}_f) \cdot A(\vec{r}_{mn} \cdot \hat{u}_0) \cdot A(\hat{u} \cdot \hat{u}_0) \cdot \exp[jk(|\vec{r}_{mn} - \vec{r}_f| + \vec{r}_{mn} \cdot \hat{u}) + j\alpha_{mn}] \quad (3)$$

where F is the feed pattern function, A is the reflectarray element pattern function, \vec{r}_{mn} is the position vector of the m th element, and α_{mn} is the required compensating phase of the m th element calculated by Eq. (2). The $\cos^q \theta$

factor is used for both F and A functions with no azimuth (ϕ) dependence.

3.4. Reflectarray Geometry Design

Determination of the geometry of a reflectarray basically consists in determining its f/D ratio, which is governed by its desired aperture efficiency. The aperture efficiency (η_a) can be defined as the product of the illumination (η_i) and spillover (η_s) efficiencies: $\eta_a = \eta_i \times \eta_s$. By integrating the pattern function of Eq. (3), the illumination efficiency for a center-fed reflectarray can be obtained in a closed form [30] as given by

$$\eta_i = \frac{[(1 + \cos^{q+1} \theta_e)/(q+1)] + [(1 - \cos^q \theta_e)/q]^2}{2 \tan^2 \theta_e [(1 - \cos^{2q+1} \theta_e)/(2q+1)]} \quad (4)$$

and the spillover efficiency is given by

$$\eta_s = 1 - \cos^{2q+1} \theta_e \quad (5)$$

where q is the exponent of the feed pattern function represented by $\cos^q \theta$ and θ_e is half of the subtend angle from the feed to the reflectarray aperture. The reflectarray element is approximated by cosine function. Equations (4) and (5) are calculated by assuming a circular aperture only for demonstration of the design procedures. Similar closed-form equations can be easily obtained for square, rectangular, or elliptical apertures by performing proper integrations. To give an example of how Eqs. (4) and (5) can be utilized to optimize a reflectarray design, Fig. 5 shows the calculated curve of spillover and illumination efficiencies versus the feed pattern factor q (feed beamwidth) for a 0.5-m 32-GHz reflectarray with a fixed f/D ratio of 1.0 ($\theta_e = 26.6^\circ$). It demonstrates that the maximum aperture efficiency is achieved at $q = 10.5$ or when the feed has a -3 dB beamwidth of 29° . Another curve, shown in Fig. 6, gives aperture efficiency as a function of f/D ratio for

Figure 5. Spillover and illumination efficiencies versus feed pattern shape.

Figure 6. Aperture efficiency versus f/D ratio.

the same 0.5-m 32-GHz reflectarray when the feed beamwidth is fixed at 33.4° with $q=8$. In this case, the maximum aperture efficiency is achieved when the f/D ratio is 0.87. It can be seen that curves derived from Eqs. (4) and (5) are essential in obtaining an optimum efficiency design. The preceding discussion has been limited to the center-fed reflectarray. Offset reflectarray can also be optimally designed by using equations similar to Eqs. (4) and (5).

4. BANDWIDTH

The bandwidth performance of a reflectarray [11] is no match for that of a parabolic reflector, where infinite bandwidth theoretically exists. The bandwidth of a printed microstrip reflectarray is limited primarily by two factors: (1) the narrow bandwidth of the microstrip patch elements on the reflectarray surface and (2) the differential spatial phase delay. The microstrip patch element generally has a bandwidth of about 3–5%. To achieve wider bandwidth for a conventional microstrip array, techniques such as using thick substrate for the patch, stacking multiple patches, and using sequentially rotated subarray elements have been employed. More than 15% bandwidths have been reported. The second reflectarray limiting factor, the differential spatial phase delay, can be best explained by referring to Fig. 7, where the differential spatial phase delay, ΔS , is the phase difference between the two paths, S_1 and S_2 , from the feed to the reflectarray elements. This ΔS can be many multiples of the wavelength (λ) at the center operating frequency. It can be expressed as $\Delta S = (N + d)\lambda$, where N is an integer and d is a fractional number of a free-space wavelength λ . At each element location, d is compensated by an appropriate phase delay achieved by the reflectarray element design (achieved by variable patch size, variable phase-delay line length, etc.). As frequency changes, the factor $(N + d)\lambda$ becomes $(N + d)(\lambda + \Delta\lambda)$. Since the design and the compensating phase for each element is fixed for the center frequency, a frequency excursion error will occur in the reradiated phase front. The amount of phase change in each path when compared to a reference path, say, S_1 , is $(N + d)\Delta\lambda$, which can constitute

Figure 7. Differential spatial phase delay of reflectarray.

a significant portion of a wavelength or 360° . To reduce the amount of frequency excursion error, the integer number N must be reduced. Several methods can be used to reduce N :

1. Design the reflectarray with a larger f/D ratio and hence minimize the difference between paths S_1 and S_2 .
2. Simply avoid the use of a reflectarray with a large electrical diameter. The effects of f/D ratio and diameter on bandwidth performance were given in Figs. 5 and 6.
3. Reduce frequency excursion error by using time-delay lines or partial time-delay lines instead of the phase delays. In other words, when using the phase-delay line technique (not the variable-patch-size technique), instead of using $d\Delta\lambda$ for the delay-line length, $(N + d)\Delta\lambda$ could be used for the delay line. Certainly, additional line insertion loss and needed real estate for the lines are issues to be encountered.
4. Increase the bandwidth by using, instead of a complete flat reflectarray surface, a concavely curved reflectarray with piecewise flat surfaces. This curved reflectarray will remain advantageous over a curved parabolic reflector; for instance, its beam can be scanned to large angles with a phase shifter inserted into each element, and, for a space-deployable antenna, the piecewise flat surfaces in some cases can be folded more easily into a smaller stowed volume.

In order to mitigate the bandwidth problem, a recent (as of 2003) technique of using multilayer stacked-patch elements [20] has not only increased the element bandwidth but also reduced the effect of differential spatial phase delay. As a net result, the bandwidth has increased from a few percent to more than 10%. Multiband techniques can also be applied to the reflectarray. Recently, two dual-band techniques have been developed for the X- and Ka-band frequencies: (1) use of a double layer with two different-size rings and variable angular rotations [25] and (2) use of a double layer with X-band crossed dipoles over Ka-band patches [26]. To summarize, although the narrow-bandwidth characteristic is the primary shortcoming of a

Figure 8. A 3-m Ka-band inflatable reflectarray (the shining structure in front of the aperture is the surface flatness measurement device).

reflectarray, several techniques can be employed to improve bandwidth performance.

5. APPLICATIONS AND RECENT DEVELOPMENTS

In addition to those possible reflectarray applications mentioned in Sections 1 and 2, it is appropriate to present some details of several important applications and recent developments here. One is a Ka-band circularly polarized inflatable reflectarray [21] with a 3-m-diameter aperture developed by the Jet Propulsion Laboratory (JPL) for NASA's future spacecraft communication antenna application. As shown in Fig. 8, the antenna uses a torus-shaped (doughnut-shaped) inflatable tube to support and

Figure 10. Ku-band reflectarray with shaped contour beam capability (courtesy of Professor Dave Pozar, Univ. Massachusetts). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

tension a 3-m thin-membrane reflectarray surface. This circularly polarized reflectarray, having approximately 200,000 elements using the variable-angular-rotation technique [11,12], is considered electrically the largest reflectarray ever built. The reflectarray, which has a “natural” flat surface, retains its required surface tolerance [0.3 mm RMS (root mean square) in this case] by the inflatable structure much more easily than would a “non-natural” parabolic surface, particularly for long space flight. The design of this inflatable antenna was later improved, equipping the antenna with rigidizable inflatable tubes [21,31] in order to survive the hazardous space

Figure 9. Measured radiation pattern of the 3-m Ka-band inflatable reflectarray.

Figure 11. A measured contour beam plot of the reflectarray shown in Fig. 10. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

environment, such as bombardment by space debris and strenuous thermal effects (induced by solar flares, UV, radiation, etc). This reflectarray achieved an aperture efficiency of 30% with room for improvement and excellent far-field pattern shape with average sidelobe and cross-polarization levels below -40 dB as shown in Fig. 9. A second important development of the reflectarray is the achievement of a shaped contour beam by using the phase synthesis technique. This reflectarray, shown in Fig. 10, was developed by the University of Massachusetts [19] for a commercial application to provide Earth contour beam coverage. A typical calculated contour beam of this antenna, using the phase synthesis technique, is plotted in Fig. 11. Since a reflectarray generally has many thousands of elements, it has many degrees of freedom in design to provide an accurate and uniquely required contour beam. A third important development is a dual-frequency reflectarray, where the two frequencies are widely sepa-

rated, such as the X and Ka bands. The developed prototype antenna, shown in Fig. 12, is circularly polarized and uses variable-angular-rotation annular rings [25]. It was developed by the Texas A&M University for JPL/NASA's future space communication application. This antenna, with a diameter of 0.5 m, uses a multilayer configuration in which the X-band annular rings are placed above the Ka-band rings and serve as a frequency-selective surface to allow the Ka-band signal to pass through. The measured results indicate that there is only minimal impact on X-band performance, due to the presence of the Ka-band elements. The measured radiation patterns of the Ka-band reflectarray both without and with the X-band layer are shown in Figs. 13 and 14, respectively. There is no significant difference between the two patterns. However, the measured Ka-band gain of the dual-frequency dual-layer antenna is about 1.0 dB lower than that of the Ka-band alone antenna. The purely Ka-band reflectarray (Fig. 13) has a measured aperture efficiency of 50%, while the dual-frequency dual-layer antenna has a Ka-band efficiency of about 40%. In other words, the X-band annular rings did somewhat impact Ka-band performance. Efforts need to be carried out in the future to minimize this impact. One more recent development that is worth mentioning is a reflectarray having a rectangular aperture intended for the NASA/JPL wide-swath ocean altimeter (WSOA) radar application. This reflectarray uses variable-size patches as elements. The required rectangular aperture, as shown in Fig. 15, consists of five flat subapertures connected together to form a curved reflectarray [32]. The curving of the long dimension of the rectangular surface is to minimize the incident angles from the feed for the end elements and thus to optimize the radiation efficiency for all elements. The radiation efficiency here indicates the measure of amount of energy of each element that is reradiated in the desired mainbeam direction. The advantage of using reflectarray with flat subapertures is to allow mechanical folding of the flat panels into a compact structure for

Figure 13. Measured radiation pattern of the single-layer Ka-band reflectarray.

spacecraft launch vehicle stowage. Preliminary test data indicate that this reflectarray is functioning properly, and some minor improvements are currently being carried out.

6. SUMMARY

The reflectarray antenna has come a long way. However, its development and application had not been widely adapted until the early 1990s, when the printable microstrip reflectarray was introduced. Except for its narrow-bandwidth characteristic, the reflectarray has many advantages over a parabolic reflector antenna type. The mainbeam of a reflectarray can be designed to tilt to a large angle from its broadside direction. Phase shifters can be implanted into the elements for wide-angle electronic beam scanning. For large-aperture spacecraft antenna applications, the reflectarray's flat surface allows the antenna to be constructed as an inflatable structure with relative ease in maintaining its surface tolerance in comparison to a curved parabolic surface. Its flat surface also can be made of multiple flat panels for ease in folding into a more compact structure for launch vehicle stowage. Very accurate beam shape can be achieved with phase synthesis technique for Earth contour beam coverage

applications. Due to these multitudes of capabilities, the door has just opened for the development, research, and application of printed reflectarray antennas. Two major areas that need further improvement in performance are the reflectarray's bandwidth and radiation efficiency.

REFLECTOMETERS, TIME-DOMAIN

ANDREW RUSEK
Oakland University
Rochester, Michigan

1. INTRODUCTION

Time-domain reflectometry is a measurement technique applied to determine the location, type, and quantitative character of discontinuities distributed in signal transmission channels such as computer or telephone networks, printed circuit boards, or other systems where signal delays are observed. Testing such systems, called *devices under test* (DUT), with TDR involves use of a fast pulse generator along with a *sampling oscilloscope* [11] and test fixture. Signals generated by the pulse generator are sent through the test fixture to the DUT. The most popular testing signal generated in broadband TDR systems is a steplike voltage. The signals are registered at the input to the *test fixture* by means of a sampling oscilloscope with coherent sampling, time transformation, and a track-and-hold vertical deflection system. Such a device allows the display of very small levels of reflected signals on the top of high levels of applied signals with minimal distortion.

TDR techniques can be enhanced when not only the input terminals of the DUT but also the output terminals are accessible by the oscilloscope. Measurements made from the output terminals, often called time-domain transmission (TDT) tests, include propagation delay and a pulse transmission function. Transmission tests can also

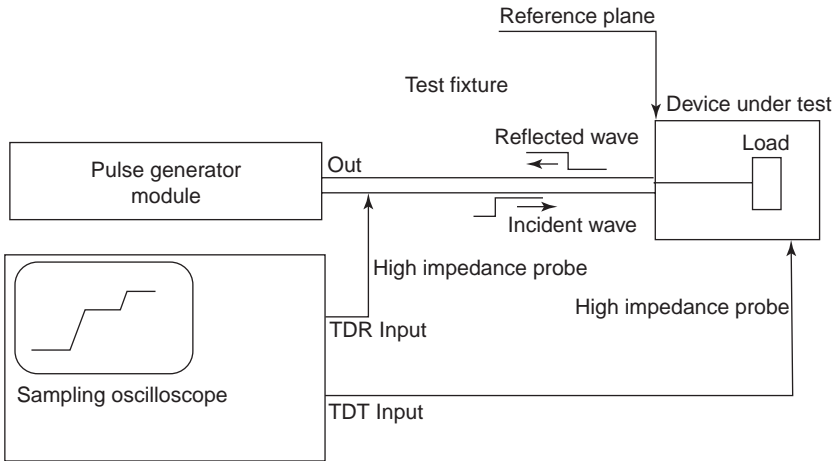

Figure 1. Block diagram of a time-domain reflectometer with time-domain transmission.

show the effects of mutual coupling between adjacent transmission channels, such as printed circuit board (PCB) traces.

In the article, the TDR measurement techniques are described, including basic properties and limitations of a real system such as finite risetime of the pulses, smooth transitions, small overshoots, jitter, and noise. Major examples demonstrated here include tests of the following:

- Resistance
- Capacitance
- Inductance
- Transmission-line characteristic impedance
- Inserted discontinuities of inductive, capacitive, and mixed types
- Differential and common-mode transmission-line impedances

In addition, effects of *transmission-line losses* and processes for correcting TDR test channel distortions are described. SPICE simulations are frequently used in conjunction with TDR measurements to enhance identification of characteristics related to the discontinuities [10,14,15]. The results of PSPICE simulations, included here to illustrate the normalization processes, are based on a demonstration version of this program [16]. The last part of the article demonstrates practical applications of TDR/TDT systems [3,4,16,17].

1.1. Applications of Time-Domain Reflectometry/ Time-Domain Transmission

TDR/TDT systems have found use in both electrical and nonelectrical areas. The following list includes a number of the most popular applications [1,9,12]:

1. Conductor length and return loss determination
2. Finding short and open connections in cables
3. Location of bad splices, loose connectors, and crimps
4. Location of moisture and water in cables
5. Measurement of cable parameters, such as characteristic impedance, losses, and propagation velocity
6. Determining signal integrity, and performing failure analysis of printed circuit boards used in high-speed digital and analog circuits
7. Evaluation of microstrip connections
8. Computer network cable tests
9. Characterization of integrated circuit packages
10. Sensing liquid levels

2. TIME-DOMAIN REFLECTOMETRY PRINCIPLES

2.1. Basic TDR/TDT Systems

A functional block diagram of a TDR/TDT is shown in Fig. 1. The step generator signal is transmitted through a test fixture such as transmission line (Fig. 2), and is finally

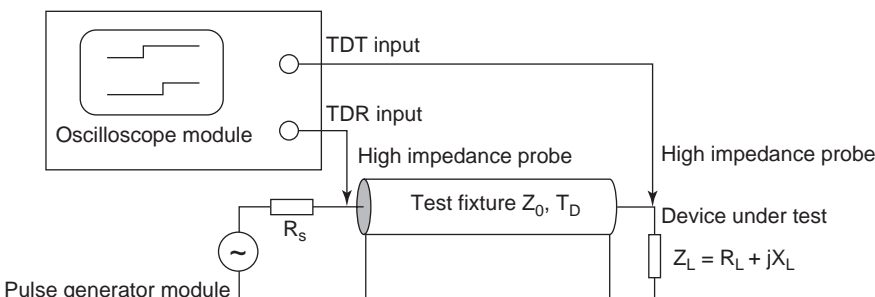

Figure 2. Impedance tests with a 50-Ω transmission-line test fixture.

applied to the device or system under test (DUT). The test fixture impedance is usually matched to that of the generator. If the DUT impedance is not equal to the characteristic impedance of the transmission line of the test fixture, part of the incident voltage is reflected from the DUT. The reflected signal, which is delayed in relation to the incident voltage, appears as a step change on top of the

incident wave. The location of the impedance discontinuity d can be calculated from the transit time measured from the reflection and the reference point, marked from the front edge of the incident voltage signal

$$d = \frac{v_p \cdot t_d}{2} \tag{1}$$

Figure 4. TDR input and TDT input voltages for parallel $R_L C$ loads of the 50-Ω transmission-line test fixture. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 5. TDR input and TDT input voltages for series $R_L C$ loads of the 50- Ω transmission-line test fixture. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

where v_p is a wave propagation velocity and t_d is the transit time.

Figure 3 shows the voltages observed in a TDR/TDT system when the transmission line of the test fixture is matched to the source and the signals are reflected from pure resistive loads. The voltage amplitude reflected from the DUT, divided by the amplitude of the incident wave, determines the reflection coefficient at the load ρ_L . When an unknown resistance is connected to the source-matched transmission line, the value of the resistance

can be calculated as follows:

$$Z_L = Z_0 \left(\frac{1 + \rho_L}{1 - \rho_L} \right) \tag{2}$$

This equation is applied in the TDR/TDT internal processor to calculate the load parameters [15,16] (see also PSPICE simulations of differential TDR/TDT, Figs. 15 and 17). Figures 4–7 illustrate the voltage waveforms when the load of the test fixture (transmission line) is a

Figure 6. TDR input and TDT input voltages for parallel $R_L L$ loads of the 50- Ω transmission-line test fixture. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

combination of either resistance and capacitance, or resistance and inductance. In all cases shown, the load resistance is varied and either C or L is maintained constant. From steady-state voltage levels following the reflection, as well as from the shapes of the waves themselves, which reveal the time constant, it is possible to identify the character of the load and the values of unknown components. With this information, the parameters of the equivalent circuits representing the load can be evaluated from the equations listed in Table 1.

The waves that have been presented so far show the behavior of short transmission lines in which the losses, which are due largely to the skin effect, are negligible. In longer transmission lines the distributed losses distort the signals traveling along the lines. Examples of transmitted and reflected waves in a short terminated transmission line are shown in Fig. 8. For comparison, a lossless case is included. From these waveforms, it is possible to determine changes of the transmission-line resistance over the length of the cable.

Practical transmission channels in PCBs with packages of the integrated circuits may have longer connecting leads inserted between some sections of transmission lines or larger conductive surfaces shunting the signal. The TDR/TDT tests for such cases can be modeled as shown in Fig. 9. Two examples of the waveforms in these circuits are illustrated in Figs. 10 and 11.

2.2. Sources of Error

Three major sources of error are encountered in TDR/TDT tests:

1. Cables and connectors of the test fixture [2,6,7].
2. Oscilloscope

3. Test generator

Cables and connectors connecting the generator with the tested device introduce their own *reflections*, in addition to the reflections caused by the tested device (DUT). They also introduce distributed losses, which increase at higher frequencies. This reduces the speed of transition of generator pulses.

Oscilloscopes introduce two types of error. One is caused by bandwidth limitation, which leads to the “smoothing” of fast voltage transitions. The other type of

Table 1. Parameters of Equivalent Circuits Representing Load in Basic TDR/TDT Systems

Figure 10. TDR and TDT input voltages for the system with an inductor inserted between transmission lines. Risetime of the input pulses is varied to show the distortion levels. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

errors includes coupling of the trigger channel into signal channel, interchannel interference, and input circuit mismatches to the test fixture [2,6,7].

Real testing pulses of TDR/TDT pulse generators have finite risetimes, and their top parts are not ideally flat. Some generators may produce pulses with overshoots. Associated with both the sampling oscilloscope and the generator are the errors caused by both jitter and noise. All these distortions limit TDR/TDT system resolution and make the observed waves more difficult to analyze, especially when the TDR/TDT system is used to test closely located small discontinuities of the transmission channel.

2.3. Corrections of Measurement Errors

Error correction can be effectively performed using internal signal processors built into modern TDR/TDT systems. One of the simplest methods of error correction is waveform subtraction. The method could be used to minimize errors common to both the tested device and the reference, such as trigger and *channel crosstalk errors*, and reflections from the test fixture and connectors. In the process of measurement, the common reference device is connected to the end of the test fixture. The test results in terms of the TDR input voltage are stored and the reflected part of this wave is computed. This reflected wave is then

Figure 11. TDR and TDT input voltages for the system with a capacitor connected to the ground between transmission lines. Risetime of the input pulses is varied to show the distortion levels. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

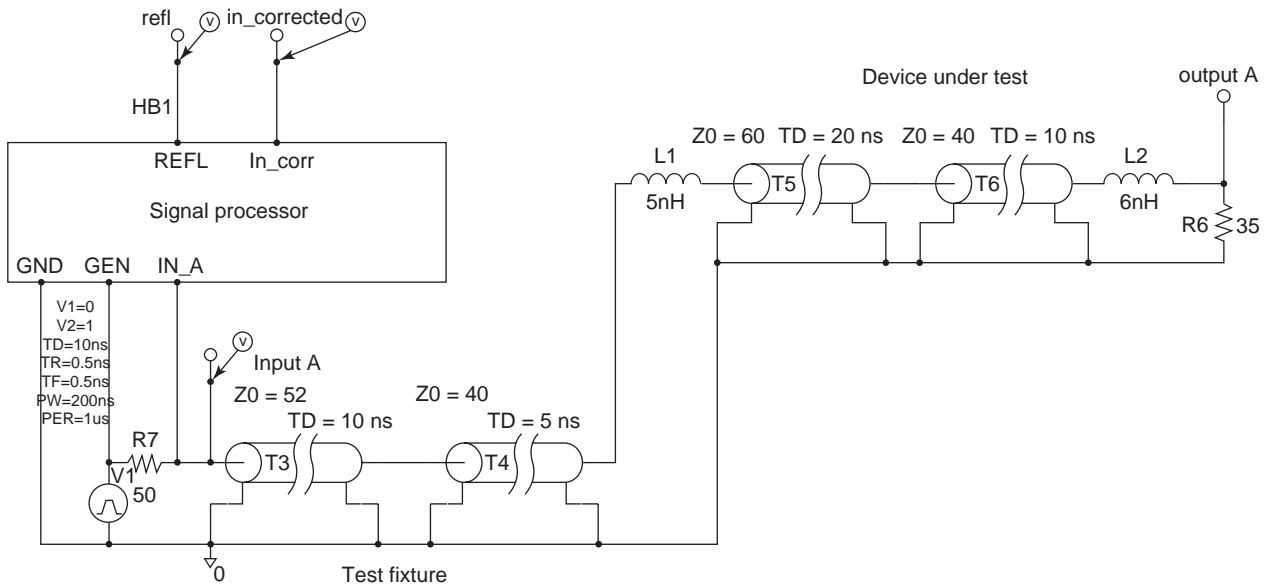

Figure 12. Simulated TDR/TDT system with imperfect test fixture.

subtracted from the input voltage obtained in the second phase of the measurements when the DUT is connected. The results of this procedure are limited to the specific risetime of the system. For instance, faster pulses reveal more discontinuities, which may not be important in particular applications.

The waveform subtraction method is illustrated by means of PSPICE simulations (PSPICE is a PC version

of SPICE). Figures 12 and 13 show the process of compensation for errors introduced by the test fixture composed of two transmission-line sections, T3 and T4. The characteristic impedances of these lines are 52 and 40 Ω, respectively. The device under test (DUT) is a connection of two transmission lines, two inductances and one resistor (L1, T5, T6, L2, and R6). Initially, the matching resistor (50 Ω) is connected to the end of the test fixture. Then,

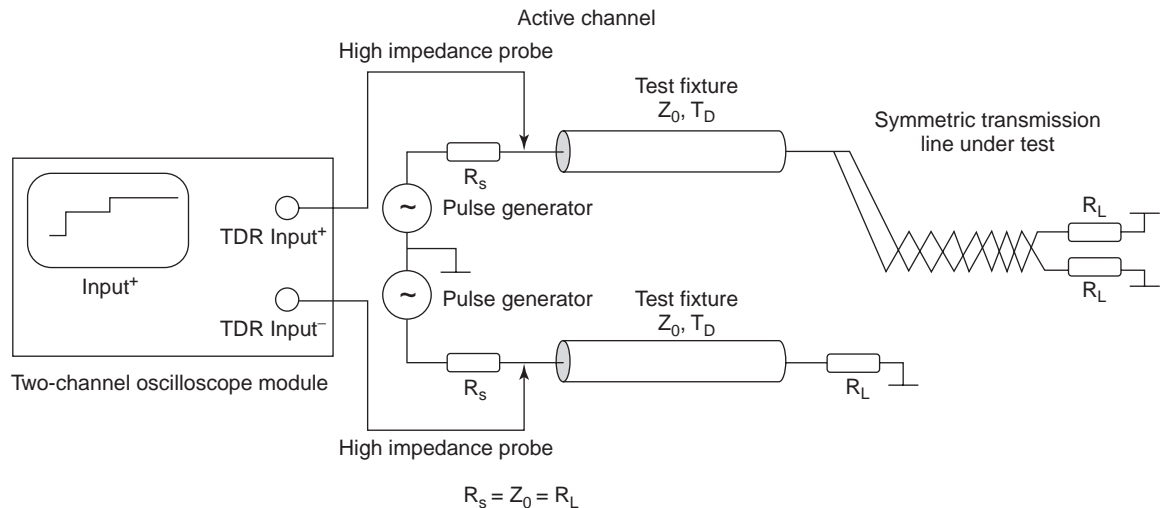

Figure 16. Single-channel measurement of a common-mode impedance with a 50-Ω transmission-line test fixture.

Figure 18. Effects due to termination resistor leads: (a) microstrip; (b) expanded TDR waveform (reprinted with permission of Agilent Technologies). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 19. TDR measurements with the DUT at the end of imperfect test fixture: (a) block diagram; (b) unnormalized measurement results showing the effects of the test fixture (reprinted with permission of Agilent Technologies).

the calculated reflected waves are subtracted from the results of final tests while the DUT is connected. In the simulations, the calculations are performed in a parallel manner so the 50-Ω tests are done internally, inside the processing box. When the test fixture reflections can be isolated in time from the DUT reflections, it is possible to process the latter signals by windowing and creating corresponding impedance profiles [16]. It is still necessary to calibrate the test fixture with the reference device connected to the end of the test fixture as in the waveform subtraction method described earlier.

A significant reduction of the TDR/TDT system errors caused by the pulse generator speed limits can be achieved in a TDR/TDT system that takes advantage of digital signal processing called *normalization* [3,4]. The normalization process refers the measurement results to a test signal with a predefined risetime [5]. The measurement results are enhanced by digital filtering to boost high-frequency components of the processed signals. In this way,

Figure 20. The unnormalized response of the DUT, measured without the test fixture (to demonstrate the results of normalization) (reprinted with permission of Agilent Technologies).

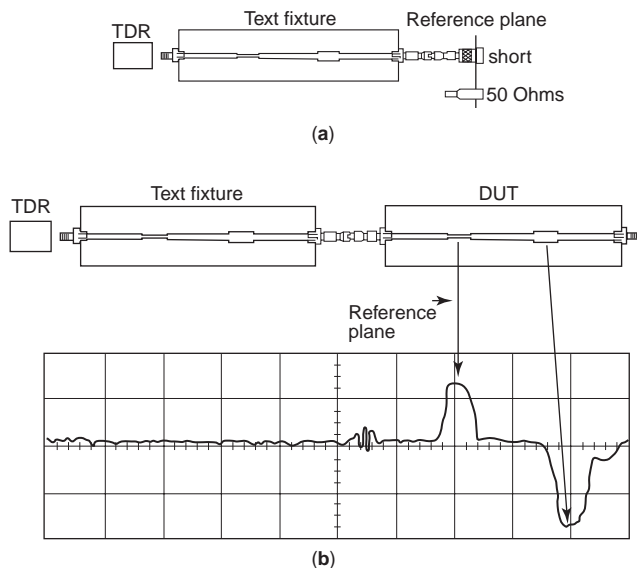

Figure 21. Normalized calibration that uses a short, then a 50-Ω termination to define a reference plane and generate a digital signature (filter): (a) circuit with the test fixture; (b) corrected measurements (reprinted with permission of Agilent Technologies).

the results of measurements can be enhanced as if the tests were performed in a faster TDR/TDT system [7].

2.4. TDR/TDT System Limitations

Most high-frequency TDR/TDT systems have been designed to investigate circuits whose impedance levels are close to 50 Ω. According to Ref. 2, 50-Ω systems are sufficiently accurate (<0.5% error) to measure load resistances or transmission-line characteristic impedances above 10 Ω. Testing changes of impedances or impedance profiling along the transmission channel, the lowest limit is 30 Ω to maintain errors below 1% [13].

The effects of the finite risetime of the TDR/TDT system limit the spatial resolution of the TDR measurements. The minimum distance that separates two consecutive discontinuities can be expressed as

$$\Delta d = \frac{c}{\sqrt{\epsilon_r}} \frac{t_r}{4} \tag{3}$$

where t_r is the system risetime, c is the open-space wave velocity, and ϵ_r is the relative dielectric constant of the transmission-line dielectric [3]. For instance, if the risetime is 20 ps and the relative dielectric constant is 2, then the minimum distance between two consecutive discontinuities is about 1 mm. This expression must be modified when the *jitter* is present in the measurement system. The jitter error has the same effect as if the equivalent risetime of the system had increased, thus reducing the spatial resolution.

System noise reduces the ability of TDR to detect small reflection amplitudes. Oscilloscope noise can reach the level of one division corresponding to maximum sensitivity of the scope (about 1 mV per division). Assuming that

Figure 22. Example of the crosstalk in a hybrid power divider: (a) microstrip circuit; (b) expanded TDR waveforms (reprinted with permission of Agilent Technologies).

the incident pulse observed has an amplitude of 100 mV, reflection coefficients as small as 0.01 can be registered without major corruption caused by the noise. Better results can be achieved when analog smoothing or digital filtering is applied.

2.5. Differential Time-Domain Reflectometry

Differential time-domain reflectometry (DTDR) and reflectometers have been used to investigate symmetric transmission channels or lines such as *twisted-pair* or *slotted striplines* [8,14]. In DTDR systems, two pulses of opposite polarity are generated and applied to the tested symmetric DUT. Figure 14 shows a general block diagram for such a system. The *differential-mode impedance* can be determined from the reflections related to the differential input voltage, as shown in Fig. 15. The basic calculations are performed by the system processor, based on Eq. (2), and the results are displayed. *Common-mode impedance* can be also measured by using a single channel of the DTDR system (Fig. 16). The results obtained from Eq. (2) are multiplied by 2 if both transmission-line conductors are tested, as shown in Fig. 17. A drawback of differential TDR systems is that they require good pulse alignment.

The errors introduced by misalignment can be reduced by means of normalization processes [8].

3. EXAMPLES OF TDR/TDT TESTS AND TDR/TDT APPLICATIONS

3.1. TDR/TDT Test Examples

The following examples demonstrate the results of practical tests performed by a TDR/TDT measurement system [3,4]. Figure 18 shows the reflections observed when a long-lead resistor is connected to the end of a 50-Ω microstrip test fixture. The results from the measurement are displayed below the waveform. For example, the inductance of the resistor leads is 4.779448 nH, as the display shows. The next group of figures (Figs. 19–21) illustrate the process of normalization for a complex DUT. The test fixture was purposely selected to show the effectiveness of the normalization processes. The presence of the test fixture, which is normally used to delay unknown reflections with respect to the front of the test pulse, introduces visible signal distortions. The corrected measurements are shown in the last figure of this group. Normalization corrects for the effects of the test fixture and enhances the

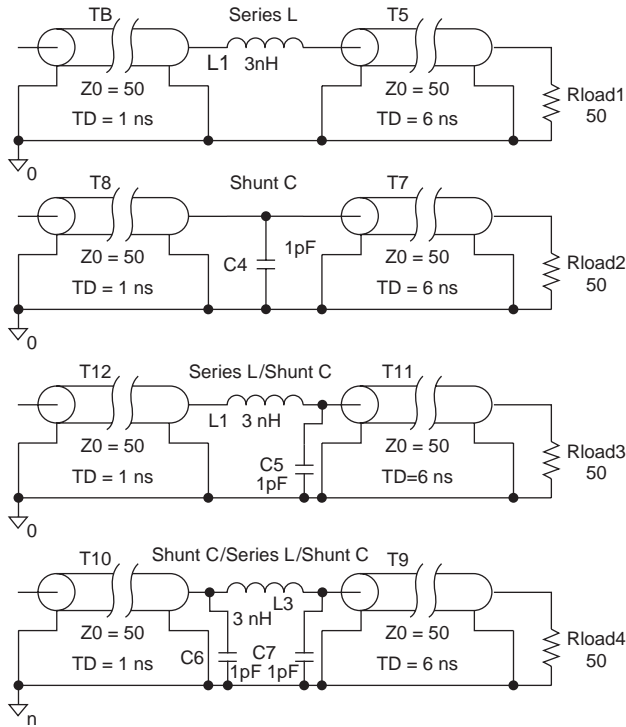

Figure 23. Typical examples of discontinuities represented in terms of lumped components.

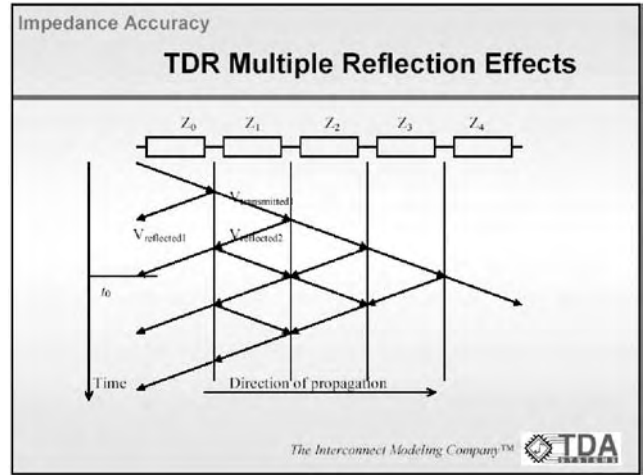

Figure 25. Bounced diagram for a cascade of transmission lines with different impedances (reproduced with permission of TDA Systems).

final reflections by shaping the reflections from the tested load as if faster testing pulses had been applied.

Figure 22 portrays the results from tests involving a hybrid power divider. The interaction between the two transmission-line branches introduces a crosstalk signal at point 2 of the tested board. The first reflection (point 1),

Figure 24. TDR input voltages observed in the circuit with two transmission lines and a reactance circuit inserted between them: (a) inductance between two transmission lines; (b) capacitance connected to the ground between two transmission lines; (c) inductance between two capacitances to the ground connected between two transmission lines. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

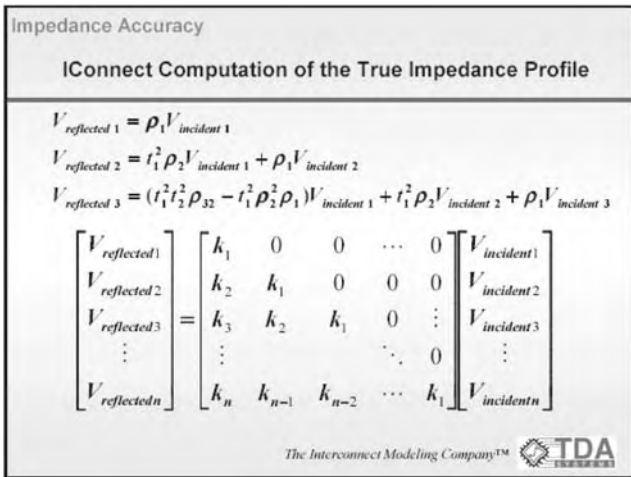

Figure 26. Expressions used to calculate the “true impedance profile” from the “raw impedance profile” using TDR input voltage levels (reproduced with permission of TDA Systems).

with its level below the centerline of the scope screen, suggests that the initial, single section of the transmission line has a characteristic impedance greater than the impedance of the test fixture. The end terminations of the hybrid power divider introduce very small reflections due to lead inductances of the two resistors.

3.2. Application of TDR/TDT to Investigate Signal Integrity of High-Speed Circuits

Recently, increased data rates in communication and computer systems, often reaching subnanosecond switching

speed, have created a need to introduce several gigabit standards and relate to them measurement methods. Conducting traces of the printed circuits, packaging connections, board connectors, and the connection of shorter or longer cables can degrade the *signal integrity* of the systems due to reflections, crosstalk, radiation, and losses in conductors and dielectrics. Application of the TDR/TDT measurement technique, combined with effective computer modeling, can help test the signal integrity of such systems during the initial design of circuit interconnections [16,17]. Figure 23 shows the composition for typical discontinuities connected between two sections of transmission lines, and Fig. 24 presents the corresponding TDR responses, which serve as basic signatures to help identify the types of discontinuities, find their structure, and, finally, determine the values of equivalent components.

In many practical systems, the TDR images are very complex because of the effects of *multiple reflections* caused by many discontinuities within the signal transmission channels. In such cases, hardware measurements can be enhanced by means of a computational method known as the *inverse scattering algorithm*, which was developed by TDA Systems Company [16,17]. To use such a technique, the *raw profile* of impedance is calculated from the input voltage data. Then the incident wave is computed from a reference TDR signal when a well-defined termination such as a short or open circuit is connected instead of the tested lines. The *true impedance profile* is then computed on the basis of the inverse scattering algorithm.

If a signal transmission forms a cascade of short sections of transmission lines of different impedances, the true impedance profile can be calculated from Eq. (2) by

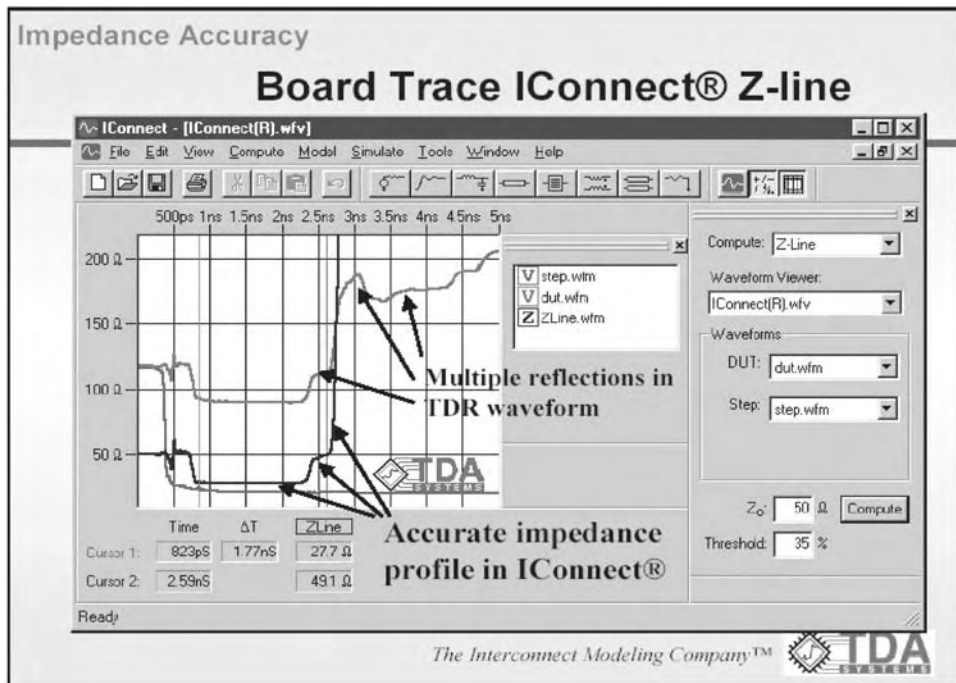

Figure 27. IConnect software application applied to determine the “true impedance profile” from the TDR voltages (reproduced with permission of TDA Systems).

applying it to section junctions. A sequence of bouncing waves is assembled, and from the observed voltage levels, the reflection coefficients are calculated at each junction. Then Eq. (2) can be directly applied to find corresponding line impedances. Such processes are illustrated by means of Figs. 25–27. The reflections can be compared with simulation to increase the accuracy of the final modeling.

4. SUMMARY

This article has described the basic theory behind time-domain reflectometry. In addition, several practical aspects such as reflections and their analysis for resistive and nonresistive loads terminating transmission lines have been demonstrated. Both asymmetric and symmetric transmission-line TDR parameter tests have been also covered. Several practical oscilloscope displays have been included to illustrate normalization processes, which have been additionally reinforced by simulations. Finally, software-enhanced high-speed interconnect modeling was briefly discussed.

REFLECTOR ANTENNAS (PARABOLIC ANTENNAS, DISH ANTENNAS)

MARCO A. B. TERADA
New Mexico State University
Las Cruces, New Mexico

1. INTRODUCTION

Reflector antennas have been of significant importance for decades for several areas of electrical engineering, ranging from telecommunications and radars to deep-space exploration and radio astronomy. This is due to the high-gain characteristic of reflector antennas, typically above 30 dBi over wide frequency bandwidths, as well as its feasibility to accommodate high levels of power. If we extend the concept of a reflector antenna to a reflecting mirror and the human eye viewed as the feed antenna operating in receiving mode, reflector antennas have been known for centuries. Optical astronomers have long been using reflecting mirrors in telescopes in order to enhance the visibility of stars, planets, and other celestial bodies.

The basic principle of operation of a parabolic reflector is that all rays emanating radially from a point source located at the focal point are reflected as a concentrated bundle of parallel rays, which can propagate for very long distances without excessive attenuation. Conversely, incident rays parallel to the axis of symmetry of the paraboloid are all reflected toward its focal point, which concentrates the received signal in a single point. In that case, if the human eye or camera is placed a little bit behind the reflector focal point, an image with enhanced luminosity and definition is formed (see Fig. 1).

However, reflector antennas are wideband devices by nature, not being limited only to operate in frequencies covered by the spectrum of visible light. Radio telescopes, for example, search for celestial radio sources in a wide range of frequencies (e.g., 300 MHz–40 GHz). In this case, the radio sources and corresponding frequencies are

Figure 1. Basic principle of operation of a parabolic reflecting mirror. The paraboloid surface is formed by rotating the parabolic curve with respect to its axis of symmetry (s axis).

marked on charts according to their physical locations in the sky, forming maps similar to the ones elaborated by optical astronomers. Feed antennas are employed to receive the signals from the celestial radio sources at different bandwidths. The Very Large Array (VLA) in New Mexico for example, is an array of 27 shaped 25-m dual reflector antennas widely used in radioastronomy (see Fig. 2). Another example is the Green Bank Radio Telescope, the largest steerable reflector antenna in the world, discussed in certain detail in Section 3.3.

One of the first reflector antennas operating at radio-frequencies was built by Hertz in 1888, and consisted on a sheet of zinc of about 2×1.2 m, molded as a parabolic cylinder and illuminated by a dipole feed [1]. Since then, reflector antenna technology have gradually evolved toward the modern state of art known today for the purpose of improving electrical performance and/or simplifying the mechanical structure (see Fig. 3). The most basic form is the single axisymmetric parabolic reflector shown in Fig. 3a, which is still in widespread use primarily at low frequencies and for low-cost applications. Large reflectors frequently use an axisymmetric dual reflector system with a parabolic main reflector as shown in Fig. 3b. The sub-reflectors are hyperbolic (Cassegrain system) or elliptical (Gregorian system). These systems offer a shorter transmission line (or waveguide) run to the feed antenna and are often used as Earth terminal antennas in satellite communication networks.

Axisymmetric single and dual reflectors suffer from aperture blockage due to the presence of feed/subreflector and supporting mechanical structures in front of the main reflector aperture. This problem is solved by using an offset system with a main reflector that is a section of a paraboloid of revolution, as shown in Figs. 3c and 3d. Design and construction of offset reflectors are more elaborated than their symmetric counterparts.

Remarkable technological advancements were achieved during World War II, as reflectors were widely

Figure 3. The evolution of reflector antenna systems: (a) single axisymmetric reflector; (b) dual axisymmetric reflector; (c) single offset reflector; (d) dual offset reflector. The main reflectors are parabolic.

employed in radar and communication systems [2]. However, it was only with the proliferation of digital computers in the late 1960s that most accurate analysis and synthesis algorithms were developed, especially the ones related to the configurations in Figs. 3c and 3d; see [3–7] for further information. Closed-form analysis algorithms are generally only applied to symmetric reflectors [4,8].

Figure 2. The *Very Large Array* (VLA) in New Mexico is a radiotelescope consisting of 27 shaped 25-m dual-reflector antennas. (Courtesy of the National Radio Astronomy Observatory—NRAO/AUI/NSF).

In addition, substantial improvements on the electrical performance of both axisymmetric and offset dual reflector configurations were obtained with shaping algorithms, an effort possible only with efficient numerical processing combined with a solid knowledge of differential geometry and electromagnetics [5,9,10]. The axisymmetric, dual shaped reflector was introduced in the 1970s [9] and is popular for large Earth station antennas. The offset, dual shaped reflector has a demonstrated aperture efficiency of 84.9% [11] and has been enjoying an increase in popularity. As a consequence, the analysis and design of reflector antennas are now a specialized and unique area in applied electromagnetics, responsible for many distinguished positions in industry and academics.

For the past few decades (as of 2003), reflector antennas have been applied mostly to the areas of satellite communications and wireless networks, deep-space exploration, and electronics defense. Besides specific designs applied to unique purposes, such as radiotelescopes and spacecrafts, reflector antennas are currently also being produced on a very large scale for commercial wireless applications, supporting the globalization process through engineering projects of aggregated values of more than hundreds of billions of dollars. The large international satellite operators, for example, such as Intelsat and Panamsat, allow many developing countries to have proper communication links to the rest of the world. Thus reflector antennas also have an important social impact, connecting people throughout the world, even the ones located in extremely remote areas of Earth, such as Indian tribes, exploration sites, and ships and vessels. In particular, VSAT (very-small-aperture-terminal) systems are proliferating in the world, connecting together branches of large corporations, such as chains of super markets, banks, and car manufacturers. The VSAT market is expected to grow at a rate of 20% per year [12].

Other examples of substantial social and economical impacts are the satellite-based broadband communication systems, such as the Hughes Spaceway and Intelsat Wild Blue in which well-defined multibeam coverage is required, and DTH (direct-to-home) satellite TV systems, such as Dish Network/Echostar and others, which employ small offset parabolic antennas to receive the satellite signals at our homes. As we can see, reflector antennas are present in our lives as major gateways for the exchange of information and also, in a more discrete profile, in defense systems responsible for sustaining our physical integrity and welfare. Reflector antennas can therefore be considered one of the most successful electrical devices of all times, especially due to their significant importance in many modern engineering systems and applications, such as wireless communications, satellite TV, and electronics defense, as well as in the exploration of our galaxy and beyond.

2. THE PARABOLIC REFLECTOR ANTENNA AND OTHER SINGLE-REFLECTOR SYSTEMS

2.1. Preliminary Considerations and Geometry

Single-reflector systems, such as the parabolic reflector antenna, consist of a reflecting surface illuminated by a

feed antenna, usually a horn. It is necessary to know the radiation characteristics of the feed antenna in order to evaluate correctly the electrical performance of the reflector system. A more in-depth discussion is presented in Section 5. In the next few sections we employ simple analytical models to describe the radiation properties of feed antennas. Once the feed pattern is known, the total radiation pattern of the reflector system can be obtained using the techniques described in Section 4, in combination with the geometric properties of the reflector itself, which is the main subject of this and following sections.

The general geometry of a parabolic reflector is shown in Fig. 4, and all associate symbols are listed in Table 1. Note that Fig. 4 is a cross-sectional view of the three-dimensional paraboloid. If a full rotation is performed with $H=0$ with respect to the axis of symmetry (s axis) in Fig. 4, an axisymmetric paraboloid of diameter D_p is formed. The offset reflector is generated from a subsection of the axisymmetric paraboloid. We limit our analytical analysis presented next to axisymmetric and offset parabolic reflectors with a circular projected diameter. However, other projected shapes, such as the elliptical one, are also used in practice with some extension, especially as Earth station antennas in communication links with synchronous satellites. An effort is made to discuss this and other types of reflector antennas.

2.2. Basic Equations

First we consider the axisymmetric parabolic reflector, which is obtained from Fig. 4 for $H=0$ and $\Psi_f=0^\circ$ (i.e., the feed antenna mainbeam peak is aimed at the reflector apex, point A). For this particular case, D_p is the diameter of the projected aperture and the aperture plane is the $x_f y_f$ plane, in which we define polar coordinates (ρ_f, ϕ_f) . Furthermore we associate the spherical coordinates (r_f, θ_f, ϕ_f) to the rectangular system $x_f y_f z_f$ shown in Fig. 4. The parabolic curve can then be expressed in any ϕ_f as

$$r_f = \frac{2F}{1 + \cos \theta_f} = F \sec^2 \frac{\theta_f}{2} \tag{1}$$

Figure 4. Geometry for the axisymmetric ($H=0$) and offset parabolic reflector. See Table 1 for definitions of parameters.

Table 1. Definitions of Symbols for Single Configuration

Symbols	Definitions
D	Diameter of the projected aperture of the parabolic main reflector ($D = D_p$ for an axisymmetric paraboloid)
D_p	Diameter of the projected aperture of the parent paraboloid
H	Offset of reflector center ($H = 0$ for an axisymmetric paraboloid)
F	Paraboloid focal length
Point F	Focal point
Point A	Apex of the parent paraboloid
Point B	Point on main reflector that bisects subtended angle viewed from focal point
Point C	Point on main reflector that projects to the center of the projected aperture
Point P	Point on main reflector corresponding to the ray arising from the peak of the feed pattern
ψ_f	Angle of feed antenna pattern peak relative to reflector axis of symmetry (s); the feed is directed toward point P
ψ_B	Value of ψ_f that bisects the reflector subtended angle (i.e., feed is aimed at point B)
ψ_C	Value of ψ_f when the feed is aimed at the reflector point C corresponding to the aperture center
$(\psi_U - \psi_L)$	Angle subtended by the parabolic main reflector as viewed from the focal point

or

$$F - r_f \cos^2 \frac{\theta_f}{2} = 0 \quad (2)$$

and the projection of r_f onto the aperture plane is

$$\rho_f = r_f \sin \theta_f = 2F \tan \theta_f \quad (3)$$

which yields $\rho_f = 0$ at the reflector apex ($\theta_f = 0^\circ$), and $\rho_f = D_p/2$ at the reflector edge ($\theta_f = \psi_0 = \psi_L = \psi_U$).

The axisymmetric paraboloid is completely specified in terms of its diameter D_p and curvature rate F/D_p . The greater is F/D_p , the flatter is the reflector. Common values are usually between 0.25 and 1.0. At the reflector edge, Eq. (3) becomes $D_p/2 = 2F \tan \psi_0$, which yields

$$\psi_0 = 2 \tan^{-1} \left(\frac{1}{4 \frac{F}{D_p}} \right) \quad (4)$$

The unit vector \hat{n} , normal to the parabolic surface, can be found by normalizing the gradient of Eq. (2) and is given by

$$\hat{n} = -\hat{r}_f \cos \frac{\theta_f}{2} + \hat{\theta}_f \sin \frac{\theta_f}{2} \quad (5)$$

The angle α_i between the surface normal, given by Eq. (5), and an incident ray coming from the focal point can then be calculated from

$$\cos \alpha_i = -\hat{r}_f \cdot \hat{n} = \cos \frac{\theta_f}{2} \quad (6)$$

Finally, the angle α_r between the correspondent reflected ray and surface normal can be determined by enforcing Snell's law on the reflector surface: $\alpha_r = \alpha_i$. Thus

$$\cos \alpha_r = \cos \frac{\theta_f}{2} = \hat{z} \cdot \hat{n} \quad (7)$$

where $\hat{z} = -\hat{r}_f \cos \theta_f + \hat{\theta}_f \sin \theta_f$. Equation (7) shows that *all rays coming from the focal point F are reflected by the parabolic surface as a collimated beam parallel to the z*

axis, which is coincident with the s axis for the axisymmetric reflector. Thus the total pathlength from all rays coming from the focal point F to the aperture plane is given by

$$r_f + r_f \cos \theta_f = r_f(1 + \cos \theta_f) = 2F \quad (8)$$

where Eq. (1) was employed in the derivation. Equation (8) shows that the total pathlength is constant, and we conclude that the phase distribution of a wave coming from a point source located at the focal point of a parabolic reflector will be constant across the aperture plane after reflection. This result yields another very important property of parabolic reflectors, namely, that *a parabolic reflector illuminated by a feed antenna with a unique phase center located at the focal point produces a uniform phase distribution across the aperture plane*. As already seen, the beam is also collimated, forming a section of a plane wave. Nevertheless, the amplitude distribution is not uniform, reaching a maximum at the center of the projected aperture and decreasing toward the edges of the axisymmetric paraboloid.

These basic properties make the parabolic reflector so widely used as reflector antennas. Although herein derived for the axisymmetric paraboloid, they are also valid for the offset case (i.e., $H \neq 0$ in Fig. 4). Offset reflectors offer significantly reduced aperture blockage, as the feed is not directly in front of the reflector, although still located at the focal point F , yielding higher gains when compared to axisymmetric reflectors of similar aperture sizes. From Fig. 4 we see that the feed needs to be tilted by an angle ψ_f in order to direct its pattern toward the offset reflector; otherwise large spillover (i.e., feed radiation missing the reflector) and associated gain loss are introduced. In many systems, the feed pointing angle ψ_f is set equal to the angle that bisects the reflector ψ_B , or to the angle pointed toward the center of the projected aperture ψ_C . The influence of the feed pointing angle ψ_f on the electrical characteristics of offset parabolic reflector antennas is discussed in Section 2.4. The angles shown in Fig. 4 are obtained from the following relations

$$\psi_L = 2 \tan^{-1} \left(\frac{4H - D_p}{4F} \right) \quad (9)$$

$$\psi_U = 2 \tan^{-1} \left[\frac{1}{4 \left(\frac{F}{D_p} \right)} \right] \quad (10)$$

$$\psi_B = \frac{\psi_L + \psi_U}{2} \quad (11)$$

$$\psi_C = 2 \tan^{-1} \left(\frac{H}{2F} \right) \quad (12)$$

with

$$D_p = D + 2H \quad (13)$$

As we see, there are many parameters necessary to specify completely a parabolic reflector antenna. However, before we design reflector systems, it is necessary to study a few of their characteristics and properties. This knowledge is essential for selecting appropriate configurations for specific applications. Long-distance and frequency reuse communication systems, for example, require antennas with high gain and low cross-polarization. Reflector antennas are particularly suitable for such applications due to their high gain. However, an in-depth understanding of their depolarization characteristics is necessary, in order to achieve designs that guarantee a suitable isolation between orthogonally polarized channels in frequency reuse systems. This and other properties that are almost exclusive to reflector antennas are discussed in the next section.

2.3. Cross-Polarization, Beam Squint, and Beam Deviation

2.3.1. Cross-Polarization. Polarization is a basic characteristic of an electromagnetic wave and describes the motion of the electric field vector at a fixed point in space as a function of time. The polarization of an antenna is the polarization of its radiated wave when operating in the transmitting mode. Generally, the polarization of any antenna system can be decomposed into two orthogonal components in the far field, referred to as *copolarization* and *cross-polarization*, respectively. In the particular case of reflector antenna systems, the copolarization is usually taken to be the one presented by the feed antenna employed to illuminate the reflector. As a consequence, the cross-polarization is orthogonal to the feed antenna main polarization. This agrees with Ludwig's third definition of cross-polarization [13] and is the one employed here. *Cross-polarization level* (XPOL) is defined quantitatively as the ratio of the peak in the cross-polarized radiation pattern to the peak value of the copolarized pattern (i.e., the mainbeam peak), usually expressed in decibels.

As mentioned previously, reflector antennas cannot be properly evaluated without first describing the feed antenna. A detailed discussion about modeling feeds is presented in Section 5. Here we employ an analytical model that, despite its simplicity, approximates reasonably well the copolar radiation properties of feeds usually encountered in practice, such as conical corrugated horns. The radiation pattern \vec{E}_f of an idealized balanced feed (i.e., the primary radiation is symmetric in ϕ_f) with a fixed phase

center can be described by [3]

$$\vec{E}_f = \frac{e^{-jkr_f}}{r_f} C(\theta_f) [\hat{\theta}_f \cos \phi_f - \hat{\phi}_f \sin \phi_f] \quad (14)$$

where k is the free-space wavenumber $2\pi/\lambda$ and

$$C(\theta_f) = G_0 10^{(FT/20)(\theta_f/\theta_{f0})^2} \quad (15)$$

where FT is the feed taper in decibels at $\theta_f = \theta_{f0}$ and the gain normalization constant G_0 is found by numerical integration of Eq. (15); see [for further details. We first examine the axisymmetric reflector of Table 2 using a balanced feed as described by Eq. (14), which is purely linearly polarized (LP) along the x axis, with the Gaussian pattern of Eq. (15) yielding a 10 dB beamwidth of 70° ; specifically, $FT = 10$ and $\theta_{f0} = 35^\circ$. A y_f -polarized feed pattern can be obtained from Eq. (14) by replacing the argument ϕ_f with $(\phi_f - \pi/2)$. In addition, a circularly polarized feed is obtained by combining the x_f -polarized pattern in Eq. (14) with a y_f -polarized pattern that is in phase quadrature (i.e., multiplied by a factor of j). The physical optics portion of the commercial code GRASP (general reflector antenna synthesis package) is used to compute the radiation patterns [14][14]. The physical optics formulation applied to the analysis of reflector antennas is discussed in Section 2.4.

For the axisymmetric configuration of Table 2, the computed level of XPOL displayed in Fig. 5 is very low; i.e., maximum of -65.35 dB below the main beam peak of 48.62 dBi. Typically, the feed assembly and supports, although not taken into account by the computer simulations, will create more XPOL than this. Although illustrated for a particular case, this is a general result (9), and we conclude that reflector-induced XPOL in axisymmetric reflectors illuminated by balanced feeds is often negligible. In addition, according to Fig. 5, the XPOL peaks are all located in the 45° planes.

Cross-polarization behavior of offset reflectors is illustrated with a derivative of the 171λ axisymmetric parent reflector of Table 2. The portion of the upper half of the axisymmetric reflector is retained such that the offset reflector of a 85.5λ projected aperture diameter is just fully offset (i.e., the bottom of the reflector just touches its axis of symmetry). If the feed remains pointed at the apex of the parent paraboloid (i.e., $\psi_f = 0^\circ$), negligible XPOL is generated [15]. However, this leads to large spillover and associated gain loss. Therefore, in practice the feed is tilted to direct its pattern toward the reflector, resulting in the introduction of high XPOL.

The offset configuration of Table 2 is not symmetric about the yz plane, and therefore XPOL is not canceled in this plane as in the axisymmetric case. In fact, it is exactly in the yz plane that the peak XPOL levels occur. However, reflector symmetry is still present about the xz plane, and no substantial XPOL occurs in that plane. These results are demonstrated using the GRASP code for the offset reflector example with the XPOL contour plot shown in Fig. 6, for which the feed has a pointing angle of $\psi_f = \psi_B = 39.81^\circ$, computed according to Eq. (11). The feed again has

Table 2. Axisymmetric and Offset Parabolic Reflector Configurations

Property	Axisymmetric	Offset
	<i>Reflector Configuration</i>	
Shape	Parabolic	Parabolic
Projected diameter D , (λ)	171	85.5
Parent reflector diameter D_p , (λ)	171	171
F/D_p	0.3	0.3
Offset of reflector center H , (λ)	0	42.75
	<i>Feed Configuration (On Focus)</i>	
Polarization	Linear (x_r)	Linear (x_r)
Pattern shape	Gaussian; Eqs. (14), (15)	Gaussian; Eqs. (14), (15)
Gain G_b , (dBi)	14.04	14.04
10-dB beamwidth (deg)	70	70
Feed angle ψ_b (deg)	0	39.81

the pattern given by Eqs. (14) and (15), with a 10 dB beamwidth of 70° . The computed peak XPOL is -22.4 dB relative to the copolarized beam maximum of 47.39 dBi. Figure 6 indicates that the copolarized pattern is still symmetric, and the XPOL peaks are located at the copolar -6 dB contour line.

This example is typical of single offset reflectors and shows that single offset paraboloids illuminated by conventional feeds are limited by XPOL performance [9]. It is worth noting that cross-polarization arises as a result of the reflector curvature and the tilting of the feed. A planar reflector for instance does not depolarize an incident field coming in a direction perpendicular to the reflector. Thus we note that XPOL reduces as the reflector curvature rate F/D_p increases. However, this reduction is not significant in offset reflectors because of the substantial feed tilting normally encountered in practice [15]. A XPOL level of about -22 dB is often unacceptably high [3,7]. In Section

3.2 we discuss procedures to reduce XPOL in offset parabolic reflectors. Next we discuss an important property of parabolic reflector antennas, inherently related to cross-polarization.

2.3.2. Beam Squint. As we have seen, offset reflectors offer significantly reduced aperture blockage but introduce high XPOL when illuminated by a LP feed. On the other hand, offset parabolic reflectors fed by a circularly polarized (CP) feed presenting a balanced radiation pattern do not have substantial XPOL. However, beam squint does occur [9,16]; that is, the mainbeam peak squints off of the reflector axis in the plane perpendicular to the plane of symmetry (i.e., beam squint occurs in the yz plane of Fig. 4). The beam squints to opposite sides depending on the sense of CP. Beam squint can be a major problem in satellite and deep-space communications if not carefully

Figure 5. Contour plots in decibels of the computed co- and cross-polarized patterns of the 171λ -diameter axisymmetric parabolic reflector specified in Table 2.

Figure 6. Contour plots in decibels of the computed co- and cross-polarized patterns of the 85.5λ -diameter just fully offset parabolic reflector specified in Table 2.

taken into account. A practical formula for the prediction of the beam squint angle θ_S in offset parabolic reflectors with on-focus CP feeds is [16]

$$\theta_S = \mp \sin^{-1} \left(\frac{\sin \psi_f}{2Fk} \right) \quad (16)$$

where F is the focal distance and k is the free space wave-number $2\pi/\lambda$. A negative θ_S means that the beam is squinted toward the left (left-hand CP feed), and conversely, a positive θ_S indicates a squint to the right (right-hand CP feed). Equation (16) shows that the amount of squinting is inversely proportional to the focal distance F ; that is, longer focal length reflectors experience less beam squint. If the feed is displaced from the focal point, an equation similar to Eq. (16) is derived as in Ref. 17. In offset parabolic configurations illuminated by off-focus CP feeds, beam squint occurs simultaneously with an effect called *beam deviation*, treated in the next section. Because of sense reversal encountered on reflection from the main reflector, the sense of the far-field radiation is opposite that of the feed [18]. For example, a right-hand circularly polarized (RHCP) feed produces a left-hand circularly polarized (LHCP) radiation in the reflector far field, as illustrated next.

We consider as an example a just fully offset configuration with a diameter $D=18.8\lambda$, $F/D_p=0.25$, and $H=9.4\lambda$, illuminated by a CP feed with a pattern of 10 dB beamwidth of 70° . This geometry was selected because it is used in VSAT applications at 18.5 GHz and measured data are available [3,9]. Figure 7 shows copolarized pattern cuts computed by GRASP [14] in the xz plane with opposite sense CP feeds. For the RHCP main-beam case (the feed is LHCP) the squint is to the left as observed in Fig. 7. Conversely, the LHCP mainbeam squints to the right. From Fig. 7 we note that the angle

Figure 7. Computed RHCP and LHCP far-field patterns of a $18.8\text{-}\lambda$ just fully offset parabolic reflector. Note the beam squint effect. The LHCP (ooo) and RHCP (+++) cross-polarized patterns are associated with the RHCP and LHCP beams, respectively.

between the two beams (total beam separation) is 0.700° , which is in agreement with the value of 0.686° from Eq. (16). The reported measured value [3,9] is 0.750° . Finally, Fig. 7 also shows that circular XPOL is low (maximum of 42.71 dB below the gain of 33.88 dBi for any of the feed polarizations). The absence of reflector-induced circular XPOL in offset paraboloids with on-focus feeds is a general result, not limited to just fully offset paraboloids (17).

Although circular XPOL is low, there are a substantial number of LP cross-polarized fields present at any given instant of time, in both the aperture distribution and far-field pattern of the offset reflector [19]. This, in conjunction with the fact that the orthogonal components of the incident field are not in phase, which is the case of circularly polarized feed antenna, are the two necessary and sufficient conditions to generate beam squint [17]. We now present a brief explanation of the beam squint generation mechanism.

The electric field components on the left side of the reflector ($y > 0$ in Fig. 4) always lead or lag in phase relative to the ones on the right side, depending on whether the primary field is LHCP or RHCP [19]. This leads to a phase slope condition across the aperture, which squints the mainbeam to the left (negative angles in Fig. 7) or to the right (positive angles in Fig. 7). In order to illustrate the process, consider any two points in the projected aperture of the offset paraboloid that are equidistant from the reflector plane of symmetry. If the feed is LHCP, the electric field at those points rotates counterclockwise (RHCP mainbeam), as shown by Fig. 8. Thus, the electric field vector to the left is leading the one to the right, and as a final result (considering the influence of all points), the beam squints to the right (the view in Fig. 8). This is equivalent to a negative θ_S in Eq. (16), or to a squint to the left in the yz plane of the reflector coordinate system (negative angles in Fig. 7).

2.3.3. Beam Deviation. When a feed is laterally displaced from the focal point of a reflector, either axisymmetric or offset, the pattern mainbeam is scanned to the opposite side of the reflector axis. This is referred to as *beam deviation*, and arises from a tipping of the aperture field phase plane relative to the reflector aperture plane.

Figure 8. Beam squint generation mechanism.

The mainbeam direction determined on the basis of these considerations is herein referred to as the *reference axis*, which is tilted from the reflector axis (i.e., the z axis in Fig. 4) according to the amount of feed displacement. Note that for an axisymmetric configuration, the reflector and reference axes intersect at the apex of the parent paraboloid (point A in Fig. 4). If a CP feed is displaced from the focal point of an axisymmetric or offset paraboloid, both beam squint and deviation are present at the same time. Thus the amount of beam squint should be added to the reference axis in order to determine accurately the final position of the mainbeam.

For a feed displacement δ_f along the positive y_f direction as shown in Fig. 4, the reference axis is tilted in the direction opposite that of the reflector axis by an angle θ_D , computed according to

$$\theta_D = [\text{BDF}] \tan^{-1} \left(\frac{\delta_f}{F} \right) \quad (17)$$

where [BDF] is the beam deviation factor, which can be approximately determined for small feed displacements δ_f , in axisymmetric and offset paraboloids, by [3,20]

$$[\text{BDF}] = \frac{1 + 0.36 \left[4 \frac{F}{(D_p - 2H)} \right]^{-2}}{1 + \left[4 \frac{F}{(D_p - 2H)} \right]^{-2}} \quad (18)$$

The nonuniform aperture phase distribution introduced by the feed displacement is responsible for the beam deviation, as already commented, but also lead to pattern deterioration, which include beam broadening and null filling. These effects increase as δ_f becomes larger, resulting in substantial gain loss. Nevertheless, scanning of the beam by feed displacement is a technique widely used in practice, especially when it is difficult or impossible to move the reflector itself.

2.3.4. Summary of Main Results. There are a large number of possible reflector geometries, feed types, locations, and polarizations. Representative configurations were examined in the previous sections to provide specific values as well as general conclusions. The many possible configurations employing a parabolic reflector are summarized in Table 3 together with XPOL, beam squint, and beam deviation effects. Table 3 shows that unbalanced feeds (i.e., the primary radiation pattern is not symmetric) usually generate substantial XPOL independent of the feed polarization or reflector configuration. Beam squint normally occurs with circularly polarized feeds, except for small reflector antennas (i.e., $D < 12\lambda$ and $F/D_p < 0.25$), where it can also be present with a linearly polarized illumination [21]. Also, displacing the feed from the focal point normally generates XPOL and beam deviation. Table 3 presents a complete overview of the various depolarization and beam-pointing properties of single-parabolic-reflector antennas, which is of fundamental importance for designing effective reflector configurations.

2.4. Design and Manufacturing of Axisymmetric and Offset Parabolic Reflector Antennas

Design of reflector antennas presents a challenge to the antenna engineer, especially since so many parameters are available for adjustment. The main purpose of this section is to present a complete procedure to design axisymmetric and offset reflectors, as well as provide some insights on the basic tradeoffs inherent to the process.

Within this context, we start by examining the influence of feed-pointing angle, ψ_f , on gain (G), sidelobe level (SLL), and cross-polarization (XPOL) of offset reflectors having $H > D/2$ (i.e., general offset reflectors). Feed-pointing angle is a parameter of significant influence on the electrical behavior of reflector antennas, providing many insights on XPOL behavior. Scattering from supporting structure (struts) is not included, but for an offset configuration it is typically negligible. An offset reflector is

Table 3. Polarization and Beam-Pointing Characteristics of Single Parabolic Reflectors

Reflector Geometry	Location	Feed Type	Polarization	Cross-Polarization	Beam Squint
Axisymmetric	Onfocus	Balanced	Linear	No	No

			Circular	Yes	Yes

^aBeam deviation also occurs; see Section 2.3.3.

^bExcept for small reflector antennas (i.e., $D < 12\lambda$ and $F/D_p < 0.25$); see Ref. 21 for further details.

chosen with a diameter $D = 85.5\lambda$, $F/D_p = 0.3$, and offset distance $H = 5D/8$, corresponding to a geometry that is popular in VSAT applications. The balanced feed pattern employed to illuminate the reflector is x_f -polarized, as modeled by Eqs. (14) and (15), with a 10 dB beamwidth of 70° .

Figure 9 shows G , SLL, and XPOL computed by GRASP [14] as the feed pointing angle, ψ_f , is varied for the selected configuration. We note from Fig. 9 that the gain curve has a broad peak, and the sidelobe level is not sensitive to feed pointing, except at very small angles ($\psi_f < 30^\circ$). Only the near-in sidelobes were considered in this analysis, and therefore spillover from the feed, which is particularly high for $\psi_f < 40^\circ$ and $\psi_f > 60^\circ$, was not included in Fig. 9. XPOL, however, decreases with decreasing ψ_f . Although illustrated for a particular case example, this is a generic and important result, showing that *in the limiting case where the feed is pointed at the apex of the parent paraboloid* (i.e., $\psi_f = 0^\circ$), *negligible XPOL is generated* [15]. However, this leads to large spillover and associated gain loss. Therefore, in practice the feed is tilted to direct its pattern toward the reflector, which introduces high cross-polarization. For approximate designs, as is often sufficient in practice, the feed can be aimed within the range $40^\circ \leq \psi_f \leq 60^\circ$ in order to keep spillover losses (and consequent gain loss) reasonable. For the particular configuration herein considered, peak gain operation is achieved with $\psi_f = 47^\circ$, which yields $G = 47.52$ dBi.

A classical design scenario has now emerged. The feed-pointing angle ψ_f is reduced until desirable cross-polarization performance is achieved or until gain is reduced as far as can be accepted. If, on the other hand, SLL is a critical parameter, then ψ_f can be optimized to yield nearly the lowest SLL over a practical range of angles, with only small reductions in G and XPOL [15]. This is discussed in more detail in the procedure for designing parabolic antennas, presented next.

Figure 9. Gain G , sidelobe level (SLL), and cross-polarization level (XPOL) as a function of the feed-pointing angle ψ_f for an offset parabolic reflector with a 85.5λ diameter.

After the considerations discussed previously, we now have a reasonable understanding of the basic concepts of reflector antennas. The following steps are similar to those outlined in [22] and summarize a procedure to design axisymmetric ($H = 0$) and offset reflector antennas.

1. *Determination of Reflector Diameter.* The following equation is very useful to estimate a value of D to achieve a required gain G [20]

$$g_{[\text{not in dB}]} = \epsilon_{\text{ap}} \frac{4\pi A_p}{\lambda^2} = \epsilon_{\text{ap}} \left(\frac{\pi D}{\lambda} \right)^2 \quad (19)$$

where A_p is the physical area of the antenna aperture and ϵ_{ap} is the *aperture efficiency*, typically 0.65 (65%) for many parabolic reflector systems used in practice. Note that $G = 10 \log g$ [dB].

2. *Determination of Offset Distance.* The offset distance H controls the amount of blockage caused by the feed and supporting structure on the reflector projected aperture. Many reflectors nowadays are just fully offset paraboloids ($H = D/2$); that is, the bottom of the reflector just touches its axis of symmetry. This configuration avoids the blockage from the feed supporting structure (struts) and waveguide, although part of the feed aperture is still directly in front of the reflector. Nevertheless, the total blockage area is still significantly smaller than the one presented by axisymmetric configurations ($H = 0$). Values of H larger than $D/2$ can overcome blockage but also increase the total volume occupied by the reflector, which in some cases is not recommended. In addition, the manufacturing process and associated adjustments become more difficult as H increases.
3. *Selection of Reflector Curvature.* Values usually encountered in practice for the reflector curvature, F/D_p , are between 0.25 and 1.0, where D_p is given by Eq. (13). Higher values ease the manufacturing process (i.e., the reflector is flatter), but require a narrower feed pattern to illuminate the reflector, which results in larger feed antennas. A typical value nowadays is $(F/D_p) = 0.3$ which yields a compact design.
4. *Determination of Feed Pattern.* An important parameter for determining the necessary feed pattern is the *reflector illumination* RI, which in dB is given by

$$\text{RI} = 20 \log \left[\cos^2 \left(\frac{\theta_f + \psi_f}{2} \right) \right] + 20 \log(\cos^q \theta_f) \quad (20)$$

where the first term on the right-side is normally referred to as *spherical spreading loss*, and accounts for the power spreading due to spherical propagation of the wave between the focal point and the parabolic reflector surface. The second term in the right side of Eq. (20) is the normalized feed pattern in decibels of

$$C(\theta_f) = \cos^q \theta_f \quad (21)$$

which is a pattern model widely used in practice with Eq. (14), as an alternate to the one given by

Eq. (15). The main advantage of Eq. (21) over Eq. (15) is that the directivity of the feed, or its gain if ohmic losses are not taken into account, can be found analytically in closed form with [4]

$$g_{f[\text{not in dB}]} = 4q + 2 \quad (22)$$

where g_f is the gain of the balanced feed modeled by Eqs. (14) and (21). The parameter q can be obtained from Eq. (20) for a required reflector illumination (RI) in decibels at a direction θ_f as

$$q = \frac{\frac{\text{RI}}{20} - \log \left[\cos^2 \left(\frac{\theta_f + \psi_f}{2} \right) \right]}{\log(\cos \theta_f)} \quad (23)$$

An usual value for RI at the reflector edges, often referred to as *edge illumination* (EI), is -11 dB and assures optimal gain performance for axisymmetric paraboloids ($\psi_f = 0^\circ$ and $\theta_f = \psi_L = \psi_U$) [20].

In offset reflectors, $\psi_L \neq \psi_U$, but a specified value of EI at both edges can still be obtained by solving for ψ_f the equation formed by imposing that $q(\theta_f + \psi_f = \psi_L) = q(\theta_f + \psi_f = \psi_U)$, which yields $q(\theta_f = \psi_L - \psi_f) = q(\theta_f = \psi_U - \psi_f)$. Once ψ_f is determined, the parameter q can be calculated directly from Eq. (23) for the specified value of RI (i.e., EI), at either $\theta_f + \psi_f = \psi_L$ or $\theta_f + \psi_f = \psi_U$, since they now should yield the same result. Under this condition, the edge illumination is called *balanced*, and yields near-minimum side-lobe levels over practical ranges of feed pointing, with only small penalties in gain and cross-polarization [15]. A graphical technique to determine ψ_f for the same condition was introduced in [15], and is especially indicated when only measured feed patterns are available.

In practice, however, it is common to find offset systems employing $\psi_f = \psi_B$, Eq. (11), or $\psi_f = \psi_C$, Eq. (12). For either case the edge illumination is in general unbalanced. As a consequence, different values of q are obtained with Eq. (23), depending whether $\theta_f + \psi_f = \psi_L$ or $\theta_f + \psi_f = \psi_U$. A simple arithmetic mean can then be taken to specify the required feed pattern. Although approximate, this simple procedure yields reasonably good results in practice and is well suited for our purposes.

Once the parameter q is determined, Eqs. (22) and (19) can be used to estimate the aperture diameter, or area, of the required feed antenna. A typical value of $\epsilon_{\text{ap}} = 0.55$ (55%) can be used for feed horns. A more exact approach is available when the feed antenna is an open-ended rectangular waveguide of wide and narrow dimensions a and b , or an open-ended circular waveguide of radius a . For those cases, the waveguide dimensions can be determined from Eq. (22) respectively with $g_f = 32ab/\pi\lambda^2$ ($\epsilon_{\text{ap}} \approx 0.81$) or $g_f = 10.5\pi a^2/\lambda^2$ ($\epsilon_{\text{ap}} \approx 0.84$). If the result indicates a feed antenna with an aperture considered too large, a higher value of RI (i.e., EI at the reflector edges) should be employed to avoid unnecessary blockage. For an offset reflector, a larger value of H can also be tried and the whole procedure needs to be repeated.

Figure 10. Just fully offset parabolic reflector antenna built and tested for satellite TV reception at C band. (Courtesy of Carlos Muller, Univ. Brasilia.)

The aforementioned design procedure was successfully employed to obtain the preliminary design of a 1.6 m just fully offset paraboloid, built and tested for satellite TV reception at the C band (see Fig. 10). Nevertheless, the use of a suitable computer code before the manufacturing process is highly recommended to confirm the electrical performance of the reflector system. Techniques often implemented in numerical codes for the analysis of reflector antennas are discussed in Section 4.

As a final note, we mention that surface distortions from ideal parabolic shapes are normally introduced in any manufacturing process. Random reflector surface errors can be accounted for by modifying Eq. (19), such as to include a *random surface error efficiency*, ϵ_{rs} [20]:

$$g_{[\text{not in dB}]} = \epsilon_{\text{ap}} \epsilon_{\text{rs}} \left(\frac{\pi D}{\lambda} \right)^2 \quad (24)$$

where the total aperture efficiency became the product ($\epsilon_{\text{ap}} \epsilon_{\text{rs}}$):

$$\epsilon_{\text{rs}} = e^{-(2\beta\delta_s)^2} \quad (25)$$

The parameter δ_s is the root-mean-square (RMS) surface deviation and is approximately one-third of the peak-to-peak error [20]. Detailed information on other efficiency factors left in ϵ_{ap} can be found in the literature [20]. Mass production of reflectors using presses and molds to shape glass fibers and other components normally yield $\delta_s \approx 0.01\lambda$ ($\epsilon_{\text{rs}} = 0.98$ or 98%). Errors larger than that can cause significant gain loss and pattern deterioration due to the introduction of phase errors. Machined metal reflectors are very accurate and have $\delta_s \approx 0.04\text{--}0.5$ mm for a very large band of operating frequencies (from Ku band

down to S band). In fact, reflector antennas are wideband devices by nature, limited at the upper frequencies by the smoothness of the reflector surface and at the lower ones by the reflector electrical size. The operating bandwidth of a reflector antenna in practice is normally set by the bandwidth of the feed antenna employed to illuminate the reflector. Reflector antennas are normally fabricated from aluminum, graphite or carbon-fiber-reinforced plastic (CFRP) and glass fibers or glass-fiber-reinforced plastic (GFRP). Although herein illustrated for parabolic reflectors, random surface errors occur in any type of reflector antenna, such as the ones discussed next.

2.5. Other Single-Reflector Systems

A few other types of parabolic reflectors can also be obtained from Fig. 4, including offset configurations. The *parabolic cylinder*, for example, is generated by displacing the parabolic curve along the y -axis. This yields a focal line in contrast to the focal point of the parabolic reflector. A feedline or a linear array of feed antennas must be placed along the focal line for proper illumination of the reflector. Another example is the *parabolic torus*, formed by rotating the parabolic curve with respect to an axis perpendicular to the s axis of Fig. 4. The axis of revolution is in general placed at a distance from the apex greater than F and is confined to the plane shown by Fig. 4. Thus the parabolic torus possess a focal arc and can be visualized as a curved parabolic cylinder. Multiple feeds are normally employed to illuminate different sections of the reflector, producing independent beams with a single reflector antenna, a configuration widely used in satellite communications.

An example of a reflector antenna not generated by a parabolic curve is the spherical reflector, which is a section of a sphere. The Arecibo Observatory, located in Puerto Rico, employs an axisymmetric spherical main reflector with a diameter of 305 m for radio astronomy, ionospheric research and radar investigation of celestial bodies. A line feed is used because parallel rays coming from space are reflected along the reflector axis [23]. This is in contrast to the parabolic cylinder where the focal line is perpendicular to the reflector axis of symmetry. However, the spherical reflector possesses not only a focal line but also a focal region where feeds can be placed [24]. Dual offset shaped reflectors have also been proposed as feed systems, in order to correct the nonuniform phase distribution characteristic of spherical reflectors [23]. Dual- and multiple-reflector systems are treated in the next section.

3. MULTIPLE-REFLECTOR ANTENNA SYSTEMS

3.1. Cassegrain, Gregorian, and Multiple-Reflector Systems

Dual-reflector systems, such as the ones in Figs. 2b and 2d, can be formed by adding to the parabolic reflectors previously studied, a hyperbolic reflector (Cassegrain system) or an elliptical reflector (Gregorian system). Hyperbolic and elliptical reflectors have two focal points, F_1 and F_2 , and are normally referred to as *subreflectors* because of

their smaller size when compared to the parabolic main reflector.

It is known [3,25] that any ray coming from one of the focal points, say, F_2 , is reflected by an ellipsoid surface towards the other focal point, F_1 . For the hyperbolic surface, the reflection occurs such that the reflected ray appears to come from F_1 . Thus, any circular cone of rays (i.e., a section of a spherical wave) emanating from F_2 and directed to an elliptical, or hyperbolic, subreflector will then be reflected as another circular cone of rays with vertex at the other focal point F_1 . Furthermore, if F_1 is coincident with the paraboloid focal point F , and the feed is located at F_2 , a perfect circular cone of rays originated at F_1 will illuminate the paraboloid. Because of the parabola reflecting property, a section of a plane wave will then appear at the paraboloid aperture plane.

There are a few basic advantages of dual configurations over single ones; for instance, they provide a shorter waveguide run to the feed antenna. In addition, dual configurations present lower noise when used as satellite–Earth terminals. This is due to the limited noise introduced by the feed spillover beyond the subreflector, given that it is now directed to cold sky rather than hot earth (ground) as in the single-reflector case. Many satellite communication networks employ dual configurations as Earth terminal antennas. Finally, the inclusion of the subreflector introduces another degree of freedom, which can be used to enhance electrical performance, such as by canceling XPOL in offset systems, and/or prescribing the main aperture amplitude and phase distributions in dual shaped reflectors.

Within this context, dual shaped reflectors can be used to illuminate larger reflectors, such as the Arecibo (Puerto Rico) spherical reflector [23], forming a multiple-reflector system. In this case, they are shaped to correct the phase aberration characteristic of spherical reflectors. They can also be used to enhance the scanning properties of spherical reflectors [26].

A multiple-reflector system can also be formed with a parabolic main reflector, which is illuminated by a sequence of hyperboloids and/or ellipsoids employed as subreflectors. The subreflectors must be properly arranged such that a spherical wave is formed after each reflection. It can be shown [27] that such a multiple-reflector system is always equivalent to a single parabolic reflector, normally referred to as the *equivalent paraboloid*. This concept also applies to Cassegrain and Gregorian systems [25,27], and is especially useful to determine the conditions for canceling XPOL in offset systems, as discussed next.

3.2. Conditions for Minimizing Cross-Polarization in Offset Cassegrain and Gregorian Systems

The Cassegrain and Gregorian offset configurations of Fig. 3d can be optimized to cancel reflector-induced XPOL. We focus our discussion on the Gregorian system, but all main results presented here are also valid for the Cassegrain system [3,24,25]. Although less compact, the Gregorian configuration has been increasingly used in practical applications, especially as it allows the main reflector to have a

just fully offset geometry (i.e., the bottom of the main reflector just touches its axis of symmetry). Cost-effective designs often require that an existing single offset reflector mold be used to construct the main reflector of a dual configuration. However, many such existing molds in industry are for just fully offset geometries, which justifies the recent preference for Gregorian configurations. In order to upgrade an existing mold to a dual offset Cassegrain system, a main reflector other than just fully offset is required to avoid blockage. This is due to the fact that the hyperbolic subreflector, in contrast to the elliptical one, is located above the axis of symmetry of the parent main reflector, as shown by Fig. 3d. In addition, the Gregorian configuration allows the main reflector to be used also as a single-focused configuration without the need of removing the subreflector; see Section 3.3 for further details. Nevertheless, Cassegrain configurations have also been widely used in many practical systems, and all conditions for minimizing XPOL herein discussed also apply to them.

The general geometry of a dual offset Gregorian configuration is shown in Fig. 11, and the symbols are defined in Table 4. Although not shown in Fig. 11, the main reflector projected aperture is circular, such as the one in Fig. 4. The subreflector employed in a Gregorian offset design is a section of a parent ellipsoid described by the expression

$$\frac{(x_S - c)^2}{(f_S + c)^2} + \frac{y_S^2 + z_S^2}{(f_S + c)^2 - c^2} = 1 \quad (26)$$

where all variables and coordinates are as defined in Fig. 11 and Table 4. It is worth mentioning that the projections of the subreflector onto the $y_S z_S$ and $x_S y_S$ planes are ellipses.

As mentioned above, the geometry of Fig. 11 is equivalent to a single parabolic system. Furthermore, we saw previously that if the feed-pointing angle, ψ_f , is coincident with the reflector axis of symmetry, no substantial XPOL is generated. This condition can be satisfied for the equivalent single paraboloid, provided the original dual configuration of Fig. 11 satisfies the following relation [28]

$$\tan \alpha = \frac{|e^2 - 1| \sin \beta}{(1 + e^2) \cos \beta - 2e} \quad (27)$$

where e is the subreflector eccentricity ($0 < e < 1$ for an ellipsoid and $e > 1$ for a hyperboloid), $e = c/(f_S + c)$. Equation (27) is generally referred to as *Mizugutch condition* and has the following alternate form known as *Dragone condition* [25,27]

$$\tan \frac{\alpha}{2} = \frac{e + 1}{|e - 1|} \tan \frac{\beta}{2} \quad (28)$$

where the term $(e + 1)/(|e - 1|)$ is normally referred to as the *subreflector magnification*, M . Rusch et al. [25] gave a condition based on the same equivalent paraboloid concept that simultaneously minimize XPOL and spillover loss (i.e., feed radiation missing the subreflector)

$$\tan \frac{\beta}{2} = \left(\frac{e - 1}{e + 1} \right)^2 \tan \left(\frac{\beta + \psi_c}{2} \right) \quad (29)$$

where ψ_c is the angle subtended to the center of the main reflector and is given by Eq. (12). The Rusch condition, Eq. (29), can be applied only to dual systems employing a parabolic main reflector with a circular projected aperture, in contrast to Mizugutch or Dragone conditions,

Figure 11. General geometry of the dual offset Gregorian reflector antenna. The symbols are defined in Table 4.

Table 4. Definitions of Symbols for Dual Configuration

Symbols	Definitions
D	Diameter of the projected aperture of the parabolic main reflector
D_p	Diameter of the projected aperture of the parent paraboloid
H	Offset of reflector center
F	Paraboloid focal length
Point F_1	Common focal point of the parabolic main reflector and ellipsoidal subreflector
Point F_2	Ellipsoid focal point; feed antenna location
Point A	Apex of the parent paraboloid
Point A_S	Apex of the ellipsoidal subreflector
Point B	Point on subreflector which bisects subtended angle viewed from F_2 ; point B also results from the intersection of the ray coming from point C on the main reflector and the feed axis (z_f)
Point C	Point on main reflector that projects to the center of the circular projected aperture
ψ_C	Angle of feed antenna pattern peak after reflecting on the subreflector relative to the main reflector axis of symmetry (s)
$(\psi_U - \psi_L)$	Angle subtended by the parabolic main reflector as viewed from the focal point F_1
D_S	Height of the ellipsoidal subreflector
e	Subreflector eccentricity ($0 < e < 1$ for an ellipsoid)
c	Half of the ellipsoid interfocal distance
f_S	Distance between a focal point and the closest ellipsoid apex
α	Feed pointing angle measured relative to the ellipsoid axis of symmetry (x_S)
β	Angle between the ellipsoid and parent paraboloid axes of symmetry (x_S and s , respectively)
γ	Angle between the main reflector and feed axes (s and z_f)
θ_E	Half of the angle subtended by the subreflector as viewed from the feed antenna location (ellipsoid focal point F_2)

Eqs. (27) and (28), which can be applied to reduce XPOL of systems with arbitrary projected apertures. Although more restrictive, the Rusch condition, in addition to XPOL, also minimizes spillover loss, given that the resulting equivalent paraboloid is constrained to be always axisymmetric [25]. This yields the feed axis of the original dual configuration pointing in the direction that bisects the subreflector subtended angle, as shown in Fig. 11. Enforcement of Mizugutch or Dragone conditions in general does not result in an axisymmetric equivalent paraboloid, which may lead to high spillover loss even though XPOL is kept to a minimum. In fact, the result in the Rusch condition, Eq. (29), can be visualized as the one particular solution of Eq. (27) or (28) that yields an axisymmetric equivalent paraboloid with $\psi_f = 0^\circ$, thus simultaneously minimizing XPOL and spillover loss.

It is important to note that Eqs. (27)–(29) are effective to reduce only the reflector-induced XPOL. A simple worst case model for predicting the influence of feed XPOL in reflector systems is [7]

$$\text{XPOL}_S = \text{XPOL}_F + \text{XPOL}_R \quad (30)$$

where XPOL_S , XPOL_F , and XPOL_R are respectively the cross polarization levels of the total system, the feed, and the reflector(s). XPOL here is expressed as a field ratio (not in decibels, using the $10^{\text{value in dB}/20}$ transformation). The simple result in Eq. (30) shows that either the feed or the reflector XPOL can dominate the system XPOL. Since dual offset configurations satisfying any of the conditions in Eqs. (27)–(29) yield low reflector XPOL, system XPOL is usually limited by feed XPOL. We use, as an example, a low cross-polarized dual offset Gregorian reflector antenna, employing a just fully parabolic main reflector with a 2.4-m diameter. When a feed XPOL value of -32 dB is

included, the system XPOL computed by GRASP [14] increases from -48.19 to -31.75 dB. Equation (30) yields -30.75 dB, which is in good agreement for such a simple formula. In addition, Eq. (30) can also be used to predict a feed XPOL level required to attend a given specification of system XPOL.

A clever way to minimize feed XPOL in synchronous satellite reflector systems is by using a *dual-gridded* reflector [29], normally made of carbon-fiber-reinforced plastic (CFRP). In this configuration, the parabolic reflector consists of two almost completely superimposed shells, such that the respective focal points fall in different locations to be fed by different feed antennas. Each shell reflects only one type of linear polarization. In a single *dual-gridded* configuration, the phase center of each one of the feeds is placed at the focal point of the parabolic shell that reflects the corresponding feed polarization. Thus the XPOL of the feed generating one type of polarization will be reflected only by the shell with a different focal point. This causes the XPOL beam to scan off boresight, as seen in Section 2.3.3. With the proper choice of orientations for the two shells, the XPOL beams generated by both feeds are steered off Earth coverage while the COPOL beams are kept at the desired locations.

As an illustration of using the minimum XPOL conditions expressed in Eqs. (27)–(29), we consider the offset parabolic system discussed next.

3.3. The Green Bank Radio Telescope

The Green Bank (Radio) Telescope (GBT) is the largest fully steerable radio telescope in the world (see Fig. 12). Its offset design provides a clear 100-m-diameter projected aperture. The GBT structure can be pointed to view the

Figure 12. The Green Bank Radio Telescope reflector antenna. The 100-m main reflector consists of 2000 solid panels. The structure can be pointed to view the entire sky down to a 5° elevation angle, and is the largest fully steerable radio telescope in the world. (Courtesy of the National Radio Astronomy Observatory—NRAO/AUI/NSF.)

entire sky down to a 5° elevation angle using a wheel-and-track mechanical design. The reflecting surface consists of 2000 solid panels that can be positioned using actuators behind the panels. A laser-ranging system is used to determine the positions of the panels, adjusting surface accuracy with closed-loop control.

The GBT is connected to radiometers that can receive signals in several frequency bands. From 290 to 1230 MHz, the GBT operates as a single offset reflector using a feed assembly aimed directly at the main reflector. From 1 to 45 GHz, it operates as a Gregorian dual offset reflector using the feeds in the receiver room that are aimed at the ellipsoidal subreflector. The Gregorian con-

figuration has the focal points in the area between the subreflector and the main reflector, allowing the subreflector to remain fixed even when the telescope operates in the single offset reflector mode. This is not possible with a Cassegrain configuration [30].

We start by examining the GBT single offset configuration, with the characteristics listed in Table 5, employing the codes GRASP [14] and PRAC [7]. Further information on the parabolic reflector analysis code (PRAC) are presented in Section 4.2. The performance values, also listed in Table 5, were computed at 15 GHz in the plane normal to the plane of symmetry (i.e., the yz plane of Fig. 4). Note that both codes yield very similar results for this

Table 5. GBT Single-Offset-Reflector Configuration and Computed Performance Values

a. Main Reflector Configuration		
Shape	Offset paraboloid	
Projected diameter D	100 m	
Parent reference Diameter D_p	208 m	
Focal length F	60 m	
Offset of reflector center H	54 m	
b. Feed Configuration (On Focus)		
Computation	PRAC	GRASP
Polarization	Linear (x_f) cosine ^{4,58} ; Eqs. (14), (21)	Linear (x_f)
Pattern shape		Gaussian; Eqs. (14), (15)
Gain G_f (dBi)	13.08	13.14
10-dB beamwidth, degrees (deg)	77.92	77.92
Feed angle (ψ_f), degrees (deg)	42.77	42.77
System performance gain G (dBi)	82.87	82.79
Cross-polarization level (XPOL) (dB)	-21.54	-21.56
Sidelobe level (SLL) (dB)	-26.72	-27.21
Aperture efficiency ϵ_{ap} (%)	78.48	77.05

Table 6. GBT Dual Offset Reflector Configuration and Computed Performance Values

a. Reflector Configuration Values		
Main Reflector Configuration	Subreflector Configuration	
Shape: offset paraboloid	Shape: offset ellipsoid	
Projected diameter D , 100 m	Projected height D_S , 7.55 m	
Parent reference diameter D_p , 208 m	Parameter c of ellipse, 5.9855 m	
Focal length F , 60 m	Parameter f_S of ellipse, 5.3542 m	
Offset of reflector center H , 54 m	Eccentricity e 0.5278	
Angle (β), 5.58°	Angle (β), 5.58°	
b. Computed Performance Values		
Feed Configuration (On Focus)	GRASP	System Performance (GRASP)
Polarization	Linear (x_f)	Gain G 82.83 dBi
Pattern shape	Gaussian; Eqs. (14), (15)	Cross-polarization level (XPOL) -43.01 dB
Gain G_f	21.31 dBi	Sidelobe level (SLL) -22.56 dB
10-dB beamwidth	30°	Aperture efficiency ϵ_{ap} 77.76%
Angle (α)	17.91°	
Angle (γ)	12.33°	

geometry. We note from Table 5 that gain is 82.87 dBi and XPOL is -21.54 dB (61.33 dBi), as computed by PRAC.

In order to lower XPOL, we upgrade the GBT single offset system of Table 5 to a low cross-polarized dual offset Gregorian antenna according to Eq. (29). Design parameters, such as the desired subreflector size, were obtained from [1]. The resulting configuration is listed in Table 6 and agrees with [30]. New dual configurations employing the same GBT offset main reflector of Table 5 can be obtained using different design parameters, such as a new subreflector size or feed configuration, as discussed in [31].

Table 6 also presents the performance values at 15 GHz computed with GRASP in the same plane considered for the single offset configuration discussed previously. We note that XPOL is now -43.01 dB, more than 20 dB lower than the XPOL of the single configuration in Table 5. However, a feed antenna with high XPOL will likely degrade the total system XPOL performance, as addressed in the previous section.

4. ANALYSIS METHODS AND EVALUATION

4.1. Geometric and Physical Optics Formulations

In both geometric optics (GO) and physical optics (PO) formulations, the ultimate goal is to determine equivalent currents that can then be integrated to obtain the far-field patterns, a process well described in the literature on aperture antennas [20]. Here we focus on the assumptions and approximations inherent to each of these formulations, as well as on their intrinsic differences.

The GO technique yields the aperture fields assuming that Snell's law is satisfied on reflection. The far-field patterns can then be calculated using a Fourier transform directly, which is equivalent to obtaining equivalent currents and then integrating as described later in this section. With the use of image theory, it is necessary to know only the electric field distribution over the reflector pro-

jected aperture \mathbf{E}_r , which is computed from the incident electric field \mathbf{E}_i (i.e., the feed radiation), with [20]

$$\mathbf{E}_r = 2(\hat{n} \cdot \mathbf{E}_i)\hat{n} - \mathbf{E}_i \quad (31)$$

where \hat{n} is the unit vector normal to the surface; see Eq. (5). Equation (31) assumes that at the point of reflection the reflector is planar and perfectly conducting. In addition, the incident wave from the feed antenna is treated locally as a plane wave. These same assumptions are also used by the PO technique to determine the surface currents, \mathbf{J}_s , over the reflector as follows

$$\mathbf{J}_s = 2\hat{n} \times \mathbf{H}_i \quad (32)$$

where \mathbf{H}_i is the incident magnetic field from the feed antenna, and can be computed from Eq. (14), recalling that in the far-field $\mathbf{H} = (\hat{r} \times \mathbf{E})/\eta$ (where η is the free-space characteristic impedance). The PO approximation assumes that currents exist only over the side of the reflector directly illuminated by the feed antenna.

The far-field pattern can then be determined by summing up the individual contributions of each current point over the surface, taking into account the different amplitudes and phases due to the excitation and spatial location. Antenna theory shows that a unitary point source of current radiates a spherical wave, which is normally referred to as the *free-space Green function* ($e^{-jkr}/4\pi r$); see [20] for further details. In the limit, as the current distribution becomes continuous, such as the one given by Eq. (32), the weighted sum of spherical waves becomes an integral, yielding the radiated patterns.

Note that the integration process for obtaining the patterns is the same of the one employed by the GO technique, given that once the aperture distribution is determined from Eq. (31), equivalent currents can then be obtained and integrated over the reflector aperture. This process is equivalent to computing the Fourier

transform of the aperture distribution given in Eq. (31). One difference between GO and PO is that PO currents are determined over the reflector *curved* surface and the GO equivalent currents, over the *planar* projected aperture; the latter are already in a format more appropriate for integration through a Fourier transform. However, the use of a Jacobian transformation [3,4] maps the PO currents over the reflector curved surface to the planar aperture, yielding the possibility of also using Fourier transforms for performing the integration. Analytical integration is possible only for arbitrary symmetric reflectors [4,8], and numerical techniques are normally required to evaluate offset reflectors, as discussed in the next section.

The PO formulation is generally considered more accurate than GO to evaluate offset reflectors, especially if XPOL assessment is of main concern. However, pattern accuracy as determined from both techniques degrade beyond the mainbeam and near-in sidelobes. The pattern in the far-out region is dominated by diffraction effects, especially scattering from the reflector and/or subreflector edges. This is accounted for by augmenting GO with the use of the geometrical theory of diffraction (GTD) or augmenting PO with edge currents through the physical theory of diffraction (PTD); see [20] and [32] for further details. However, the near-in pattern region is, most of the time, the region of interest when analyzing high-gain antennas such as the reflector antennas considered here.

4.2. Numerical Implementation and Accuracy Evaluation

In this section we discuss one of many possible numerical implementations of the PO formulation addressed above; see [4] for alternate procedures. Reflector surface currents are computed from Eq. (32) for the balanced feed model given by Eqs. (14) and (21). A set of coordinate transformations, rotations, and translations is necessary in order to describe the far-field patterns as a function of the reflector local coordinate system $\{xyz\}$, given that the feed pattern is described as a function of the feed local coordinate system $\{x_f y_f z_f\}$. Although not shown, Eulerian angles [33] are employed for generality, and we mention that a solid background on geometry and vector calculus is normally required for the analysis of reflector antennas.

The procedure employs a Jacobian transformation, as discussed previously, and evaluates numerically the following integral [4] using a numerical procedure based on the Gauss–Zirniké integration method [34]

$$\vec{E}(\vec{r}) = -j \frac{\eta}{2\lambda} \frac{e^{-jkR}}{R} (\vec{I} - \hat{r}\hat{r}) \cdot \int_{s'} \int \vec{J}(\vec{r}') J_{\Sigma} e^{jk\hat{r} \cdot \vec{r}'} ds' \quad (33)$$

where $\hat{r} \cdot \vec{a}$ is shorthand for $\hat{r}(\hat{r} \cdot \vec{a})$, and $(\vec{I} - \hat{r}\hat{r})$ is included to remove the radial component (far-field approximation) [4]. The unit dyad \vec{I} is equal to the identity matrix for our purposes, and the Jacobian transformation, J_{Σ} [4,33], is employed to allow the integral to be evaluated over the reflector planar projected aperture s' . However, the currents are still defined over the reflector curved surface. In addition, the Jacobi–Bessel method [33] is used to express part of the kernel in Eq. (33) as a sum over a set of

orthogonal functions defined on the antenna aperture. Within this context, numerical integration is necessary only to evaluate the coefficients of the series expansion, which employs the modified Jacobi polynomials in the radial direction and a Fourier series in the circumferential direction.

The aforementioned procedure was implemented in the code PRAC (parabolic reflector analysis code) [7]. PRAC is a user-friendly code developed by the author to analyze axisymmetric and offset parabolic reflectors, and yields the co- and cross-polarized radiated fields with high accuracy and efficiency. PRAC is currently being used by many universities and major industries worldwide, and an academic version of the code is distributed with [20].

In order to evaluate the accuracy of the code, we select as a baseline configuration for analysis a just fully offset paraboloid with a diameter $D = 85.5\lambda$, $F/D_p = 0.3$, and offset distance $H = 42.75\lambda$. The reflector illumination is modeled by the balanced feed described by Eqs. (14) and (21), with a 10 dB beamwidth of 78° ($q = 4.57$ yielding a feed gain of 13.07 dBi). The offset reflector choice corresponds to a 1.8-m-diameter VSAT Earth terminal antenna operating at 14.25 GHz, similar to the one shown in Fig. 13.

Figure 14 shows the computed co- and cross-polarized patterns and measured data for the example offset parabolic reflector in the plane normal to the plane of symmetry (i.e., the yz plane). XPOL is expected to be maximum at

Figure 13. Just fully offset parabolic reflector antenna with a projected aperture diameter of 1.8 m (courtesy of Nick Moldovan, Prodelin Corp.).

Figure 14. Computed and measured radiation patterns at 14.25 GHz of a 1.8-m single-offset parabolic reflector antenna.

this plane, as discussed in Section 2.3.1. We note from Fig. 14 that the results obtained with PRAC are in good agreement with the measured data. The measured gain of 46.78 dBi is about 0.8 dB below the computed gain of 47.60 dBi due to losses and system imbalances. System XPOL is also a little overestimated by the computer simulations for this example. In fact, the measured system XPOL is -22.00 dB, whereas PRAC yields -21.27 dB. Nevertheless, PRAC yields a valuable estimate on how the reflector system behaves electrically, showing the necessity of a numerical evaluation previous to the manufacturing process. It is worth mentioning that analysis of this same baseline configuration with the physical optics portion of GRASP [14], yielded almost identical results [7], with the exact same locations for the nulls and peak side lobes and XPOL lobes, confirming the accuracy of PRAC and PO analysis for evaluating offset reflectors.

As final notes on the analysis of reflector antennas, we mention that the lower integration limit in Eq. (33) can be set such that to account for an equivalent circular area of blockage, normally caused by the feed and supporting structure in axisymmetric reflectors. In addition, the integral in Eq. (33) can also be evaluated over areas s' other than the circular, in order to analyze reflectors with projected apertures such as the elliptical one. Reflectors with elliptical apertures present a far-field pattern with a mainbeam that is narrower in the plane containing the major axis of the ellipse, and are used in practice to transmit signals to synchronous satellites. The main advantage is a more compact design, when compared to the full circular aperture, offering less resistance to wind and saving material during the manufacturing process. The lower gain (i.e., wider beam) in the plane containing the minor axis of the ellipse does not degrade system performance for this particular application, given that only a single belt

of synchronous satellites exists and therefore beam resolution is required only in one plane. Finally, both GO and PO formulations can also be used to evaluate dual- and multiple-reflector systems. The simplest procedure is to first determine the radiation pattern of the system formed by the feed antenna and subreflector, and then use this result as the incident field on the next subreflector or main reflector. It is also common to employ GO for the subreflector analysis and then PO in the final step to evaluate the main reflector for better accuracy. This combination saves computer time as GO analysis is generally faster than PO [20].

5. FEED ANTENNAS

Feed antennas for reflector configurations are normally horn antennas (sectoral, pyramidal, conical corrugated, etc.), although wire antennas and others are also encountered in practice. The sectoral horn, for instance, is used for illuminating reflectors with elliptical projected apertures, which were discussed previously. In addition, it is also common to have an array of horns or other type of feed antennas illuminating shaped reflectors or large reflectors, such as radiotelescopes. This is because the array yields better control on the phase distribution employed to illuminate the reflector, enhancing beam contour and beam-scanning performance. Equation (17) can be used to set the initial positions for the feed antennas [3]. A contoured beam is required to illuminate properly an specified region of Earth, as seen from a satellite, and can be accomplished with the shaping of the reflector or with the use of a feed array; see also Section 6 for more details. An example of a multifeed array illuminating a parabolic reflector for contoured beam applications is the Intelsat-9 series of C-band and Ku-band satellites, built by Space Systems/Loral (see Fig. 15). The transmit feed array has more than 100 feed horns and is located on the Earth deck tower, facing the largest reflector shown in Fig. 15, which is a parabolic reflector with a superquadric projected aperture. Feed horns, as well as the remaining parts of the feed chain (polarizer, orthomode transducer, diplexer, etc.), can be manufactured with very good precision and electrical performance from aluminum, magnesium, titanium, graphite, or carbon-fiber-reinforced plastic (CFRP), glass fiber reinforced plastic (GRFP) and other materials.

We start by discussing analytical models that approximately describe the electrical behavior of feed antennas usually encountered in practice. It is not our intention to analyze feed antennas completely, but rather present simple analytical models that can be useful to antenna engineers as a first approximation to real feed patterns or more sophisticated models available in the literature [35]. The simplest model is the balanced feed given by Eq. (14), normally used with Eq. (15) or (21). Balanced radiation patterns can be obtained in practice with the use of multimode horns, like the Potter horn, and hybridmode horns, such as the conical corrugated ones [24,35]. An alternate version of Eq. (14) can be obtained for feeds presenting different pattern cuts in the E plane ($\phi_f = 0^\circ$) and H plane ($\phi_f = 90^\circ$). The feed patterns in these two planes are

Figure 15. Intelsat-9 series of seven C-band and Ku-band satellites. The transmit feed array contains more than 100 feed horns and is located on the Earth-deck tower, facing the largest reflector shown in the figure. (Courtesy of Space/Systems Loral and Intelsat.)

usually all that is known. As in Eq. (14), we assume that the feed is purely linearly polarized in the x_f direction, yielding [3]

$$\mathbf{E}_f = \frac{e^{-jkr_f}}{r_f} [\hat{\theta}_f C_E(\theta_f) \cos \phi_f - \hat{\phi}_f C_H(\theta_f) \sin \phi_f] \quad (34)$$

where $C_E(\theta_f)$ and $C_H(\theta_f)$ denote the feed pattern cuts in the E and H planes, respectively. A y_f -polarized feed pattern, as well as circularly polarized ones, can be obtained from Eq. (34) introducing the modifications already suggested in Section 2.3.1. Note that Eq. (34) reduces to Eq. (14) for $C_E(\theta_f) = C_H(\theta_f) = C(\theta_f)$, yielding a balanced illumination.

As discussed in Section 2.3.4, balanced feeds yield improved performance when illuminating reflector systems. A type of balanced feed antenna widely used in practice is the corrugated conical horn, also often referred to as the *scalar horn*. Corrugated conical horns present a phase center that is reasonably stable with frequency [24,35], in addition to a copolarized pattern that is nearly balanced for practical purposes and can be well modeled by Eqs. (14) and (15) or (21).

The main purpose of using corrugations is to obtain the same boundary conditions around the inside of the horn. For corrugation depths of a quarter wavelength, the short circuit at the bottom is transformed to an open circuit at the top of the corrugation, yielding boundary conditions that appear to be more uniform as the number of corrugations per wavelength increase [20]. This yields a symmetric radiation pattern down to as low as -25 dB over a

reasonably wide operational bandwidth, typically of 1.6:1 or more.

The cross-polarized pattern, however, may contain peaks in the 45° planes [35]. As discussed in Section 3, and approximately modeled by Eq. (30), feed XPOL peaks appear in the far-field patterns of dual reflector systems, even with the enforcement of the conditions given by Eqs. (27)–(29). In order to minimize feed XPOL, a careful design and construction process must be performed. The corrugation depths must be set properly to achieve resonance, taking into account all dimensions related to the corrugations as well as the general geometry of the horn [24]. The process has been successfully accomplished in practice, often also employing sections of tapered and/or dual-depth corrugations, yielding horns presenting balanced copolar patterns and XPOL levels below -35 dB over practical operational bandwidths [24,36].

6. ADVANCED TOPICS AND RESEARCH

6.1. Reflector Antenna Upgrading

Reflector antenna designs have evolved through several configurations in order to increase performance and/or reduce structural complexity. Electrical parameters that are of prime interest are aperture efficiency, sidelobe level (SLL), and, more recently, cross-polarization level (XPOL). All topics discussed here apply to the various types of reflectors addressed previously. However, the offset configuration is the one most likely to retain in the near future the largest percentage of the reflector antenna market.

We first focus our attention on XPOL. Reflector antennas presenting low XPOL performance (e.g., $\text{XPOL} \leq -35 \text{ dB}$) are necessary for frequency reuse applications, in which an overlap of orthogonally polarized channels is permitted. Many efforts are being conducted to develop these kinds of antennas for mass production [7,37]. Dual offset reflectors can be designed for low-cost construction, provided that specific manufacturing constraints are carefully taken into account [7], an effort that can be achieved only with the increased interest of industry. Single offset systems illuminated by a matched feed [24] or a feed with a lens [37] can also be designed to satisfy stringent requirements on XPOL, yielding very compact designs. In the latter case, the lens is designed such that it replaces the subreflector, and in both cases bandwidth performance is not obtained as easily as with the dual-reflector configuration. Research continues to be conducted within the area, yielding innovative solutions that provide satisfactory XPOL performance while attending practical manufacturing specifications. Cost-effective solutions normally require that attendance of a particular specification, such as low XPOL, be achieved with minimal capital outlay, which implies on using the maximum amount of infrastructure and technology already implemented. In particular, as mentioned previously, there is a tendency to employ existing molds for the main reflector, a concept referred to as *reflector upgrading* [7].

Within this context, existing single offset reflector molds are normally used to construct the main reflector of a dual configuration. However, many such molds are for just fully offset geometries, which in general produce a dual reflector configuration that is Gregorian with the feed axis z_f intersecting the main reflector (see Fig. 11). The same problem may also occur in certain Gregorian configurations even when the main reflector is not just fully offset. The final design should provide suitable clearance between the bottom of the main reflector and the feed axis in order to access the feed antenna with a straight section of waveguide, thus reducing the complexity and cost of the manufacturing process. This setup is achieved by rotating the parent ellipsoid (i.e., the conical surface from where the subreflector is generated) until the desired clearance is obtained. The rotation is performed in a way such that the feed remains pointed toward the intersection of the new subreflector and the ray coming from the center of the main reflector, thus avoiding the introduction of spillover and phase errors.

The non-conventional design obtained after the rotation of the parent ellipsoid may present a XPOL degradation due to the fact that the minimum XPOL conditions, Eqs. (27)–(29), are no longer satisfied. A simple solution to this problem is to alter the value of the subreflector eccentricity, while keeping all orientation angles constant. In general, eccentricity values greater than the one employed before the rotation will reduce system XPOL [7], yielding a low cross-polarized dual offset Gregorian antenna that has adequate clearance between the feed axis and the bottom of the main reflector. In addition, the resulting configuration has the ability to operate with either a linearly polarized (LP) or a circularly polarized (CP) feed over a wide bandwidth without the need of being repositioned

(no substantial beam squint). Conversely, subreflector rotation can also be utilized with CP feeds to achieve beam scanning through beam squint, given the introduction of linear XPOL in a controlled way [38]. The process keeps the reflector system focused at all times, avoiding pattern degradations and sustaining broad operational bandwidth.

Compact designs for reflector systems is also a subject that has been investigated for years. It is desirable, for example, to upgrade a main reflector with a subreflector that is as small as possible. In addition, with the spreading of satellite TV at Ku band (see Figs. 16 and 17) employing single offset systems for reception, there is now widespread interest to minimize the size of the reflector while maintaining a required gain performance. This is only possible by increasing aperture efficiency through the reduction of diffraction effects and feed blockage. High-performance feeds are also necessary, especially if they are located close to the reflector, such as in a very compact design, requiring a complete near-field analysis. Finally, microelectronics technology is integrating both low- and high-frequency hardware to the feed system. It is common nowadays to find feeds that already include low-noise amplifiers, downconverters, and other electrical devices in a single unit.

6.2. Shaped, Deployable, and Frequency-Selective Reflector Surfaces

Reflector antennas can be shaped to improve gain and aperture efficiency. The basic concept is to shape the subreflector of a dual-reflector system to obtain the desired amplitude distribution at the main reflector projected aperture, normally nearly uniform for maximizing gain, and then shape the main reflector to recover the uniform phase distribution that was disturbed by shaping the subreflector. Resulting aperture efficiencies are usually in the range of 70–80%, although higher values have been reported for dual shaped offset systems [11]. The fundamental tradeoff that antenna designers must face, in this case, is the achievement of such efficiencies while still achieving satisfactory sidelobe levels.

Another topic certain to continue receiving attention in the future is the shaping of single-reflector systems for contoured beam applications. A contoured beam is necessary to illuminate efficiently from a satellite specific regions of Earth. This avoids unnecessary coverage of regions outside the satellite main service area. Reflector shapes for contoured beam and high-gain applications, especially for the offset case, are normally obtained numerically through elaborated synthesis and optimization processes [3–5,9,10,39], which include the feed antenna or array. Also important is the mathematical and numerical modeling of the surfaces to yield results possible to be implemented in practice [40]. Research has been conducted comparing the electrical performance of the following three configurations: (1) shaped reflector with a single feed, (2) parabolic reflector with a feed array, and (3) shaped reflector with a small feed array (hybrid configuration). Preliminary results indicate that the electrical performance (mainly gain and isolation) peaks for the first

Figure 16. The MBSat satellite owned by Mobile Broadcasting Corporation (MBCO) of Japan and SK Telecom of Korea employs an unfurlable 12-m S-band reflector and two Ku-band reflectors to provide Japan and South Korea separately with over 50 channels of CD-quality audio and TV-quality video, traffic, and emergency information; newspaper and magazine content; games; and other services. (Courtesy of Space/Systems Loral.)

two configurations, with the hybrid one falling between them. In particular, state-of-the-art space technology employs a single receive/transmit feed illuminating a shaped reflector, nowadays a configuration with similar electrical performance to the parabolic reflector illuminated by a large feed array but with a quicker production time. The iPSTAR-1 satellite, for example, employs three Ku-band shaped reflectors on the Earth deck tower, in addition to the multibeam Ku-band and Ka-band deployable reflectors on the east and west panels, (see Fig. 18). Most shaped reflectors are fabricated from carbon-fiber-rein-

forced plastic (CFRP) using graphite molds, although other materials can also be used; see Section 2.4.

Reconfigurable shapes, deployable reflectors, and polarization- or frequency-selective surfaces require an in-depth study of electrical and magnetic materials, showing that reflector antenna engineering is currently impossible without large interdisciplinary activities. Frequency-sensitive surfaces, for example, reflect only radiation in specific frequency bandwidths [1]. A four-frequency reflector system has been used for the ESA/NASA Cassini mission to Titan, the largest moon of Saturn [1]. The subreflector

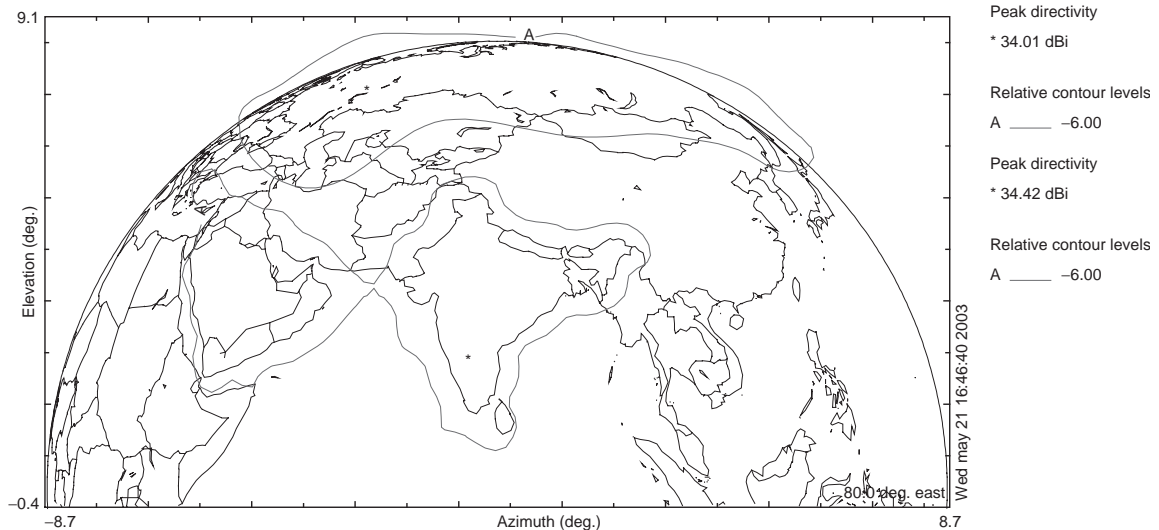

Figure 17. Reflector antenna 6-dB contours for Russia and India/Middle East coverages for a geosynchronous Ku-band satellite positioned at an orbital location of 80° east. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 18. The iPSTAR-1 broadband satellite, owned by Shin Satellite Plc of Thailand, uses seven reflectors to generate 84 Ku-band spot beams, three Ku-band shaped beams, and 16 Ka-band spot beams, to provide direct-to-desktop last-mile services, including multimedia and data communication to customers in Asia, India, and Australia (courtesy of Space/Systems Loral).

carried by the Voyager spacecraft is another example, being transparent to radiation at S band and reflecting at X band. The subreflector was manufactured with X-band resonant aluminum crosses etched on a Mylar sheet, yielding reflecting and transmitting losses lower than 0.1 dB [1]. Geometries other than crosses can be obtained through the optimization techniques presented in the Section 6.4.

In particular, reflectors that can be deployed in space deserve distinct attention. The classical solution is the so-called umbrella reflector [1], which works well for axisymmetric and offset configurations. An idea that seems promising for the offset case is a configuration that opens similarly to a manual fan. An alternative to the classical umbrella configuration is an unfurlable configuration that

becomes self-sustained after deployment, such as the 12-m S-band meshed reflector antenna used in the MBSat satellite; see Fig. 16 for details. In addition, inflatable reflectors have also been investigated, with the successful construction and testing of a few prototypes.

6.3. Reflector Antenna Isolation

Isolation is one of the most important parameters related to reflector antennas in wireless communication networks, assessing the level of interference between multiple antenna beams within the same system or different systems. The multiple beams may be generated by the same or different reflector antennas. Isolation is normally accounted and optimized at the reflector antenna level [41].

Table 7. Definitions of Symbols for Transmit Isolation

$g_d(x_d)$	Gain of the transmit antenna serving the desired coverage at any and all points x_d within coverage “ d ”
$g_i(x_d)$	Gain of the transmit antenna serving the interfering coverage “ i ” with the same frequency and sense of polarization as the desired coverage “ d ” and at any and all points x_d within coverage “ d ”
$g_{\min,i}$	Minimum coverage gain of the transmit antenna serving the interfering coverage “ i ”
$g_{\min,d}$	Minimum coverage gain of the transmit antenna serving the desired coverage “ d ”
$EIRP_{\min,d}$	Minimum coverage $EIRP$ of the transmit antenna serving the desired coverage “ d ”
$EIRP_{\min,i}$	Minimum coverage $EIRP$ of the transmit antenna serving the interfering coverage “ i ”

Worst-case figures combined with error margins and tolerances are then employed to assess and optimize system level performance. We start by presenting procedures to evaluate beam-to-beam and composite isolation in wireless networks. The procedures are then implemented at an antenna level for a case example of a multibeam satellite network. It is worthy mentioning that the transmit isolation is always assessed over the *desired* beam(s), whereas the receive isolation over the *interfering* beam(s).

6.3.1. Transmit Beam-to-Beam Isolation. The *transmit isolation* between two cell coverages (i.e., physical area or space illuminated by the beams) is defined as the power ratio between the copolar pattern of the desired coverage “ d ” and the copolar or crosspolar pattern of the interfering coverage “ i ” at any point “ x_d ” within coverage “ d .” The transmit isolation between the two coverages is referred to here as “[$I_{TX}(x_d)$] $_{di}$ ” and defined by the following equation:

$$[I_{TX}(x_d)]_{di} = 10 \log_{10} \left(\frac{g_d(x_d) g_{\min,i} EIRP_{\min,d}}{g_i(x_d) g_{\min,d} EIRP_{\min,i}} \right) \quad (35)$$

where all symbols are as defined in Table 7.

6.3.2. Receive Beam-to-Beam Isolation. The receive isolation between two cell coverages is defined as the power ratio between the copolar pattern of the interfering coverage “ i ” and the copolar or cross-polar pattern of the desired coverage “ d ” at each point x_i within coverage “ i .” The receive isolation between the two coverages is referred to here as “[$I_{RX}(x_i)$] $_{di}$ ” and defined by the following equation

$$[I_{RX}(x_i)]_{di} = 10 \log_{10} \left(\frac{g_i(x_i) g_{\min,d} S_{\max,d}}{g_d(x_i) g_{\min,i} S_{\max,i}} \right) \quad (36)$$

where all symbols are as defined in Table 8.

Table 8. Definitions of Symbols for Receive Isolation

$g_i(x_i)$	Gain of the receive antenna serving the interfering coverage “ i ” with the same frequency and sense of polarization as the desired coverage “ d ” at the X% worst-case point “ x_i ” within coverage “ i .”
$g_d(x_i)$	Gain of the receive antenna serving the desired coverage “ d ” at the X% worst-case point “ x_i ” within coverage “ i .”
$g_{\min,d}$	Minimum coverage gain of the receive antenna serving the desired coverage “ d ”
$g_{\min,i}$	Minimum coverage gain of the receive antenna serving the interfering coverage “ i ”
$S_{\max,d}$	Maximum coverage power flux density within the desired coverage “ d ”
$S_{\max,i}$	Maximum coverage power flux density within the interfering coverage “ i ”.

6.3.3. Transmit Composite Isolation. The isolation between a desired cell coverage “ d ” and all other interfering cell coverages “ i ” is referred to here as the *composite transmit isolation* [$I_{TX}(x_d)$] $_d$ and defined as

$$[I_{TX}(x_d)]_d = 10 \log_{10} \left[\frac{1}{\sum_{d(d) \neq d(i)} \left(\frac{g_d(x_d) g_{\min,i} EIRP_{\min,d}}{g_i(x_d) g_{\min,d} EIRP_{\min,i}} \right)^{-1}} \right] \quad (37)$$

where all symbols are as defined in Table 7.

6.3.4. Receive Composite Isolation. The isolation between a desired cell coverage “ d ” and all other interfering cell coverages “ i ” is referred to here as the *composite receive isolation* [$I_{RX}(x_i^+)$] $_d$ and defined as

$$[I_{RX}(x_i^+)]_d = 10 \log_{10} \left[\frac{1}{\sum_{d(d) \neq d(i)} \left(\frac{g_i(x_i) g_{\min,d} S_{\max,d}}{g_d(x_i) g_{\min,i} S_{\max,i}} \right)^{-1}} \right] \quad (38)$$

where x_i^+ denotes a set of points x_i at the interfering coverages “ i ” ($i \neq d$) and all other symbols are as defined in Table 8. Note that the sum includes the desired receiving beam at multiple interfering locations resulting in the set of locations x_i^+ , in which each element accounts from the contribution from one interfering receiving beam at a location x_i within the interferer. The locations x_i are different within each interferer and in practice are the points resulting in the worst-case within X% of the area within each interferer. [$I_{RX}(x_i^+)$] $_d$ is an array where each element is the composite isolation of the desired receiving beam over X% of the total aggregated interfering coverage area. For each element the set x_i^+ is different.

Table 9. Transmit Isolation for 80°E*India Coverage*

Beam-to-beam C/I (dB)
 Carrier (beam): indiane_TX; interferer (beam): russia_TX
 Evaluated over polygon: India coverage

 Percentage of area: 90% 95% 100%
 Worst-case C/I (dB): 27.11 24.98 11.84

6.3.5. Numerical Results. In this section the beam-to-beam and composite isolation are computed for a synchronous multibeam satellite positioned at an orbital location of 80° east. The reflector antenna 6-dB numerical contours for the Russia and India/Middle East coverages are shown in Fig. 17. Note that the India/Middle East beam is actually a single antenna beam, for which the isolation is computed separately for the India and Middle East coverages. Specific Earth station positions and XPOL isolation are omitted for simplicity. In addition, the input power and the flux density over different beams are assumed to be uniform.

The results for the transmit isolation are listed in Table 9. Note that the isolation values normally used are the ones computed based on 90% of the coverage areas (e.g., 28.89 dB for the India coverage). Nevertheless, the overall worst-case situations need to be assessed on a case-by-case basis, mostly with respect to their physical location, before a design is deemed completed. Similarly the receive isolation results are listed in Table 10. The beam-to-beam receive isolation needs to be assessed within each interfering coverage area, contrarily to the transmit case, which is always computed within the desired coverage area, as shown in the previous sections. In practice, the isolation tables are normally presented with detailed coverage plots showing the areas of non-compliance. Furthermore the isolation is also computed or estimated from the real measured patterns at various stages of manufacturing and integration, such as beam-forming network (BFN), array or feed antenna sniffing, near-field tests before and after environmental tests (vibration, hot and cold conditions), reflector system on mockup structure in CATR (compact antenna testing range), and reflector system on real structure in CATR after environmental tests (vibration and thermal vacuum); see Fig. 19.

6.4. Neural Networks and Genetic Algorithms Applied to the Synthesis of Reflector Antennas

As we have seen, reflector antenna applications range from very specific and unique systems, such as deployable reflectors and radiotelescopes (see Section 3.3), as well as large-scale production for commercial wireless networks, like earth terminals in VSAT networks and small receiving antennas for satellite TV. In addition, reflector antennas are also used in radar systems and other devices directly related to electronic warfare and defense. Because of the wide range of applications and commercial importance, it is essential to have reliable alternate algorithms to design effective reflector configurations. Analytical and numerical tools currently used with applied electromagnetics and appear to work well for the synthesis of reflector antennas, although relatively mature to other areas such as controls and signal processing, are neural networks and genetic algorithms [42–46].

The basic concept of using neural networks for designing reflector antennas is to first relate a few radiation patterns, or other parameter of interest, directly to the reflector geometries that generated them according to a previously selected analysis algorithm. The process is normally referred to as “training” the neural network. Once the training is completed, the desired radiation pattern is employed as the input parameter, such that the neural network yields as a result the corresponding reflector

geometry. Finally, the selected analysis technique is used on the resulting geometry to validate the process. This type of synthesis has been successfully implemented to determine reflector shapes for contoured beam applications [42]. Reflector antenna synthesis based on neural networks is normally very fast because analysis techniques are required only for the training of the network. Also currently under investigation is the effectiveness of using neural networks at a real-time level to reduce XPOL, noise, and interferences in single offset systems.

Genetic algorithms (GAs), on the other hand, rely on an optimization search to elect a suitable design. The initial set of configurations, referred to as the basis *population*, is formed by relating random designs to chromosomes, each one formed by a sequence of binary numbers that define the corresponding reflector geometry. A figure of merit is then assigned to each chromosome; these figures increase as the electrical performance of the configuration is closer to the desired one. Chromosomes with the highest figures of merit are elected to cross with the remaining ones, a process called *crossover* [43–45]. In addition, the best chromosomes (i.e., the ones with the highest figures of merit) are often duplicated before crossover, eliminating the worst ones, a procedure referred to as *natural selection* [43–45]. After the crossover is completed, a few binary numbers in a subset of chromosomes can be randomly altered, simulating the process of *mutation* in biological evolution. All figures of merit are then recomputed, and the whole process is repeated if the desired performance has not been achieved.

The aforementioned procedure is a basic description of a genetic algorithm, although variants are often encountered in practice [43–45]. A major advantage of GAs over other optimization techniques is that once the process has converged, more than one configuration attaining the desired performance is often encountered. It is also common to find configurations that are very different than classical solutions and could not be easily conceived through straightforward reasoning. Practical manufacturing constraints can then be considered for choosing the most adequate reflector antenna configuration.

Acknowledgments

REFRACTION AND ATTENUATION IN TROPOSPHERE

JEREMY E. ALLNUTT
Virginia Tech/Northern Virginia
Center
Falls Church, Virginia

Electromagnetic energy, often referred to in communications as *the signal* and traced in diagrams as a *ray*, travels at the speed of light c when in a vacuum, whether in the form of X-rays, visible light, or a radiowave. The value of c is 3×10^8 m/s. When the signal passes through a medium that is not a vacuum, it travels more slowly. The ratio between c and the speed in the medium v is the *refractive index* of the medium, denoted by $n = c/v$. The refractive index of a medium does not just affect the speed of electromagnetic energy flowing through it; it can also cause the magnitude of the signal to fluctuate over time periods on the order of a second or longer, due to variations in the refractive index within the medium. These signal fluctuations, called *scintillations*, are usually small and approximately symmetric about the average level of the signal, although this is not always so in severe scintillations. Where two dissimilar media form a common boundary, the different refractive indices of the media will cause the signal direction to diverge from its path if the incident direction is not normal to the boundary. This is called *refraction*, and the incident and refracted directions either side of the boundary are given by Snell's law (e.g., see Ref. 1).

The average refractive index of a medium is called the *bulk* refractive index, and it affects the average direction of the electromagnetic energy. Most media are not completely homogeneous, however; small volumes of different refractive indices will exist within the larger scale of the medium. These variations, which can exist over dimensions as small as a few centimeters in the troposphere, are termed the *small-scale* refractive index variations of the medium. They are like bubbles of air in a glass of soda. In the troposphere, the mixing of the small-scale "bubbles" within the larger scale of the medium can be caused by convection currents, due to heating of the air by the ground, or by turbulent effects in wind shear aloft. These variations give rise to the scintillations noted above.

In addition to changing the direction of travel of an electromagnetic signal and/or causing scintillations, a medium can both extract energy from a signal passing through it and alter the orientation sense of the electric vector (the polarization) of the signal as it passes through. The loss of energy is called *attenuation*, and the change in polarization sense is generally referred to as *depolarization*. In general, the longer the path through a medium is, the greater will be its effect on the electromagnetic signal passing through it. For this reason, paths through the atmosphere at low elevation angles will have greater ray bending, scintillation, attenuation, and depolarization than paths at high elevation angles.

1. REFRACTIVE EFFECTS

1.1. Bulk Refractive Effects

In still air, the atmosphere assumes a spherically stratified form with layers of generally decreasing refractive index lying one above the other. The refractive index of a given portion of the atmosphere will therefore vary far more quickly with change in height than with change in horizontal position. For this reason, an electromagnetic signal (a ray) leaving Earth's surface at an elevation angle of $< 90^\circ$ will bend away from the normal to the surface (see Fig. 1a). The curvature will be contained in one plane, the projection of which onto Earth's surface is the azimuth direction. If r is the radius of curvature of the ray [2], then

$$\frac{1}{r} = -\frac{\cos \theta}{n} \frac{dn}{dh} \quad (1)$$

where

θ = angle of the ray path to the horizontal at the point considered

n = refractive index of the atmosphere

dn/dh = vertical gradient of refractive index at a height h above Earth's surface

The minus sign indicates that the refractive index decreases with increasing altitude. For terrestrial radio systems, the elevation angle θ will be almost zero and, since the refractive index is almost unity, Eq. (1) will reduce to the approximate form

$$\frac{1}{r} = -\frac{dn}{dh} \quad (2)$$

If the radius of Earth is a , the difference in curvature between the ray path and the curvature of Earth along the terrestrial link is given by

$$\frac{1}{a} - \frac{1}{r} = \frac{1}{a} + \frac{dn}{dh} = \frac{1}{ka} = \frac{1}{R_e} \quad (3)$$

Here R_e is Earth's effective radius given by the product ka , where k is the effective Earth radius factor. The effective radius of Earth is often used in ray-tracing diagrams of the vertical profiles of terrestrial radio systems, because it allows for the average ray bending along the path (see Figs. 1b, 1c). Ray bending on satellite-to-ground paths may cause signal loss due to the spreading of the antenna beam. This effect, and that of elevation-angle-of-arrival variations, are negligible at elevation angles above about 3° and will be significant only for large antennas (diameter > 100 wavelengths).

The atmosphere has a *dry* and a *wet* refractive index component, the former due to the gases in the atmosphere (principally nitrogen and oxygen), and the latter due to the water vapor that is taken up into the atmosphere. Combining the two components together into a composite refractive index n gives

$$n - 1 = \frac{77.6}{T} \left(P + 4810 \frac{e}{T} \right) \times 10^{-6} \quad (4)$$

Figure 1. (a) Apparent and real directions to an Earth satellite, illustration of methods of ray tracing; (b) real radius and a curved ray path; (c) effective radius and a geometric ray path.

where

- P = atmospheric pressure (hPa)
- T = absolute temperature (K)
- e = water vapor pressure (hPa)

The hectopascal (hPa) is the same as a millibar.

The water vapor pressure e can be related to the relative humidity by [3]

$$e = \frac{He_s}{100} \tag{5}$$

and

$$e_s = a \exp\left(\frac{bt}{t+c}\right) \tag{6}$$

where

- H = relative humidity (%)
- t = temperature ($^{\circ}\text{C}$)
- e_s = saturation vapor pressure (hPa) at the temperature t

and the coefficients a , b , and c are as follows:

For water:

- $a = 6.1121$
- $b = 17.502$
- $c = 240.97$

For ice:

- $a = 6.1115$
- $b = 22.452$
- $c = 272.55$

The vapor pressure e is related to the water vapor density ρ (g/m^3) by [3]

$$e = \frac{\rho T}{216.7} \text{ (hPa)} \tag{7}$$

The refractive index of air is so close to unity that Eq. (4) is often rewritten as

$$n = 1 + 10^{-6} N \tag{8}$$

where N is the *refractivity* of the atmosphere and is given by $(77.6/T)(P + 4810e/T)$, with the same units as in Eq. (4).

1.1.1. Refractivity Profile. The refractivity profile is described by a mean refractive index gradient, which generally decreases exponentially with increasing altitude. A reference standard atmosphere for calculating the refractive index as a function of height $n(h)$ is given by [3]

$$n(h) = 1 + 10^{-6} N_0 \exp\left(\frac{-h}{h_0}\right) \tag{9}$$

where

- h = height above mean sea level (km)
- h_0 = reference altitude = 7.35 km
- N_0 = average value of atmospheric refractivity at mean sea level = 315

Rewriting Eq. (9) in terms of the refractivity, we have

$$N(h) = N_0 \exp \frac{-h}{h_0} \tag{10}$$

The rate of change of the refractivity profile with height dN/dh can be related to the parameter k used earlier. Sample values are given below [4]:

dN/dh (N/km)	k
157	$\frac{1}{2}$
0	1
-40	$\frac{4}{3}$
-157	∞
-200	-3.65

From this table above, it is clear that, when dN/dh is less than -157, the radius of curvature of Earth is greater than the radius of curvature of a signal that is initially propagating horizontal to the surface of Earth. The signal will therefore propagate beyond what would normally be the local horizon. This is a form of anomalous propagation, and the mechanism is referred to as *ducting*.

1.1.2. Refractive Ducts. Ducting is defined as occurring when a radio ray originating close to Earth’s surface is sufficiently refracted that it is either bent back toward the Earth surface or travels along a path that is parallel to the surface. Ducts are formed when layers of air having a relatively high refractive index are above layers with a relatively low refractive index. This *inversion* of the normal exponentially decaying refractive index profile with height is rare and leads to anomalous propagation conditions. Anomalous propagation, and the enhanced signal levels it causes at unlikely distances from the transmitter, is key to the estimation of potential interference between terrestrial systems caused by ducts. A signal will become trapped in a duct if the initial direction of the transmission (the angle of incidence) is very close to that of the horizontal refractive index boundaries of the duct. Typically, the angle of incidence of the signal, as it meets the boundary between the inversion layer and the atmosphere above, has to be smaller for thinner ducts. Typical values for a refractivity gradient of -300 N/km are [2] as

follows:

Critical Angle of Incidence (deg)	Duct Thickness (m)
0.1	10
0.14	20
0.22	50

Frequency also plays a part in the ducting. The higher the frequency, the smaller the duct thickness consistent with trapping. For the same -300 N/km profile assumed above, the minimum trapping frequency for a surface duct increases from approximately 2-2.5 GHz to 4-10 GHz to 25 GHz as the duct thickness changes from 40 to 30 m to 20 to 10 m, to 5 m, respectively [2]. The necessary condition for ducting to occur at a given elevation angle is given by [5]

$$\theta < \theta_c \tag{11}$$

where θ is the elevation angle and θ_c is the critical elevation angle above which ducting will not occur. The critical angle is given by

$$\theta_c = (2|\Delta M|)^{1/2} \text{ (mrad)} \tag{12}$$

where M is the modified refractivity (and $M = N + 10^6 h/a$, with h the height above the ground and a the radius of Earth), and ΔM is the change in M across the ducting layer. As an example, for θ_c to equal 1° , the required ΔM is 152.3.

Assuming a surface duct 50 m in height, the M lapse shown above corresponds to a refractivity gradient of 840 N-units/km. Refractivity gradients of this magnitude are extremely rare, and so ducting is normally limited to terrestrial radio systems or satellite-to-ground paths where the elevation angle is below 1° . The latter condition is not expected in commercial system used because it leads to poor propagation, but may have military applications in some situations.

1.1.3. Signal Delay. A signal propagating in the atmosphere will travel at a speed that is less than the speed of light in a vacuum. If a ranging system is being employed, such as the Global Positioning System (GPS), which ignores the true speed of the signal through the atmosphere, an error will be made in calculating the range. There will be two components of range error (here, range *delay*, since the signal will arrive later than expected). These are the range delay Δ_d due to dry air and the range delay Δ_w due to the moisture in the air. Typical values [6] are given in the table below for a path that exits the atmosphere to a satellite where the refractive index of the atmosphere is assumed to be unity. The range error values have been increased by 2% from those in Ref. 5 to allow for the additional atmosphere encountered from the 80 km height used in Ref. 5 for the target. Regression analyses [7] have shown that these typical range errors can be reduced in practice by 25% by incorporating site latitude, height above sea level, and time of day within the calculation

procedure:

Initial Elevation Angle (deg)	Elevation Angle Error (mdeg)	Range Error (m)
0	595	106
5	159	25.5
50	13.4	3.2

1.2. Small-Scale Refractive Effects

The air is rarely still; differential heating and cooling effects within the atmosphere induce wind currents from balmy breezes to tornado-force hurricanes and tropical cyclones. The resultant turbulence in the troposphere will cause small-scale changes in the refractive index. These in turn will lead to relatively rapid variations in the amplitude, phase, and angle of arrival of a signal [8]. The effect on the signal is usually described by one of the following observations:

1. The log amplitude χ (dB), which equals the ratio of the instantaneous amplitude of the observed signal to its mean amplitude
2. The scintillation variance of σ_χ^2 in dB² or the intensity σ_χ in dB_{rms}, which are the variance and root mean square of the log amplitude χ , respectively [8]

On terrestrial paths, the turbulence occurs in the *boundary layer*—the part of the troposphere that is next to the surface of Earth. In general, the signal fluctuations due to turbulence on terrestrial paths are neither performance- nor availability-limiting, the major propagation impairments being multipath (due to multiple atmospheric rays and ground reflections) and (for systems operating at frequencies above about 10 GHz) rain attenuation. On Earth-space paths, the primary cause of major tropospheric scintillations is cumulus clouds on warm, humid days. The attendant air entrainment process caused by the convective activity within the cloud structure induces turbulence; the more humid and hot the conditions are, the more severe the scintillations become. Similarly, the lower the elevation angle, the larger the amplitudes of both signal enhancements and degradations become. In most systems, tropospheric scintillation will affect the performance of only the link and not its availability [9]. At elevation angles below about 5°, however, low-angle fading effects become evident [10,11], and they can be system-limiting (i.e. cause a link outage). Figure 2 illustrates the general concept of performance and availability thresholds for digital communication systems [12].

1.3. Prediction of Tropospheric Scintillation

In most systems, it is the probable signal degradation that is required for the link budget analysis (signal enhancements being of relevance only for potential front-end amplifier saturation or for likely interference to other systems). The currently accepted modeling procedure to

Figure 2. Example of annual statistics of bit error ratio (BER) versus time percentage for a given link.

calculate the effective signal reduction due to tropospheric scintillations on an Earth-space path [13] uses the wet term of the refractivity at ground level as the input parameter to predict the scintillation variance. The step-by-step procedure from Ref. 13 is given below for elevation angles $\geq 4^\circ$:

Parameters required for the method include: t = the average surface ambient temperature (°C) at the site for a period of one month or longer; H = average surface relative humidity (%) at the site for a period of one month or longer; f = frequency (GHz), where $4 \text{ GHz} \leq f \leq 20 \text{ GHz}$; θ = path elevation angle, where $\theta \geq 4^\circ$; D = physical diameter (m) of the Earth station antenna; and η = antenna efficiency; if unknown, $\eta = 0.5$ is a conservative estimate.

- Step 1. For the value of t , calculate the saturation water vapor pressure e_s (kPa), as specified in Ref. 3.
- Step 2. Compute the wet term of the radio refractivity N_{wet} , corresponding to e_s , t , and H as given in Ref. 3.
- Step 3. Calculate the standard deviation of the signal amplitude σ_{ref} used as a reference:

$$\sigma_{\text{ref}} = (3.6 \times 10^{-3}) + (10^{-4} \times N_{\text{wet}}) \text{ dB}$$

- Step 4. Calculate the effective pathlength L according to

$$L = (2h_L) / \sqrt{[\sin^2 \theta + 2.35 \times 10^{-4}]^{1/2} + \sin \theta} \text{ m}$$

where h_L is the height of the turbulent layer; the value of $h_L = 1000 \text{ m}$

Step 5. Estimate the effective antenna diameter D_{eff} from the geometric diameter D and the antenna efficiency η :

$$D_{\text{eff}} = (\eta)^{1/2} D \quad \text{m}$$

Step 6. Calculate the antenna averaging factor from

$$g(x) = \left\{ \left[3.86(x^2 + 1)^{11/12} \right] \times \sin\left(\frac{11}{6} \arctan \frac{1}{x}\right) - 7.08x^{5/6} \right\}^{1/2}$$

with

$$x = 1.22(D_{\text{eff}})^2 \frac{f}{L}$$

where f is the carrier frequency in GHz

Step 7. Calculate the standard deviation of the signal for the considered period and propagation path:

$$\sigma = \sigma_{\text{ref}}(f)^{7/12} \frac{g(x)}{(\sin \theta)^{1.2}}$$

Step 8. Calculate the time percentage factor $a(p)$ from the time percentage p of concern in the range $0.01 < p \leq 50$:

$$a(p) = -0.061(\log_{10} p)^3 + 0.072(\log_{10} p)^2 - 1.71 \log_{10} p + 3.0$$

Step 9. Calculate the scintillation fade depth for the time percentage p by

$$A_s(p) = a(p)\sigma \quad \text{dB}$$

This procedure has been found to accurately predict frequencies at least up to 30 GHz, although it tends to underpredict slightly at all frequencies in the hot, humid summer months. At higher frequencies (>30 GHz) it is expected that the same $f^{7/12}$ scaling law will apply as shown in step 7 above, although this anticipated result has not been tested experimentally. The fading portion of the tropospheric scintillation A_s is seldom significant for Earth-space paths at elevation angles above 20° for the frequency bands currently in operation (4–30 GHz). As the elevation angle decreases, or the frequency band increases, tropospheric scintillation fading becomes more significant. For example, at 11 GHz, A_s is less than 0.5 dB for 0.01% of an average year at elevation angles on the order of 30° . For the same frequency, A_s approaches 3 dB at elevation angles of 3.2° (11). These values of A_s are for non-raining periods and so will affect the performance of the system.

2. GASEOUS ABSORPTION

When a molecule or atom is nonsymmetric in its structure, it will have a preferred orientation if placed in an electric

field. Such molecules or atoms are said to be *polar*. Polar molecules or atoms cause far more loss to a radio signal than nonpolar molecules or atoms, since the application of an external field causes the polar molecules or atoms to reorient themselves. The reorientation (or relaxation) of the dipoles will remove energy from the applied field and cause heating of the medium. This is the principle of a microwave oven. The major constituents of the troposphere, oxygen and nitrogen, are electrically nonpolar, and so no absorption due to electric dipole resonance will take place. Oxygen, however, is a paramagnetic molecule with a permanent magnetic moment that causes resonant absorption at particular frequencies. Water and water vapor, which both contain two oxygen atoms, are therefore polar molecules, and so absorption occurs as a result of resonance at critical frequencies.

2.1. Oxygen and Water Vapor Resonance Lines

The specific gaseous attenuation γ (dB/km) is given by

$$\gamma = \gamma_o + \gamma_w \quad (\text{dB/km}) \quad (13)$$

where γ_o and γ_w are the specific attenuations (dB/km) due to dry air (essentially oxygen) and water vapor, respectively. The specific attenuation needs to be multiplied by the length of the path over which it operates to arrive at total path attenuation. On terrestrial paths, this is simply the distance between the transmitter and receiver L (km), and the path attenuation A (dB) is given by

$$A = \gamma L = (\gamma_o + \gamma_w)L \quad (\text{dB}) \quad (14)$$

For Earth-space paths, the situation is not so straightforward, since the density and make up of the atmosphere change rapidly with height. The value of L used must be able to take account of the density and other variations along the link through the atmosphere.

Figure 3, abstracted from Fig. 3 of Ref. 14, gives the total zenith gaseous attenuation at frequencies up to 1 THz (10^{12} Hz) for two conditions: a standard atmosphere and a dry atmosphere. A standard atmosphere is defined

Figure 3. Zenith attenuation due to atmospheric gases (from Fig. 3 of Ref. 14). Curve A: standard atmosphere (7.5 g/m^3); curve B: dry atmosphere. (© ITU; reproduced with permission.)

as having the following surface characteristics: pressure 1013 hPa, temperature 15°C, and water vapor density 7.5 g/m³. In general, the dry atmosphere curve in Fig. 3 shows the resonance absorption lines of oxygen, while the standard atmosphere curve is a summation of the resonance absorption lines of water vapor and oxygen. A software code (in Matlab) that calculates the total gaseous attenuation in a line-by-line fashion up to a frequency of 1 THz is available from the Radiocommunication Bureau of the ITU in Geneva.

For nonzenith paths, it is necessary to know not only the specific attenuation at each point in the link but also the length of the path that has this specific attenuation. To derive the incremental pathlengths, ray bending through the atmosphere must be considered (see Fig. 1a). A full procedure to accomplish this is given in Ref. 14. In this procedure, formulae are given for the precise calculation of γ_o and γ_w , and the total zenith attenuation is calculated from

$$A_z = \gamma_o h_o + \gamma_w h_w \quad (\text{dB}) \quad (15)$$

where h_o is the equivalent height of the dry gaseous absorption and h_w is the equivalent height of the water vapor absorption. Typical values of h_o and h_w are 6 km and 2.1 km (during rainy conditions), respectively. For elevation angles between 10° and 90°, a cosecant law gives the total gaseous attenuation A , namely

$$A = \frac{A_z}{\sin \varphi} \quad (\text{dB}) \quad (16)$$

where φ is the elevation angle. For elevation angles below 10°, a more accurate formula that takes account of the real length of the atmospheric path is required [14]. For most Earth-space systems, gaseous absorption is not significant compared with the other impairments. It also changes very little with time and so is usually relatively easy to factor into a system design.

3. RAIN ATTENUATION

Attenuation due to rain is made up of two components: absorption and scattering. Absorption takes place when the incident signal energy is transformed into mechanical energy, thereby heating the raindrop. Scattering occurs when the incident signal is redirected away from the desired propagation path without energy loss to the raindrop. The relative importance of scattering and absorption is a function of the complex index of refraction of the raindrop and the size of the raindrop relative to the wavelength of the signal [15]. The significance of the scattered component generally increases with both the signal frequency and the size of the raindrop. In general, attenuation due to rain increases with increasing signal frequency for a given rain rate. Typical annual cumulative statistics for frequencies of 12, 18.7, 39.6, and 49.5 GHz on paths at an elevation angle of approximately 38° in Europe are shown in Fig. 4 (some data were extracted from Ref. 16). These curves show a monotonic increase in attenuation

Figure 4. Average annual cumulative statistics of total path attenuation at an elevation angle of about 38° in Europe (some data extracted from Ref. 16).

with decreasing time percentage, which is typical of temperate climates. There is evidence, however, that in tropical, high-rain-rate regions there is a saturation effect in the attenuation and rainfall rate statistics at low time percentages, leading to a breakpoint in the cumulative statistics [17]. This and other features of high-rain-rate regions make the accurate prediction of attenuation due to rain very difficult for those locations.

Rain rarely consists of a homogeneous collection of raindrops falling at a constant rate. The size, shape, temperature, and fall velocities usually vary in a dynamic manner along the path. To calculate the attenuation of a radio signal passing through rain it is necessary to invoke a drop-size distribution and to integrate the attenuation contributions of the various raindrops along the path through the rain. The characteristics of rain vary so much in space and time that it is necessary to resort to empirical methods that employ statistical averaging. The accepted approach is to use a power-law representation based on the rainfall rate R (usually a rainfall rate measured at a point on the ground close to the communications link). The specific attenuation γ (dB/km) in rain is related to the rainfall rate R (mm/h) by the power law relationship

$$\gamma = kR^\alpha \quad (\text{dB/km}) \quad (17)$$

where k and α are regression coefficients [18] that take account of absorption and scattering.

3.1. Prediction of Attenuation

Rain attenuation prediction models fall into two classes: (1) those that attempt to analyze the physics of the process and model the constituents of storm cells and so on and (2) those that use empirical approaches with simplified assumptions. To date, those that use empirical methods have demonstrated the most consistent accuracy on a global basis (although, with the strong emphasis currently on the development of accurate, worldwide climatic parameter maps, a physical modeling approach should eventually prevail). For empirical methods, the key to

the prediction process is the development of a procedure that enables the user to move seamlessly from point rainfall rate on the ground to average rainfall rate along the path at any elevation angle. This approach is described below, abstracting directly from the current ITU-R prediction procedure for calculating rain attenuation on a satellite-to-ground path, as set out in Ref. 13:

The following parameters are required: $R_{0.01}$ = point rainfall rate for the location for 0.01% of an average year (mm/h); h_s = height above mean sea level of the Earth station (km); θ = elevation angle; f = frequency (GHz). The geometry is illustrated in Fig. 5. The method is applicable up to at least 30 GHz.

Step 1. Calculate the effective rain height h_R for the latitude of the station ϕ :

$$h_R \text{ (km)} = \begin{cases} 5 - 0.075(\phi - 23) & \text{for } \phi > 23^\circ \text{ Northern Hemisphere} \\ 5 & \text{for } 0^\circ \leq \phi \leq 23^\circ \text{ Northern Hemisphere} \\ 5 & \text{for } 0^\circ \geq \phi \geq -23^\circ \text{ Southern Hemisphere} \\ 5 + 0.1(\phi + 21) & \text{for } -71^\circ \leq \phi < -21^\circ \text{ Southern Hemisphere} \\ 0 & \text{for } \phi < -71^\circ \text{ Southern Hemisphere} \end{cases}$$

Step 2. For $\theta \geq 5^\circ$ compute the length of the slant path L_s below the rain height from

$$L_s = \frac{h_R - h_s}{\sin \theta} \quad \text{km}$$

For $\theta < 5^\circ$, the following formula is used:

$$L_s = [2(h_R - h_s) / \{[\sin^2 \theta + 2(h_R - h_s) / 8500]^{1/2} + \sin \theta\}] \quad \text{km}$$

Step 3. Calculate the horizontal projection L_G of the length of the slant path from

$$L_G = L_s \cos \theta \quad \text{km}$$

Step 4. Obtain the rain intensity $R_{0.01}$ exceeded for 0.01% of an average year at the site.

Step 5. Calculate the reduction factor $r_{0.01}$ for 0.01% of the time for $R_{0.01} \leq 100$ mm/h

$$r_{0.01} = \frac{1}{1 + L_G/L_0}$$

where $L_0 = 35 \exp(-0.015 R_{0.01})$ and, for $R_{0.01} > 100$ mm/h, use the value 100 mm/h in place of $R_{0.01}$.

Step 6. Obtain the specific attenuation, γ_R , using the frequency dependent regression coefficients k and α [18] by using

$$\gamma_R = k(R_{0.01})^\alpha \quad \text{dB/km}$$

Step 7. The predicted attenuation exceeded for 0.01% of an

average year is obtained from

$$A_{0.01} = \gamma_R L_s r_{0.01} \quad \text{dB}$$

Step 8. The estimated attenuation to be exceeded for other percentages of an average year, in the range 0.001–1%, is determined from the attenuation exceeded for 0.01% of an average year by using

$$\frac{A_p}{A_{0.01}} = 0.12p^{-(0.546 + 0.043 \log p)}$$

Note that the variability of the weather from year to year will cause this prediction method to vary similarly. Average accuracy better than about 35% should not be expected for any given year.

4. DEPOLARIZATION

The *polarization* sense of a wave usually refers to the preferred orientation of the electric vector. A perfectly polarized wave will have no component of its electric field in the orthogonal sense. There are only two states for a perfectly polarized wave: linear and circular. For linear polarization, it is common to use vertical and horizontal as the two orthogonal (linear) reference axes. For circular polarization, right-hand circular polarization (RHCP) and left-hand circular polarization (LHCP) are the two orthogonal (circular) reference senses. Depolarization from one reference polarization sense to the other occurs when

Figure 5. Schematic presentation of in Earth-space path (from Fig. 1 in Ref. 13). (© ITU; reproduced with permission.)

the signal passes through an anisotropic medium and the polarization sense of the signal is not aligned with the principal axes of the medium. Rain can be such a medium.

Raindrops exist in a dynamic medium: the atmosphere. When the drops are very small, surface tension forces (which strive to keep the drop perfectly spherical) far exceed the aerodynamic forces on the raindrop (which seek to shape the drop to conform with the external pressures). Under these conditions, the raindrops remain spherical and the rain medium appears symmetric to the signal. No signal depolarization therefore results. As the drops become larger, however, through coalescence with other drops on collision in the rain medium, the surface tension forces can no longer keep the drops spherical. The drops distort into elliptical shapes and so exhibit preferred orientation directions along the major and minor axes of the ellipsoid. Differential attenuation and phase shift will occur on component signals propagating along these axes and will result in signal depolarization. The degree of depolarization measured is called the *cross-polarization discrimination* (XPD) and is defined as

$$\text{XPD} = 20 \log_{10} \frac{E_{\text{co}}}{E_{\text{cross}}} \quad (\text{dB}) \quad (18)$$

where E_{co} is the field measured in the wanted (copolarized) polarization and E_{cross} is the field measured in the unwanted (cross-polarized) polarization. If the differential attenuation (α , nepers) and differential phase (β , radians) caused by a medium are known, XPD can be calculated from

$$\text{XPD} = 20 \log_{10} \left| \frac{e^{-(\alpha+j\beta)} + 1}{e^{-(\alpha+j\beta)} - 1} \right| \quad (\text{dB}) \quad (19)$$

Generally α and β are not known, and it is usual to model XPD against rain attenuation.

4.1. Prediction of Cross-Polarization Discrimination

The most often used prediction method for calculating XPD is that in the ITU-R Recommendation 618 [13]. The procedure is abstracted directly below:

The following parameters are needed: A_p , the rain attenuation (dB) exceeded for the required percentage of time p for the path in question; τ = tilt angle of the linearly polarized electric field with respect to the horizontal (for circular polarization, use $\tau = 45^\circ$); f = frequency (GHz); θ = path elevation angle (degrees). The method is applicable to frequencies between 8 and 35 GHz.

Step 1. Calculate the frequency-dependent term

$$C_f = 30 \log(f) \quad \text{for } 8 \leq f \leq 35 \text{ GHz}$$

Step 2. Calculate the rain-attenuation-dependent term

$$C_A = V(f) \log A_p$$

where

$$V(f) = 12.8f^{0.19} \quad \text{for } 8 \leq f \leq 20 \text{ GHz}$$

$$V(f) = 22.6 \quad \text{for } 20 < f \leq 35 \text{ GHz}$$

Step 3. Calculate the polarization improvement factor

$$C_\tau = -10 \log[1 - 0.484(1 + \cos 4\tau)]$$

The improvement factor $C_\tau = 0$ for $\tau = 45^\circ$ (which is equivalent to circular polarization) and reaches a maximum value of 15 dB for linearly polarized signals with $\tau = 0^\circ$ or 90° .

Step 4. Calculate the elevation-angle-dependent term

$$C_\theta = -40 \log(\cos \theta) \quad \text{for } \theta \leq 60^\circ$$

Step 5. Calculate the canting-angle-dependent term

$$C_\sigma = 0.0052\sigma^2$$

where σ is the effective standard deviation of the raindrop canting angle distribution, expressed in degrees; σ takes the value 0° , 5° , 10° , and 15° for 1%, 0.1%, and 0.01%, and 0.001% of the time, respectively.

Step 6. Calculate the rain XPD not exceeded for $p\%$ of the time:

$$\text{XPD}_{\text{rain}} = C_f - C_A + C_\tau + C_\theta + C_\sigma \quad \text{dB}$$

Step 7. Calculate the ice-crystal-dependent term

$$C_{\text{ice}} = \text{XPD}_{\text{rain}} \times \frac{0.3 + 0.1 \log p}{2} \quad \text{dB}$$

Step 8. Calculate the XPD not exceeded for $p\%$ of the time, including the effects of ice crystals:

$$\text{XPD}_p = \text{XPD}_{\text{rain}} - C_{\text{ice}} \quad \text{dB}$$

For frequencies below 8 GHz, the following scaling formula can be used for $4 \leq f_1, f_2 \leq 30$ GHz:

$$\text{XPD}_2 = \text{XPD}_1 - 20 \log \frac{f_2 [1 - 0.484(1 + \cos 4\tau_2)]^{1/2}}{f_1 [1 - 0.484(1 + \cos 4\tau_1)]^{1/2}}$$

The component for ice depolarization C_{ice} in the preceding formulation is known to underestimate the degree of ice crystal depolarization encountered on low-elevation-angle paths.

Depolarization can be system-limiting in the lower frequency bands, where rain attenuation is not significant (e.g., in the C band, which is the 6/4-GHz uplink/downlink pair for many satellite systems). As the frequency goes up, however, the amount of depolarization observed per decibel of attenuation becomes less and less until, by Ka band (the 30/20 GHz uplink-downlink pair), depolarization is rarely system-limiting. In analog systems, an XPD margin

of 12 dB is usually required to operate successfully. In digital systems, this margin can be reduced because of the possibility of adding coding to the signal. When two satellite links share the same transponder, but are using opposite polarizations (this is referred to as *polarization frequency reuse*), depolarization caused by ice crystals can be a problem. This is because the unwanted (depolarized) component of one link caused by the ice crystals entering the channel of the wanted signal in the satellite transponder without any attenuation having occurred.

5. ATTENUATION DUE TO CLOUDS AND FOG

Fog or mist is essentially supersaturated air in which some of the water has precipitated out to form small droplets of water, usually ≤ 0.1 mm in diameter [19]. Fog is formed mainly from two processes—radiation and advection [6]—and rarely extends more than 100 m above the ground. For this reason, fog is usually ignored in satellite-to-ground links design for frequencies below about 100 GHz. Clouds, however, are much more complicated.

Several models are available for the prediction of cloud attenuation [19–23], but there remain two major difficulties in turning these into link design tools: (1) an accurate cumulative distribution of the vertical and horizontal extent, on a global basis, of those clouds that contribute to slant path attenuation; and (2) separating this attenuation contribution from that due to rain formed in some of the cloud processes. Many measurements of rain attenuation implicitly include attenuation due to clouds. Understanding, and accurately predicting, the contribution of clouds to path attenuation is a key element in the modeling of the proposed V-band (50/40 GHz) satellite services. Of equal importance will be the development of modeling procedures that can predict the combined effects of all the attenuating phenomena on an Earth–space link [24,25].

6. ATTENUATION EFFECTS ON INFRARED AND VISIBLE LIGHT

The far infrared (~ 1 THz), infrared (~ 10 THz), and visible (~ 100 THz) portions of the electromagnetic spectrum have been utilized for many applications. Figure 3 shows that, for a dry atmosphere, the total zenith attenuation is only about 1 dB at 1 THz. This value of zenith attenuation is fairly constant for frequencies through visible light (100 THz). A “window” in the standard atmosphere exists around 890 GHz, the frequency of HCN masers, but the zenith attenuation at this frequency is still two orders of magnitude higher than that in the dry atmosphere (i.e., 100 dB vs. 1 dB total zenith attenuation). For all three frequency ranges, the key attenuating elements in the atmosphere are aerosols, usually cloud and fog droplets. Thick fog (liquid water density ≈ 0.5 g/m³) will cut visibility to 50 m (19). Most free-space laser links are therefore short-range (< 1 km) unless extraordinary powers are contemplated, such as the ~ 1 MW chemical oxygen iodine laser (COIL) planned for missile interception. At such huge power levels, though, the almost instantaneous heating process caused by the passage of the beam through the

atmosphere will modify the constituents along the path, thereby altering the transmission characteristics significantly.

RESONANT TUNNELING DIODES

KOICHI MAEZAWA
Nagoya University
Nagoya, Japan

1. INTRODUCTION

Recent (as of 2003) progress in epitaxial growth technology has made it possible to fabricate thin structures where quantum effects emerge. In these thin structures, the wavelike nature of electrons dominates the current–voltage characteristics. Electrons can penetrate barriers (tunneling), interfere, and create standing waves. A resonant tunneling diode (RTD) exploits such effects. RTDs are characterized by unique current–voltage characteristics showing negative differential resistance (NDR). They consist of extremely thin semiconductor heterolayers with thicknesses of 1 to 10 nm.

Figure 1 shows an example of the RTD structure along with the conduction band diagram. The structure consists of wide-bandgap and narrow-bandgap semiconductors. Typically, it is made of GaAs/Al_xGa_{1-x}As system on GaAs substrate or In_{0.53}Ga_{0.47}As/In_{0.52}Al_{0.48}As system on InP substrate; the GaAs and In_{0.53}Ga_{0.47}As are narrow-bandgap semiconductors, and the Al_xGa_{1-x}As and In_{0.52}Al_{0.48}As are wide-bandgap ones. This structure is grown by molecular-beam epitaxy (MBE) or metallorganic chemical vapor deposition (MOCVD), which can grow epitaxial layer with one-monolayer precision.

Figure 1. An example of the RTD structure with its conduction band diagram. This structure contains a quantum well, which is formed when a narrow-bandgap layer is sandwiched between two wide-bandgap layers.

This structure contains a quantum well, which is formed when a narrow-bandgap layer (well) is sandwiched by two wide-bandgap layers (barriers). In the well, the energy of electrons is quantized due to the wavelike nature of electrons. (The wavelength must be such that half the wavelength (or an integer multiple) matches the thickness of the quantum well, because the electron wave is fixed at the barriers.) Electrons having an energy equal to the quantized energy levels can pass through the barriers, while those that don't have an extremely small chance of passing through. Consequently, unique current–voltage characteristics having NDR are obtained with this structure. An example of such characteristics is shown in Fig. 2. (In this figure, the anomalous steplike structures shown in the negative differential resistance region are due to the spurious effect arising from oscillation within the measuring system.)

RTDs are attracting much attention because of their potential for high-speed operation as well as for high functionality due to the NDR. RTDs with 712 GHz oscillation [1] and 1.5 ps switching [2] have already been reported, and several functional RTD-based circuits [3], which include an oscillator, a mixer, multiple-valued logic, and a neuronlike weighted-sum function [4], have also been reported. These functions reduce the number of devices used, leading to lower power dissipation. Another advantage, one of the most important ones, is that RTDs can operate at room temperature. This differentiates RTDs from most other quantum effect devices, which can operate at only cryogenic temperatures. Thus RTDs are regarded as most practical quantum effect devices for ultra-high-speed analog and digital applications in the near future.

2. OPERATING MECHANISM

The operating mechanism of RTDs is explained here for a simple double-barrier RTD, although there are many

Figure 2. Current-voltage curve of the RTD. This curve is characterized by the NDR.

variations of the structure. Figure 3 shows a conduction band diagram of the RTD for various applied voltages along with current-voltage characteristics. For simplicity, it is assumed that the quantum well has only one subband, which has a minimum energy of E_0 . The current-voltage characteristics can be explained by the energy and momentum conservation through tunneling, as follows.

The z direction is set perpendicular to the wafer surface. This ensures that the translational symmetry in the xy plane holds during tunneling. Hence, the x and y components of the momentum, k_x and k_y , must be conserved at the tunneling, assuming where is no scattering. This indicates that the kinetic energy for z -directional motion and for motion perpendicular to the z direction must be conserved independently. Thus the electrons in the

emitter can go through the barrier into the well if the z component of the momentum k_z has a special value expressed as

$$k_{z0} = \frac{\sqrt{2m^*(E_0 - E_C)}}{\hbar} \tag{1}$$

where E_C is the energy of the conduction band edge of the emitter, m^* the electron effective mass, and \hbar Planck's constant divided by 2π . The current is proportional to the number of electrons having momentum k_{z0} of the above-mentioned value. This can be easily understood from Fig. 4, which illustrates the Fermi sphere for the degenerately doped emitter. Initially, the number of electrons

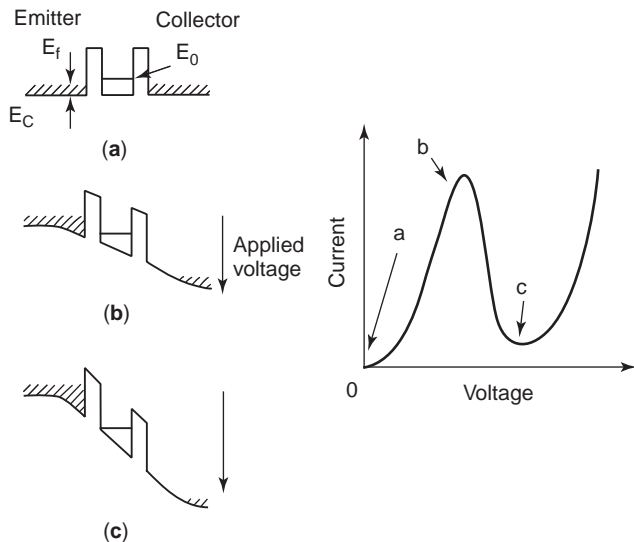

Figure 3. Conduction band diagram of the RTD for various applied voltages with current-voltage characteristics.

Figure 4. Fermi sphere for the degenerately doped emitter. The number of tunneling electrons is proportional to the area of the shaded disk.

with momentum k_{z0} is very small, or 0 at $T = 0$ K, when E_0 is larger than E_F . Their number then increases proportionally to the area of the shaded disk in Fig. 4 when $E_C < E_0 < E_F + E_C$. The electrons in the disk are in the resonant state. The area of the disk πk^2 is expressed as

$$\pi k^2 = \frac{2\pi m^*(E_F - (E_0 - E_C))}{\hbar^2} \quad (2)$$

In the simple approximation that ignores the band bending, E_C is linearly dependent on the applied voltage. This means that current increases linearly with increase in the applied voltage. Then, the number of electrons abruptly decreases when E_0 drops under E_C . Finally, nonresonant current increases with increasing applied voltage beyond this point. The nonresonant current arises from several mechanisms; examples are direct tunneling of thermally excited electrons, scattering, and imperfections of the structure. The result is the current–voltage characteristics shown in Fig. 3.

3. EFFECTS OF SCATTERING

Here, let us briefly consider the effects of scattering. Scattering destroys phase coherence and breaks the transition rule. Possible scattering centers include impurities, phonons, electrons, and interface roughness. Taking scattering into account in RTD theory is difficult and is still an evolving problem.

From a qualitative point of view, scattering in the well, which breaks the phase coherence of electrons, doesn't change the operating mechanism discussed above, if the scattering rate is not large enough to prevent energy-level formation. This is because the mechanism depends only on the fact that the electrons tunnel into the two-dimensional state in the well. It is called “sequential tunneling” when the scattering rate is large enough to destroy all coherence before electrons leave the well [5].

On the other hand, scattering plays an important role in determining peak and valley currents quantitatively [6]. In particular, it has been reported that scattering due to interface roughness has a significant effect on those currents [7]. The interface roughness breaks the translational symmetry in the xy plane, which results in broader resonance, and hence a larger valley current.

4. OPERATION SPEED

One of the most significant advantages of RTDs is their extremely high operation speed. In discussing the limit of the operation speed, it is important to differentiate two response times: the so-called “tunneling time” and the “ RC time.” The former is the time it takes electrons to tunnel through the RTD structure, and is related to quantum mechanics. The latter is the time required to charge the capacitance of the RTD, and is related to circuit theory.

Let us first consider the tunneling time [8]. Suppose that the electric field in the RTD structure changes from the nonresonant state to resonant state at a certain time t_0 . The amplitude of the wavefunction in the quantum well

changes to its steady-state value in response to this change. The tunneling time is the time required for this change. This time is of the order of the resonant state lifetime, τ_{life} , or the “escape” time, which is the time it takes an electron in the quantum well to escape from it. (In the most simple approximation, the tunneling time is the twice the escape time, because the tunneling time consists of two processes, tunneling into the well and from the well.) From simple theory, this time is determined by the energy level width Γ as

$$\tau_{\text{life}} = \frac{\hbar}{\Gamma} \quad (3)$$

The energy-level width Γ is determined as the half-width of the transmission probability function through the resonant state. Roughly speaking, Γ exponentially decreases with increasing barrier thickness and height. This means that a shorter tunneling time can be obtained with thinner and lower barriers, although there is a tradeoff against the peak-to-valley ratio. This time determines the fundamental speed limit for ideal RTDs, and it can be as short as 0.1 ps [9].

However, various nonidealities in the real RTDs affect the tunneling time. These nonidealities include barrier asymmetry, interface roughness, and inelastic scatterings. Several theoretical and experimental studies have been devoted to clarifying the tunneling time of RTDs. A time-resolved photoluminescent measurement using ultrashort pulses [10] has revealed that the escape time from a two-dimensional well agrees reasonably well with Eq. (3). On the other hand, the tunneling time was estimated from the high-frequency characteristics of quantum-well-base transistors [11]. These devices were heterojunction bipolar transistors with a base layer consisting of a resonant tunneling double barrier structure. The results again showed that the tunneling time is in reasonable agreement with Eq. (3). The resonant lifetime described in Eq. (3) is a useful guideline for designing high-speed RTDs, although further studies are necessary to clarify the tunneling time in real systems. In addition to the tunneling time, the transit time across the collector depletion layer affects RTD response when large spacer layers are used.

Next, we will discuss the operation speed limited by RC time. In most applications, the operation speed of RTDs is limited not by the intrinsic tunneling time but by the charging time of RTD capacitance. RTDs are accurately described by the equivalent circuit in Fig. 5. This circuit consists of a voltage-dependent current source $I_{\text{RTD}}(V)$, a voltage-dependent capacitor $C_{\text{RTD}}(V)$, and a series resistor R_s . Here, the parallel combination of $I_{\text{RTD}}(V)$ and $C_{\text{RTD}}(V)$ represents an intrinsic RTD, and the R_s is the sum of series resistances such as the contact resistances. An investigation of the capacitance $C_{\text{RTD}}(V)$ is extremely important in determining the maximum operation speed of RTD circuit. A schematic diagram of the capacitance–voltage curve is shown in Fig. 6 with the current–voltage curve as a reference. The capacitance of the RTD is extracted from the results of microwave S -parameter measurements [12]. In short, there are two main points: (1) the capacitance is roughly equal to that calculated from the undoped spacer layer and the depletion layer of the device, except for the

Figure 5. Equivalent circuit of the RTD. This circuit consists of a voltage-dependent current source, a voltage-dependent capacitor, and a series resistor.

voltage near the peak; and (2) there is an anomalous peak structure in the NDR region, as shown in Fig. 6. This peak is due to resonant electrons accumulated in the well. This must be taken into account to discuss operating speed precisely. Note that $I_{RTD}(V)$ and $C_{RTD}(V)$ do not depend on the frequency when the frequency is sufficiently smaller than the intrinsic limit determined by the lifetime discussed above. (Occasionally, quantum inductance was inserted to the equivalent circuit when the frequency approaches the intrinsic limit. This inductance, however, is difficult to discriminate from wiring inductance.)

Here, consider the operation speed limits for two typical applications. The first is an oscillator [13]. The NDR of RTDs can act as the basis for a very fast and simple oscillator. The maximum frequency of the oscillation f_{max} is expressed as

$$f_{max} = \frac{1}{2\pi C} \left[\frac{-G_{max}}{R_S} - G_{max}^2 \right]^{1/2} \quad (4)$$

where G_{max} is the maximum negative conductance in the NDR region and C is the capacitance at the voltage where G_{max} obtained. This is the frequency above which the dynamic current through the capacitance masks the NDR. Consequently, no oscillation occurs above this frequency. This frequency can be extremely high, for example, 1.24 THz [1].

The second example is the switching time for the resistance-load RTD circuit [14]. Figure 7 shows the load

Figure 6. Schematic diagram of the capacitance–voltage curve with a current–voltage curve as a reference. An anomalous peak structure is shown in the NDR region.

diagram and the switching mechanism of the circuit. A small pulse applied to the bias terminal makes the circuit switch from OFF state to ON state. This switching time can be calculated from the equivalent-circuit model, and is approximated to be a few times RC , where C is the average capacitance in the NDR region and the R is the negative resistance. Extremely short switching times of 1.7 ps [15] and 1.5 ps [2] have been reported for InAs/AlSb and InAs/AlAs RTDs, respectively.

It is worth noting the advantages of RTDs compared to Esaki diodes, or tunnel diodes. The I – V curves of Esaki

Figure 7. Load line diagram of the resistive load RTD switch circuit. The circuit switches its state in response to a small pulse (V_{pulse}) applied to the bias voltage. A small pulse applied to the bias terminal makes the circuit switch from OFF state to ON state.

diodes show NDR similar to RTDs, and several applications similar to RTDs have been studied. The one of most important advantages of the RTD is the ability to obtain a high peak current density with a relatively low capacitance. For example, an extremely high current density of 6.8 GA/m^2 is obtained with a capacitance of about 1.5 mF/m^2 [2]. These values indicate that the speed index, which is defined as the peak current density divided by the capacitance per unit area J_p/C , is as large as 4.55 V/ps . (The speed index corresponds to the speed of voltage variation, when the RTD capacitance is charged by its peak current.) This is much larger than those of Esaki diodes, which are smaller than 0.1 V/ps . This is possible because the current density of RTDs can be increased by changing the barrier and the well thicknesses, and this can be achieved without decreasing depletion layer thickness. On the other hand, one must increase impurity density to decrease tunnel barrier (= depletion-layer) thickness in order to increase current density in Esaki diodes. Consequently, the maximum operation speed of RTDs can be much higher than that of Esaki diodes. Furthermore, RTDs can avoid degradation observed in Esaki diodes due to impurity diffusion at the highly doped p-n junction.

5. RTD VARIATIONS

Several variations of RTDs have been studied. The one variation is an RTD with more than two barriers. The purpose of using multiple barriers is to obtain a multiple-peak I - V curve, which can be used for application for multiple-valued logic [16]. Also, the triple-barrier structures have been used to make a sharp peak. This is because the first quantum well plays the role of an energy filter [17].

Several materials other than GaAs/AlAs or In GaAs/InAlAs systems have also been studied. In particular, the AlSb/GaSb/InAs systems is attracting much attention because of its unique band lineups. Two different structures have been proposed for this material system [18,19]. One is the AlSb/InAs/AlSb double-barrier quantum-well structure, which has a band diagram similar to that of AlAs/GaAs. This heterostructure has a larger barrier height than AlAs/GaAs, so a larger peak-to-valley (P/V) current ratio can be obtained. The other is the resonant intervalley tunneling diode (RITD), which exploits the type II band alignment of the AlSb/GaSb/InAs system. (The conduction band minimum of InAs is lower than the valence band maximum of GaSb; see Fig. 8.) RITDs consist of a GaSb well sandwiched by AlSb barriers with InAs emitter/collector layers. In the GaSb well, quasibound states are formed in the valence band. This allows electrons in the emitter to tunnel through the valence band state of GaSb to the collector. In this structure, the bandgap of GaSb blocks the leakage current at the valley voltage. Consequently, an extremely high P/V ratio of more than 20 is possible at room temperature.

The implementation of RTDs with a Si-based material system has attracted increasing attention. Several types of devices were reported, which include an SiO_2/Si , SiGe/Si , CaF_2/Si , and $\gamma\text{-Al}_2\text{O}_3/\text{Si}$ systems [20]. Until now, only limited performance has been obtained for these systems

Figure 8. Conduction band diagram of the resonant intervalley tunneling diode.

(low P/V ratio, low peak current density). This is due to the higher electron mass in Si compared to that of the compound semiconductors. Further effort would be necessary to realize high-performance Si-based RTDs. However, the emergence of high-performance Si-based RTDs would have an extremely significant impact, because highly functional circuits using them could be implemented in Si VLSIs.

6. DEVICE MODELING

A device model of the RTDs suitable for circuit simulation is significant for designing circuits using RTDs. The equivalent-circuit model shown in Fig. 5 is generally used with a parasitic inductance L_s connected serially. For the I - V curve, the most simple model is the piecewise linear approximation. This is convenient to obtain general view of the circuit behavior. However, it's not sufficient for precise circuit design. Some model equations of RTD I - V curves have been proposed for circuit simulation. These equations are simple to use in circuit simulators, but can be closely fitted to experimental I - V curves. Among these, Schulman's model [21] is often used because it shows better fit for high-performance RTDs. Their equation is shown below, which is based on the physical current equation but some variables are treated as fitting parameters:

$$I(V) = I_{\text{RT}}(V) + I_{\text{NRT}}(V) \quad (5)$$

$$I_{\text{RT}}(V) = A \log \left[\frac{1 + \exp[(B - C + n_1 V)]}{1 + \exp[(B - C - n_1 V)]} \right] \times \left(\frac{\pi}{2} + \arctan \frac{C - n_1 V}{D} \right) \quad (6)$$

$$I_{\text{NRT}}(V) = A_0 \left(\exp \frac{V}{n_0} - 1 \right) \quad (7)$$

Figure 9. Model I - V curve fitted to the experimental data.

Here, $A_0, A, B, C, D, n_0, n_1$ are the fitting parameters. The model I - V curve is shown in Fig. 9 with the experimental one.

The C - V characteristics are more difficult to implement. This is because the precise measurement of capacitance for high-performance RTDs is very difficult because of its extremely small value and the difficulty in biasing the RTDs in NDR region. At present, capacitance calculated from the depletion layer thickness is often used for simulation. This is a reasonably good approximation in a moderate frequency range. However, for higher frequency ranges close to the cutoff frequency of the RTDs, it should be necessary to take the effect of electron accumulation in the well into account.

7. APPLICATIONS

Several possible RTD applications that exploit the NDR characteristics are now being developed. Although most of them are similar to those once proposed for Esaki diodes, progress in related device technology and the ultra-high-speed potential of RTDs open up new possibilities. The most attractive applications are microwave/millimeter-wave analog circuits [13]. They include an oscillator, a frequency multiplier, a mixer, and a trigger [22]. Some of these applications are discussed in detail here.

7.1. Oscillators

Oscillators based on NDR have been studied intensively. Oscillation frequencies up to 712 GHz with InAs/AlSb RTDs are the highest achieved to date and exceed those of any other solid-state devices [1]. The most significant problem that impedes use of RTD oscillators in real applications is the output power [23]. For example, output powers reported so far were 50 μ W at 205 GHz, 28 μ W at 290 GHz, and 0.3 μ W at 712 GHz. One of the most significant reasons for these small powers is the limited area of the RTD available in the circuit. This limitation is imposed to avoid oscillations in bias circuit. Small $V_v - V_p$ (V_v = valley voltage), and hence, large negative conductance makes this problem difficult to solve. Series integration of RTDs is one promising technique to overcome this

problem. However, biasing such series connected RTDs in the NDR region is unstable even when the total bias voltage V_{bias} satisfies the condition $nV_p < V_{\text{bias}} < nV_v$ (n = number of RTDs connected serially). In fact, the total voltage is distributed such that all RTDs are biased in the positive differential resistance regions. To solve this problem dynamic biasing techniques using a subfrequency excitation have been proposed [24]. Decreasing the parasitic resistance is also a significant problem for realizing high-frequency oscillators because this resistance restricts the available power as well as the maximum oscillation frequency. An interesting technique for decreasing collector contact resistance is to use the undoped Schottky contacts for the collector [25]. When the RTD is biased in the operating voltage, the forward-biased Schottky contact has no barrier that impedes electrons flowing from collector to the metal.

7.2. Mixers

The RTD has the ability to act as a mixer because of the rapid variation of the conductance with voltage. For a diode oscillating with a DC bias at the center of the NDR region, the time-varying small-signal dynamic conductance changes from a large negative value at the DC bias point to a small, perhaps positive, value at both extrema of the oscillation amplitude. Consequently, the RTDs can act as a mixer when the RF and LO signals are input.

7.3. Frequency Multipliers

As described above, the RTD shows a strong nonlinearity. The Fourier series of the conductance then has large coefficients at its first few harmonics, especially the even harmonics if the I - V curve is antisymmetric about the bias point. These harmonics can be used for frequency multipliers.

7.4. Clock Recovery Circuits and Frequency Dividers

Interesting applications relative to the resonant tunneling oscillators have been proposed. These are based on the injection-locking phenomenon, or more generally, the bifurcation phenomenon in the resonant tunneling oscillator circuits. First is an optoelectronic clock recovery circuit as shown in Fig. 10 [26]. The circuit consists of an oscillator, which is constructed with an RTD and a transmission line, and an extremely high-speed photodiode called UTC PD (uni-traveling-carrier photodiode). The essential synchronization principle is injection locking of the RTD oscillator using the photocurrent generated by UTC PD. It was reported that the integrated circuit fabricated on an InP substrate extracted an electrical 11.55-GHz clock signal from 11.55-Gbps RZ (return-to-zero) optical data streams in a wide locking range. Furthermore, the extraction of a subharmonic clock from 46.2 Gbps input datastreams was also reported. This indicates that this circuit also works as a frequency divider with an optical input.

The similar locking phenomenon was also adapted to a frequency divider shown in Fig. 11 [27]. This simple circuit can be regarded as a Van der Pol oscillator with an oscillating input. It is known in the field of nonlinear physics

Figure 10. Circuit diagram of the clock recovery circuit.

that this type of circuit yields various signal patterns including long period signals, whose period T is integer-multiple of the input period T_0 ($T = nT_0$). This behavior is known as a *bifurcation phenomenon*, which is closely related to chaos. (In fact, this circuit also shows chaotic behavior under certain conditions, and several applications using controlled chaos could be realized, e.g., communication using chaos synchronization, and encryption.) Ultra-high-frequency operation at 88 GHz of the 1–2 frequency divider has been realized with this circuit.

Several circuits have also been proposed for digital applications [3]. The latching function due to the bistability of RTD circuits is the basis for most of these applications. A typical example of such a circuit is a (multiple-valued) memory, which uses RTDs connected in series or parallel with appropriate load.

8. RESONANT TUNNELING TRANSISTORS AND INTEGRATION WITH CONVENTIONAL TRANSISTORS

An RTD has only two terminals, which restricts the use of resonant tunneling phenomena. Adding a control terminal to RTDs extends their usability to a variety of applications. The most straightforward way to do this is to merge RTD with conventional transistors to make a composite device. This approach has been used to build resonant tunneling bipolar transistors (RTBTs) [3], resonant (tunneling) hot-electron transistors (RHET) [28], and gated RTDs. The RTBTs have a resonant tunneling structure at the emitter/base junction region or in the base. An RHET

is similar to RTBT and has a resonant tunneling structure at the emitter of the hot-electron transistor. Consequently, these devices have negative transconductance in emitter-grounded transistor characteristics. These nonlinear input–output characteristics can be applied to several circuits, such as an XOR (exclusive-OR) logic gate with only one transistor. On the other hand, gated RTDs have Schottky or junction gates around the emitter to control RTD area, and show an NDR with controlled peak current. These devices are used for a functional logic gate called a “MOBILE” (monostable–bistable transition logic element) [4], and are useful in investigating the physics of very small tunneling structures [29].

The other and more practical way to add control terminals is to connect RTDs with conventional transistors to make parallel or series circuits. Integration of RTDs with transistors is necessary in order to do this, but this has a significant advantage beyond merely adding a control terminal. One can use both RTD circuits and conventional transistor circuits according to their merits and demerits. Integration of RTDs with HEMTs or bipolar transistors have been proposed, and several circuits have been also reported using such devices [30–32].

In general, two configurations are used to connect an RTD and a transistor: parallel and serial configurations, as shown in Fig. 12. (Here, field-effect transistors are used for instance. The following discussion is valid for bipolar transistors.) The parallel circuit can be regarded as an NDR device capable of peak current modulation. On the other hand, the serial circuit, which has two options, connecting the RTD at source or drain, shows a negative transconductance. The former is used for the logic gate

Figure 11. Circuit diagram of the chaos generator (frequency divider).

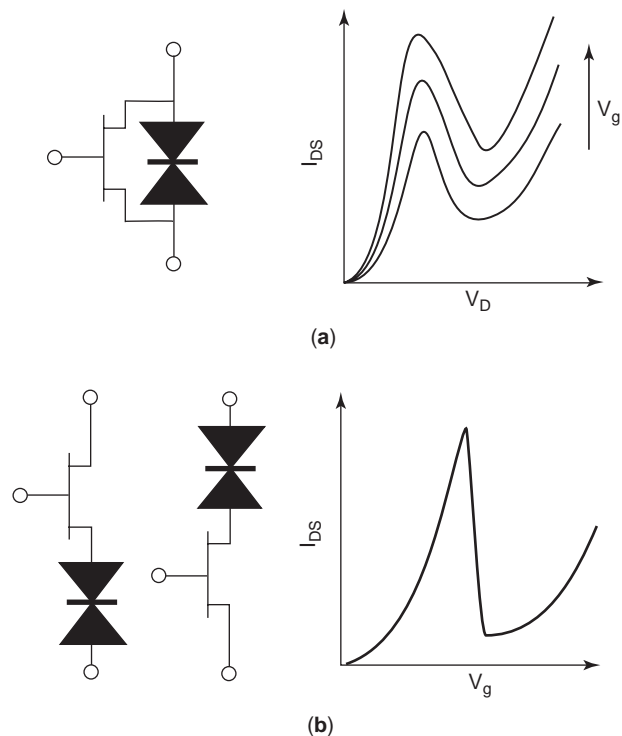

Figure 12. Basic configurations of the RTD/FET circuit together with its I - V characteristics.

MOBILE, and the latter is also used for various analog and digital applications. Here, some applications of these circuits will be discussed in detail.

8.1. MOBILE [Monostable-Bistable (Transition) Logic Element]

The MOBILE [33] is a functional logic gate exploiting the NDR of RTDs. It consists of two serially connected NDR devices with FET(s) connected parallel to the NDR device(s). The simplest form of the MOBILE, shown in Fig. 13, works as a clocked inverter, together with the load line diagram. The key point is that it employs the monostable-to-bistable transition of the circuit, and the circuit is driven by oscillating the bias voltage to produce the transition. A stable point S in the $V_{bias} < 2V_p$ region splits into two branches, S_1 and S_2 , when V_{bias} increases through $2V_p$. A small difference in the peak current between the two NDR devices determines the circuit's state after the transition. Therefore, the circuit forms a logic gate if the peak current of the NDR devices can be modulated according to input signals. The oscillatory varying bias voltage acts as a clock. The MOBILE switches its state only at the rising edge of the bias voltage (it works as a clock) and maintains its state while the bias voltage is high (edge-trigger and latch operation).

Several application circuits of the MOBILE have been reported, which include a 35-Gbps D-FF, and a 34-GHz T-FF. Moreover, replacing the input HEMT by a photodiode, a 80-Gbps optical D-FF has been demonstrated [34]. Owing to the function of the MOBILE, the numbers of devices used in the circuits have been reduced considerably in comparison to those of the conventional circuits.

Figure 13. Operating principle of the MOBILE inverter: (a) basic configuration; (b) load diagrams for various V_{bias} .

Figure 14. Schematic cross-sectional view of the RTHEMT with its equivalent circuit.

8.2. RTHEMT (Resonant Tunneling High-Electron-Mobility Transistor)

The RTHEMT [35,36] is one of the most promising devices, which incorporates an RTD at the source of a HEMT. It features a pronounced NDR and a negative transconductance. Figure 14 shows the schematic cross-section and the equivalent circuit of the RTHEMT. The RTD layers are grown on top of the HEMT layers. Its $I_{DS}-V_{GS}$ characteristics are shown in Fig. 15. As shown in the figure, strong nonlinear characteristics including negative transconductance, are observed for the RTHEMT. Note that this negative transconductance can be obtained in a wide range of the drain voltage due to the feedback of the nonlinear source resistance. This is in marked contrast with the configuration where the RTD is connected to the drain, which shows negative transconductance in relatively small range.

This folded $I_{DS}-V_{GS}$ curve is useful for fabricating frequency multipliers. A frequency doubler MMIC integrating RTHEMT and on chip impedance-matching circuit have been successfully fabricated. The discontinuous change in the drain current in $I_{DS}-V_{GS}$ characteristics is also valuable for various nonlinear circuits. This yields extremely high-order harmonics in its output. These high-order harmonics can be used for a pulse generator for the sampling phase detector and a signal source for injection-locking oscillator.

Figure 15. $I_{DS}-V_{GS}$ characteristics of the RTHEMT.

9. SUMMARY

Resonant tunneling diodes exploit the quantum tunneling effect emerging in nanometer-scale thin semiconductor heterostructures. The RTDs feature strong nonlinear current-voltage characteristics exhibiting negative differential resistance and also extremely high operation frequency. These features make the RTDs extremely useful for nonlinear microwave/millimeter-wave circuits as well as high-speed digital circuits. RTDs are excellent candidates for the high-frequency and low-power applications of the near future, and vigorous efforts to build and perfect them shall continue.

Consider an electromagnetic wave in free space impinging on a flat metal sheet as shown in Fig. 1. If the direction of propagation is normal (i.e., perpendicular) to the metal surface, the wave reflects off the metal sheet in the same direction from which it originated. This is an example of *retrodirective* behavior, or simply, *retrodirectivity*. However, this does not imply that the metal sheet is a retrodirective system, because this behavior is observed only at normal incidence, when $\theta = 0^\circ$. If the incoming wave is incident at an arbitrary, nonnormal angle θ , the reflected wave does not bounce off the metal sheet at θ , as required for a retrodirective system, but instead at the specular angle $-\theta$ predicted by Snell's law. Moreover, if the direction of propagation is parallel to the metal surface ($\theta = 90^\circ$), the wave only grazes the sheet and there is no reflection at all. Retrodirectivity requires that the incoming wave bounce back in the same direction from which it originated, regardless of what that direction is.

Although one metal sheet cannot function as a retrodirective system, two or more metal sheets can. Figure 2 illustrates a retrodirective system formed by intersecting two mutually perpendicular, flat metal sheets. Since each quadrant forms a corner shape, the resulting structure is called a *corner reflector* [1], and provides retrodirectivity for any angle of incidence in the x - y plane. The system is easily extended to three dimensions by intersecting the two metal sheets in Fig. 2 with a third metal sheet that is

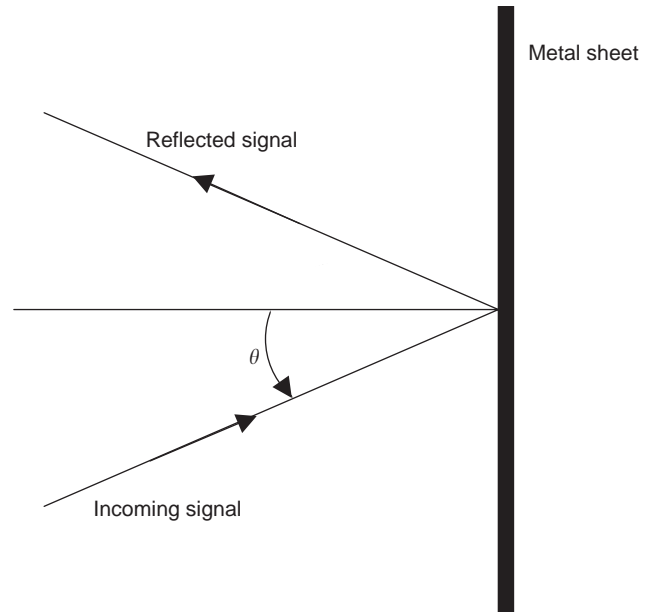

Figure 1. Reflection from a metal sheet. Retrodirective behavior occurs only at normal incidence ($\theta = 0^\circ$). At other angles of incidence, the reflected wave does not bounce back in the same direction from which it originated.

mutually perpendicular to both, creating a three-dimensional corner in all eight octants. Multiple reflections off of any one corner cause incoming waves from all possible angles in three-dimensional space to be reflected back in the same direction of the originating wave, giving rise to true retrodirectivity. We define a *retrodirective system*, then, as one that reacts to an incoming signal (often called an *interrogating* or *pilot signal*) from an unspecified direction by transmitting a response to that same direction, regardless of what that direction is. The response is completely automatic, and is performed without any prior knowledge of the location of the source.

Basic retrodirective systems such as the corner reflector were originally proposed as passive reflectors for use as radar targets, as they are capable of providing radar

Figure 2. For a corner reflector, retrodirectivity is observed for waves incident from any angle in the x - y plane.

cross sections much larger than their physical size. But with advances in high-frequency electronics, more recently developed retrodirective systems have become more functional by providing modulation or gain, making them useful for wireless communication applications [2,3]. The autonomous beamsteering feature of retrodirective systems make them attractive for automatic pointing and tracking systems, microwave-tracking beacons, radio-frequency identification (RFID), solar power satellites, and crosslinks for small-satellite networks.

In each of these applications, the scenario is similar. An omnidirectional interrogating signal is transmitted in all directions. The retrodirective system, on receiving this signal, automatically transmits a response back to the interrogator. For microwave-tracking beacon applications, the interrogator uses this response to track the beacon's position. For RFID applications, the retrodirective tag's response includes inventory control information.

Retrodirective systems excel in applications where communication links are not fixed, as in base-to-mobile or mobile-to-mobile communications. The autonomous beamsteering is achieved at a purely hardware level, providing a means for creating secure, efficient, directive systems for satellite communications, wireless local-area networks, terrestrial peer-to-peer communications, or covert battlefield communications, without adding additional processing or system design strain.

One more recently proposed application of retrodirective systems is for the emerging area of small-satellite networks [4]. The smaller mass of nanosatellites (10 kg) and picosatellites (1 kg) make them more economical to develop and launch into orbit. Networks of small satellites promise increased mission flexibility and success by distributing the tasks and subsystems typical of a single large satellite. An autonomous small-satellite network also reduces the possibility of catastrophic single-point failure; if one satellite fails, others can take up the slack until a replacement is launched. However, the challenge in designing a distributed small-satellite network—especially a dynamically reconfigurable one—is in establishing and maintaining a reliable crosslink with other satellites in the network without a priori knowledge of their positions.

Omnidirectional antennas are the obvious choice for crosslinking satellites that are subject to constant repositioning, but this leaves the network susceptible to eavesdropping by unauthorized ground stations as well as by satellites outside the network but still within range of the constellation. Omnidirectional antennas are also inefficient, as power is radiated in all directions, not just in the direction of the receiver. Retrodirective crosslinks between satellites moving randomly in space provide the benefits of not only self-steering but also directivity. The high directivity associated with retrodirective systems improves not only network security but also the communication link efficiency by minimizing power consumption; this reduces the burden on transmitting and receiving amplifiers while still mainlining a reasonable link margin. The simplicity of the retrodirective approach is important for small satellites in which power is at a premium.

It is important to note that the automatic, self-steering function of retrodirective systems is performed autom-

atically, without the use of phase shifters, digital circuitry, or software. Compared to conventional phased-array antennas in which the phasing of the array is user controlled, a retrodirective system is self-phasing. Compared to smart antennas that rely on digital signal processing for beam control, retrodirective systems are much simpler and potentially faster because digital computations are not needed.

Much of the early work in retrodirective systems is reviewed in Ref. 5. This article focuses on more recent developments in antenna array systems that exhibit retrodirective behavior, and thus are called *retrodirective antenna arrays*. First, basic concepts in antenna arrays are reviewed, followed by a discussion of the two basic retrodirective array architectures. Next, methods for characterizing the arrays are reviewed. Finally, examples of more advanced retrodirective arrays and systems are presented.

1. BASIC RETRODIRECTIVE ARRAY ARCHITECTURES

Although the corner reflector is well suited for applications such as radar targets or markers, it is not particularly useful for wireless communications: (1) it is difficult to integrate electronics that are necessary for modulating the retrodirected signal; (2) corner reflectors must be large with respect to a wavelength to minimize the effects of edge diffraction, which distorts the retrodirected radiation pattern; and (3) the very nature of corner reflectors prohibits them from being planar and low-profile, which are desirable features for many applications.

For wireless applications, it is more common to use retrodirective *antenna arrays*, which lend themselves to integration with electronic circuits, are smaller and lighter than corner reflectors, and can be made planar and low-profile. An antenna array is composed of individual radiating elements. By combining individual antennas in an array, one can achieve higher directionality and the ability to steer the beam.

To illustrate, consider the four-element array shown in Fig. 3, consisting of four isotropic antennas spaced a

Figure 3. A four-element antenna array. If the elements are excited with a phase gradient that is increasingly negative from left to right, the mainbeam will appear to the right of broadside.

distance d apart. An isotropic antenna is one that radiates equally in all directions. The radiation from each element constructively interferes in certain directions (creating mainlobes and sidelobes) and destructively interferes in others (creating nulls), resulting in what is known as an *antenna radiation pattern*. An antenna's radiation pattern is the same whether it is transmitting or receiving.

The directions of constructive and destructive interference depend on the spacing between elements relative to the wavelength as well as the excitation of each element. For example, if each antenna element is excited at the same time (i.e., in phase), the radiation constructively interferes to create a mainbeam that forms in the broadside direction, defined as the two directions that are perpendicular to the array axis. If each antenna element is excited with a time delay between successive elements (i.e., with a progressive phase shift), the mainbeam forms in the direction corresponding to the amount of delay induced. The mainbeam direction is the one for which the path delay for each element compensates for the excitation delay for each element, resulting in a mainlobe that forms along the direction for which the radiation from each element adds in phase. It is therefore the phase gradient across the array that determines the direction of the mainbeam. If the element phase excitation is increasingly negative in moving from the left to the right, the mainbeam will appear to the right of the broadside direction, as shown in Fig. 3.

Conventional phased-array antennas are able to steer their beams by exciting elements with phase shifters. In contrast, retrodirective antenna arrays steer their beams automatically, without any phase shifters, in response to an interrogating signal.

1.1. Van Atta Arrays

Van Atta arrays [6] consist of pairs of antenna elements equally spaced from the center of the array with equal-length transmission lines (Fig. 4). The signal received by one antenna is reradiated by its pair, causing the order of reradiation to be flipped with respect to the center of the array. The phase gradient of the array is therefore re-

Figure 4. A Van Atta array, consisting of pairs of antennas connected with equal-length transmission lines.

versed (positive to negative, negative to positive) to achieve the proper phasing for retrodirectivity. Since the lengths of the connecting transmission lines are equal, the only frequency-dependent component in the Van Atta array is the antenna element. The use of broadband antennas and nondispersive transmission lines allows the array to perform over a wide bandwidth. However, this array configuration is restricted to planar wavefronts and planar topologies.

Figure 5 shows a microstrip patch antenna reflector array using the Van Atta architecture, developed at Texas A&M University [7]. The microstrip patch antennas are aperture-coupled with feedlines printed on the backside of the substrate, preventing undesired radiation from the feed networks and making the design compact. The array achieves wide angular coverage by taking advantage of both scattered and retrodirected fields. Radiation pattern measurements show a beamwidth larger than 120° , while a metal plate of the same size provides only a 10° beamwidth. Another type of Van Atta array, shown in Fig. 6, was developed at National Chiao Tung University [8]. The prototype array has six elements, each containing two slot antennas. Backradiation from the slot antennas is short-circuited with a metal reflector placed behind the array, which also serves to increase the radar cross section (RCS).

These two examples were proposed for intelligent vehicle highway system (IVHS) applications. The arrays successfully provide large radar cross sections in a wide angular range without any electronic circuitry, except for integrated switches in the transmission lines to provide modulation. The study shows promising results for other applications such as RFID.

1.2. Phase-Conjugating Arrays

A more popular technique for realizing retrodirective arrays is based on phase conjugation. This approach uses the same idea of the reversal of a phase gradient in the Van Atta array, but phase reversal is achieved at each antenna element instead of relying on antenna pairs.

In this scheme, shown in Fig. 7, heterodyne mixing [9] causes the incoming radiofrequency (RF) signal at each element to mix with a local oscillator (LO), creating the following mixing product:

$$\begin{aligned} V_{IF} &= V_{RF} \cos(\omega_{RF}t + \theta_n) \cdot V_{LO} \cos(\omega_{LO}t) \\ &= \frac{1}{2} V_{RF} V_{LO} [\cos((\omega_{LO} - \omega_{RF})t - \theta_n) \\ &\quad + \cos((\omega_{LO} + \omega_{RF})t + \theta_n)] \end{aligned} \quad (1)$$

If the LO frequency is twice the RF frequency, we obtain the following:

$$V_{IF} \propto \cos(\omega_{RF}t - \varphi) + \cos(3\omega_{RF}t + \varphi) \quad (2)$$

Note that the first term in (2), which is the lower sideband product (intermediate frequency, or IF signal) has the same frequency as the RF, but with a reversed, or

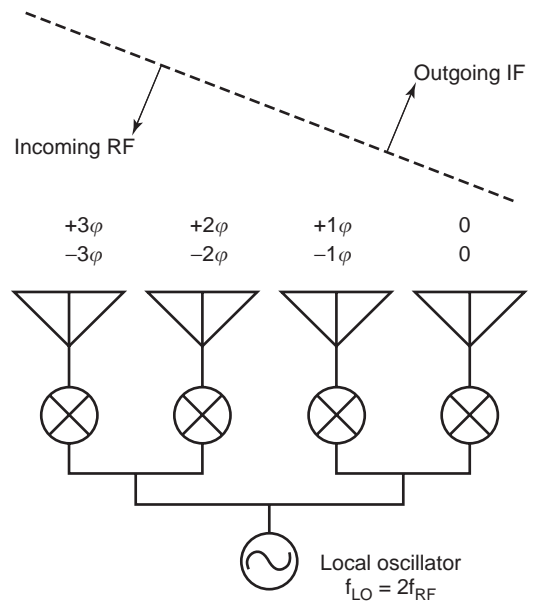

Figure 7. Phase-conjugating array using heterodyne mixers. The phase gradient associated with the incoming (RF) wave is conjugated, causing the outgoing (IF) wave to be retrodirected back toward the source.

conjugated phase. An array of such phase-conjugating elements causes the same kind of phase reversal as in the Van Atta array, resulting in a reradiated beam back toward the source direction.

In this method, it is important to eliminate undesired signals so that only the desired phase-conjugated signal radiates from the array. The upper sideband product in (2) and the LO leakage can easily be filtered and suppressed since their frequencies are far apart from the phase-conjugated signal frequency. Another signal that must be suppressed is the RF signal that leaks directly from the input to the output of the phase conjugator. This signal is exactly the same frequency as the desired IF signal, but is not phase-conjugated. The non-phase-conjugated RF leakage creates a specular beam that is the mirror image of the desired retrodirective beam. For example, if the retrodirected beam is formed at 20° , then the leakage signal will form at -20° .

Therefore, RF leakage suppression is one of the key challenges in the phase-conjugating heterodyne method. Since it is impossible to filter out the RF leakage, as its frequency is the same as that of the phase-conjugated signal, balanced mixer topologies are usually used to eliminate undesired signals.

1.2.1. Passive Phase-Conjugating Arrays. Figure 8 shows an example of the phase-conjugating architecture—an eight-element array using ratrace diode mixers that was developed at the University of California, Los Angeles (UCLA) [10]. Mounted between ports 2 and 4 of a dual-frequency ratrace coupler is a pair of series diodes, the center of which is short-circuited at the LO and RF/IF frequencies by two radial stubs. The 12-GHz LO and 6-GHz RF signals are applied through filters, which effectively isolate the LO from the RF/IF signals. RF-IF isolation is achieved by the balanced structure of the ratrace coupler. The measured conversion loss of the mixer is 5–7 dB over a RF frequency range from 5.5 to 6.5 GHz, while good RF-IF isolation is maintained over the range. The bidirectional characteristic of the circuit permits retrodirectivity for any polarization by using the two orthogonal modes of a patch antenna.

1.2.2. Active Phase-Conjugating Arrays. Passive, diode-based phase conjugators generally provide better RF-IF isolation than do active, transistor-based phase conjugators, especially when no bias is required. The major shortcoming of passive phase conjugators is the conversion loss, which limits the distance between the interrogator and the retrodirective array. The use of active devices such as metal semiconductor field-effect transistors (MESFETs) is attractive as they can provide conversion gain during the mixing process. Active phase conjugators make it possible for the retrodirective array to transpond an amplified signal back to the source location, without the need for additional amplifiers.

Figure 9 shows an example of this approach, developed at UCLA [11]. Like the design in Fig. 8, this circuit uses a dual-frequency ratrace coupler. The LO and RF signals are applied to FET mixers out of phase, resulting in cancellation of the RF and LO leakage while a phase-con-

jugated signal from each channel of the balanced mixer combines in phase at the output port. The measured conversion gain is about 6 dB, and the RF-IF isolation is better than 20 dB at the center frequency.

UCLA modified its phase conjugator design to eliminate the need for a dual-frequency combiner, thus simplifying the design and making it more compact [12]. As shown in Fig. 10, the interrogating RF signal is split into two channels that are 90° out of phase, while the LO is applied in phase. Phase-conjugated IF signals from the two channels are combined in phase, while the RF leakage is canceled before retransmission. The balanced structure suppresses the undesired RF leakage, achieving 20 dB of RF-IF isolation and a conversion gain of 3.2 dB. The array operates in the 6-GHz band, with a 12-GHz LO applied in phase to each phase conjugating element through a corporate feed network.

The strength of the phase-conjugating technique is the recreation of a wavefront. Unlike the Van Atta architecture, this technique allows an array to retrodirect a signal to the source through obstacles or in the near field [13], as shown in Fig. 11. It also accommodates nonplanar wavefronts and surfaces.

1.3. Characterization

Figure 12 illustrates the two standard measurements for characterizing the self-steering performance of a retrodirective antenna array: bistatic and monostatic radar cross sections (RCSs). In both cases, an interrogating signal provided by a horn antenna impinges on the array under test, whereupon the retrodirected signal is transmitted back (ideally in the same direction from which it originated) to a second receiving horn antenna. In the bistatic case, the interrogating antenna remains stationary while the receiving antenna is scanned. The resulting measurement shows a mainlobe in the direction of the source, with nulls or sidelobes in other directions. In the monostatic case, both the interrogating and receiving antennas are collocated and simultaneously scanned. Since the interrogating and retrodirected signals are both in the same direction, the peak of the array radiation will always be in the direction of the receiving antenna, and thus the monostatic pattern will exhibit a relatively flat pattern, without nulls.

Since the interrogating and retrodirected signals share the same frequency, there is always unavoidable coupling between the interrogating and receiving horns. In a phase-conjugating array or modified Van Atta array, this problem is overcome by slightly offsetting the frequencies so that the two signals can be resolved on a spectrum analyzer. For instance, the following frequencies could be used: an interrogating signal of 4.99 GHz, an LO signal of 10.00 GHz, and a retrodirected signal of 5.01 GHz. Phase conjugation is achieved even if the interrogating and retrodirected frequencies are not identical, but the deviation between these two frequencies leads to a pointing error in the return beam. The amount of the error depends on this frequency difference as well as the incoming beam angle, since the amount of progressive phase shift needed for array beamsteering is a function of antenna element spacing in terms of wavelength.

Figure 8. Passive phase-conjugating array using ratrace diode mixers: (a) phase-conjugating unit cell; (b) eight-element prototype. (Courtesy of IEEE [10].)

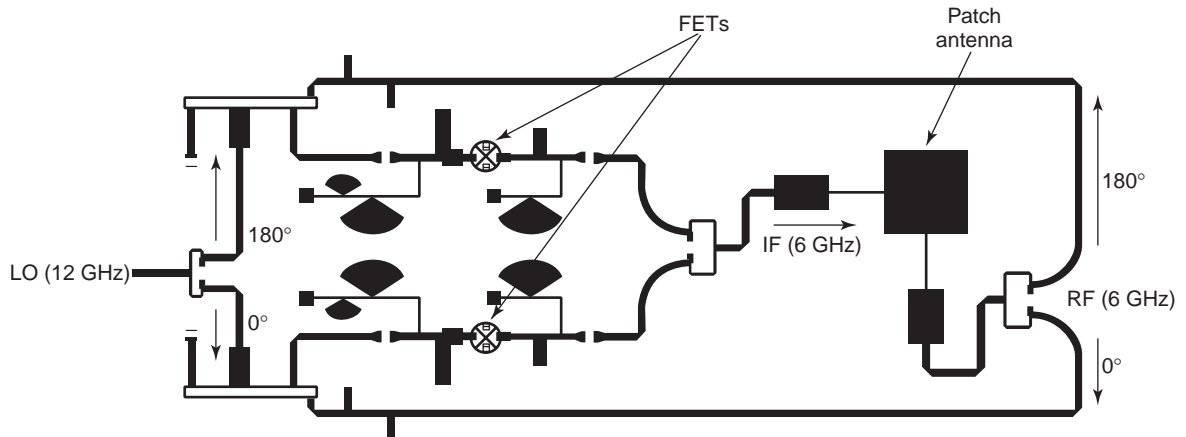

Figure 9. Balanced active phase conjugator integrated with antenna. (Courtesy of IEEE [11].)

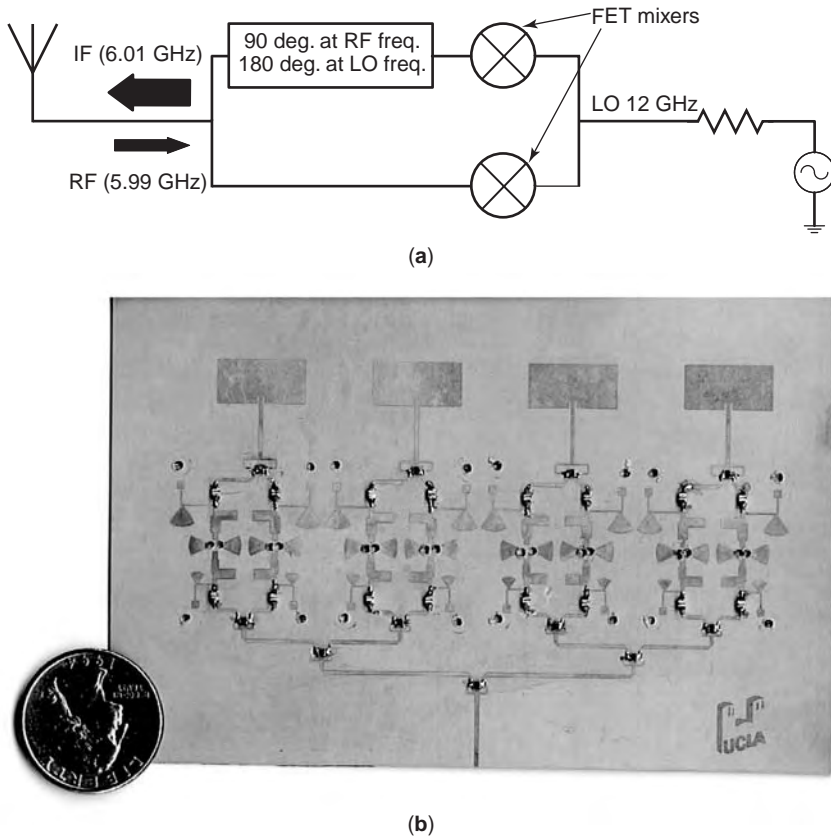

Figure 10. Active phase-conjugating array using MESFET mixers: (a) phase-conjugating unit cell; (b) four-element prototype (external LO not shown). (Courtesy of IEEE [12].)

Retrodirective arrays can be either one-dimensional, as in the examples presented previously, or two-dimensional, as presented in the next section. Bistatic and monostatic RCS measurements can therefore be taken over several planar cuts, as Fig. 13 shows. The theoretical bistatic RCS is given by

$$\begin{aligned} \sigma_{\text{bistatic}}(\theta, \theta_0, \phi, \phi_0) &= \frac{\lambda_0^2}{4\pi} G_c D_{\text{patch}}(\theta_0, \phi_0) D_{\text{patch}}(\theta, \phi) D_{\text{array}}(\theta, \theta_0, \phi, \phi_0) \end{aligned} \quad (3)$$

Figure 11. Reconstruction of the wavefront in a (a) phase-conjugating array and (b) a Van Atta array.

where θ_0, ϕ_0 are the RF source angles, G_c is the circuit gain, D_{patch} is the element directivity, and D_{array} is the directivity of the array, given by

$$\begin{aligned} D_{\text{array}}(\theta, \theta_0, \phi, \phi_0) &= \frac{|\text{AF}(\theta, \theta_0, \phi, \phi_0)|^2}{U_0(\theta_0, \phi_0)} \\ &= \frac{4\pi |\text{AF}(\theta, \theta_0, \phi, \phi_0)|^2}{\int_0^{2\pi} \int_0^\pi |\text{AF}(\theta', \theta_0, \phi', \phi_0)|^2 \sin \theta' d\theta' d\phi'} \end{aligned} \quad (4)$$

where AF is the array Factor.

In the bistatic RCS measurement, the radiation pattern of the array is fixed since the position of the RF interrogating source (i.e., θ_0, ϕ_0) is fixed, suggesting that the integration of the array factor U_0 is constant. Therefore, the directivity of the array simply depends on the angle θ

Figure 12. A retrodirective signal is characterized by (a) bistatic RCS and (b) monostatic RCS measurements.

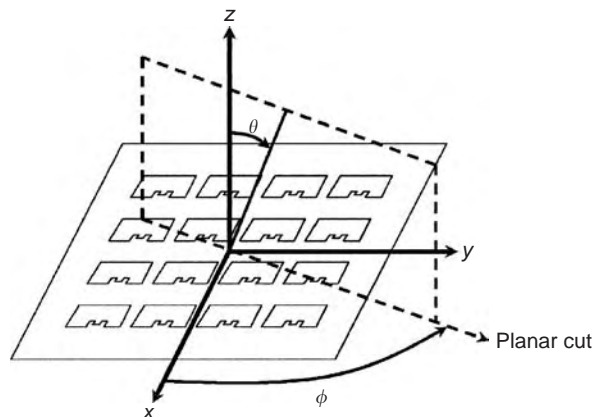

Figure 13. Coordinate system for the RCS measurement of a retrodirective array.

where the receiving horn is located. The normalized bistatic pattern is

$$\sigma'_{\text{bistatic}}(\theta, \phi)|_{\theta_0, \phi_0} = \frac{|\text{AF}(\theta, \phi)|_{\theta_0, \phi_0}|^2 D_{\text{patch}}(\theta, \phi)}{\max(|\text{AF}(\theta, \phi)|_{\theta_0, \phi_0}|^2 D_{\text{patch}}(\theta, \phi))} \quad (5)$$

where AF is the array factor. Since the array factor is maximum at the angle of the incoming RF signal, the mainlobe of the bistatic RCS pattern should point in the direction of the source. Typical bistatic RCS patterns are shown in Fig. 14.

In the monostatic RCS measurement, the interrogating and receiving antennas are collocated and moved together ($\theta = \theta_0, \phi = \phi_0$) to measure the radiation from the array, and thus the receiving antenna is always in the direction of the mainlobe. The monostatic RCS pattern is

given by

$$\sigma_{\text{monostatic}}(\theta, \phi) = \frac{\lambda_0}{4\pi} G_c D_{\text{patch}}^2(\theta, \phi) D_{\text{array}}(\theta, \phi) \quad (6)$$

In the monostatic RCS measurement, the radiation pattern varies as θ, ϕ changes. This implies that the array directivity at the peak is not constant, and depends on the scanning angle, that is, the position of the RF and IF horns, θ, ϕ [15,16]. The normalized monostatic pattern is given by

$$\sigma'_{\text{monostatic}}(\theta, \phi) = \frac{D_{\text{patch}}^2(\theta, \phi)/U_0(\theta, \phi)}{\max(D_{\text{patch}}^2(\theta, \phi)/U_0(\theta, \phi))} \quad (7)$$

A typical monostatic RCS pattern is shown in Fig. 15.

1.4. Array Design Considerations

In addition to the choice of architecture (Van Atta vs. phase conjugation, passive vs. active), the retrodirective system design must also include the appropriate choice of antenna element since this is often the limiting factor in the angular coverage of a retrodirective array. As shown in Fig. 16, the radiation pattern of the array is the product of the element and array factor directivities, but the maximum value of the product of these two directivities does not correspond to the peak of the array factor when a nonisotropic element is used. This results in a beam-pointing error, defined as the deviation of the mainbeam from that of the array factor pattern. Using an antenna element with low directivity, such as a microstrip patch, or increasing the number of elements reduces this error. Using a low-directivity element also decreases the dependence of the retrodirected power on the interrogation angle.

Figure 14. Examples of theoretical (dashed) and experimental (solid) bistatic RCS patterns when the interrogating signal is incident at $0^\circ, -10^\circ, -20^\circ,$ and -30° [14]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 15. Example of a monostatic RCS pattern [14]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Additional insight into the beam pointing error, as well as methods for mitigating it, can be found in Ref. 17.

Another consideration is the spacing between elements in the array. As in other types of phased arrays, this

spacing limits the scanning range of a retrodirective array. To avoid grating lobes in the radiation pattern that result in scan angle limitations, the array spacing must satisfy the following condition for a given interrogation angle

$$d < \frac{\lambda_0}{(1 + |\sin \theta_{inc}|)} \tag{8}$$

where d is the array spacing, λ_0 is the free-space wavelength of the interrogating RF signal, and θ_{inc} is the incident angle of the incoming signal. For scanning from -90° to $+90^\circ$ without grating lobes, d must be less than a half-wavelength of the RF signal.

The monostatic RCS is useful in evaluating the wide-angle coverage of a retrodirective array. The bistatic RCS is useful for evaluating the antiintercept capability (low sidelobe power levels) beam-pointing errors, and scan angle limitations.

2. TWO-DIMENSIONAL RETRODIRECTIVE ARRAYS

While the one-dimensional (1D) retrodirective arrays discussed in the previous section may be suitable for terrestrial applications, two-dimensional (2D) retrodirectivity is

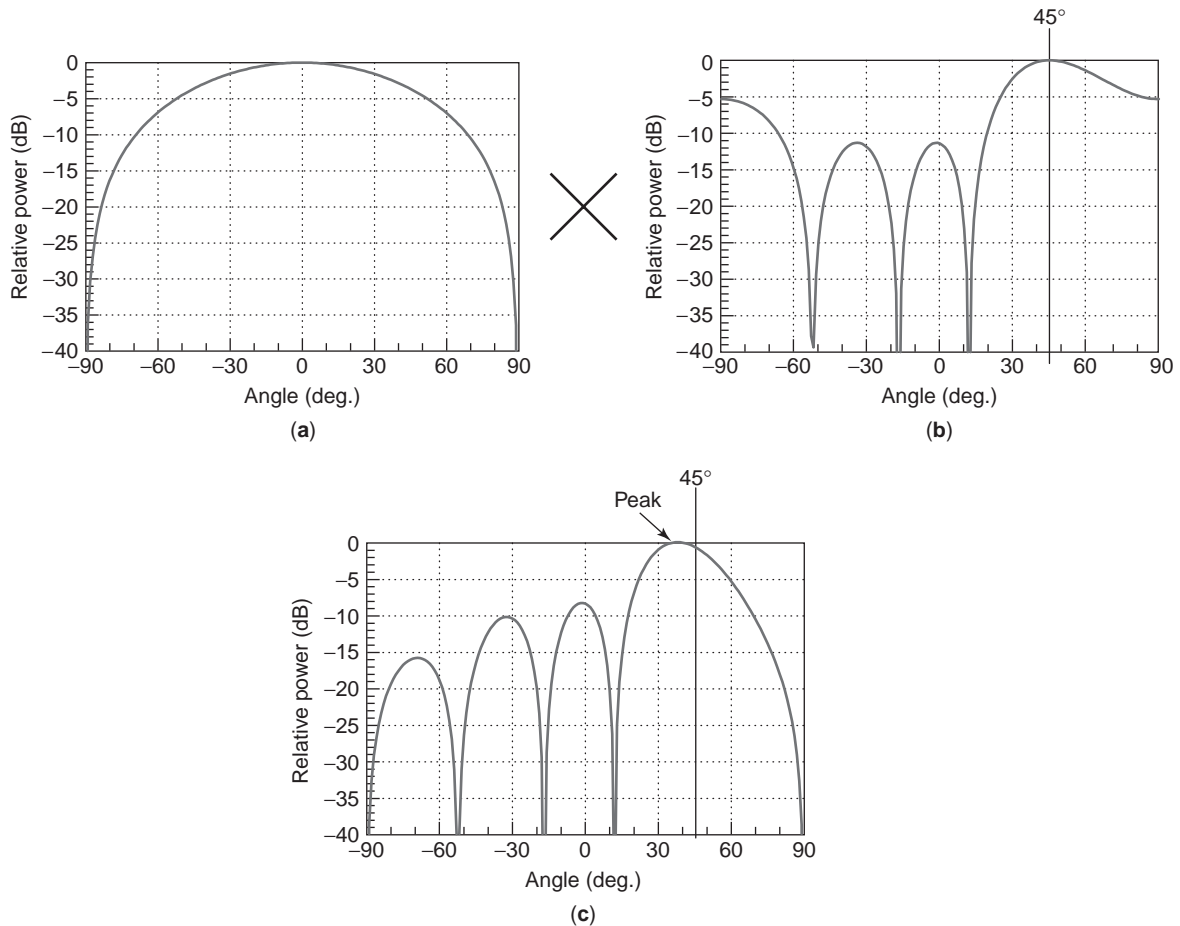

Figure 16. The beam-pointing error in a retrodirective array arises, in part, because of the directivity of the antenna element: (a) element pattern; (b) array factor pattern; (c) combined element-array pattern. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

necessary for terrestrial-to-space or space-to-space communications. However, implementing large 2D arrays based on traditional techniques is not as straightforward as simply adding more elements. For Van Atta arrays [18–20], the network of transmission lines connecting elements from one side of the array to the other becomes complicated as they must overlap each other. For phase-conjugating arrays, the maximum array size is limited by factors such as the complexity of a large corporate LO feed network and supplying enough LO power from a single source. In addition, the $\lambda/2 \times \lambda/2$ cell limitation for avoiding grating lobes have limited most 2D arrays to a maximum size of 4×4 elements. Several approaches have been proposed to overcome these issues.

2.1. Spatially Fed Local Oscillator

Researchers at the University of Hawaii (UH) developed a retrodirective diode grid array using a spatially fed LO [21]. Antiparallel diodes distributed over the grid enable third-order mixing. The LO is spatially applied to both front- and backsides of the grid, and mixed with the interrogating RF signal. The four-wave mixing scheme eliminates the need for an LO at twice the RF, allowing the system to use one frequency band for both RF and LO.

UH researchers developed a second phase-conjugating array in which the LO is spatially fed through slot-coupled patch antennas to eliminate LO feed networks [22]. Since there is no corporate feed network, each element of the

array is decoupled, allowing for 2D implementation without added complexity. A four-element 1D prototype was demonstrated at 5.35 GHz. The RF and LO signals received from patch antennas are combined through a diplexer and fed to the gate of a MESFET. The phase-conjugated IF from the drain is retransmitted through the IF patch antenna, which is cross-polarized to the RF antenna, reducing the coupling between the receiving and transmitting antennas. The measured results showed promising results for 2D implementation of this approach in the future.

2.2. Phase-Conjugating Arrays Using Self-Oscillating Mixers

A second type of phase-conjugating array developed at UH replaces the conventional mixers with self-oscillating mixers (SOMs) [23]. Phase-locking the SOM elements at the LO frequency while isolating them at the RF ensures proper operation. Since the LO signal is generated at each element, a corporate feed network is unnecessary, allowing for easier implementation of larger 2D arrays. This technique also makes it possible to provide enough LO power to each phase-conjugating element in a relatively large array.

UH's first experimental SOM array demonstrated retrodirectivity over 360° using a 96-element active antenna conformally wrapped around a dielectric cylinder [24]. More recently, a 16-element array using a different design was demonstrated in Ref. 25. As shown in Fig. 17, adjacent

Figure 18. $\phi = -45^\circ$ bistatic RCS patterns for scattering angles of $\theta = 0^\circ$, $\theta = -15^\circ$, and $\theta = +30^\circ$ and monostatic radiation pattern. (Courtesy of IEEE [25].)

elements are coupled through the source of pseudomorphic high-electron-mobility transistors. Since the drain terminal is shared for RF, IF, and LO signals, a diplexer is inserted to ensure that the RF/IF sees the antenna only while the LO is terminated into a $50\text{-}\Omega$ load. By mounting the patch antennas in the back of the phase-conjugating circuitry, the unit cell size is reduced to $0.37\lambda \times 0.45\lambda$, satisfying (8). An external locking LO signal can be applied to an element at the edge to reduce phase noise or modulate the phase-conjugated signal. Measured monostatic and bistatic RCS patterns are shown in Fig. 18, illustrating retrodirectivity in both the azimuth and elevation planes.

3. RETRODIRECTIVE ARRAYS FOR MILLIMETER-WAVE SYSTEMS

Retrodirective arrays operating at millimeter-wave frequencies may have niche applications in 60-GHz satellite crosslink or 77-GHz automotive collision-avoidance applications. In addition, the millimeter-wave band offers the benefits of broader bandwidth and smaller size.

3.1. Millimeter-Wave Van Atta Arrays

Westinghouse Electric Corporation proposed a millimeter-wave retrodirective transponder for collision/obstacle avoidance and navigation/location [26]. The array is based

on the Van Atta architecture with modulators. The 8×1 array consists of five-element subarrays, allowing the system to both receive and transmit more power.

One of the first active retrodirective arrays to be demonstrated at millimeter-wave frequencies is a two-element Van Atta array [27]. Developed by researchers at the Queen's University of Belfast, this array receives a 65.5-GHz signal that is then downconverted to 62.5 GHz

Figure 19. Full-duplex retrodirective array. (Courtesy of IEEE [30].)

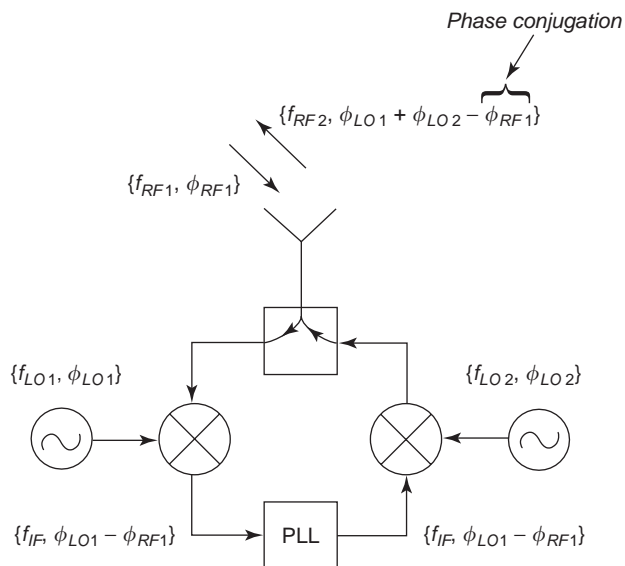

Figure 20. Phase conjugation using double mixing. (Courtesy of IEEE [30].)

and amplified with GaAs MMICs. By crossing the 62.5-GHz transmitting antennas, a Van Atta architecture is realized.

3.2. Millimeter-Wave Phase-Conjugating Arrays

Retrodirective arrays based on the phase-conjugating method are seldom feasible in the millimeter-wave band,

due to the requirement of having a LO at twice the RF frequency.

Recognizing this, Queen’s University of Belfast proposed using balanced subharmonic mixers for higher-frequency retrodirective arrays [28]. Subharmonic mixing halves the LO frequency requirement, while the balanced structure provides isolation between RF, IF, and LO frequencies, which typically may be less than a few percent apart. A prototype circuit based on two pairs of antiparallel diodes in a ratrace hybrid was built at RF, IF, and LO frequencies of 990, 970, and 980 MHz, respectively. This configuration exhibited good RF/IF and LO/IF isolation of 36 and 34 dB, respectively.

A second approach for higher-frequency applications is a dual-conversion phase-conjugating circuit [29]. Phase conjugation is achieved by mixing the incoming RF signal with an LO signal whose frequency is slightly higher than the RF. The resulting IF contains the phase conjugate of the RF and can be easily upconverted through a conventional mixer. This configuration reduces the cost of the system since the LO frequency is reduced to slightly higher than the RF frequency.

4. RETRODIRECTIVE SYSTEM EXAMPLES

The preceding sections have shown how retrodirective systems have evolved from high-reflectivity radar targets to components that can serve in wireless communication systems. This section presents four system-level examples in which retrodirective arrays show promise.

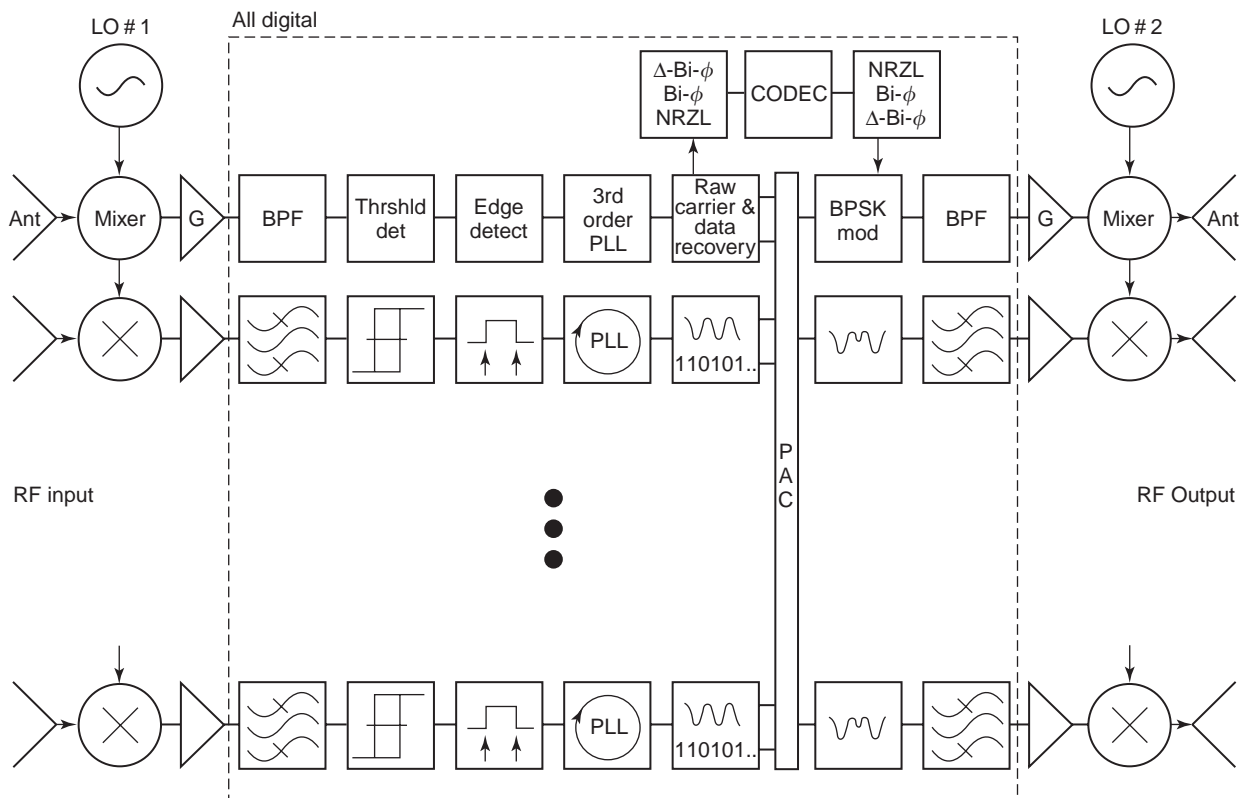

Figure 21. System architecture of the full-duplex array proposed in Ref. 30. (Courtesy of IEEE.)

Figure 22. Photographs of the reconfigurable array in Ref. 31: (a) antenna side; (b) circuitry side. (Courtesy of IEEE.)

4.1. Full-Duplex Retrodirective Array

To enable duplex retrodirective communication, it is necessary for a retrodirective array to have a receiver function in addition to the transponder function. Figure 19 shows a full-duplex retrodirective array system developed at the University of Michigan [30]. Each phase conjugator employs two mixers. The frequency of the LO applied to the first mixer is slightly higher than that of the incoming RF signal. This mixing process generates a low-frequency phase-conjugated IF signal, which then proceeds to a carrier/data recovery circuit followed by a BPSK (binary phase shift keying) modulator as shown in Figs. 20 and 21. The output signal is upconverted by the second mixer and transmitted, and the recovered data are processed by an A/D converter. The carrier recovery system allows the retrodirective array to use the modulated RF signal as an interrogating RF signal, enabling full-duplex retrodirective array communications. Using a 78.125 kbps (kilobits per second) data rate, a full-duplex data transmission test resulted in a bit error rate of better than 10^{-6} for 10 dB signal-to-noise ratios without error correction.

4.2. Reconfigurable Retrodirective/Smart Antenna Array

Figure 22 shows a retrodirective/smart antenna array for wireless sensor systems, developed at UCLA [31]. The active integrated antenna array can be reconfigured as a direct-conversion receiver or a retrodirective transponder, simply by changing the LO frequency. If time-division duplexing is employed, the system can be used for half-duplex communications. Figure 23 shows the schematic of the reconfigurable circuit. The received signal is first amplified by a low-noise amplifier at the Σ port of a ratrace coupler and applied to the resistive FET mixers in phase.

An LO signal is divided into two paths, with one path experiencing a delay of 180° at 11.6 GHz and 45° at 2.9 GHz. When a 2.9-GHz LO is applied, the circuit serves as a sub-harmonic direct conversion receiver (receiving mode). I and Q channels are obtained through lowpass filters from the drain sides. When an 11.6-GHz LO is applied, the circuit functions as a phase conjugator (retrodirective transponder mode). The phase-conjugated signal is amplified by an amplifier at the Δ port of the ratrace coupler. It is also possible to modulate the phase-conjugated signal by applying data signals into the baseband ports of this circuit.

4.3. Fading Reduction in a Multipath Environment

When scatterers exist within the communication path, there are multiple paths of signal propagation that can lead to fading and interference. Researchers at Millilab in Finland and the University of Hawaii demonstrated how multipath propagation in the presence of a retrodirective

Figure 24. Ideal point-to-point communication with a phase-conjugating retrodirective antenna in a multipath environment with reflecting objects [32].

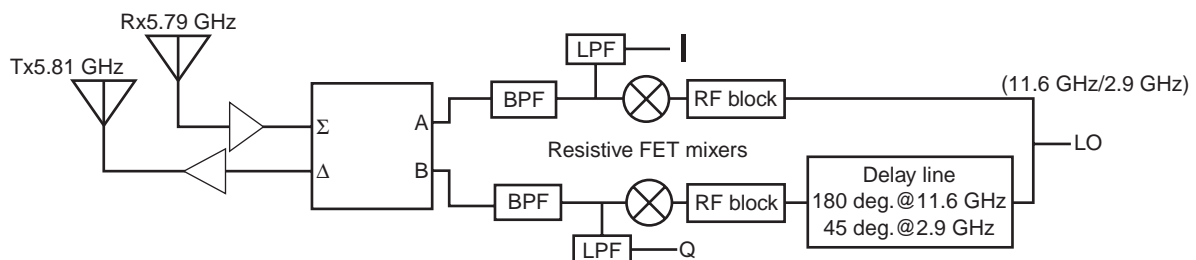

Figure 23. Schematic of the multifunctional circuit proposed in Ref. 31. (Courtesy of IEEE.)

Figure 25. Retrodirected signal from a practical array in response to a single ray from the omnidirectional interrogator [32].

array could reduce fading [32]. The technique is based on the observation that retrodirected signals from a phase-conjugating retrodirective array coherently arrive at the interrogator. The received signal at each element of an array can be described as the sum of multiple signals from several directions. The phase conjugate of the received signal is therefore the sum of the phase conjugates of the multipath signals. Therefore, the radiation pattern of the retrodirective array has a beam toward each incoming direction, and the signals added in phase at the interrogating source point, as shown in the idealized case of Fig. 24. In the practical case of finite antenna size, beams reflect back from the retrodirective array through the mainbeam as well as the sidelobes (Fig. 25). The mainbeam rays add coherently while the sidelobe rays add incoherently, thus limiting the method in practical systems. Nevertheless, experimental results showed a 40 dB reduction in fading in a multipath environment.

4.4. Self-Steering Crosslinks for Picosatellite Networks

As mentioned at the beginning of this article, an interesting application of retrodirective arrays is its use in self-steering crosslinks in a picosatellite network. Designing for space applications presents new challenges. First, the zero-gravity, free-floating nature of picosatellites necessitates two-dimensional tracking, and therefore a two-dimensional retrodirective array. Moreover, since picosatellites are too small to have attitude control systems, it is impossible to determine the orientation of each satellite, thus requiring circular polarization to prevent polarization mismatch. Undergraduate students at the University of Hawaii developed 10-GHz circularly polarized, two-dimensional, phase-conjugating arrays based on quadruple subharmonic mixing, to relax the local oscillator frequency requirement [33]. These antennas will be used in a network of two picosatellites to be launched into low-Earth orbit. For a network containing multiple satellite nodes, each satellite would have both an onboard omnidirectional interrogator and retrodirective transponder. The link is initiated by one satellite's omnidirectional interrogating signal, which is coded for an intended receiver. That receiver then sends a retrodirective signal back to the interrogator, whereupon it switches to retrodirective mode and the link is established. The use of coded signals

prevents unauthorized third-party interrogation, and helps in setting up multiple links between nodes.

In addition to the four applications presented above, retrodirective systems are also applicable for non-communication-related applications as well, such as in solar power satellites. Although they cannot compete in many applications where smart antennas now dominate, retrodirective systems are expected to fill several niches where simplicity, small form factor, and minimal power requirements are needed.

Atlanta, Georgia

1. NOTATION AND REFERENCES

The notation used here for voltages and currents correspond to the following conventions. Phasors are represented by uppercase letters and lowercase subscripts, for instance, V_s, I_s . Root-mean-square (RMS) values are represented by lowercase letters and lowercase subscripts, for example, v_s, i_s . Mean-square values are represented by the square of the RMS value, for instance, v_s^2, i_s^2 .

The low-noise literature contains a very large number of references. It is impossible to give a comprehensive list of these in an article of this scope. Only a selected list of references is given in the Bibliography.

2. THE V_N – I_N AMPLIFIER NOISE MODEL

A general noise model of an amplifier can be obtained by reflecting all internal noise sources to the input. In order for the reflected sources to be independent of the impedance of the signal source, two noise sources are required: a series voltage source and a shunt current source. In general, these sources are correlated. Figure 1 shows the amplifier noise model with a Thévenin input source, where V_s is the source voltage, $Z_s = R_s + jX_s$ is the source impedance, and V_{ts} is the thermal noise voltage generated by the source. The mean-square value of V_{ts} is given by the Nyquist formula

$$v_{ts}^2 = 4kTR_s\Delta f \quad (1)$$

where $k = 1.38 \times 10^{-23}$ J/K is the Boltzmann constant, T is the absolute temperature, and Δf is the bandwidth over which the noise is measured. The sources V_n and I_n are the noise sources representing the internal noise generated by the amplifier.

The amplifier output voltage V_o is given by

$$V_o = \frac{AZ_i}{Z_s + Z_i} \frac{Z_L}{Z_o + Z_L} [V_s + (V_{ts} + V_n + I_n Z_s)] \quad (2)$$

where A is the voltage gain, Z_i is the input impedance, Z_o is the output impedance, and Z_L is the load impedance. The equivalent noise input voltage V_{ni} is defined as the voltage in series with V_s that generates the same noise

Figure 1. $V_n - I_n$ amplifier model with Thévenin source.

voltage at the output as all noise sources in the circuit. It consists of the terms in parenthesis in Eq. (2) and is given by

$$V_{ni} = V_{ts} + V_n + I_n Z_s \quad (3)$$

Note that this is the noise voltage across Z_i considering Z_i to be an open circuit; thus, it is the Thévenin input noise voltage.

The mean-square value of V_{ni} is given by

$$v_{ni}^2 = 4kTR_s \Delta f + v_n^2 + 2v_n i_n \text{Re}(\gamma Z_s^*) + i_n^2 |Z_s|^2 \quad (4)$$

where $\gamma = \gamma_r + j\gamma_i$ is the complex correlation coefficient between V_n and I_n and it is assumed that V_{ts} is independent of both V_n and I_n . The *signal-to-noise ratio* is given by

$$\text{SNR} = \frac{v_s^2}{v_{ni}^2} = \frac{v_s^2}{4kTR_s \Delta f + v_n^2 + 2v_n i_n \text{Re}(\gamma Z_s^*) + i_n^2 |Z_s|^2} \quad (5)$$

This is expressed in decibels by the relation $10 \log(v_s^2/v_{ni}^2)$.

Figure 2 shows the amplifier noise model with a Norton input source, where I_s is the source current, $Y_s = G_s + jB_s$ is the source admittance, and I_{ts} is the thermal noise current generated by the source. The mean-square value of I_{ts} is given by the Nyquist formula

$$i_{ts}^2 = 4kTG_s \Delta f \quad (6)$$

The amplifier output voltage V_o is given by

$$V_o = \frac{A}{Y_s + Y_i} \frac{Z_L}{Z_o + Z_L} [I_s + (I_{ts} + V_n Y_s + I_n)] \quad (7)$$

The *equivalent noise input current* I_{ni} is defined as the current in parallel with I_s that generates the same noise voltage at the output as all noise sources in the circuit. It consists of the terms in parenthesis in Eq. (7) and is given by

$$I_{ni} = I_{ts} + V_n Y_s + I_n \quad (8)$$

Note that this is the input noise current considering Y_i to be a short circuit, namely, the Norton input noise current.

Figure 2. $V_n - I_n$ amplifier noise model with Norton source.

The mean-square value of I_{ni} is given by

$$i_{ni}^2 = 4kTG_s \Delta f + v_n^2 |Y_s|^2 + 2v_n i_n \text{Re}(\gamma Y_s) + i_n^2 \quad (9)$$

where it is assumed that I_{ts} is independent of V_n and I_n . The *signal-to-noise ratio* is given by

$$\text{SNR} = \frac{i_s^2}{i_{ni}^2} = \frac{i_s^2}{4kTG_s \Delta f + v_n^2 |Y_s|^2 + 2v_n i_n \text{Re}(\gamma Y_s) + i_n^2} \quad (10)$$

This is expressed in decibels by the relation $10 \log(i_s^2/i_{ni}^2)$.

3. NOISE FACTOR AND NOISE FIGURE

The *noise factor* F of an amplifier is defined as the ratio of its actual SNR to the SNR if the amplifier is noiseless, where the temperature is taken to be the *standard temperature* $T_0 = 290$ K. When it is expressed in decibels, it is called *noise figure* and is given by $\text{NF} = 10 \log(F)$. Often, it is convenient to express F in terms of the amplifier *noise resistance* R_n , its *noise conductance* G_n , its *correlation impedance* Z_γ , and its *correlation admittance* Y_γ . These are related to v_n^2 , i_n^2 , and γ by

$$R_n = \frac{v_n^2}{4kT_0 \Delta f} \quad (11)$$

$$G_n = \frac{i_n^2}{4kT_0 \Delta f} \quad (12)$$

$$Z_\gamma = R_\gamma + jX_\gamma = \gamma \frac{v_n}{i_n} = (\gamma_r + j\gamma_i) \frac{v_n}{i_n} \quad (13)$$

$$Y_\gamma = G_\gamma + jB_\gamma = \gamma^* \frac{i_n}{v_n} = (\gamma_r - j\gamma_i) \frac{i_n}{v_n} \quad (14)$$

Consider the amplifier driven by a Thévenin source in Fig. 1. If the amplifier is noiseless, its *signal-to-noise ratio* is given by $\text{SNR} = v_s^2/v_{ts}^2$, where v_s^2 is the mean-square source voltage and v_{ts}^2 is the mean-square thermal noise voltage generated by the source resistance R_s given by Eq. (1). The *noise factor* F is obtained by dividing the noiseless amplifier SNR by Eq. (5) to obtain

$$F = \frac{v_s^2/v_{ts}^2}{v_s^2/v_{ni}^2} = 1 + \frac{v_n^2 + 2v_n i_n \text{Re}(\gamma Z_s^*) + i_n^2 |Z_s|^2}{4kT_0 R_s \Delta f} \quad (15)$$

It follows that a noiseless amplifier has the *noise factor* $F = 1$. An alternate expression for F is obtained when the amplifier noise parameters are expressed in terms of R_n , G_n , and Z_γ . It is

$$F = 1 + \frac{R_n + 2G_n \text{Re}(Z_\gamma Z_s^*) + G_n |Z_s|^2}{R_s} \quad (16)$$

The value of Z_s that minimizes F is called the *optimum source impedance* and is denoted by $Z_{\text{opt}} = R_{\text{opt}} + jX_{\text{opt}}$. It is obtained by setting $\partial F/\partial R_s = 0$ and $\partial F/\partial X_s = 0$ and solving

for R_s and X_s . It is given by

$$Z_{\text{opt}} = [(1 - \gamma_i^2)^{1/2} - j\gamma_i] \frac{v_n}{i_n} = \left(\frac{R_n}{G_n} - X_\gamma^2 \right)^{1/2} - jX_\gamma \quad (17)$$

The corresponding minimum value of the noise factor is given by

$$F_{\text{min}} = 1 + \frac{v_n i_n}{2kT_0 \Delta f} [\gamma_r + (1 - \gamma_i^2)^{1/2}] = 1 + 2G_n(R_\gamma + R_{\text{opt}}) \quad (18)$$

It can be shown that F is related to F_{min} by

$$F = F_{\text{min}} + \frac{G_n}{R_s} |Z_s - Z_{\text{opt}}|^2 \quad (19)$$

If G_n , F_{min} , and Z_{opt} are given for an amplifier, it can be shown that

$$i_n^2 = 4kTG_n \Delta f \quad (20)$$

$$\gamma_i = \frac{-\text{sgn}(X_{\text{opt}})}{[1 + (R_{\text{opt}}/X_{\text{opt}})^2]^{1/2}} \quad (21)$$

$$v_n^2 = \left(\frac{X_{\text{opt}}}{\gamma_i} \right)^2 i_n^2 \quad (22)$$

$$\gamma_r = \frac{2kT_0 \Delta f}{v_n i_n} (F_{\text{min}} - 1) - (1 - \gamma_i^2)^{1/2} \quad (23)$$

where $\text{sgn}(X_{\text{opt}}) = X_{\text{opt}}/|X_{\text{opt}}|$.

If the amplifier driven by a Norton source in Fig. 2 is noiseless, the signal-to-noise ratio is given by $\text{SNR} = i_s^2/i_{\text{ts}}^2$, where i_s^2 is the mean-square source current and i_{ts}^2 is the mean-square thermal noise current generated by the source conductance G_s given by Eq. (6). The noise factor F is obtained by dividing the noiseless amplifier SNR by Eq. (10) to obtain

$$F = \frac{i_s^2/i_{\text{ts}}^2}{i_s^2/i_{\text{ni}}^2} = 1 + \frac{v_n^2 |Y_s|^2 + 2v_n i_n \text{Re}(\gamma Y_s) + i_n^2}{4kT_0 G_s \Delta f} \quad (24)$$

An alternate expression for F is obtained when the amplifier noise parameters are expressed in terms of R_n , G_n , and Y_γ :

$$F = 1 + \frac{R_n |Y_s|^2 + 2R_n \text{Re}(Y_\gamma Y_s) + G_n}{G_s} \quad (25)$$

The value of Y_s that minimizes F is called the *optimum source admittance* and is denoted by $Y_{\text{opt}} = G_{\text{opt}} + jB_{\text{opt}}$. It is obtained by setting $\partial F/\partial G_s = 0$ and $\partial F/\partial B_s = 0$ and solving for G_s and B_s . It is given by

$$Y_{\text{opt}} = [(1 - \gamma_i^2)^{1/2} + j\gamma_i] \frac{i_n}{v_n} = \left(\frac{G_n}{R_n} - B_\gamma^2 \right)^{1/2} + jB_\gamma \quad (26)$$

The corresponding minimum value of the noise factor is given by

$$F_{\text{min}} = 1 + \frac{v_n i_n}{2kT_0 \Delta f} [\gamma_r + (1 - \gamma_i^2)^{1/2}] = 1 + 2R_n(G_\gamma + G_{\text{opt}}) \quad (27)$$

It can be shown that F is related to F_{min} by

$$F = F_{\text{min}} + \frac{R_n}{G_s} |Y_s - Y_{\text{opt}}|^2 \quad (28)$$

If R_n , F_{min} , and $Y_{\text{opt}} = G_{\text{opt}} + jB_{\text{opt}}$ are given for an amplifier, it can be shown that

$$v_n^2 = 4kTR_n \Delta f \quad (29)$$

$$\gamma_i = \frac{\text{sgn}(B_{\text{opt}})}{[1 + (G_{\text{opt}}/B_{\text{opt}})^2]^{1/2}} \quad (30)$$

$$i_n^2 = \left(\frac{B_{\text{opt}}}{\gamma_i} \right)^2 v_n^2 \quad (31)$$

$$\gamma_r = \frac{2kT_0 \Delta f}{v_n i_n} (F_{\text{min}} - 1) - (1 - \gamma_i^2)^{1/2} \quad (32)$$

where $\text{sgn}(B_{\text{opt}}) = B_{\text{opt}}/|B_{\text{opt}}|$.

3.1. The Noise Factor Fallacy

The noise factor can be a misleading specification. If an attempt is made to minimize F by adding resistors either in series or in parallel with the source at the input of an amplifier, the SNR is always decreased. This is referred to as the *noise factor fallacy*. Potential confusion can be avoided if low-noise amplifiers are designed to maximize the SNR. This is accomplished by minimizing the equivalent noise input voltage or current. If a series resistor must be included at the amplifier input, its value should be much smaller than the source impedance. If a parallel resistor must be included at the amplifier input, its value should be much larger than the source impedance.

4. NOISE-MATCHING NETWORKS

Lossless noise-matching networks are used to transform the source impedance into the optimum impedance that minimizes the noise factor. These networks can be either lumped-element networks or microstrip networks. Two *noise matching networks* are described in the following examples.

Example 1. With a 50- Ω transmission line test fixture, the reflection coefficient seen looking out of the input terminals of an amplifier that minimizes its noise factor F at 900 MHz is determined to be $\Gamma_{\text{opt}} = 0.7 \angle 23.7^\circ$. Determine the lengths ℓ_1 and ℓ_2 of the transmission lines in the matching network of Fig. 3 that cause the source impedance seen by the amplifier to be the optimum source impedance Z_{opt} . The source resistance is $R_s = 50 \Omega$. The

Figure 3. Transmission-line noise-matching network.

characteristic impedance of the two transmission lines in the network is $Z_{c1} = Z_{c2} = 75 \Omega$.

Solution: With $Z_c = 50 \Omega$, specifically, the line impedance of the text fixture used to measure Γ_{opt} , the optimum source impedance is calculated from

$$Z_{opt} = Z_c \frac{1 + \Gamma_{opt}}{1 - \Gamma_{opt}} \quad (33)$$

to obtain $Z_{opt} = 122.6 + j135.2 \Omega$. The reflection coefficient at the amplifier end of T_1 is calculated from

$$\Gamma_{11} = \frac{Z_{opt} - Z_{c1}}{Z_{opt} + Z_{c1}} \quad (34)$$

to obtain $\Gamma_{11} = 0.4230 + j0.3539$. This has the magnitude $|\Gamma_{11}| = 0.5988$. The reactance of T_2 is calculated from

$$X_2 = \pm Z_{c1} \left[\frac{1 - |\Gamma_{11}|^2}{|\Gamma_{11}|^2 (1 + Z_{c1}/R_s)^2 - (1 - Z_{c1}/R_s)^2} \right]^{1/2} \quad (35)$$

to obtain $X_2 = 42.58 \Omega$, where the positive solution has been used. The electrical length of T_2 is calculated from

$$\beta \ell_2 = \tan^{-1} \left(\frac{X_2}{Z_{c2}} \right) \quad (36)$$

to obtain $\beta \ell_2 = 29.58^\circ$. The reflection coefficient at the source end of T_1 is calculated from

$$\Gamma_{12} = \frac{R_s |jX_2 - Z_{c1}|}{R_s |jX_2 + Z_{c1}|} \quad (37)$$

to obtain $\Gamma_{12} = -0.4654 + j0.3767$. The electrical length of T_1 is calculated from

$$\beta \ell_1 = \frac{1}{2} \arg \left(\frac{\Gamma_{12}}{\Gamma_{11}} \right) \quad (38)$$

to obtain $\beta \ell_1 = 52.39^\circ$.

Example 2. For the amplifier of Example 1, determine X_1 and X_2 in the lumped-element noise-matching circuit shown in Fig. 4.

Solution: The source impedance is $R_s = 50 \Omega$ and the optimum impedance is $Z_{opt} = R_{opt} + jX_{opt} = 122.6 + j135.2 \Omega$. To transform R_s into Z_{opt} , X_1 is calculated from

$$X_1 = \pm \sqrt{R_s R_{opt} \left[1 + \left(\frac{X_{opt}}{R_{opt}} \right)^2 \right] - R_s^2} \quad (39)$$

Figure 4. Lumped-element noise-matching network.

This yields $X_1 = \pm 105.3 \Omega$. X_2 is calculated from

$$X_2 = \frac{R_s^2 + X_1^2}{(R_s X_{opt}/R_{opt}) - X_1} \quad (40)$$

For $X_1 = +105.3 \Omega$, this gives $X_2 = -270.9 \Omega$. For $X_1 = -105.3 \Omega$, it gives $X_2 = +84.68 \Omega$.

5. NOISE TEMPERATURE

The internal noise generated by an amplifier can be expressed as an equivalent input-termination noise temperature. When the source is represented by a Thévenin equivalent circuit, the noise temperature T_n is the temperature of the source resistance that generates an open-circuit thermal noise voltage equal to the internal noise generated in the amplifier when referred to its input. The *noise temperature* is given by

$$T_n = \frac{v_n^2 + 2v_n i_n \operatorname{Re}(\gamma Z_s^*) + i_n^2 |Z_s|^2}{4kR_s \Delta f} \quad (41)$$

When the source is represented by a Norton equivalent circuit, the noise temperature is the temperature of the source conductance that generates a short-circuit thermal noise current equal to the internal noise generated in the amplifier when referred to its input. The noise temperature is given by

$$T_n = \frac{v_n^2 |Y_s|^2 + 2v_n i_n \operatorname{Re}(\gamma Y_s) + i_n^2}{4kG_s \Delta f} \quad (42)$$

The noise temperature is related to the noise factor by

$$T_n = (F - 1)T_0 \quad (43)$$

where the source temperature is taken to be the standard temperature T_0 . This holds for the amplifier with either the Thévenin or the Norton source.

6. MULTISTAGE AMPLIFIER

The noise factor of a *multistage amplifier* is given by

$$F = F_1 + \frac{F_2 - 1}{G_{a1}} + \cdots + \frac{F_N - 1}{G_{a1} G_{a2} \cdots G_{a(N-1)}} \quad (44)$$

where F_j is the noise factor of the j th stage, G_{aj} is its available power gain, and N is the number of stages. If G_{a1}

can be made large enough, this equation implies that $F \simeq F_1$. However, increasing G_{a1} may not make the second term arbitrarily small. For example, consider the case where $Z_{o1} = R_{o1} + j0$. In this case, it can be shown that $G_{a1} \propto R_{o1}$. Thus the second term in Eq. (44) can be written

$$\frac{F_2 - 1}{G_{a1}} \propto \frac{1}{4kT_0\Delta f} \left[\frac{v_{n2}^2}{R_{o1}^2} + \frac{2v_{n2}i_{n2}\text{Re}(\gamma_2)}{R_{o1}} + i_{n2}^2 \right] \quad (45)$$

where v_{n2}^2 and i_{n2}^2 , respectively, are the mean-square noise voltage and current of the second stage and γ_2 is the complex correlation coefficient between V_{n2} and I_{n2} . By increasing R_{o1} , G_{a1} can be made arbitrarily large. However, the second term in the expression for F cannot be made arbitrarily small by making R_{o1} arbitrarily large unless i_{n2}^2 is negligible.

Let T_n be the noise temperature of the overall amplifier and T_{nj} the noise temperature of the j th stage. It can be shown that T_n is given by

$$T_n = T_{n1} + \frac{T_{n2}}{G_{a1}} + \cdots + \frac{T_{nN}}{G_{a1}G_{a2}\cdots G_{a(N-1)}} \quad (46)$$

7. EFFECT OF A MATCHING NETWORK ON NOISE

Lossless matching networks are commonly used between a source and the input to an amplifier to obtain either a maximum power gain or a minimum noise factor. For maximum power gain, the output impedance of the matching network must be equal to the conjugate of the amplifier input impedance. Such a network is called a *conjugate impedance-matching network*. For minimum noise factor, the output impedance of the matching network must be equal to the optimum source impedance. Such a network is called a *noise-matching network*.

Figure 5 shows a lossless matching network between the input to an amplifier having an input impedance $Z_i = R_i + jX_i$ and a Thévenin signal source having an output impedance $Z_s = R_s + jX_s$. Denote the input impedance of the matching network by $Z_{im} = R_{im} + jX_{im}$ and its output impedance by $Z_{om} = R_{om} + jX_{om}$. It can be shown that the mean-square equivalent noise input voltage in series with V_s is

$$v_{ni}^2 = 4kTR_s\Delta f + \frac{R_s}{R_{om}} [v_n^2 + 2v_n i_n \text{Re}(\gamma Z_{om}^*) + i_n^2 |Z_{om}|^2] \quad (47)$$

The noise factor is given by

$$F = \frac{v_{ni}^2}{4kTR_s\Delta f} = 1 + \frac{v_n^2 + 2v_n i_n \text{Re}(\gamma Z_{om}^*) + i_n^2 |Z_{om}|^2}{4kTR_{om}\Delta f} \quad (48)$$

This is the same as the noise factor calculated at the output of the matching network.

The noise factors at the source and at the output of the matching network are equal because a lossless matching network cannot add noise. Thus it follows that the signal-to-noise ratio is also the same at the input to the matching network as at the input to the amplifier. However, these conclusions do not hold for a lossy matching network.

Equation (48) can be used to predict the noise factor for any arbitrary matching network. For example, Z_{om} might be chosen to be the optimum source impedance to minimize F . Alternately, it can be chosen for a conjugate impedance match to maximize the power gain. For a conjugate match, Z_{om} is replaced with Z_i^* in Eqs. (47) and (48). Because v_{ni}^2 and F are then functions of Z_i , it is difficult to predict how changes in Z_i affect the noise. This is because V_n , I_n , and γ in the noise model are, in general, related to Z_i . For example, V_n , I_n , γ , and Z_i may all be functions of the bias current in the amplifier input stage. A change in the bias current to vary Z_i can cause a change in V_n , I_n , and γ . Thus the effects cannot be examined in detail unless the relations between the variables are known.

Example 3. An amplifier is driven from a source with a resistive output impedance $R_s = 50 \Omega$. At the operating frequency $f = 10$ MHz, the amplifier has a resistive input impedance $R_i = 25 \Omega$ and the noise parameters $v_n = 0.447$ nV/ $\sqrt{\text{Hz}}$, $i_n = 31$ pA/ $\sqrt{\text{Hz}}$, and $\gamma = 0.12 - j0.44$. Calculate the noise figure (a) with a conjugate impedance-matching network between the source and the amplifier and (b) assuming that the matching network is designed so that the amplifier sees its optimum source impedance.

Solution: (a) For a conjugate impedance match, the noise figure is

$$\text{NF} = 10 \log \left[1 + \frac{v_n^2 + 2v_n i_n \text{Re}(\gamma Z_i) + i_n^2 |Z_i^*|^2}{4kTR_i\Delta f} \right] = 5.062 \text{ dB}$$

(b) The optimum source impedance is given by Eq. (17):

$$Z_{opt} = [(1 - \gamma_i^2)^{1/2} - j\gamma_i] \frac{v_n}{i_n} = 13 + j6.35$$

Thus the minimum noise figure is

$$\begin{aligned} \text{NF}_{\min} &= 10 \log \left[1 + \frac{v_n^2 + 2v_n i_n \text{Re}(\gamma Z_{opt}^*) + i_n^2 |Z_{opt}|^2}{4kTR_{om}\Delta f} \right] \\ &= 4.414 \text{ dB} \end{aligned}$$

This is 0.648 dB lower than for part (a).

Figure 5. Amplifier with a Thévenin source and an input-matching network.

Figure 6. Amplifier with a Norton source and an input-matching network.

Figure 6 shows a lossless matching network between the input to an amplifier having an input admittance $Y_i = G_i + jB_i$ and a Norton source having an output admittance $Y_s = G_s + jB_s$. Denote the input admittance of the matching network by $Y_{im} = G_{im} + jB_{im}$ and its output admittance by $Y_{om} = G_{om} + jB_{om}$. It can be shown that the mean-square equivalent noise input current in parallel with I_s is

$$i_{ni}^2 = 4kTG_s\Delta f + \frac{G_s}{G_{om}}[v_n^2|Y_{om}|^2 + 2v_n i_n \text{Re}(\gamma Y_{om}) + i_n^2] \quad (49)$$

The noise factor is given by

$$F = \frac{i_{ni}^2}{4kTG_s\Delta f} = 1 + \frac{v_n^2|Y_{om}|^2 + 2v_n i_n \text{Re}(\gamma Y_{om}) + i_n^2}{4kTG_{om}\Delta f} \quad (50)$$

For a conjugate match, Y_{om} is replaced with Y_i^* in these equations.

8. NOISE CIRCLES

In RF design, the contours on the Smith chart for the reflection coefficient seen looking out of an amplifier input for constant F are important. These contours are circles. Thus they are called *noise circles*. These are described in this section for both the impedance and admittance Smith charts.

Figure 7 shows an amplifier with a Thévenin source and a lossless input matching network. Let the impedance seen looking into the output of the matching network be $Z_{om} = R_{om} + jX_{om}$. Let us write $Z_{om} = Z_{opt} + \Delta Z$, where $\Delta Z = \Delta R + j\Delta X$ represents the amount by which Z_{om} deviates from the source impedance Z_{opt} , which minimizes the noise factor. Define the variable z as

$$z = \frac{|1 - \Gamma_{opt}|^2}{4} \frac{|\Delta Z|^2}{Z_c R_{om}} \quad (51)$$

where Γ_{opt} is the reflection coefficient seen looking into the output of the matching network for the case $Z_{om} = Z_{opt}$ and

Figure 7. Amplifier with a Thévenin source and a lossless input-matching network.

Z_c is the characteristic impedance of the transmission line on which Γ_{opt} is calculated. It can be shown that the contours of constant F on an impedance Smith chart are circles of radius c centered at the point with rectangular coordinates (a, b) where

$$a = \frac{\text{Re}(\Gamma_{opt})}{1 + z} \quad (52)$$

$$b = \frac{\text{Im}(\Gamma_{opt})}{1 + z} \quad (53)$$

$$c = \left[\frac{z}{1 + z} \left(1 - \frac{|\Gamma_{opt}|^2}{1 + z} \right) \right]^{1/2} \quad (54)$$

On any noise circle, the noise factor is constant and is given by

$$F = F_{min} + G_n \frac{|\Delta Z|^2}{R_{om}} \quad (55)$$

Because b/a is independent of ΔZ , it follows that the centers of the noise circles lie on a straight line passing through the origin and the point Γ_{opt} on the Smith chart. Figure 8a shows an example impedance Smith chart with the point $\Gamma_{opt} = 0.5 \angle -135^\circ$ and three surrounding noise circles labeled Γ_1 , Γ_2 , and Γ_3 , corresponding to $z = 0.3$, $z = 0.5$, and $z = 0.7$, respectively.

Figure 9 shows an amplifier with a Norton source and a lossless input-matching network. Let the admittance seen looking into the output of the matching network be $Y_{om} = G_{om} + jB_{om}$. Let us write $Y_{om} = Y_{opt} + \Delta Y$, where $\Delta Y = \Delta G + j\Delta B$ represents the amount by which Y_{om} deviates from the source admittance Y_{opt} , which minimizes the noise factor. Define the variable y as

$$y = \frac{|1 + \Gamma_{opt}|^2}{4} \frac{|\Delta Y|^2}{Y_c G_{om}} \quad (56)$$

where Γ_{opt} is the reflection coefficient seen looking into the output of the matching network for the case $Y_{om} = Y_{opt}$ and Y_c is the characteristic admittance on the transmission line on which Γ_{opt} is calculated. It can be shown that the contours of constant F on an admittance Smith chart are circles of radius c centered at the point with rectangular coordinates (a, b) , where

$$a = \frac{\text{Re}(\Gamma_{opt})}{1 + y} \quad (57)$$

$$b = \frac{\text{Im}(\Gamma_{opt})}{1 + y} \quad (58)$$

Figure 8. Smith charts showing the optimum reflection coefficient Γ_0 and three noise circles: (a) impedance chart; (b) admittance chart.

$$c = \left[\frac{y}{1+y} \left(1 - \frac{|\Gamma_{\text{opt}}|^2}{1+y} \right) \right]^{1/2} \quad (59)$$

On any circle, the noise factor is constant and is given by

$$F = F_{\text{min}} + R_n \frac{|\Delta Y|^2}{G_{\text{om}}} \quad (60)$$

Because b/a is independent of ΔY , it follows that the centers of the noise circles lie on a straight line passing through the origin and the point Γ_{opt} on the Smith chart.

Figure 8b shows an example admittance Smith chart with the point $\Gamma_{\text{opt}} = 0.5 \angle -135^\circ$ and three surrounding noise circles labeled Γ_1 , Γ_2 , and Γ_3 , corresponding to $y = 0.568$, $y = 0.983$, and $y = 1.33$, respectively. These values are chosen to give the same radii of the corresponding circles on the two charts. It follows from Eqs. (55) and (60), however, that the value of F on corresponding circles is not the same unless the following relation holds:

$$G_n \frac{|\Delta Z|^2}{R_{\text{om}}} = R_n \frac{|\Delta Y|^2}{G_{\text{om}}} \quad (61)$$

9. GAIN CIRCLES

Compromises are often made in RF amplifier design between lowest noise and highest gain. In this section, the contours of constant gain on the Smith chart are described. Like the noise factor contours, the constant gain contours are circles. Thus they are called *gain circles*. Given a Smith chart with both the noise circles and the gain circles plotted for a particular amplifier, the effect of the input-matching network on both noise and gain can be visualized.

Consider the amplifier model of Fig. 7, where the source is represented by a Thévenin equivalent. Let us write $Z_{\text{om}} = Z_i^* + \Delta Z$, where $\Delta Z = \Delta R + j\Delta X$ represents the amount by which Z_{om} deviates from Z_i^* . The relative efficiency of η of the input matching network can be

written

$$\eta = \frac{1}{1+h} \quad (62)$$

where h is given by

$$h = \frac{|\Delta Z|^2}{4R_i(R_i + \Delta R)} \quad (63)$$

It can be shown that the contours on an impedance Smith chart for which η is constant are circles of radius c centered at the point with rectangular coordinates (a, b) where

$$a = \frac{|Z_i/Z_c|^2 - 1}{|Z_i/Z_c|^2 + 2(R_i/Z_c)(1+2h) + 1} \quad (64)$$

$$b = \frac{-2(X_i/Z_c)}{|Z_i/Z_c|^2 + 2(R_i/Z_c)(1+2h) + 1} \quad (65)$$

$$c = \frac{4(R_i/Z_c)[h(1+h)]^{1/2}}{|Z_i/Z_c|^2 + 2(R_i/Z_c)(1+2h) + 1} \quad (66)$$

Because b/a is independent of h , it follows that the centers of the gain circles lie on a straight line passing through the origin of the Smith chart.

Consider the amplifier model of Fig. 9, where the source is represented by a Norton equivalent. Let the relative efficiency η of the input matching network be given by

Figure 9. Amplifier with a Norton source and a lossless input-matching network.

Eq. (62), where h is given by

$$h = \frac{|\Delta Y|^2}{4G_i(G_i + \Delta G)} \quad (67)$$

It can be shown that the contours on an admittance Smith chart for which η is constant are circles of radius c centered at the point (a, b) , where

$$a = \frac{1 - |Y_i/Y_c|^2}{|Y_i/Y_c|^2 + 2(G_i/Y_c)(1 + 2h) + 1} \quad (68)$$

$$b = \frac{2(B_i/Y_c)}{|Y_i/Y_c|^2 + 2(G_i/Y_c)(1 + 2h) + 1} \quad (69)$$

$$c = \frac{4(G_i/Y_c)[h(1 + h)]^{1/2}}{|Y_i/Y_c|^2 + 2(G_i/Y_c)(1 + 2h) + 1} \quad (70)$$

Because b/a is independent of h , it follows that the centers of the gain circles lie on a straight line passing through the origin of the Smith chart.

Example 4. An amplifier designed to operate at the frequency $f = 1.9$ GHz from a source with an output impedance $Z_s = 50 \Omega$ has the specifications: optimum source reflection coefficient for minimum noise $\Gamma_{opt} = 0.52 \angle 68.8^\circ$, minimum noise figure $NF_{min} = 1.39$ dB, noise resistance $R_n = 20.4 \Omega$, input reflection coefficient $\Gamma_i = 0.68 \angle -86^\circ$. The reflection coefficients are measured with a test fixture having the characteristic impedance $Z_c = 50 \Omega$. (a) A noise-matching network is to be used between the source and the amplifier. On an admittance Smith chart, plot the point representing Γ_{opt} and the noise circle for which the noise is 0.25 dB higher than its minimum value. (b) A conjugate impedance matching network is to be used between the source and the amplifier. On the same chart, plot the point representing the reflection coefficient seen looking out of the amplifier input and the gain circle for which the gain is 1 dB lower than its maximum value.

Solution: (a) The point representing Γ_{opt} is shown on the admittance Smith chart in Fig. 10. At this point, the normalized source admittance is $Y_{opt}/Y_c = 0.443 - j0.589$ and the noise factor is

$$F_{min} = 10^{NF_{min}/10} = 1.377$$

For 0.25-dB higher noise, the noise figure is $NF_1 = NF_{min} + 0.25 = 1.64$. The corresponding noise factor is

$$F_1 = 10^{NF_1/10} = 1.459$$

Equations (56) and (60) can be combined to calculate y to obtain

$$y = \frac{|1 + \Gamma_{opt}|^2 F_1 - F_{min}}{4 R_n Y_c} = 0.082$$

Figure 10. Admittance Smith chart for Example 3.

where $Y_c = 0.02$ S. The coordinates (a, b) of the center of the -0.25 -dB noise circle and its radius c are calculated from Eqs. (57)–(59) as follows:

$$a = \frac{\text{Re}(\Gamma_{opt})}{1 + y} = 0.174$$

$$b = \frac{\text{Im}(\Gamma_{opt})}{1 + y} = 0.448$$

$$c = \left[\frac{y}{1 + y} \left(1 - \frac{|\Gamma_{opt}|^2}{1 + y} \right) \right]^{1/2} = 0.239$$

The noise circle is shown labeled Γ_1 in Fig. 10.

(b) For a conjugate impedance-matching network, the reflection coefficient seen looking out of the amplifier input is $\Gamma_{om} = \Gamma_i^* = 0.68 \angle +86^\circ = 0.047 + j0.678$. This reflection coefficient maximizes the normalized gain of the matching network and is labeled η_0 in Fig. 10. On the gain circle for which the normalized gain of the matching network is -1 dB, the value of η in Eq. (62) is $\eta_1 = 10^{-1/10} = 0.794$. The corresponding value of h is $h_1 = 1/\eta_1 - 1 = 0.259$. The normalized amplifier input admittance is given by

$$\frac{Y_i}{Y_c} = \frac{G_i}{Y_c} + j \frac{B_i}{Y_c} = \frac{1 - \Gamma_i}{1 + \Gamma_i} = 0.345 + j0.871$$

The coordinates (a, b) of the center of the -1 -dB gain circle and its radius c are calculated from Eqs. (68)–(70) as follows:

$$a = \frac{1 - |Y_i/Y_c|^2}{|Y_i/Y_c|^2 + 2(G_i/Y_c)(1 + 2h) + 1} = 0.042$$

$$b = \frac{2B_i/Y_c}{|Y_i/Y_c|^2 + 2(G_i/Y_c)(1 + 2h) + 1} = 0.595$$

$$c = \frac{4(G_i/Y_c)[h(1+h)]^{1/2}}{|Y_i/Y_c|^2 + 2(G_i/Y_c)(1+2h) + 1} = 0.269$$

The gain circle is shown labeled η_1 in Fig. 10. If the source admittance lies in the intersection of the noise circle and the gain circle, the noise factor is within 0.25 dB of its minimum value and the relative power gain of the input matching network is within 1 dB of its maximum value.

10. MEASURING THE NOISE FACTOR

Consider the noise model of an amplifier given in Fig. 1. Consider the source to be a white-noise source having the spectral density $S_v(f) = v_s^2/\Delta f \text{ V}^2/\text{Hz}$ and a real output impedance $Z_s = R_s$. Let v_{o1} be the value of v_o with the input noise source set to zero: $S_v(f) = 0$. The temperature of R_s is specified to be the standard temperature $T_0 = 290 \text{ K}$. Let $S_v(f)$ be increased until the RMS output voltage increases by a factor r : $v_{o2} = rv_{o1}$. It can be shown that the noise factor is given by

$$F = \frac{S_v(f)}{(r^2 - 1) \times 4kT_0R_s} \quad (71)$$

In making measurements, a commonly used value for r is $r = \sqrt{2}$. In this case, the output noise voltage increases by 3 dB when the source is activated. Note that the expression for F is independent of the amplifier noise bandwidth, gain, and input impedance. However, the spectral density of the white noise input source must be known.

11. DETERMINATION OF NOISE PARAMETERS

Let the noise factor F be measured for N values of source admittance, where $N \geq 4$. Denote the noise factor values by F_i and the source admittance values by $Y_i = G_i + jB_i$. By Eq. (25), we can write

$$F_i = 1 + R_n \left(G_i + \frac{B_i^2}{G_i} \right) + 2R_n G_\gamma - 2R_n B_\gamma \frac{B_i}{G_i} + \frac{G_n}{G_i} \quad (72)$$

where $Y_\gamma = G_\gamma + jB_\gamma$ is the correlation admittance given by Eq. (14). The object is to use the measured values of F to determine the noise resistance R_n , the noise conductance G_n , and the correlation admittance Y_γ .

Define the mean-square error function

$$\begin{aligned} \varepsilon^2 = \sum \left[(F_i - 1) - R_n \left(G_i + \frac{B_i^2}{G_i} \right) \right. \\ \left. - 2R_n G_\gamma + 2R_n B_\gamma \frac{B_i}{G_i} - \frac{G_n}{G_i} \right]^2 \end{aligned} \quad (73)$$

where the summation extends over the range $1 \leq i \leq N$. The values of R_n , G_n , G_γ , and B_γ , which minimize ε^2 , represent a best estimate of the noise parameters. These values can be obtained by simultaneous solution of the set of equations $\partial \varepsilon^2 / \partial R_n = 0$, $\partial \varepsilon^2 / \partial G_n = 0$, $\partial \varepsilon^2 / \partial (R_n G_\gamma) = 0$, and

$\partial \varepsilon^2 / \partial (R_n B_\gamma) = 0$, where $R_n G_\gamma$ and $R_n B_\gamma$ are considered independent variables. This procedure leads to the following solution

$$\begin{bmatrix} R_n \\ 2R_n G_\gamma \\ -2R_n B_\gamma \\ G_n \end{bmatrix} = A^{-1} \begin{bmatrix} \sum \left(G_i + \frac{B_i^2}{G_i} \right) (F_i - 1) \\ \sum (F_i - 1) \\ \sum \frac{B_i}{G_i} (F_i - 1) \\ \sum \frac{1}{G_i} (F_i - 1) \end{bmatrix} \quad (74)$$

where the matrix A is given by

$$A = \begin{bmatrix} \sum \left(G_i + \frac{B_i^2}{G_i} \right)^2 & \sum G_i + \frac{B_i^2}{G_i} & \sum B_i + \frac{B_i^3}{G_i^2} & \sum 1 + \frac{B_i^2}{G_i^2} \\ \sum G_i + \frac{B_i^2}{G_i} & N & \sum \frac{B_i}{G_i} & \sum \frac{1}{G_i} \\ \sum B_i + \frac{B_i^3}{G_i^2} & \sum \frac{B_i}{G_i} & \sum \frac{B_i^2}{G_i^2} & \sum \frac{B_i}{G_i^2} \\ \sum 1 + \frac{B_i^2}{G_i^2} & \sum \frac{1}{G_i} & \sum \frac{B_i}{G_i^2} & \sum \frac{1}{G_i^2} \end{bmatrix} \quad (75)$$

The matrix A is singular if the ratios $a_{m1,n}/a_{m2,n}$ are equal for all elements in any two rows. With 4 rows, there are six combinations of two rows. It follows that the matrix is singular if the values of G_i and B_i lie on one of the contours defined by

$$G^2 + B^2 = k_1^2 \quad (76)$$

$$(G - k_2)^2 + B^2 = k_2^2 \quad (77)$$

$$G + (B - k_3)^2 = k_3^2 \quad (78)$$

$$B = k_4 G \quad (79)$$

$$G = k_5 \quad (80)$$

$$B = k_6 \quad (81)$$

where k_1 through k_6 are constants. Figure 11 shows example plots of these equations on the (G, B) plane. The k values are chosen so that the curves intersect at two common points. The curves labeled a – f correspond, in order, to Eqs. (76)–(81). Two curves labeled c , d , and f correspond to positive and negative values of k_3 , k_4 , and k_6 , respectively.

Given the solution for R_n , G_n , G_γ , and B_γ , the solutions for v_n^2 , i_n^2 , and γ are

$$v_n^2 = 4kT_0 R_n \Delta f \quad (82)$$

$$i_n^2 = 4kT_0 G_n \Delta f \quad (83)$$

$$\gamma = \frac{v_n}{i_n} (G_\gamma - jB_\gamma) \quad (84)$$

Figure 11. Example contours on which the matrix A is singular.

Because the quantity $(F - 1)$ is involved in the calculations, large percentage errors in $(F - 1)$ can be caused by small percentage errors in F when F has a value close to 1. Thus the solutions can be sensitive to experimental errors. Another problem lies in the choice of the values of G_i and B_i for which F is measured. If the values lie on or near one of the curves that makes the A matrix singular, the solutions can be unstable. To minimize this problem, the values of G_i and B_i should be chosen randomly.

RF/WIRELESS PACKAGING

STEPHANE PINEL
 MANOS TENTZERIS
 DANIELA STAICNLESCU
 JOY LASKAR
 Georgia Institute of Technology
 Atlanta

The demand for increasingly higher rates of data, voice, and video and for the integration of various technologies (digital, analog, RF, optical) has driven in emerging high-performance applications such as personal communication networks, wireless local-area networks (WLAN), “last-mile” RF optical networks, and millimeter (mm)-wave sensors. These RF/wireless applications have defined a trend toward more flexible and reconfigurable systems, since they impose very stringent specifications never reached before in terms of low noise, high linearity, low power consumption, small size and weight, and low cost. The electronics packaging industry has proliferated to a point where its technology is at least as, if not more, important than, the semiconductor technology that it is designed to serve. The increase in silicon complexity and integration has imposed demanding requirements on packaging technology for higher I/O counts, finer lead pitch, enhanced heat dissipation, and high-speed, reliable interconnects. This places a further strain on packaging requirements. Microprocessor, RF and millimeter-wave packaging are undergoing major changes driven by technical, business, and economic factors. In its early evolution, the influence of the package on performance was limited; however, as the systems evolve to provide increasing performance and operation frequencies, the package must evolve to keep up, and packaging design must ensure that it can optimally enable the systems functionality. From the traditional role of a protective mechanical enclosure, the modern package has been transformed into a sophisticated thermal and electrical management platform. Furthermore, system architecture and design techniques have had a significant impact on the complexity and cost of packaging. The need to optimize the total solution (chip, package, board, and assembly) has never been more important to maximize performance and minimize cost.

More recent advances in high-frequency packaging indicate a migration from wirebond (where the chip or die is interconnected to the package only on the periphery of the die) to flip-chip (where the die is interconnected to the package using the entire die area); and from ceramic to organic packages, with cartridge and multichip technologies emerging as key form factors. With the “segmentation” of the high-frequency computing market (mobile, desktop, server, and associated subsegments), a significant proliferation of packaging types tailoring functionality and costs to the different applications specifications can be seen.

The RF front-end module is the core of these systems, and its integration poses a great challenge. Microelectronics technology, since the invention of the transistor, has

revolutionized many aspects of electronic products. The integration and cost path has led the microelectronics industry to believe that this kind of progress can continue forever, leading to the so-called system-on-chip (SoC) approach [1] for all applications. But it's becoming clear that it is still a dream to produce a complete on-chip solution for the novel wireless communication front-ends. Considering the characteristics of the RF front-end modules, such as high performance up to 100 GHz operating frequency, large number of high performance discrete passive components, design flexibility, reconfigurable architecture, low power consumption, compactness, customized product, short time to market, and low cost, the so-called system-on-package (SoP) approach [2,3] has emerged as the most effective means to provide a realistic integration solution. The strength of SoP is based on multilayer technology using low-cost and high-performance materials. Using this 3D topology, high-density hybrid interconnect schemes, as well as various compact passive structures, including inductors, capacitors, antennas, and filters can be directly integrated into the substrate. Thus, high-performance modules can be implemented while achieving simultaneously cost and size reduction.

In Section 1, we will give some background information on electronic packaging, including its evolution and the key driving forces. In Section 2 we will give further details on the current packaging technologies at the chip level and the board level. In Section 3 we will describe the so-called RF SoP concept and its application to the RF front-end module integration. Examples of practical implementation and futures trends will also be given. The modeling and the optimization techniques enabling fast and accurate designs will also be described.

1. BACKGROUND

Electronic packaging has been one of the greatest challenges of the semiconductor industry. The primary function of a package is to provide a means for electrical connectivity from the semiconductor device to a printed wiring board (PWB), also known as a printed-circuit board (PCB). It provides a path for power to be applied to the chip as well as a way for the data signals to be transmitted into and out of the chip. Its secondary function is to house and protect the fragile chip from harsh environmental conditions, such as moisture, light, and dust, that might hinder its performance. Finally, the package provides a pathway for dissipating the heat generated by the semiconductor device. This last function is becoming increasingly important and significantly more difficult to achieve at the beginning of this twenty-first century, as new applications require integrated circuit complexity, operating frequencies, and power consumption to reach new height [4]. Inherently, it is a synergy of various different factors (electrical, mechanical, thermal, material) that have to be considered during an accurate design and fabrication process, as shown in Fig. 1.

The major driving forces for the RF and wireless packaging technology are

- Material, Manufacturability and Cost
 - Materials: ceramic versus organic
 - Manufacturability depending on process control, cycle time, reparability, equipment downtime, design tolerances
 - Costs from fabrication, testing, rework, tuning (if required), yield loss

Figure 1. Critical factors along the design cycle of an RF package. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

- Electrical Design
 - Connectors, which play a dominant role in determining performance limits (each connection has parasitic capacitance, resistance, and inductance that limit speed, potentially distort signals, and add noise)
 - Interconnect density, 2D or 3D routing, crosstalk, transmission loss (resistive and radiation)
 - Matched impedances
 - Low ground resistance
- Thermal Design. The objective is to remove the heat from the junctions of the ICs by (1) preventing dopants from moving and (2) avoiding self-heating effects
 - How to remove heat (from the front or backside of the IC)
 - Thermal conductivity of the substrate
 - Forced air, liquid cooling, monophasic cooling, dual-phase cooling
- Reliability / Mechanical Design
 - Susceptibility to thermal stresses induced by CTE mismatch
 - Tensile modulus (“stiffness”)
 - Hermeticity
- Testability. There are two types and two phases:
 - On wafer: (1) in-process testing (nondestructive); (2) stress/reliability testing (destructive)
 - On MCMs: (1) substrate; (2) assembled module

1.1. 1970–1995

The original package devices were typically large. They were connected to the outside world by means of long leads, or pins that needed to be inserted through holes in the printed-circuit boards (PCBs). These devices came to be known as “through-hole” devices for that reason and were made of metal, ceramic, and plastic. The most predominant of these packages in the 1970s and 1980s was the dual-in-line package (DIP) [5], which is still in use today. The DIP’s main limitation was the lead count with an upper limit of 64 pins. After that point, the package simply became too large for any practical applications. A solution to this was the pin grid array (PGA) [6], which was using a two-dimensional array of pins protruding from the bottom of the package. The PGA package could have around 200 pins on average.

The main problem with through-hole devices was their size. Furthermore, despite recent improvements [7], their performance at high frequencies was quite limited. The trend in PCB manufacturing was to increase density while decreasing board area and increasing signal frequencies. Through-hole devices did not easily allow this to happen. In the 1980s, through-hole devices began to give way to a new packaging technology called *surface mount technology* (SMT) [8]. The leads from these packages were mounted directly to rectangular pads on the surface of the PCBs and did not require holes to be drilled into the PWBs. As a result, the width of the leads could be smaller and the

spacing between the leads (lead pitch) could be decreased. This allowed for a package with the same number of pins as a traditional through-hole device to be significantly smaller, despite the fact that both devices were made with the same materials. Common surface mount devices included the plastic leaded chip carrier (PLCC) and the small outline integrated circuit (SOIC). More recently, the quad flat pack (QFP) has become a predominant fine-pitch, high-lead-count package solution. Figure 2 illustrates most of the previous topologies, and Fig. 3 shows some popular packaging devices used through the 1980s and 1990s.

Both through-hole and surface mount devices mentioned above were connecting the silicon chip to the external package leads by means of a process known as *wire bonding* [9,10]. Very fine wires were attached directly to the silicon chip at one end and connected to the package leads at the other end. This process has been very well understood in the semiconductor industry and can be performed with very high yield for very low cost. It does, however pose problems, as I/O count, density, and operating frequencies increase and package lead pitch decreases. Another process for connecting to the outside world is tape-automated bonding (TAB) [9].

1.2. 1995–Today

Today, as semiconductor technology continues the mini-mization trend, the level of complexity on a single silicon chip is becoming greater and greater. This leads to more functionality in a smaller area, higher I/O counts, higher frequencies, and higher heat dissipation requirements. All the technologies listed up to this point have been inadequate and impractical to satisfy all of these requirements. This is not to say that they do not still have a place in modern integrated circuit design, but they will not meet the needs of leading-edge technologies and, in particular, in the case of very demanding high-frequency performance, such as that of RF and millimeter-wave integrated systems. So, new packaging technologies have emerged since the mid-1990s that are aimed at solving the I/O, frequency and heat challenges.

The first generation of these solutions continue to use the same wire bonding technology used in traditional packages, while accommodating advances in interconnect technology. Flip-chip technology [also called *direct chip attach* (DCA)] has emerged as a possible alternative to wire bonding [11]. Regardless of the interconnect technology, the most promising packaging technology being pursued at the present is the ball grid array (BGA) package, which is a descendant of the pin grid array (PGA) package discussed earlier. Instead of through-hole pins, the BGAs have small conductive balls that are soldered directly to the surface of printed-circuit boards. As the balls are located on the bottom of the package, an obvious disadvantage is the inability to visually inspect the connections between the package and the PWB. As a result, the assembly process for PWBs using BGA technology must be very precise with very low tolerance for error. Its advantages in I/O count, I/O density, and heat dissipation easily outweigh this somewhat minor disadvantage [12].

Figure 2. Various packaging topologies.

In 1999, the Semiconductor Industry Association (SIA) released *The National Technology Roadmap for Semiconductors* [13]. According to SIA, the increase in total I/O and I/O density, as packaging has evolved from PGA through QFP and now to BGA, has been quite dramatic, but represents only a first step along the required growth path. Growing at an average compound rate of 12.6%, high-performance package I/O has reached 2800 by the year 2004. Commodity products, while growing at a less aggressive 8.2% rate, require over 400 I/O. In the future, cost will be more than ever the driving factor. It is expected that packaging costs per pin will continue to decrease in the coming years, but the overall packaging pin count is expected to increase at a faster rate than the cost decrease. The increase in pin count is also expected to affect the substrate and the system-level costs. Packaging geometries are often classified in two independent areas of focus: single-chip and multichip packages. It is expected that devices such as QFPs will reach a maximum lead count of 300 and lead pitch will reach a minimum of 0.5 mm [9]. After this point, the package body size and

the surface mount assembly complexity become cost ineffective and multichip solutions have to be investigated.

Also, these recent years have highlighted the thermal management as a significant challenge. As a result, handheld or portable devices that do not use forced air and rely on the operator's hand to dissipate the heat from the unit need new heatsink technologies and materials with better thermal conductivity. On the other hand, the cost-performance market (desktop processors) requires forced-air cooling. Flip-chip could be a possible enhancement to the forced-air cooling as the backside of the silicon chip provides a "direct, efficient heat path from the chip to the heatsink." Existing heatsink solutions are predicted to be ineffective above 50 W in applications where forced air is not a viable solution because of market requirements. A reduction of internal thermal resistance and better air cooling techniques are critical for thermal solutions. The high-end market, with predicted power consumption between 110 and 120 W per chip, will pose an even greater challenge necessitating a closed-loop cooling system that meets market and customer requirements. In general,

Figure 3. Popular packaging devices used through the 1980s and 1990s [9].

flip-chip is predicted to become the predominant technology for chip-to-next-level interconnect, since it enables the reduction of a level of interconnect. Commodity products will continue to use advanced forms of wire bonding until the cost of flip-chip becomes affordable for that market. Another important challenge is the matching of the coefficient of thermal expansion (CTE) between the silicon chip and the substrate. When using organic substrates, underfills will be required with high reliability, ease of manufacturability, stronger attachment at the interface, and higher resistance to moisture. Liquid-crystal polymers (LCPs) with engineered CTE could be a solution [14].

2. CURRENT PACKAGING TECHNOLOGIES

2.1. Chip Technology

2.1.1. Ball Grid Array (BGA). BGA packages allow for PWB space savings since an array of solder bumps (or

balls) is used in place of traditional package pins. The bumps have the advantage of shorter electrical patch to the motherboard, which improves the electrical performances at high frequencies. Also, they occupy a smaller area on the board for the same I/O count, while providing finer pitches and lower cost. Micro-BGA (μ BGA) is a chip-scale package that uses much smaller bumps than the traditional BGA. A typical BGA solder ball is 500–750 μ m in diameter and has a 1000–1250 μ m pitch, while a typical μ BGA NiAu ball is 50–100 μ m in diameter and has a 500–750 μ m pitch. An example of a BGA package developed for millimeter-wave application is presented in Fig. 4.

The BGA is made of an alumina substrate that acts as a carrier for the chip. Through-hole vias (signal, ground, and thermal) are realized by laser drilling and are filled with a CuW alloy. Thin-film metal (copper or gold) are deposited and patterned on both sides. Then the substrate is bumped with BGA or μ BGA balls. The chip is directly wired bonded on top of the substrate.

Figure 4. BGA package for millimeter-wave applications. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

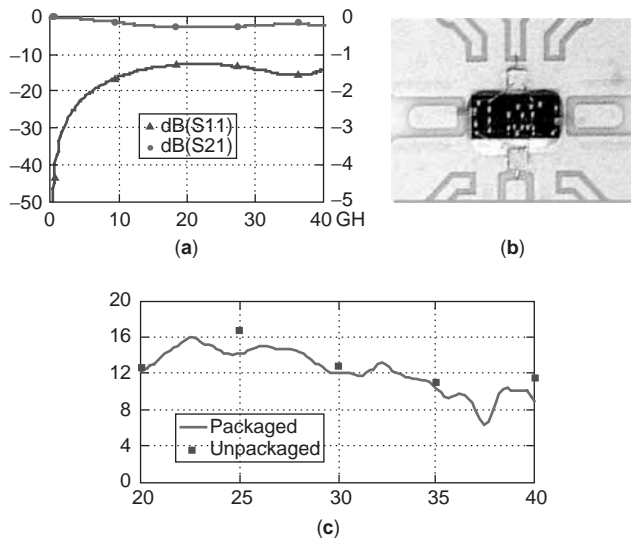

Figure 5. (a) Millimeter-wave performance of a single BGA transition; (b) 20–40 GHz wideband HP GaAs PHEMT MMIC amplifier on a BGA package; (c) millimeter-wave performance of the packaged amplifier. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

BGA and μ BGA packages have become more increasingly popular since the early 1990s for high-frequency applications up to 20 GHz. For the growing wireless communications systems operating at millimeter-wave frequencies such as local multipoint distribution services, BGA and μ BGA packages have also exhibited, with a proper transition design, excellent performance above 30 GHz. A single transition can exhibit an insertion loss of >0.3 dB at 36 GHz as shown in Fig. 5a. A 20–40-GHz wideband HP GaAs PHEMT MMIC amplifier mounted on a BGA package using conductive epoxy is shown in Fig. 5b. A comparison of performance (gain performance is depicted in Fig. 5c) of bare die and the package amplifier confirms that the BGA is a low-loss package and is applicable for millimeter-wave frequencies.

An example of a BGA applied to a 3D integrated module concept is presented in Fig. 6 [16]. In the proposed module concept, two stacked LTCC substrates are used and board-to-board vertical transition is insured by μ BGA balls [17,33]. Standard BGA balls ensure interconnection of this high-density module with a motherboard such as FR4 board. The top and the bottom substrates are dedicated respectively to the receiver and transmitter building

Figure 6. 3D integrated RF front-end module concept view using BGA and μ BGA. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

blocks of the RF front-end module. The two parts are separated by the μ BGA “layer” to improve the crosstalk performance of the module.

Ball grid arrays are expected to be the solutions for packages requiring over 200 pins and will be implemented using wirebonding in the lower I/O density parts and flip-chip in the higher-I/O-count and higher-power devices. Ultra-fine-pitch (UFP) wirebond technology will allow for a larger die to be placed on smaller substrates and effective pad pitches below $60 \mu\text{m}$. It is expected that increasing circuit density will enable the accommodation of more than 1000 I/Os and die shrinkage (size reduction) by 20–50%. Placing a larger die with more functionality on a smaller substrate results in significant cost savings, as the substrate is a driving factor in the cost of the device. Recent (as of 2004) trends indicate that I/O counts for leading-edge devices grow at a rate of approximately 10 times every 14 years.

Liquid encapsulant underfills will likely be needed to relieve the stress due to CTE differences between the chip and the BGA package substrates. Chip-scale packages using fine-pitch μ BGA with a size in the order of the chip size will be the next level of advancement for applications where low weight and small package size are required. As the technology matures and processes become cheaper, BGAs have the potential to become the workhorse of packaging technologies, as the DIP was for the 1970s and 1980s.

2.1.2. Flip-Chip Technology (FCT). Flip-chip is a technology dating back to the 1970s that matured in the late 1990s as a widely accepted and cost-effective method for the semiconductor industry, especially for high-frequency applications [18]. The term “flip-chip” refers to flipping a silicon die or chip and mounting it face down on a substrate. A typical flip-chip bump is $25\text{--}50 \mu\text{m}$ in diameter and has a $50\text{--}100 \mu\text{m}$ pitch. A schematic of a flip-chip transition from coplanar waveguide (CPW) to coplanar waveguide is presented in Fig. 7.

Of the 60 billion integrated circuits produced in 1998, approximately 1.5% of them were manufactured using flip-chip technology. From 1997 to 1998, the number of flip-chip dies grew by 40%. An average annual growth rate of 48% for flip-chip is expected in the near future. The flip-chip capabilities have been extended up to 75 GHz [19,20] and to optical applications using glass bumps that allow for waveguiding of optical waves [21].

Figure 7. Schematic of a CPW-CPW flip-chip interconnection. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

An optimized transition for a CPW-CPW interconnect on alumina substrate is presented in Fig. 8a. The stud bumps on the die are soldered to the mounting substrate as shown in Fig. 8b. The optimization of the transition shows insertion loss of >2 dB and a return loss of >20 dB at 75 GHz.

Other issues related to flip-chip design include the presence of the resin underfill, for protecting the die from the environment, alleviating the CTE mismatch between the two substrates and increasing the fatigue life of joints. The resin changes the transition electrical performance and must be taken into account by the IC designer at the beginning of the design process. Also, a very important aspect is the development of scalable lumped-element models for the flip-chip transition. Typical models are presented in Fig. 9.

The capacitor C_1 represents the discontinuity capacitance at the chip, while the capacitor C_2 models the discontinuity capacitance at the motherboard. The inductor

L represents the inductance of the bump, and the resistors model the loss mechanism in the interconnection. For the T model, the capacitance C is due to the overlapping area of the feedline and the flipped chip and L_1 and L_2 model the inductance of the bump. The ultimate goal is to scale the values of the circuit elements with the physical attributes of the interconnection.

2.1.3. Flip-Chip versus Wirebond. Although new packaging and interconnection technologies have been introduced, wirebonding is still dominant in RF and wireless products, especially in applications up to 10 GHz, since it has strong benefits in cost and reliability. However, the stringent specifications of emerging communication systems and the use of higher frequency bands accentuate the drawbacks of the wirebonding, namely, parasitic effects and losses. When wirebonds are used as interconnects in microwave and millimeter-wave modules, they

Figure 8. (a) Side view of flip-chip transition; (b) gold stud bump soldered to the substrate; (c) S-parameter results for optimized transition to 75 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 9. Various model topologies: (a) T model; (b,c) \square models.

exhibit a high characteristic impedance due to the high inductance of the thin wire and a small capacitance due to the small dielectric constant of the airgap between the wire and the ground plane. In addition, radiation loss resulting from wire discontinuity becomes significant, particularly in the millimeter-wave frequency range.

Vertical interconnection solutions have gained a significant interest because they provide features that can eliminate the problems associated with wirebonding: poor repeatability of the manufacturing process and a drastic increase of the losses associated with increased frequency. Along with showing better electrical performance, flip-chip technology allows several chips to be mounted together on the motherboard to increase density, improve system performance, and reduce cost. This packaging technique also allows combination of passive and active devices, Si and GaAs, analog, digital, and optical circuits on the same motherboard [22]. Furthermore, the compatibility with automatic manufacturing improves the reliability and reduces the assembly cost.

In addition to these benefits, since the flip-chip die is flipped upside down, all the chip area is available for interconnect, eliminating the wirebond restriction of having all the I/Os along the chip perimeter. This, along with the short electrical path, which eliminates coupling issues, allows true chip-scale packaging and therefore increased integration levels.

Another important issue in RF packaging structures is the transmission-line choice. The two most common choices for the transmission lines to be used in a flipped, monolithic microwave integrated circuit (MMIC) are microstrip and coplanar waveguides (CPW). Coplanar MMICs are more suited to flip-chip technology because of the immediate availability of all the grounds on one surface. In addition, coplanar circuitry requires no backside processing, eliminates the need for ground vias and allows the use of a thicker, more physically robust chip. Easier matching can be achieved because of the ground–signal–ground configuration. The more recently developed finite-ground coplanar waveguides (FG-CPWs) allow for a miniaturized implementation of these planar lines [23]. On the other hand, microstrip design tools are more mature, and MMIC manufacturers prefer to make full use of their capabilities.

However, thermal performance of flip-chip packages is poor compared to wirebond. Heatsinking is more efficient when the chip is firmly in place on the vertical stackup rather, with no contact with other components other than the interconnecting bumps. The coplanar design of the PCB eliminates the need for the vias, and shunt elements can be easily removed or added if tuning is necessary. From a mechanical reliability standpoint, flip-chip technology still needs to be improved. An underfill technology—to fill the gap between the chip die and board with a dielectric material—has been introduced to improve the heat dissipation and the mechanical stability and to compensate the CTE mismatch. However, it is difficult to apply underfill technology to RF modules, since the additional dielectric loss generated from the underfill material reduces the system efficiency. Moreover, the characteristic impedance of the transmission lines on a MMIC chip is significantly modified because of the higher dielectric constant of the underfill material. To avoid this problem, all MMIC circuits should be designed to compensate for the expected impedance change.

Figure 10 presents a review of the published electrical performance for wirebond, flip-chip and BGA [24]. The test structures used in these analyses are not identical and the individual characteristics are reflected in the S (scattering) parameters. However, it can be observed that flip-chip shows evidence of lower insertion loss over the entire frequency range than the wirebond. On the other hand, the BGA performance is poor compared with flip-chip, as a result of the larger dimensions and the use of more lossy substrates for the motherboard, especially for frequencies above 40 GHz. Similar results have been reported for return loss.

2.1.4. Chip-Scale Packaging (CSP). Chip-scale packaging (CSP) is generally considered the fundamental

Figure 10. Electrical performance comparison between flip-chip, wirebond, and BGA. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

evolution required to meet most of the electronic packaging needs of the twenty-first century [25]. As defined by its proponents, CSP ranges in size from die equivalent area to, at its maximum, 120% of die area. Several configurations now in development include, among others, perimeter pad and leadframe packages, area array interposers, and μ BGAs, with target market segments ranging from low-cost consumer through high-end data processing, and I/O ranges up to 1000.

2.2. Board Packaging: MCM Definitions and Classifications

The term “multichip module” (MCM) refers to the packaging of multiple silicon dies into one device [26,27]. MCMs offer the ability to reduce package pin count by combining two or more high-pin-count devices, that would normally connect to each other at the board level, into one package, where the interconnect is performed at the chip level. The resulting packaged system needs only a reduced set of pins to connect power and signals from the outside world. It can also serve to reduce PWB real estate (an expensive commodity) and exhibits the following advantages:

- Improved performance, such as shorter interconnect lengths between dies (resulting in reduced delay time, lower RF parasitics and losses), lower power supply inductance, lower capacitance loading, less crosstalk, and lower off-chip driver power
- Miniaturization, since MCMs result in a smaller overall package size when compared to separate packaged components performing the same function, hence resulting in significant reduction of I/O to the system board
- Shorter time to market, making them attractive alternatives to ASICs (application-specific integrated circuits), especially for products with short lifecycles
- Low-cost silicon sweep, allowing integration of mixed semiconductor technology, such as SiGe or GaAs
- Hybrid configurations, including surface mount devices in the form of chip-scale or μ BGA packages and discrete chip capacitors and resistors
- Simplification of board complexity by integrating several devices onto one package, thereby reducing total opportunities for error at the board assembly level
- Capability of accommodating a variety of second-level interconnects (while BGAs are the most popular ones, leadframe solutions can be employed for plugability, enabling reconfigurability and modularity for upgrades)

The widespread use of MCMs has been hampered by a few factors. It is a relatively high-cost process. Since not all of the signals are connected to the outside world, package-level testing is difficult, so effort must be made to ensure that the die being put into the chip is good. Obtaining such “known good die” (KGD) is still a challenge. Also, the proliferation of flip-chip, BGA, and chip-scale packages for single-chip package solutions has reduced the need for chip-level system integration.

In the area of multichip packages, the SIA roadmap [13] identifies advancements in the following enabling technology solutions as requirements for the effective implementation of MCM:

- Design tools/simulators (integrated design environment)
- Flip-chip interconnect optimization
- Low-cost high-density substrate manufacturing
- Low-cost known good die (KGD).

These enabling technologies are interdependent and must be selected to be compatible to provide an integrated multichip solution. Bare chips must provide the same reliability, quality, and performance as packaged chips to be considered “known good.” Multichip packages containing two to three chips are in volume production today, and could evolve soon to include three to five chips. The evolution of these multichip packages into multichip modules with more than five chips will be driven by performance and cost requirements at the subsystem and system level, as well as improved chip reworkability and module testing techniques. The implementation and proliferation of multichip packages and modules will continue to be constrained by the availability of high-density substrates and “known good” die commensurate with the necessary cost and performance. Multichip modules will be driven by densification and cost reduction for low-end products and densification and performance for high-end products.

As mentioned above, a key factor in the development of MCM package is the availability of high-density substrates. There exist three commonly used substrate groups [9,26].:

1. *Laminate MCMs (MCM-Ls)*. These are manufactured through the lamination of sheet layers of organic dielectric, and are very similar to traditional PCB technology; in fact, the dielectric layers and the interconnects are developed in much the same way as for laminated printed-circuit boards. The line geometries and via diameters are typically half or less the size of those found in traditional circuit boards. These MCMs exhibit very low line losses up to relatively high frequencies because the lines are thick and wide; however, the vias are typically quite tall and also much wider than the lines, thus causing substantial impedance discontinuities and wavefront reflections for frequency components. A very special care has to be given for designs above 500 MHz.

2. *Ceramic MCMs (MCM-Cs)*. These MCMs are manufactured by stacking unfired layers of ceramic dielectric (i.e., in their flexible, unfired state), onto which liquid metal lines are “silk screened” using a metal ink process. The individual inked layers are then aligned, pressed together, and “cofired” at 800–900°C, or 1500–1600°C (depending on the composition of the ceramic material) into a solid planar structure, onto which integrated circuits can be installed. These MCMs can, if fabricated with excellent dimensional tolerance control, exhibit low line losses. They are for these reasons very popular for the integra-

Table 1. Comparison of MCM Technologies

Characteristic	MCM-L	MCM-C	MCM-D
Minimum linewidth (mm)	60–100	75–100	8–25
Line spacing (mm)	625–2250	125–450	25–75
Via diameter (mm)	300–500	100	8–25
Cost (\$/cm ²)	3–30	50–1000	800–8000

tion of high-frequency systems up to the millimeter-wave frequency range [28,29].

3. *Deposited (MCM-Ds)*. These components are manufactured through the deposition of organic or inorganic dielectrics onto a silicon or alumina support substrate. After each dielectric layer is deposited, one of several techniques is used to pattern metal lines as well as metal “vias” that penetrate the dielectric layers to connect adjacent metal layers. The chips are then installed on the upper surface, and attached electrically through wirebonds or other means such as tape-automated bond structures, or even by mounting the chips face down on the surface, with metal balls serving as the electrical connections between the chip and matching pads on the MCMs. The MCM-D line cross sections are typically smaller than for MCM-Cs or MCM-Ls, resulting in higher interconnect density but also higher resistive line losses; however, their via heights are typically quite small, and their via cross sections are equivalent to the linewidth, resulting in low levels of impedance discontinuity and wavefront reflections, in comparison to the MCM-Ls and MCM-Cs.

The different MCM line geometries and their respective cost are compared in Table 1.

In order to optimize cost and performance tradeoffs, the high performance of MCM-D at the low cost of MCM-L are desirable, leading to a hybrid technology called MCM-L/D, where substrate structures are formed as multiple layers of metal separated by dielectric material. Georgia Tech’s Packaging Research Center (PRC) “single-level-integrated module” (SLIM) implementation of the MCM-L/D para-

digim is shown in Fig. 11 [30,31]. This technical vision integrates all the packaging levels into one, containing layers for DC power distribution, high-density high-speed digital circuitry, embedded decoupling capacitors and termination resistors, embedded multilayer RF passives (i.e. inductors, filters, antennas), embedded optical waveguides, built-in MEMS devices, and built-in thermal management.

3. RF SoP MODULES

The dawn of the twenty-first century is witnessing a tremendous demand for wireless (untethered) communications services such as paging, analog, and digital cellular telephony, and emerging Personal Communications Services (PCS). Current commercial cellular and PCS systems are concentrated at frequency bands around 900 MHz and 1.8 GHz (S band); future allocations for PCS systems are expected around 2.4 and 5.8 GHz (through C band). Beyond the arena of mobile communications, there are numerous wireless applications, including RF identification (RFID), satellite communications, local multipoint distribution systems (LMDS), and wireless local-area networks (WLANs) operating at frequencies extending into the millimeter-wave regime (Ku to Q bands). The move to higher frequencies has been motivated by the need for more and more bandwidth for multimedia applications such as wireless real-time video transmission and internet access, and by the increased overcrowding of the lower frequency bands.

This rapid expansion of untethered communications services, along with the need for low-cost, high-efficiency system implementations, has led to an explosion in the development of integrated circuit approaches in the RF/microwave area. Highly integrated components such as frequency converters, low-noise and power amplifiers (LNAs and PAs), and frequency synthesizers are now commonplace, replacing hybrid circuits employing discrete semiconductor devices. These radiofrequency integrated circuits (RFICs) and monolithic microwave integrated

Figure 11. Georgia Tech’s Packaging Research Center (PRC) “single-level-integrated module” (SLIM) implementation of the MCM-L/D. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

circuits (MMICs) are generally packaged together with VLSI digital signal processing (DSP) and microprocessor (μ P) control chips on multilayer printed-circuit boards (PCBs). However, the system-on-chip movement has been ambushed by the cost of additional mask layers needed to marry digital logic with memory and analog function on one specific and optimum substrate. Therefore, many believe that the system-on-package (SoP) approach for the next-generation wireless solution is a more feasible option than system-on-chip (SoC), considering the obstacles faced today by SoC developers. The more recent development of materials and processes in packaging areas makes it possible to bring the concept of SoP into the RF world to meet the stringent needs in wireless communications. RF SoP is intended “to provide a complete packaging solution for RF module by integrating embedded passives components and MMIC at the package level.” SoP goes one step beyond MCM by enhancing overall performance and adding more functionalities. Wireless devices implementing complex functionality require a large amount of circuitry and consequently require a large conventional package or multichip-module (MCM) real estate. 3D integration techniques using multilayer high-density architectures in different technologies with vertical interconnect and embedded component integration are crucial for the design and development of a single package to a MCM. SoP is the art of bringing together at the system-level integrated circuits and embedded components following a codesign philosophy.

A strong alternative to complete single-chip integration is some advanced form of an MCM solution such as the one proposed in Fig. 12. It integrates antenna, filters, resonators, baluns, and other RF components. The multilayer 3D architectures have the major benefit of high integration

and compactness, while adding another degree of freedom in the module design. The materials suited for this technology include low-temperature cofired ceramic (LTCC) and high-temperature cofired ceramic (HTCC) [32], multilayer organic and LCPs (liquid crystal polymers) [33].

The basic philosophy here is to fabricate devices and circuits in the optimum available technology for their particular function (e.g., digital circuits in submicrometer CMOS, analog components in BiCMOS, RF components in GaAs or InP) and then integrate them into a system or subsystem using MCM technology. High-*Q* passive structures could potentially be embedded directly into the MCM structure. Multibeam antenna beamforming networks have been demonstrated in MCM technology. For the active analog/RF and digital/DSP functions, individual ICs can be interconnected using flip-chip bonding to eliminate bondwires (and their associated parasitic) and allow more compact MCM floor planning. An additional benefit of this approach is that complete system redesign is not necessarily needed to change one part of the subsystem/module; individual functional component dies could be upgraded as long as their interconnection scheme and footprint were kept the same to remain compatible with the MCM layout. This approach is referred to as “system on a package” (SoP), in contrast to “system on a chip.” The incorporation of MEMS, smart materials, smart antennas, and other components with mixed-signal integrated circuits in such an environment is now increasingly referred to as “mixed-technology” or “heterogeneous” integration.

To explain further the SOP concept, a general system configuration of a wireless transceiver is shown in Fig. 13. The module is composed of an MMIC chipset: power amplifier (PA), low-noise amplifier (LNA), up/down mixer (MIX), and voltage-controlled oscillator (VCO), and

Figure 12. Advanced MCM solution for gigabit wireless module.

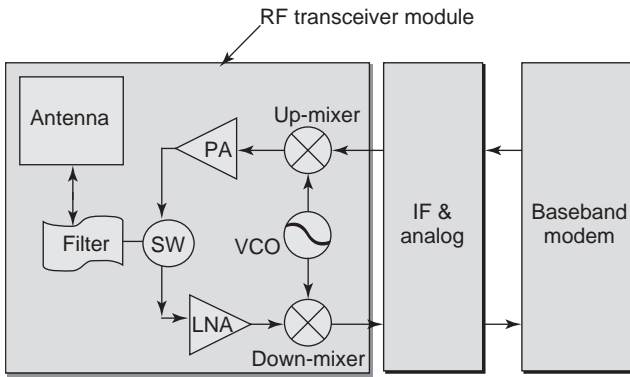

Figure 13. Block diagram of a typical RF front-end architecture.

passive components such as a filter, antenna, and external high- Q discrete passive elements for stringent blocks such as PA and VCO. The RF SoP approach includes replacing the discrete passives with embedded ones, adding more functional blocks, such as baluns and antennas, to the module and maximizing the performance of the MMIC chipset by replacing the on-chip passives with high- Q passives embedded in the package.

Figure 14 shows the technical mapping for ongoing and future RF SoP approach. It is important to note that the choice of the on-chip or off-chip (on-package) passives is dependent on the frequency band, modulation scheme, available device and packaging technology, such as the required linearity and efficiency of the PA. In VCO, the need for high- Q inductors on package is determined by the stringent phase noise specification that is coming from the modulation scheme.

Briefly, the advantages of RF SoP are

- Lower cost by using embedded passives instead of discrete components
- Flexibility for MMIC designers by embedding the high- Q passives in the package
- Minimum loss and parasitic effects by reducing the number of interconnections
- Size reduction by adopting multilayer packaging
- Easy-to-realize multifunctional RF modules in a single package

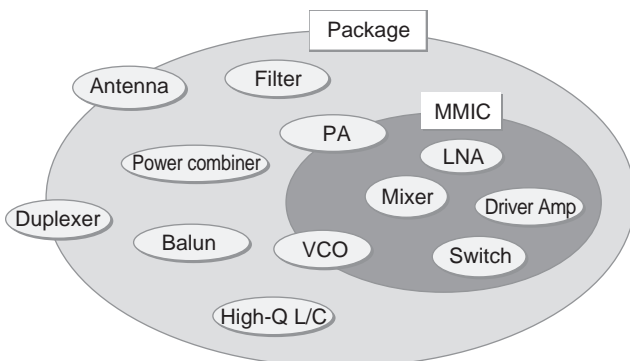

Figure 14. Technical mapping for the RF front-end SOP implementation.

- Better high-power-handling capability than MMIC chip

However, the SOP approach has various problems that are currently addressed by various research groups in the world:

- Interference between the blocks in the package
- Too many degrees of freedom in multilayer packaging to build design library
- Size constraint if antenna is included in the package

3.1. RF Front-End SoP Integration

3.1.1. SoP Integrated Passive. One of the key elements to be integrated in the RF front-end is the bandpass filter. An SoP integrated multilayer filter offers a more attractive implementation than do on-chip and discrete filters. An RF image-reject filter can be implemented with six layers of LTCC in a stripline configuration, whose three-dimensional view is illustrated in Fig. 15 [34]. Layers 6 and 0 are the top and bottom metallization which serve as the top and bottom ground planes. Two shunt inductors L_1 and L_2 were realized by the U-shaped strips fabricated on layers 4 and 3, which are located two and three layers underneath the top ground plane, respectively. The ends of the strips are connected to both grounds through vias. There is no metallization between layers 4 and 6; therefore, the top inductor strip on layer 4 is $180\ \mu\text{m}$ (two layers) away from the top ground plane while the bottom strip is 270 (three layers) away from the bottom ground plane. The required mutual inductive coupling is achieved by overlapping the L_1 and L_2 strips, which are one layer ($90\ \mu\text{m}$) apart. MIM capacitors with electrodes on layers 4 and 3 laid out beside the inductor strips were utilized to implement C_I and C_O . The V_{IC} topology was utilized to implement C_S , which is realized by two series capacitors of capacitance $2C_S$. Each of these capacitors is implemented in V_{IC} topology as a parallel combination of two capacitors with a value of C_S . Such implementation ensures the symmetry of the structure desirable for high frequency circuits. If C_S were implemented in MIM topology, the entire structure would not have been symmetric. The bottom plates of C_I and C_O are used as the top plates of the V_{IC} extended to layer 2 through via connections. The “dumb-bell”-shaped trace is inserted on layer 2 between layers 3 and 1 as the bottom plates of the V_{IC} . The extended top plates of the V_{IC} on layer 1 are used as the top MIM electrodes for the shunt capacitor C_R with the bottom ground on layer 0 as the bottom electrode. The filter prototype is given in the photograph in Fig. 16. Figure 16 also gives the measured insertion loss of 3 dB at 2.4 GHz with 40 dB rejection at 2 GHz.

3.1.2. RF SoP Integrated Module: 5.8-GHz OFDM. The integration of the antenna with the RF front-end in compact modules is one of the major challenges for the SoP implementation [35,36]. The size of the conventional patch antenna ($\lambda/2$) is often too large to be integrated with the rest of the module because it would unnecessarily increase the size of the entire system. Various approaches have

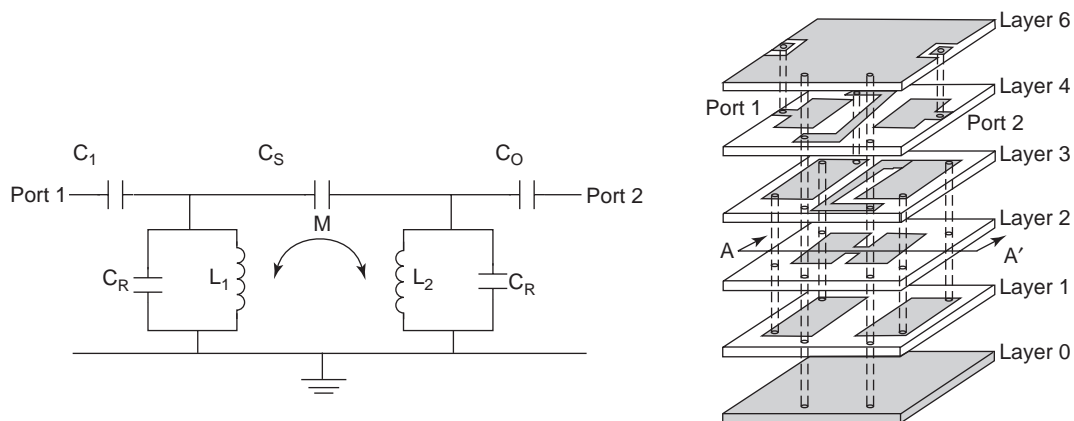

Figure 15. Configuration and 3D SOP filter.

been proposed for the miniaturization, the suppression of parasitic backside radiation (crosstalk) and the realization of multiband/multistandard antennas [37]. The concept view of the 3D integrated transceiver module with an antenna for 5.8 GHz is presented in Fig. 17. Three different multilayer subsystems—specifically, the transceiver, the filter, and the antenna—are vertically stacked and connected through vertical vias. The antenna and filter can be directly fabricated on the module using LTCC or LCP technology in order to reduce size and interconnection losses. The presented module has been designed for 20 LTCC layers. Before designing each of the embedded passives, the layers have been properly assigned. The antenna, filter, and transceiver utilize 8, 10, and 2 layers, respectively. The total size of the module is 14 × 19 × 2 mm, including all the RF functional blocks. The grounds are connected efficiently to suppress the unwanted parasitic modes. A photograph of the integrated module is shown in Fig. 17 [2].

To utilize the space of the module effectively, the geometries of the passive components are chosen very carefully. Also, innovative shielding solutions are currently investigated using metallized cavities [38] or electromagnetic bandgap (EBG) structures [39] as well as advanced simulation platforms to predict and minimize electromagnetic

interference and crosstalk within the different components of the module. In particular, electromagnetic bandgap (EBG) topologies are also used to confine the radiating field of antenna elements, therefore leading to more efficient isolation of the rest of the module, while achieving a reduction of size of the antenna, as was described in the above paragraph. Also, new design approaches based on optimization algorithms such as design of experiments (DoE) [40], feedforward neural networks [41], and genetic algorithms [42] are extensively studied and used to generate comprehensive models taking into account the fabrication and layout parameters and their impacts on electrical performances in multilayer configurations.

The RF functional blocks, including PA, LNA, mixers, and VCO, are attached on the top of the LTCC board. The specifications of the functional blocks are determined and verified through system simulations based on the IEEE 802.11a standard.

A two-section coupled stripline filter has been designed to be embedded inside the LTCC package with its input and output ports connected to the antenna and the duplexer switch through vias. A schematic view and measured performance are presented in Fig. 18. Coupled lines have been bent to fit into the module shape and via walls are used to connect ground planes and reduce

Figure 16. Photograph and measured and simulated insertion losses of the 3D SoP filter. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 17. 3D integrated LTCC RF front-end module for 802.11a WLAN. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

parallel-plate modes. Filter performances have been measured separately and exhibit a -2.9 dB insertion loss, -20.8 dB return loss, and image rejection greater than -20 dB as shown in Fig. 19b.

A cavity-backed stacked-patch antenna (CBPA) has been designed for the module. Introduction of the “soft and hard surfaces” idea has allowed for further miniaturization of the antennas [43]. This antenna has been designed for IEEE 802.11a 5.8 GHz band as shown in Fig. 19. The heights of the lower and upper patches (400×400 mils) are 8 and 32 mils, respectively. The 10 dB return-loss bandwidth of the antenna is about 4%, fully covering the required band (5.725–5.825 GHz). Also this antenna has a desirable gain (near 6 dBi) and very low cross-polarization (less than -35 dBi).

Commercial GaAs MESFET processes have been used to implement Rx and Tx chipsets. The Rx chipset consists in LNA, downconverter mixer, and VCO as shown in Fig. 20. The Tx chipset includes a double-balanced diode ring mixer and RF amplifier as shown in Fig. 21.

The LNA gain is about 13 dB, and the LNA noise is about 2.2 dB. Figure 22a shows the output spectrum of the transmitter mixer demonstrating image signal rejection of 11 dBc, and LO-to-RF rejection of 40 dB, across the VCO tuning range between 4.5 and 5.5 GHz. It also shows less than 11 dB conversion loss between IF frequency from DC to 1 GHz. The RF amplifier demonstrates a measured gain of 7 dB as shown in Fig. 22b.

3.1.3. RF SoP Integrated Module: Ku-Band Transmitter.

The implementation of a compact transmitter module is the key issue for higher data rates and broadband transmission applications of satellite communication systems in the Ku/Ka-band range. One obstacle for a compact transceiver module is the large and heavy cavity filter that cannot be easily integrated into the module. A highly integrated LTCC-based transmitter module using GaAs MESFET MMICs for Ku-band satellite communication applications is shown in Fig. 23. [44] The upconverter MMIC integrated with a VCO exhibits a measured

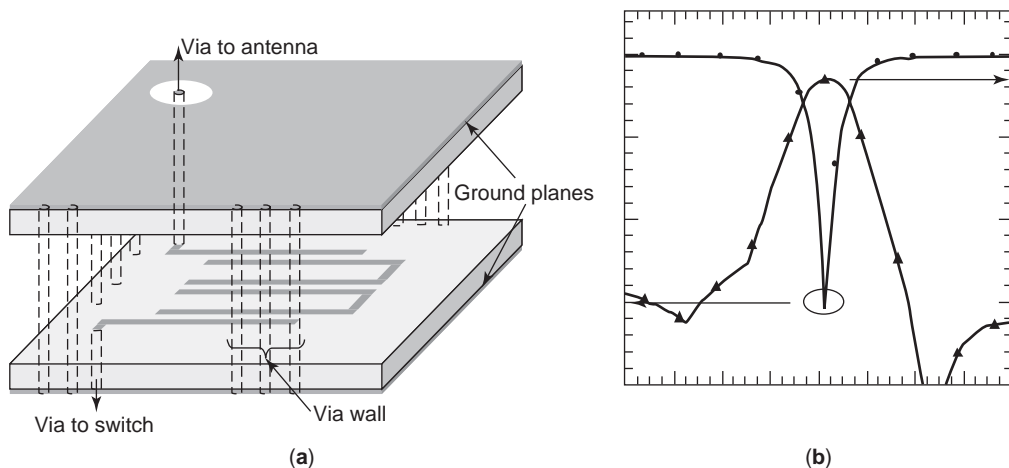

Figure 18. Embedded filter: (a) schematic; (b) performance chart. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 19. Cavity-backed patch antenna layout and performance. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

upconversion gain of 15 dB and an IIP3 (third-order input intercept point) of 15 dBm, while the power amplifier (PA) MMIC shows a measured gain of 31 dB and a 1 dB compression output power of 26 dBm at 14 GHz. Both MMICs were integrated on a compact LTCC module where an integrated front-end bandpass filter (BPF) with a measured insertion loss of 1.8 dB at 14.5 GHz was integrated. The bandpass filter for the transmitter module was implemented in a coupled-line filter topology on a multilayer LTCC substrate. The two stripline ground planes are physically connected by vias, and the actual input and output of the filter are connected to the RF amplifier and driver amplifier of the transmitter. Three segment folded edge coupled stripline filters, where the middle segment was deployed perpendicular to the first and third segments for compactness, have been designed to suppress the LO signal at 13 GHz as well as the harmonics and spurious signals. This is a balanced stripline topology where the coupled-line segments are sandwiched by two

Figure 21. Photo of the Tx chipset used in the module: (a) mixer; (b) RF amplifier. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

ground planes at an equal distance of 17.5 mils (four LTCC tape layers).

The entire transmitter chain exhibits a total gain of 32 dB and output power of 26 dBm incorporating the

wirebond loss from 14 to 15 GHz and image rejection of more than 30 dBc at 12 GHz as shown in Fig. 24a. Figure 24b shows the overall system-level diagram of the entire transmitter chain based on the measurement of each transmitter blocks. The compact module was made possible by embedding the filter and thereby saving more than 40% of real estate compared to the module if it were implemented on a typical alumina substrate.

3.2. Package Modeling and Optimization

The current drawbacks of most commercially available microwave and millimeter-wave front-ends are their relatively large size, heavy weight caused primarily by discrete components such as the filters, and separately located modules. Multilayer ceramic (i.e., LTCC) and organic-based SoP implementation are capable of overcoming this limitation by integrating components as part of the module package that would have otherwise been acquired in discrete form. On-package components not only miniaturize the module but also eliminate or minimize the need for discrete components and thereby reduce the assembly time and cost as well. The optimization of

SoP structures requires the effective modeling of complex structures that involve mechanical motion and wave propagation. Because of computational constraints, many commercial simulators utilize various approximations in order to provide fast and relatively accurate results. Popular commercial EM simulation tools include HFSS (high-frequency structure simulator) [45], SONNET [46], MicroStripes [47], and IE3D [48]. Often the size or type of circuit that can be modeled is limited by these simulators. Either the approximations used limit the applicability to specific problems, or the simulation time and/or memory is excessive. To solve numerous innovative or 3D complex problems, custom simulators employing full-wave techniques can be used. Using a custom code, approximations can be made selectively and the effect on accuracy can be determined. Popular simulation techniques [49] include the method of moments (MoM), finite-element method (FEM) in the frequency domain and finite-difference time-domain (FDTD) method, transmission-line matrix (TLM), and multiresolution time-domain (MRTD) [50] in the time domain. Frequency-domain methods are often used to simulate complex structures and can naturally handle

Figure 23. Configuration and picture of compact Ku-band transceiver module.

Figure 24. Measured gain of the module: (a) overall system gain; (b) gain variation at each level.

frequency-dependent parameters such as loss. Alternatively, time-domain simulation techniques allow the use of simple grids for complex structures, parallelize well on inexpensive hardware, and, through the use of a Fourier transform, can give the results for a wide frequency band using a single simulation. Both types of simulators can be used on most problems, although not with the same complexity.

Modern RF 3D modules and packages demand a high level of compactness and functionality. Full-wave EM numerical tools require computational complexity, which render this kind of design approach unpractical. Also, the low-frequency RF packaging design process often requires scalable equivalent circuits for the package itself. As the problems associated with the integration involve the consideration of an increasing number of factors, the design and optimization of such systems require more comprehensive and sophisticated tools. The current design and optimization methods, using the commercially available electromagnetic simulators, do not take into

account the specific effects of each of the factors involved in the design process, and the degree to which these factors interact with each other and their ranges of values. Only this type of thorough understanding of the entire system can enable the optimization and synthesis of any module or microsystem under different given conditions. An example of successful application of a combination of DoE (design of experiments) and RSM (response surface methods) is presented in Ref. 51. First, the factors that affect the performance of the system and the output figures of merit have to be identified. The next step involves the design of a factorial experiment with center-points based on a design space for these factors to determine the effect of each parameter, identify interaction between the parameters, and determine which ones are significant for each of the outputs. The experiment is run using electromagnetic simulations and/or microwave measurements, and the outputs are recorded and inputted into a statistical analysis software. After the statistical analysis of the data, significant factors are identified for all figures of merit, then RSM statistical methodology is applied for optimization. The result is an explicit set of equations that show how the outputs depend on the input variables, which are used to simultaneously optimize the figures of merit. Within the design space of the experiment, the optimized figures of merit and the required design parameters are identified.

The nonlinearity of the system, combined with the lack of analytical input-output description, suggest the use of soft computing algorithms also. Genetic algorithms (GAs) can be utilized as an optimization method of this kind. GAs search the parameter space stochastically, generating solutions that are close to the optimal. They also turn out to be very efficient for problems where small perturbations in the optimal solution lead to abrupt increase of the error.

An example of the EM/statistical hybrid method method was applied on a interdigitated coupled filter for 60-GHz applications [52]. The benchmarking structure is presented in Fig. 25. The filter is optimized for 60 GHz center frequency and maximum quality factor Q . The input variables are the linelength L and the three gaps between the lines G_1 , G_2 and G_3 .

The first-order statistical model validation showed curvature, so a second-order model has been developed and the equations describing the outputs as a function of

Figure 25. Benchmarking structure.

the inputs are

$$f_0 = 60.811 - 1.845 \left(\frac{L - 775}{25} \right) - 0.057 \left(\frac{G_1 - 60}{6} \right) + 0.164 \left(\frac{G_2 - 260}{25} \right) - 0.1 \left(\frac{G_3 - 260}{25} \right) + 0.07 \left(\frac{L - 775}{25} \right)^2 - 0.094 \left(\frac{G_2 - 260}{25} \right)^2$$

$$Q = 15.42 - 0.345 \left(\frac{L - 775}{25} \right) + 0.292 \left(\frac{G_1 - 60}{6} \right) + 1.104 \left(\frac{G_2 - 260}{25} \right) + 0.474 \left(\frac{G_3 - 260}{25} \right) - 0.104 \left(\frac{L - 775}{25} \right)^2 - 0.349 \left(\frac{G_2 - 260}{25} \right)^2$$

The filter was optimized on the basis of these equations, and the results were validated with a genetic algorithm optimization. The optimized filter insertion loss using the two methods is shown in Fig. 26.

These techniques are very flexible and can be applied to any type of design, especially in complex RF microsystems and packages where the number of factors increases and optimization is extremely difficult using only electromagnetic simulators. This gives a thorough understanding of the system behavior and integrates geometric, material, and functional parameters altogether. The approach is generic and independent of the choice of the electromagnetic simulator and statistical analysis software.

This approach has also been applied for RF and microwave flip-chip design rule development [53]. Previous work identified the factors to be considered in the design process and how they affect the assembly performance. The structure and the geometric factors are presented in Fig. 27. The design of the experimental method gave the possibility to bring all these factors together, quantify their significance, evaluate the interaction between them, and eliminate the insignificant ones from the analysis. The significant factors in this case have been found to

Figure 26. Comparison of the performance of the optimized filter using response surface methods and genetic algorithms.

Figure 27. Geometric factors for flip-chip design rule development.

be the bump diameter and height, the CPW width, and the amount of transmission-line overlap around the transition. Also, the transition was optimized by considering not only the individual effects of the variables but also the interaction between them, which can be critical in determining the optimal factor combination. Finally, fully scalable lumped element models with all these factors were developed by applying regression models to the statistical data.

3.3. Testing

Such packages are tested and characterized using microwave measurements, and various deembedding techniques are used to extract the behavior of the device under test (DUT) (see Fig. 28). Microwave measurements require adapters or launches as interface between the measurement system (coaxial cable or on-wafer probes) and the DUT. The additional parasitics added to the measurements by these adapters and launches have to be deembedded to obtain the actual performance of the device [54–56].

There are a wide variety of deembedding techniques, some involving the calibration of the network analyzer such that the parasitic effects are eliminated from the measurement level, some involving separate measurements of the parasitics and using the deembedding capabilities of a circuit simulator such as Agilent's Advanced Design System (ADS) [57] or analytical approaches.

An example of the deembedding technique used for electrically long adapters is the “through-line-line” calibration [54]. This method obtains the effect of the launches by analytically computing its S parameters. It utilizes three deembedding components, one through and two lines (lines 1 and 2) (Fig. 29), without any reflecting components such as the TRL calibration technique. The measurement reference plane is $A'B'$, as shown in Fig. 28. After deembedding, the reference planes are moved back

Figure 28. Illustration of typical deembedding application for a BGA structure.

Figure 29. Lines “Thru,” “Line1,” and “Line2” designed for deembedding the coplanar waveguide launches.

to the device under test, at the *AB* plane. Figure 28 shows the application of this method to a BGA structure.

Figure 30a shows the *S* parameters of the BGA package test structure from both original measurement and deembedded data. In the deembedded data, the loss of the DUT is smaller than in the original measurement. In Figure 30b, the deembedding method is verified with the simulation of the BGA model and very good agreement is observed.

When the circuit complexity increases, a careful calibration design is sometimes not possible and more flexible methods need to be used. If the structure to be deembed-

Figure 30. (a) Comparison of *S* parameters of the BGA test structure between the original measurement and deembedded data; (b) verification of the deembedded data with the BGA structure simulation. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

ded is measured or simulated (*AA'* and *BB'* in Fig. 28), its effect can be subtracted from the overall measurement (*A'B'*). First, two *S*-parameter measurements of the deembedding structure and of the entire system are recorded. Finally, the deembedding *S*-parameter block is cascaded in ADS on each side of the measured overall *S*-parameter block. All are simulated using the deembedding function of ADS, and then the deembedded DUT *S* parameters are obtained.

These deembedding techniques are also used for extracting the parasitic effects of the package itself for equivalent circuit model extraction [58]. These models are scalable and are very important to help the IC designer predict the entire system performance at the beginning of the design process.

3.4. Future Trends

More recent developments in advanced packaging technologies such as 3D multichip modules provide an opportunity for significant reduction in mass, volume, and power consumption. Simultaneously, emerging wireless communications applications in the RF/microwave/millimeter-wave regimes require miniaturization, portability, cost, and performance as key driving forces in the electronics packaging evolution. The system-on-package (SoP) approach [vs. the system-on-chip (SoC) technique] for module development has been proven to be the best approach for systems integration due to the real estate efficiency, cost-saving, size reduction, and performance improvement potentially involved in this integral functionality, and simultaneously satisfying the specifications of the next-generation wireless communication systems. However, current RF module integration is still based on low-density hybrid assembly technologies. Embedded ICs [59] and bumpless buildup layer (BBUL) [60] packaging technology are targeted for low-cost applications and provide great opportunities for the multigigahertz processor and ultracompact RF integrated system.

An example of this integration concept is illustrated in Fig. 31. A multilayer interconnect structure is built using modified MCM-D technology and advanced photosensitive epoxy. A low-loss interconnect is fabricated using buildup technology. Microvias with a minimum diameter of 40 μm are used to connect the different metal layers. Thus, high-density interconnect networks and integral passive components such as high-performance embedded inductors, filters, and antennas can be implemented within the multilayer wiring structure. Multigigahertz processor or RF

Figure 31. Embedded IC and bumpless build-up layer (BBUL) packaging technology concept view.

commercial chipset are placed into cavities created along the MCM-D process and covered by a final dielectric layer. Cavities provide self-alignment for the die with the interconnection structure. This approach avoids parasitics due to wirebonding, flip-chip, or BGA-type interconnection and parasitic interconnection length between the active circuitry and the passives components are greatly reduced.

New challenges such as RF MEMS integration and packaging are nowadays at the leading edge of the packaging research. Various approaches have been developed by universities or worldwide-leader packaging companies. Current techniques under investigations for the RF MEMS packaging are

- Wafer-to-wafer anodic bonding or polymer bonding/sealing at wafer scale [61]
- Thin-film encapsulation at wafer scale [62]
- Cavity in MCM-C, -L, or -D substrate combined with the use of a sealing cap [63].

Nevertheless, there is still a lack of standardization leading to excessive cost for the development of final products. Eventually, the ideal package technology will merge the standard functions (i.e., environmental protection, hermetic sealing, accelerated testing and vacuum encapsulation skills, signal isolation, mechanical stability) with design specific functions, such as the RF requirement for minimized package resonance, reduced parasitic effects, and so on.

4. CONCLUSION

Future RF and wireless communication and sensor systems will be increasingly complex, miniaturized, and reconfigurable enhancing the importance of packaging structures. High-integration technology is expected to reduce the chip size, number of components, and total system cost. Along with the migration of ICs to integrated system-on-chip (SoC), IC packaging is moving toward wafer-level packaging, and wafer-level test and burnin. The rapid progress of scaled CMOS technology and the introduction of SiGe technology since the late 1990s have improved the performance of silicon RF devices and circuits to meet the requirements. However, the difficulty in lowering the power consumption of RF and analog circuits and the size of passive components and analog transistors has diminished the appeal of the SoC approach. The SoP method will be the way to address these issues and lead to the successful transition from bulky board packaging to the multilayer micro-, nano-, and multifunctional boards for 2010 and beyond.

College Station, Texas

1. INTRODUCTION

The microstrip ring resonator was first introduced by P. Troughton in 1969 to measure the phase velocity and dispersive characteristics of a microstrip line [1]. Compared with the conventional half-wavelength resonator, the major advantage of using a ring resonator for these measurements is to avoid open-end effects. To understand the operation of a ring circuit, some complicated field

analyses based on electromagnetic field theory were developed [2]. In addition, simple transmission-line analyses were also proposed [3–5]. In the transmission-line approaches, the ring is modeled as equivalent circuits or equivalent lumped elements to overcome the field theory limitation described by dimensions and mode charts of the ring. Also, different types of rings such as microstrip, coplanar waveguide, dielectric, and slot-line rings were used to incorporate passive and active devices in MIC and MMIC [6–8]. A waveguide ring resonator is generally used for the applications need higher Q values and higher power handling [9]. With the advantages of compact size, low cost, easy fabrication, and low radiation loss, the planar ring resonator was widely used for the design of filters, oscillators, mixers, baluns, hybrids, magic T, couplers, frequency-selective surfaces, and antennas [10].

2. ANALYSIS AND MODELING OF RING RESONATORS

2.1. Field Analyses

The magnetic wall model introduced by Wolff and Knoppik was the most commonly used field theory to explain the

RING RESONATORS AND CIRCUITS

LUNG-HWA HSIEH
 KAI CHANG
 Texas A&M University
 College Station, Texas

1. INTRODUCTION

The microstrip ring resonator was first introduced by P. Troughton in 1969 to measure the phase velocity and dispersive characteristics of a microstrip line [1]. Compared with the conventional half-wavelength resonator, the major advantage of using a ring resonator for these measurements is to avoid open-end effects. To understand the operation of a ring circuit, some complicated field

analyses based on electromagnetic field theory were developed [2]. In addition, simple transmission-line analyses were also proposed [3–5]. In the transmission-line approaches, the ring is modeled as equivalent circuits or equivalent lumped elements to overcome the field theory limitation described by dimensions and mode charts of the ring. Also, different types of rings such as microstrip, coplanar waveguide, dielectric, and slot-line rings were used to incorporate passive and active devices in MIC and MMIC [6–8]. A waveguide ring resonator is generally used for the applications need higher *Q* values and higher power handling [9]. With the advantages of compact size, low cost, easy fabrication, and low radiation loss, the planar ring resonator was widely used for the design of filters, oscillators, mixers, baluns, hybrids, magic T, couplers, frequency-selective surfaces, and antennas [10].

2. ANALYSIS AND MODELING OF RING RESONATORS

2.1. Field Analyses

The magnetic wall model introduced by Wolff and Knoppik was the most commonly used field theory to explain the

Figure 1. Ring resonator (a) configuration and (b) maximum and minimum field points.

Figure 2. Ring resonator and its transmission-line model using a T network.

operation of the ring resonator [2]. This model including the curvature effects of the microstrip line can achieve an accurate expression for the physical size of the ring resonator corresponding to its electric characteristics. Also, using this analysis, Wolff and Knoppik obtained a good agreement for experiment and theoretical results in the resonant frequencies of the ring.

The ring resonator shown in Fig. 1a can be treated as a cavity resonator with electric walls on the top and bottom and magnetic walls on its sides. The electromagnetic fields are confined to the dielectric substrate between the ground plane and the ring resonator conductors. Assuming no z dependency ($\partial/\partial z = 0$), the fields are transverse magnetic (TM) in the z direction.

A solution of Maxwell's equations is

$$E_z = [AJ_n(kr) + BN_n(kr)] \cos(n\Phi) \quad (1a)$$

$$H_r = \frac{n}{j\omega\mu_0 r} [AJ_n(kr) + BN_n(kr)] \sin(n\Phi) \quad (1b)$$

$$H_\Phi = \frac{k}{j\omega\mu_0} [AJ'_n(kr) + BN'_n(kr)] \cos(n\Phi) \quad (1c)$$

where A and B are constants, k is the wavenumber, ω is the angular frequency, J_n and N_n are the Bessel function of the first and second kind of order n , and J'_n and N'_n are derivatives of the Bessel function with respect to the argument kr . With the boundary conditions $H_\Phi|_{r=r_o} = 0$ and $H_\Phi|_{r=r_i} = 0$, the eigenfunction derived from Eq. (1) is

$$J'_n(kr_o)N'_n(kr_i) - J'_n(kr_i)N'_n(kr_o) = 0 \quad (2)$$

where r_o and r_i are the outer and inner radii of the ring and $k = \omega\sqrt{\epsilon_o\epsilon_r\mu_0}$.

As r_i approaches to r_o , the eigenfunction in Eq. (2) reduces to [11]

$$[(kr_o)^2 - n^2][J_{n-1}(kr_o)N_n(kr_o) - J_n(kr_o)N_{n-1}(kr_o)] = 0 \quad (3)$$

The second term of Eq. (3) is nonzero, and thus

$$[(kr_o)^2 - n^2] = 0 \quad (4)$$

Substituting $k = 2\pi/\lambda_g$ into Eq. (4) yields the well-known equation

$$n\lambda_g = 2\pi r_o \quad (5)$$

Furthermore, a planar waveguide mode considering the fringe edge effects of the microstrip line was proposed to improve the magnetic wall model [12]. Beyond the magnetic wall model, some rigorous solutions for the ring resonator were also reported [13].

Figure 1b shows the maximum and minimum field points on the ring resonator that operates at its fundamental resonant frequency. These maximum and minimum field points indicate how the standing waves operate on the ring and can be simply derived by using a transmission-line model [14].

2.2. Transmission-Line Models

The magnetic wall model describes the physical dimensions of the ring resonator only with respect to its resonant frequencies. In addition, the rigorous solutions are limited because of their extensive computational time and difficulty for the use in applications. To extend the studies and applications, transmission-line models have been proposed [3–5]. In these models, the ring resonator is represented as an equivalent circuit; equivalent lumped elements in terms of G, L, C ; or distributed piecewise transmission lines.

Figure 2 shows a two-port ring and its equivalent circuit [3]. The ring resonator is divided into parallel transmission lines. Each line is modeled as a lossless T network as shown in Fig. 2. The equivalent impedances are given by

$$Z_a = jZ_0 \tan \frac{\beta l}{2}, \quad Z_b = -jZ_0 \csc(\beta l) \quad (6)$$

where Z_0 is the characteristic impedance of the ring resonator, β is the propagation constant, $l = \pi r$, and r is the mean radius of the ring resonator.

The input impedance of the ring circuit obtained with terminating any one of two ports is given as

$$Z_{in} = R_{in} + jX_{in} \quad (7)$$

Letting $X_{in} = 0$, we can find the resonant frequencies of the ring.

Table 1 shows the resonant frequencies compared with the magnetic wall model based on the RT/Duroid material and dimensions designed for the ring resonators as shown in Table 2. It can be seen that the transmission-line model accurately predicts the resonant frequencies within 1%. In addition, the coupling gaps between the feedlines and the ring resonator as shown in Fig. 2 affect the resonant

Table 1. Comparison between Transmission-Line and Magnetic Wall Models

Circuit	Transmission-Line Model Resonant Frequency Error (%)		Magnetic Wall Model Resonant Frequency Error (%)	
	$n = 1$	$n = 2$	$n = 1$	$n = 2$
1	0.79	0.6	0.78	0.89
2	0.56	0.28	0.63	0.38

frequency and insertion loss of the ring resonator [10]. The smaller (wider) is the gap size, the lower (higher) are the resonant frequency and insertion loss. Other coupling mechanisms can be found in the literature [15,16].

Figure 3 shows the ring resonator and its equivalent circuit in terms of G , L , and C , where α is the attenuation constant and ω_0 is the resonant angular frequency. The lumped elements G , L , and C are derived from $ABCD$, Y , and S parameters [5]. The unloaded Q of the ring can be directly calculated from G , L , and C . Table 3 shows a good agreement between the measured and calculated G , L , C , and unloaded Q of the ring resonator. The ring resonators were designed at the fundamental frequency of 2 GHz and fabricated on the dielectric constant (RT/Duroid 5870) of $\epsilon_r = 2.33$, the substrate thickness of $h = 10$ mil, the copper metallization thickness of $t = 0.7$ mil, and the width of $w = 0.74$ mm.

The distributed transmission-line model for the ring resonator is shown in Fig. 4 [4]. The whole ring resonator is divided into many small transmission-line elements. Therefore, the frequency response of the ring can be obtained by cascading many individual $ABCD$ matrices and Y and S parameters. Also, the effects of incorporated passive and active devices between any two small transmission-line elements can be easily calculated and predicted using this model. The model can also be used to study the effect of any perturbations incorporated into a portion of the ring.

3. MEASUREMENT USING RING RESONATORS

The ring resonator can be used to measure for dispersion, dielectric constant, and Q factor. By measuring the resonant frequencies of the ring resonator, the phase velocity and dispersive characteristics of a microstrip line can be obtained. The microstrip ring circuit shown in Fig. 2 consists of two feedlines, one closed-loop ring with two coupling gaps between the ring and the feedlines. The size of the coupling gaps should be large enough so that the coupling effects on the ring will not affect the resonant frequency. Equation (8) demonstrates that the ring supports waves with an integral multiple guided wavelengths equal

Table 2. Material and Dimensions of the Ring Resonator

Circuit	Substrate	Relative Permittivity	Thickness (mm)	Width (mm)	Mean Radius (mm)	Gap Size (mm)

Figure 4. Distributed transmission-line model.

to the mean circumference of the ring

$$n\lambda_g = 2\pi r, \quad n = 1, 2, 3, \dots \quad (8)$$

where n is the mode number and r is the mean radius. The dispersion in a microstrip line can be examined by the effective permittivity ϵ_{eff} . The *effective permittivity* is defined as the square of the ratio of the speed of light in free space c to the phase velocity v_p in a microstrip line:

$$\epsilon_{\text{eff}}(f) = \left(\frac{c}{f\lambda_g} \right)^2 = \left(\frac{\lambda_0}{\lambda_g} \right)^2 \quad (9)$$

Substituting Eq. (8) into Eq. (9) gives

$$\epsilon_{\text{eff}}(f_0) = \left(\frac{nc}{f_0 2\pi r} \right)^2 \quad (10)$$

Figure 5. Frequency response of a resonator.

where f_0 is the resonant frequency. Thus, the dispersion of the microstrip line can be calculated from Eq. (10). The accuracy of the dispersion calculation depends on the accuracy of the measurement of the frequency and the total circumference of the ring.

A figure of merit for a ring resonator is its Q factor. The loaded Q factor of the ring can be measured by $Q_L = f_0 / (f_2 - f_1)$, where f_0 is the angular resonant frequency and $f_1 - f_2$ is the 3 dB (half-power) bandwidth. The corresponding frequency response is shown in Fig. 5. Moreover, the unloaded Q factor of the ring can be determined by measuring the loaded Q factor and the insertion loss of the ring at the resonance. The unloaded Q factor is calculated from

$$Q_u = \frac{Q_L}{(1 - 10^{-L/20})} \tag{11}$$

where L is the insertion loss in decibels at resonance of the ring.

4. RING FILTERS

The dual-mode bandpass filter was proposed by Wolff using asymmetric coupling feedlines as shown in Fig. 6 [17]. The asymmetries perturb the fields of the ring and generate two separated modes. These two modes couple each other and increase the passband of the ring resonator. The dual-mode effects are introduced by skewing one of feedlines with respect to the other, and/or by introduction of a discontinuity (notch, slit, patch, etc.) [10]. Later on, many new configurations using orthogonal feedlines with patch

Figure 6. Asymmetrically coupling ring resonator.

Figure 7. A dual-mode ring circuit with one single coupling gap [19]. (Permission from Electronics Letters.)

perturbation on a ring resonator were introduced [18–20]. The new configuration with orthogonal feedlines and a patch perturbation provides a quasielliptic function that has two transmission zeros close to the passband to reject adjacent channel interferences as shown in Fig. 7 [19]. Also, by cascading several resonators in series, various bandpass frequency responses can be designed [21].

4.1. Dual-Mode Bandpass Filters

Figure 8 shows a dual-mode bandpass filter. The square ring resonator is fed by a pair of orthogonal feedlines, and each feedline is connected to an L-shape coupling arm [15]. Figure 8b displays the scheme of the coupling arm, which consists of a coupling stub and a tuning stub. The tuning stub attached to the end of the coupling stub extends the coupling stub to increase the coupling periphery. In addition, the asymmetric structure perturbs the field of the ring resonator and excites two degenerate modes [17]. Without the tuning stubs, there is no perturbation on the ring resonator and only a single mode is excited [22]. Comparing the filter in Fig. 8 with conventional dual-mode filters [10], the conventional filters provide only a dual-mode characteristic without the benefits of enhanced coupling strength and performance optimization.

To improve the passband performance and stopband rejection, multiple-resonator filters are normally used. Figure 9 shows the filter layout using three cascaded resonators with the same dimensions as in Fig. 8. The filter was designed at the center frequency of 1.75 GHz and fabricated on a 50-mil-thickness RT/Duroid 6010.2 substrate

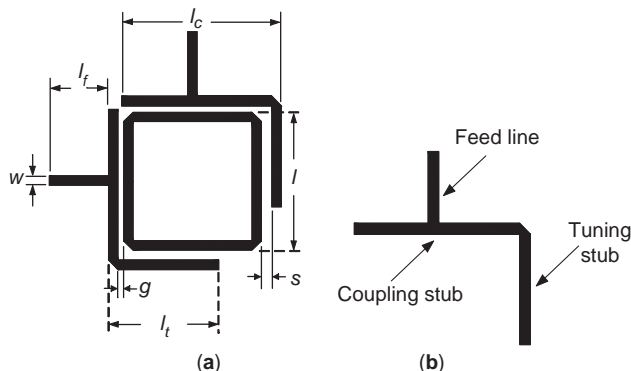

Figure 8. Dual-mode bandpass filter with enhanced coupling: (a) layout; (b) L-shape coupling arm [15]. (Permission from IEEE.)

Figure 9. Layout of the filter using three resonators with L-shape coupling arms [15]. (Permission from IEEE.)

with a relative dielectric constant of 10.2. The dimensions of the filter were $w = 1.191$ mm, $l_f = 8$ mm, $g = 0.25$ mm, $s = 0.8$ mm, $l = 17.648$ mm, $l_t = 13.5$ mm, $l_c = 19.64$ mm, $l_e = 6.2$ mm, and $w_l = 1.691$ mm. Figure 10 shows the simulated and measured results. The simulation was completed using a IE3D electromagnetic simulator [23]. The filter had an insertion loss of 2.39 dB in the passband with a 3 dB bandwidth of 145 MHz. The stopband rejection was better than 30 dB within 1–1.62 GHz and 1.85–3 GHz, respectively.

4.2. Microstrip Ring Bandpass Filters with Two Transmission Zeros

By using asymmetrically feeding on the two open-loop ring resonators, the filter shown in Fig. 11 also provides two transmission zeros [24]. In comparison with the cross-coupled structure of Ref. 25, this configuration using only two resonators can also provide a sharp cutoff frequency

Figure 10. Simulated and measured results for the filter using three resonators with L-shape coupling arms [15]. (Permission from IEEE.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 11. Layout of the filter using two open-loop ring resonators with asymmetric tapping feeders [24]. (Permission from IEEE.)

response but has lower insertion loss due to fewer conductor losses.

In Fig. 11, the total length of the resonator is $l = l_1 + l_2 = \lambda_g/2$, and the input and output feeders divide the resonators into two sections of l_1 and l_2 , where λ_g is the guided wavelength. By using *ABCD*, *Y*, and *S* parameter operations, the locations of the transmission zeros corresponding to the tapping position on the ring resonator are given by [24]

$$f_1 \cong \frac{nc}{4l_1\sqrt{\epsilon_{eff}}}, \quad f_2 \cong \frac{nc}{4l_2\sqrt{\epsilon_{eff}}}; \quad n = 1, 3, 5 \dots \quad (12)$$

To verify the calculation from Eq. (5), a filter was designed at the fundamental frequency of 2 GHz and fabricated on a RT/Duroid 6010.2 substrate with a thickness $h = 25$ mil and a relative dielectric constant $\epsilon_r = 10.2$. The dimensions of the filter are $g = 0.5$ mm, $s_1 = 0.35$ mm, $l_1 = 12.69$ mm, $w = 0.563$ mm, and $l_2 = 16.16$ mm. The measured results are shown in Fig. 12. The calculated and measured results shown in Table 4 agree well. The filter has an insertion loss of 0.95 dB at 2.02 GHz, return loss of greater than 20 dB from 1.98 to 2.06 GHz, and two transmission zeros at 1.69 GHz with -50.7 dB rejection and 2.5 GHz with -45.5 dB rejection, respectively. The 3 dB fractional bandwidth of the filter is 10.4%.

5. RING COUPLERS AND HYBRIDS

Hybrid ring couplers are widely used in various microwave integrated circuit (MIC) and monolithic microwave integrated circuit (MMIC) applications such as balanced amplifiers, balanced mixers, phase shifts, frequency discriminators, and feeding networks in antenna arrays [26–29]. The 180° hybrid ring couplers and 90° branchline couplers are commonly used in these applications. Rartrace hybrid rings and reverse-phase hybrid rings are well known for the 180° hybrid ring couplers [30,31]. Different types of hybrid couplers using slotline and coplanar waveguide structures have also been reported [6].

Figure 13 shows a microstrip hybrid ring coupler. When a unit amplitude wave is incident at port 4 of the coupler, the wave is divided into two components at the ring junction. These two components arrive in phase at ports 2 and 3, and 180° out of phase at port 1. Furthermore, if a unit amplitude is incident at port 1 of the coupler, the wave divides into two components that arrive at ports 2 and 3 with a net phase difference of 180° , and 180° out of phase at port 4.

According to the characteristics of the coupler, a balanced mixer can be built. The single balanced mixer shown in Fig. 14 consists of a hybrid ring coupler, two diodes, two RF chokes, two DC blocks, and one lowpass filter. The local oscillator (LO) is 180° out of phase at the RF port, providing the isolation between the LO and RF ports. The LO signal is split equally but is 180° out of phase at two diodes. The RF signal is split equally and in phase into two diodes. The phase noise of LO is thus canceled. Both RF and LO signals are mixed in the diodes to generate an IF signal at the output of the lowpass filter. The RF chokes provide a tuning mechanism and prevent the RF signal from leaking into ground. Figure 15 shows the measured results of a 94-GHz hybrid coupler mixer [29]. The mixer

Figure 13. A microstrip hybrid ring coupler.

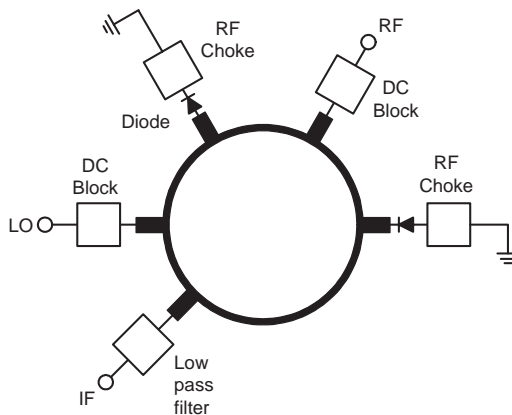

Figure 14. A hybrid coupler mixer.

has a conversion loss of less than 8 dB over a 3 GHz RF bandwidth using LO pump power of 8 dBm and less than 6.5 dB with LO pump power of 10 dBm.

6. RING ANTENNAS

In mid-1970s, microstrip antennas drew widespread attention because of their low cost and easy fabrication. Also, they could be easily used to design circularly polarized antennas, frequency-selective surface antennas, active antennas, phased arrays, reflect arrays, and so on [32–35]. New designs and applications of coplanar antennas are expected in modern wireless and personal communication systems.

6.1. Ring Antenna Circuit Models

The ring antenna shown in Fig. 16 consists of a close-loop ring conductor on one side of the substrate with a ground plane on the other side. The ring has an inside radius of r_i and an outside radius of r_o . The feedpoint radius is r_p . The total length of the ring antenna can be calculated from Eq. (8).

Since the thickness h is very small compared to the wavelength λ_0 , the variation of the electric field in the

Figure 15. Performance of a 94-GHz hybrid coupler mixer [24].

Figure 16. Configuration of a ring antenna.

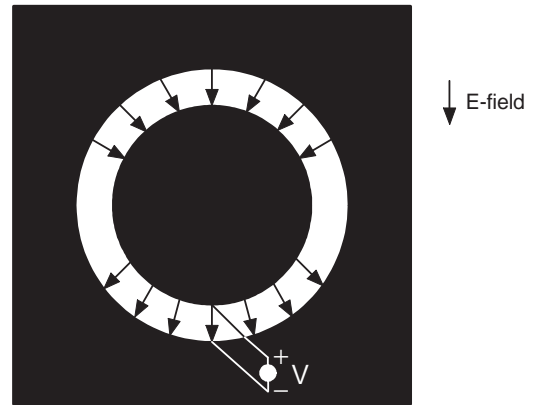

Figure 18. Slot ring feed method showing electric field.

z direction can be ignored. Without the Φ dependence, the TM modes of the electric and magnetic fields of the ring antenna are given by [36]

$$E_z(r) = A_n J_n(kr) + B_n N_n(kr) \tag{13}$$

$$H_\Phi(r) = -\frac{jk}{\omega\mu_0} [A_n J'_n(kr) + B_n N'_n(kr)] \tag{14}$$

These fields are used to define modal voltages and currents. The modal voltage is simply defined as $E_z(r)$. The modal current is rH_Φ or $-rH_\Phi$ for power propagation in the r direction, respectively. The admittance at any point r is expressed by

$$Y(r) = \frac{rH_\Phi(r)}{E_z(r)}, \quad r < r_p \tag{15}$$

$$Y(r) = -\frac{rH_\Phi(r)}{E_z(r)}, \quad r > r_p \tag{16}$$

6.2. Slot Ring Antennas

The slot antenna is a dual version of the microstrip ring antenna; a comparison is given in Fig. 17 [37]. It has a

Figure 17. Comparison of (a) microstrip ring and (b) slot ring structures.

wider impedance bandwidth than does microstrip antenna. Therefore, the bandwidth of the slot antenna is greater than that of the microstrip antenna. By introducing some asymmetry to the slot antenna, a circular polarization (CP) radiation can be obtained. The slot ring antenna in the ground plane of a microstrip transmission line can be readily made into a corporate-fed array by implementing microstrip dividers.

To use the structure as an antenna, the first-order mode is excited as shown in Fig. 18 [37]. Also, the impedance seen by the voltage source is real at resonance. All the power delivered to the ring will be radiated [37]. The resonant frequency can be calculated using the transmission-line model [37].

Figure 19 shows a multifrequency annular slot antenna [38,39]. A 50-Ω microstrip feed is electromagnetically coupled to the slot ring at point A and is extended to point C. The circuit was etched on a Keene Corporation substrate with relative dielectric constant of 2.45 and height of 0.762 mm. The widths of the microstrip (w_m) and slot ring (w_s) were 2.16 and 2.9 mm, respectively. The mean circumference of the slot ring was 93.3 mm.

Ignoring the microstrip feed and treating the slot ring antenna as a transmission line, one expects the operating frequency to be the frequency at which the circumference

Figure 19. The configuration of the multifrequency annular antenna.

Figure 20. Measured and simulated return loss of the multifrequency antenna with AC=46.85 mm [38]. (Permission from IEEE.)

of the slot ring antenna becomes one guided wavelength of the slot (λ_{gs}). A slot guided wavelength for the frequency range of interest can be obtained from [40]

$$\lambda_{gs} = \lambda_0 \left\{ 1.045 - 0.365 \ln \epsilon_r + \frac{6.3(w_s/h)\epsilon_r^{0.945}}{(238.64 + 100w_s/h)} - \left[0.148 - \frac{8.81(\epsilon_r + 0.95)}{100\epsilon_r} \right] \ln \left(\frac{h}{\lambda_0} \right) \right\} \quad (17)$$

where λ_0 is the free-space wavelength and h is the thickness of the substrate. At 2.97 GHz, λ_{gs} is equal to the mean circumference of the antenna (93.3 mm). From this information, as a first-order approximation, first-operating frequency of the slot ring antenna is 2.97 GHz. The actual operating frequency of the microstrip-fed slot ring anten-

(b)

Figure 22. Configuration of active antenna (a) Gunn diode active notch antenna using a slotline resonator (the wire for DC bias to the center of the ring is not shown) and (b) CPW-fed passive antenna (some dimensions in the figures are exaggerated to enhance detail) [34].

na can be either above or below this approximate frequency depending on the length of the microstrip stub.

The return loss of the multifrequency antenna and simulation results agree well and as shown in Fig. 20. The simulation was carried out by electromagnetic simulator [23]. Defining the operating frequency to be a frequency at which return loss is less than 10 dB, these experimental operating frequencies are centered at 2.58, 3.9, 5.03, and 7.52 GHz. The measured patterns of the antenna at resonant frequency of 2.65 GHz are shown in Fig. 21.

6.3. Active Ring Antennas

Active integrated antennas have the advantages of reducing the size, weight, and cost of many transmit and receive systems. Solid-state devices can be incorporated into an antenna to provide various functions. Two- and three-terminal solid-state devices have been integrated with various antennas to form switches, tuners, detectors, mixers, amplifiers, oscillators, Doppler sensors, and receivers. The choice between transistors and diodes is not clearcut. It depends on the type of microwave component required, operating frequency range, RF power output desired, available DC power input, and other considerations.

Figure 23. *E*-plane radiation pattern—half-power beamwidth (HPBW) = 33°, cross-polarization = 13.18 dB below copolarization; *H*-plane radiation pattern—HPBW = 47°, cross-polarization = 6.69 dB below copolarization [34]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Unlike the design of a passive antenna, the design of an integrated active antenna needs to include the effects of device packages and bias lines. The effects often cause changes in operating frequencies, lower conversion efficiencies, and higher cross-polarization levels (CPLs).

As an example, the active antenna shown in Fig. 22 consists of a Gunn diode and a slotline notch antenna stabilized with a slotline ring resonator [34]. The Gunn diode is placed across the ring resonator at a low-impedance point to meet the conditions for oscillation. The slotline ring's resonant wavelength can be determined from

$$2\pi r = n\lambda_g, \quad n = 1, 2, 3, \dots \quad (18)$$

where r is the mean radius of the slotline ring, λ_g is the guided wavelength in the slotline ring, and n is the mode number.

Figure 22a shows the circuit configuration of the active antenna, while Fig. 22b shows the coplanar waveguide

(a)

(b)

Figure 24. Configuration of Ka-band reflectarray (a) setup and (b) ring antenna [35]. (Permission from *Electronics Letters*.)

(CPW)-fed passive antenna developed for radiation pattern comparison. The antennas were etched on Duroid 5870 board with a relative dielectric constant of 2.33, substrate thickness of 62 mils (1.575 mm), and 1-oz copper metallization. The antennas are truly uniplanar, requiring no backplane for excellent performance. The slotline ring has a mean radius of 3.81 mm and a slot width of 0.18 mm. The CPW feedline in the passive antenna has a

Figure 25. Measured radiation patterns [35]. (Permission from *Electronics Letters*.)

Figure 26. Measured aperture efficiency [35]. (Permission from *Electronics Letters*.)

Figure 27. Feedback ring resonator oscillator [44]. (Permission from IEEE.)

center strip width of 1.2 mm and symmetric side gaps of 0.08 mm. A thin-wire airbridge is used to operate the CPW line in the even mode. The slotline notch antenna uses an exponential taper to match the impedance of the ring to free space. The antenna length is 6 cm, and the gap at the

feedpoint is 0.18 mm. The aluminum mount used in the active antenna also serves as the heatsink for the Gunn diode. The DC bias is provided directly to the center of the slotline ring. The active antenna radiates a clean spectrum at 9.26 GHz with a bias voltage of 10.0 V and draws 410 mA. The active antenna produces an effective power output of 27.1 mW and an effective isotropic radiated power (EIRP) of 720.0 mW. The spectrum has a phase noise of -95.33 dBc/Hz at 100 kHz from the carrier, while the second-harmonic radiation produced by the active antenna is 26.16 dB below the fundamental frequency. Figure 23 shows the radiation patterns of the active antenna.

The *E*-plane and *H*-plane patterns are smooth with cross-polarization levels of 13.18 and 6.69 dB below copolarization. The radiation *E* plane and *H* plane are 33° and 47°, respectively. The radiation pattern of the CPW-fed passive antenna is essentially similar with the exception that the cross-polarization levels are 18.74 and 16.51 or the *E* and *H* planes, respectively.

6.4. Reflect Array Using Ring Resonators

Microstrip reflectarrays have been shown to be good candidates for replacing the conventional parabolic reflector antennas. The technologies involve a flat printed array integrated with a space-feeding horn and have the advantages of low cost, low profile, easy fabrication, and flat surface [41].

Figure 24 shows the configuration of the reflectarray with a Ka-band feedhorn [35]. The reflectarray is constructed by ring resonators with two slits at the top and the bottom. Compared with the reflectarray using square patch antennas, this configuration using ring antennas can increase the operating bandwidth and reduce blockage when using in a dual-layer, dual-frequency application.

Because of the nature of reflection, an incident right-hand circularly polarized wave is reflected as a left-hand circularly polarized wave. However, by using these two slits on the ring, the reversal of polarization can be

Figure 28. Output power for the feedback ring resonator oscillator operated at the second resonant mode of the ring resonator [44]. (Permission from IEEE.)

Figure 29. Configuration of the tunable oscillator using a PET: (a) top view; (b) 3D view [44]. (Permission from IEEE.)

anceled out. Also, a simple trigonometric relation is used to calculate the required additional pathlengths to create a parabolic phase front across an array's surface. Each ring antenna is rotated counterclockwise by ϕ radians at each position when 2ϕ radians are needed for compensating these additional pathlengths. For the whole reflectarray with a diameter of 0.5 m, the repetitious behaviors of array configurations are found to be more than 4 times that of a 2π radian.

A 0.5-m reflectarray has been designed for broadside radiation at a focal distance of 350 mm corresponding to

an f/D ratio of 0.7. The ring antennas are fabricated on RT/Duroid 5870 substrate with $\epsilon_r = 2.33$ and 0.508 mm thickness. The space between rings is 0.5 free-space wavelength, which is selected to avoid grating lobes. The measured results at 31.75 GHz are shown in Fig. 25. The mainbeam has a beamwidth of 1.3° . The cross-polarization level is 40.71 dB down at broadside, and the sidelobe suppression is greater than 19.47 dB, occurring at 2° . This cross-polarization level corresponds to an axial ratio of less than 0.5 dB. The relatively high peak sidelobe is due to feedhorn blockage effects. The measured efficiency of the reflectarray is shown in Fig. 26. The efficiency is better than 40% from 31.5 to 32.5 GHz. The highest efficiency is 50% at 31.75 GHz.

7. RING OSCILLATORS

With the advantages of high Q factor, low radiation loss, low cost, and easy fabrication, the ring resonator can be used to design an oscillator. Moreover, comparing to dielectric resonator oscillators, a varactor can be easily mounted in a ring oscillator to tune the oscillation frequency [42]. Several different types of oscillators using ring resonator have been introduced [43–45].

Figure 27 shows a feedback oscillator that consists of a feedback ring circuit and a two-port negative-resistance oscillator with input and output matching networks [44]. The closed-loop ring resonator using a pair of orthogonal feedlines suppresses odd resonant frequencies and operates at even resonant frequencies. This operation is characterized by high operating resonant frequencies, similar to those of push–push oscillators [45]. Also, the high- Q ring resonator is used to reduce the noise of the two-port negative-resistance oscillator.

The active device used is a NE32484A HEMT from NEC. The dimensions of the oscillator are $l_3 = 3$ mm, $l_4 = 6.95$ mm, $l_5 = 15.19$ mm, $l_6 = 10.69$ mm, $l_7 = 7.3$ mm, $l_8 = 9.47$ mm, and $l_9 = 21.19$ mm. The two-port negative-resistance oscillator uses the one open-end terminal as a

Figure 30. Measured tuning range of 510 MHz for the tunable oscillator using a PET [44]. (Permission from IEEE.)

series-feedback element to obtain a potential instability. Also, with input and output matching networks, the two-port oscillator with an applied bias of $V_{gs} = -0.65$ V and $V_{ds} = 1$ V has a negative resistance around 12 GHz.

Figure 28 shows a measured spectrum of the oscillator with applied voltages of $V_{gs} = -0.65$ V and $V_{ds} = 1$ V. Also, as shown in Fig. 28, the oscillator is operated at the second resonant mode of the ring resonator. The oscillator has the efficiency of 48.7% with output power of 3.41 mW at 12.09 GHz. The phase noise of the oscillator is -96.17 dBc/Hz at offset frequency of 100 kHz.

Figure 29 shows a configuration of the ring resonator oscillator integrated with a piezoelectric transducer (PET) with an attached dielectric perturber. When a DC voltage is applied to the PET, the PET moves the perturber up or down vertically to change the effective dielectric constant of the ring resonator, thus varying the resonant frequency of the ring resonator [44].

Figure 30 shows the measured results of the oscillator using the PET tuning. The perturber attached on the PET has a dielectric constant of $\epsilon_r = 10.8$ and thickness of $h = 50$ mil. The tuning range of the oscillator is from 11.49 GHz (at the applied voltage of +90 V to PET) with a power output of 3.17 dBm to 12 GHz (0 V) with a power output of 5.33 dBm.

8. CONCLUSIONS

A simple and useful ring resonator has been described. Because of its advantages of high Q , low radiation loss, low cost, and easy fabrication, it has been widely used in various applications such as dispersion measurement, filters, couplers, balanced mixers, balanced amplifiers, antennas, and oscillators. It is believed that many new applications could emerge in the future.

1. INTRODUCTION

There has been increasing interest in electromagnetic scattering from rough surfaces in with applications in active and passive remote sensing for soil, ocean, ice, and so on. Satellite microwave measurements of soil and ocean surface thermal emission and radar backscattering can provide the means to predict soil moisture and ocean properties. This interest has been fueled by satellites that were recently (as of 2004) launched or are being planned such as TRMM, EOS/AQUA, ADEOS II, Windsat, NPOESS, SMOS, and HYDROS. The small-perturbation method (SPM) and Kirchhoff approximation (KA) are classical theories of wave scattering of rough surfaces. They are limited in regimes of validity and do not give the correct frequency and polarimetric dependence of electromagnetic wave scattering. New analytic methods such as small-slope approximation (SSA) and the integral equation model (IEM) have also been developed to increase the regime of validity of classical theories. With the advent of modern computers, fast numerical simulations for rough-surface scattering have become attractive. The most common methods are the fast multipole method (FMM) and the sparse matrix canonical grid (SMCG) method. The computational complexity and memory requirement of the steepest-descent FMM (SDFMM) and SMCG are $O(N)$ and $O(N \log N)$, respectively, in these fast algorithms. Using these numerical methods, we have been developing the 3D numerical Maxwell model (NMM3D) for rough surface scattering applications. Through the simulations, the computed values of bistatic scattering and emissivities based on the numerical solutions of Maxwell equations will be tabulated and provided to the user's community. The goal is to have the tables for a variety of rough surface types and parameters. In a recent text [1], we have provided the details of numerical algorithms and applications in remote sensing. The SMCG method is limited by the RMS height. A Taylor expansion is made about the flat surface. The smallness parameter is the ratio of the height to the near-field distance. We have used six terms Taylor

expansion. If the height increases, then we need to use a larger near-field distance or use more terms in the Taylor expansion. Because of height limitations in the SMCG method, thus we are presently developing the multilevel UV method. In general the numerical simulations are limited by the fact that the surface area of the sample size must be much larger than both the correlation length (to ensure that the sample has many peaks and valleys and qualifies as a statistical sample) and the wavelength (so that the tapered wave can be used to approximate a plane wave). We expect that in the near future, with the advent of computers and numerical methods, NMM3D can replace all analytic theories when the RMS heights are within $1-2\lambda$ wavelengths and correlation lengths within 10λ .

This article deals with the forward problem, and discusses matching the theoretical simulations with measured data as an example of application of the theory. However, matching of forward computations with data is only a part of the picture. The real need or application is for an inversion or retrieval of soil moisture, for example, from backscatter or brightness temperature. Usually, a spaceborne instrument (radar or radiometer) may have one or two channels of measurements at L band as in the upcoming HYDROS Mission. Based on the comparisons with experimental data, we conclude that exponential spectrum is presently the best assumption. The knowledge of an accurate a priori roughness spectrum is not needed. In the NMM3D, only two parameters are needed: the RMS height and the correlation length. These two parameters do not add additional unknowns to the present inversion scheme [2–4] because the present inversion scheme of AMSR also uses two empirical parameters: H and Q . The advantages of a physically based NMM3D are that the parameters are physical and also can be used for both passive and active remote sensing. Furthermore the same physical parameters can be used for a wide frequency range rather than individual frequencies such as H and Q . The present NMM3D can be readily incorporated in the present inversion scheme by using the physical parameters of RMS height and correlation length to replace H and Q .

In this article, we address the applications of remote sensing of land and ocean. Land, applications include soil and roughness effects at the interface between the snow and the soil underneath. For such surfaces, the roughness generally exhibits large slopes with fine-scale irregular features. The RMS height is on the centimeter scale and is small to moderate at microwave frequencies. The surface scattering tends to be diffuse. Both coherent and incoherent waves are important. For ocean surface, the RMS slope is small; however, RMS height is large at microwave frequencies. Huge ocean waves can have heights exceeding 10 m. Thus the scattered wave is incoherent with strong scattering in the specular direction.

In the present article, we will cover only a few of the most recent research results pertain to the scope of the text here. In Section 2 we describe developments in numerical simulations methods and in Section 3, results that can be applied to microwave remote sensing. In Section 2, we describe the methods of computational

electromagnetics in rough-surface simulations. We start with the SMCG method, which has been extensively used in simulations of real-life problems. Then we describe the multilevel SMCG method and the multilevel UV method, both of which were developed recently and have the potential of drastically improving computational efficiency. In Section 2.1, we describe the SMCG method and the physics-based two-grid (PBTG) method for rough surface simulations. In Section 2.2, we describe the use of the Rao–Wilton–Glisson (RWG) basis functions and the combination of the SMCG method. In Section 2.3, we describe the method of using a single-integral equation (SIE) and the combination with the multilevel SMCG. In Section 2.4, we describe rough-surface scattering using the UV method with multilevel partitioning.

In Section 3, we describe the simulation results of some real-life problems using SMCG. In Section 3.1 we describe NMM3D applications in active remote sensing and in Section 3.2, in passive remote sensing.

2. METHODS OF NUMERICAL ALGORITHMS

This section introduces the readers to the state of the art of using numerical methods to simulate roughness response at microwave frequencies. Much work still needs to be done in extensive real life simulations. What we will show are simply the results at L and C bands at 1.4 GHz for soils and at 14 GHz for ocean.

2.1. The SMCG Method and the PBTG Method for Rough Surface Simulations

The scattering of electromagnetic waves by lossy dielectric surfaces with large permittivity [5,6] has broad applications in natural media. For wet soil, the relative permittivity can be as high as $17 + i2.0$ at 1.4 GHz; for ocean surfaces, the permittivity can be as high as $39.7 + i40.2$ at 14 GHz. A common implementation of the method of moments (MoM) is to use a grid of 8–10 points per wavelength to discretize the surface. We shall call such a gridding a *single coarse grid* (SCG). Two methods are used to treat lossy dielectric surfaces. The first method is to use impedance boundary conditions [7]. The impedance boundary condition ignores the propagation from one point to all other points through the dielectric medium. For wave scattering from metallic surfaces with very large permittivity, impedance boundary condition could be used because the wave in the medium cannot propagate to the other points. However, for lossy dielectric rough surfaces with high permittivity and fine-scale irregular features, there can be rapid spatial variations of the dielectric medium Green function and surface fields. Thus the impedance boundary method is not valid for such a case. The second method is to use a dense grid with a large number of points (say, 16–20 points) per wavelength. We shall call such a gridding a *single dense grid* (SDG). The disadvantage of this SDG is that there is a large increase in central processing unit (CPU) and required memory. We have developed the PBTG method [5,6], which is an improvement over the previous two alternatives in that it has the same accuracy as the SDG and yet has a CPU

comparable with that of the SCG. The PBTG method can calculate the emissivity accurately. In PBTG, two grids are used: a dense grid and a sparse grid. The sparse grid contains the usual 8–10 points per wavelength. The dense grid ranges from 16 or a higher number of points per wavelength depending on the relative permittivity of the lossy dielectric medium. The surface fields are calculated on the dense grid. In the formulation of the surface integral equations, two Green functions are used: the free space Green function and the Green function of the lossy dielectric medium. The PBTG is based on two observations: (1) the Green function of the lossy dielectric is attenuative (spatially limited) and (2) the Green function of free space is slowly varying on the dense grid (spatial frequency-limited). Because of the Kramer–Kronig relation, a large real part of dielectric constant is usually associated with a large imaginary part at high frequency. The first observation results in a sparse matrix for the Green function of the lossy dielectric. When this Green function acts on the surface fields on the dense grid, it will be just the product of a sparse matrix and a column vector. The second observation allows us, when using the free-space Green function to act on the surface fields of a dense grid, to first average the values of surface unknowns on the dense grid and then place them on the coarse grid. Thus, the PBTG speeds up the CPU and yet preserves the accuracy of the solution. It should be mentioned that the PBTG is different from the multigrid method. The multigrid method [8,9] tries to facilitate the convergence of iteration in iterative techniques. The present method is based on scattering physics. The purpose of PBTG is to speed up the matrix–vector product that corresponds to the convolution of two Green functions with the surface fields on the dense grid.

2.1.1. Formulation and Single-Grid Implementation. Consider an electromagnetic wave $\bar{E}_i(\vec{r})$ and $\bar{H}_i(\vec{r})$, with a time dependence of $e^{-i\omega t}$ impinging on a 2D dielectric rough surface with a random height profile $z=f(x, y)$. It is tapered so that the illuminated rough surface can be confined to the surface area $L_x \times L_y$ [10]. The direction of incident wave is $\hat{k}_i = \sin \theta_i \cos \phi_i \hat{x} + \sin \theta_i \sin \phi_i \hat{y} - \cos \theta_i \hat{z}$. The incident fields are given as

$$\bar{E}_i(\vec{r}) = \int_{-\infty}^{\infty} dk_x \int_{-\infty}^{\infty} dk_y e^{ik_x x + ik_y y - ik_z z} \cdot \mathbf{E}(k_x, k_y) \cdot \hat{\mathbf{e}}(-k_z) \quad (4)$$

$$\bar{H}_i(\vec{r}) = -\frac{1}{\eta_1} \int_{-\infty}^{\infty} dk_x \int_{-\infty}^{\infty} dk_y e^{ik_x x + ik_y y - ik_z z} \cdot \mathbf{E}(k_x, k_y) \cdot \hat{\mathbf{h}}(-k_z) \quad (5)$$

for TE wave incidence

$$\hat{\mathbf{e}}(-k_z) = \frac{1}{k_\rho} (\hat{x}k_y - \hat{y}k_x) \quad (6)$$

$$\hat{\mathbf{h}}(-k_z) = \frac{k_z}{kk_\rho} (\hat{x}k_y + \hat{y}k_x) + \frac{k_\rho}{k} \hat{z} \quad (4)$$

and for TM wave incidence

$$\hat{\mathbf{h}}(-k_z) = -\frac{1}{k_\rho} (\hat{x}k_y - \hat{y}k_x) \quad (5)$$

$$\hat{\mathbf{e}}(-k_z) = \frac{k_z}{kk_\rho} (\hat{x}k_x + \hat{y}k_y) + \frac{k_\rho}{k} \hat{z} \quad (6)$$

with $k_z = \sqrt{k_1^2 - k_\rho^2}$ and $k_\rho = \sqrt{k_x^2 + k_y^2}$, where k_1 and η_1 are the wavenumber and wave impedance of free space, respectively. The spectrum of the incident wave $E(k_x, k_y)$ is given as

$$E(k_x, k_y) = \frac{1}{4\pi^2} \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy e^{-ik_x x - ik_y y} \cdot e^{i(k_{1x}x + k_{1y}y)(1+w)} \cdot e^{-t} \quad (7)$$

where $t = t_x + t_y = (x^2 + y^2)/g^2$ and

$$t_x = \frac{(\cos \theta_i \cos \phi_i x + \cos \theta_i \sin \phi_i y)^2}{g^2 \cos^2 \theta_i} \quad (8)$$

$$t_y = \frac{(-\sin \phi_i x + \cos \phi_i y)^2}{g^2} \quad (9)$$

$$w = \frac{1}{k_1^2} \left(\frac{2t_x - 1}{g^2 \cos^2 \theta_i} + \frac{2t_y - 1}{g^2} \right) \quad (10)$$

The parameter g controls the tapering of the incident wave. We use the Green functions G_1 and G_2 , which are the 3D Green functions of free space and the lower dielectric medium, respectively. They are given by

$$G_{1,2} = \frac{e^{ik_{1,2}R}}{4\pi R} \quad (11)$$

where $R = \{(x - x')^2 + (y - y')^2 + (f(x, y) - f(x', y'))^2\}^{1/2}$ and k_1 and k_2 are the wavenumbers of air and the lower dielectric medium, respectively. The Stratton–Chu formulation is used to derive the surface integral equation. Then

$$\begin{aligned} & \frac{\hat{\mathbf{n}} \times \bar{H}(\vec{r})}{2} - \hat{\mathbf{n}} \times \left\{ \int (-i\omega) \hat{\mathbf{n}}' \times \bar{E}(\vec{r}') \varepsilon_1 G_1 dS' \right. \\ & \left. + P \int [(\hat{\mathbf{n}}' \times \bar{H}(\vec{r})) \times \nabla' G_1 \right. \\ & \left. + \hat{\mathbf{n}}' \cdot \bar{H}(\vec{r}) \nabla' G_1] dS' \right\} = \hat{\mathbf{n}} \times \bar{H}^{\text{inc}}(\vec{r}) \end{aligned} \quad (12)$$

$$\begin{aligned} & \frac{\hat{n} \cdot \bar{\mathbf{E}}(\bar{\mathbf{r}})}{2} - \hat{n} \cdot \left\{ \int \hat{n}' \times \bar{\mathbf{H}}(\bar{\mathbf{r}}') i\omega\mu G_1 dS' \right. \\ & \left. + P \int [(\hat{n}' \times \bar{\mathbf{E}}(\bar{\mathbf{r}})) \times \nabla' G_1 \right. \end{aligned} \quad (13)$$

$$\begin{aligned} & \left. + \hat{n}' \cdot \bar{\mathbf{E}}(\bar{\mathbf{r}}) \nabla' G_1] dS' \right\} = \hat{n} \cdot \bar{\mathbf{E}}^{\text{inc}}(\bar{\mathbf{r}}) \\ & - \frac{\hat{n} \times \bar{\mathbf{E}}(\bar{\mathbf{r}})}{2} - \hat{n} \times \left\{ \int (i\omega) \hat{n}' \times \bar{\mathbf{H}}(\bar{\mathbf{r}}') \right. \end{aligned} \quad (14)$$

$$\begin{aligned} & \mu G_2 dS' + P \int [(\hat{n}' \times \bar{\mathbf{E}}(\bar{\mathbf{r}})) \nabla' G_2 \\ & \left. + \hat{n}' \cdot \bar{\mathbf{E}}(\bar{\mathbf{r}}) \frac{\epsilon_1}{\epsilon_2} \nabla' G_2 \right] dS' \left. \right\} = 0 \end{aligned} \quad (15)$$

$$\begin{aligned} & - \frac{\hat{n} \cdot \bar{\mathbf{H}}(\bar{\mathbf{r}})}{2} - \hat{n} \cdot \left\{ \int -\hat{n}' \times \bar{\mathbf{E}}(\bar{\mathbf{r}}') \right. \\ & \left. \times i\omega\epsilon_2 G_2 dS' + P \int [(\hat{n}' \times \bar{\mathbf{H}}(\bar{\mathbf{r}})) \times \nabla' G_2 \right. \\ & \left. + \hat{n}' \cdot \bar{\mathbf{H}}(\bar{\mathbf{r}}) \nabla' G_2] dS' \right\} = 0 \end{aligned}$$

The MoM is used to discretize the integral equation using the pulse basis functions and the method of point matching. The resulting matrix equations are

$$\begin{aligned} & \sum_{n=1}^N [Z_{mn}^{p1} I_n^{(1)} + Z_{mn}^{p2} I_n^{(2)} + Z_{mn}^{p3} I_n^{(3)} \\ & + Z_{mn}^{p4} I_n^{(4)} + Z_{mn}^{p5} I_n^{(5)} + Z_{mn}^{p6} I_n^{(6)}] = I_m^{(p)\text{inc}} \end{aligned} \quad (16)$$

for $p=1,2,3$, which correspond the surface integral equation when approaching the surface from free space and for $p=4,5,6$ when approaching the surface from the lower medium. The quantities of $I_m^{(p)\text{inc}}$ are zero for $p=4,5,6$, where

$$I_n^{(1)} = F_x(\bar{\mathbf{r}}) = S_{xy}(\bar{\mathbf{r}}_n) [\hat{n} \times \bar{\mathbf{H}}(\bar{\mathbf{r}}_n)] \hat{\mathbf{x}} \quad (17)$$

$$I_n^{(2)} = F_y(\bar{\mathbf{r}}) = S_{xy}(\bar{\mathbf{r}}_n) [\hat{n} \times \bar{\mathbf{H}}(\bar{\mathbf{r}}_n)] \hat{\mathbf{y}} \quad (18)$$

$$I_n^{(3)} = I_n(\bar{\mathbf{r}}) = S_{xy}(\bar{\mathbf{r}}_n) \hat{n} \cdot \bar{\mathbf{E}}(\bar{\mathbf{r}}_n) \quad (19)$$

$$I_n^{(4)} = I_x(\bar{\mathbf{r}}) = S_{xy}(\bar{\mathbf{r}}_n) [\hat{n} \times \bar{\mathbf{E}}(\bar{\mathbf{r}}_n)] \hat{\mathbf{x}} \quad (20)$$

$$I_n^{(5)} = I_y(\bar{\mathbf{r}}) = S_{xy}(\bar{\mathbf{r}}_n) [\hat{n} \times \bar{\mathbf{E}}(\bar{\mathbf{r}}_n)] \hat{\mathbf{y}} \quad (21)$$

$$I_n^{(6)} = F_n(\bar{\mathbf{r}}) = S_{xy}(\bar{\mathbf{r}}_n) \hat{n} \cdot \bar{\mathbf{H}}(\bar{\mathbf{r}}_n) \quad (22)$$

are surface unknowns and

$$S_{xy} = \left\{ 1 + \left[\frac{\partial f(x,y)}{\partial x} \right]^2 + \left[\frac{\partial f(x,y)}{\partial y} \right]^2 \right\}^{1/2}$$

The Z_{mn}^{pq} is the impedance elements and are determined by the free space Green function and the dielectric

medium Green function. The parameter N is the number of points we use to discretize the rough surface.

2.1.2. Physics-Based Two-Grid Method. We assume that the lower medium is lossy with large permittivity

$$\epsilon_2 = \epsilon_2' (1 + i \tan \delta) \quad (23)$$

where $\tan \delta$ stands for loss tangent. Let λ_1 and λ_2 represent the wavelength of the wave in the free space and the lower medium, respectively, and

$$n_2 = \text{integer}(\sqrt{\epsilon_2'}) \quad (24)$$

Then, the relationship between λ_1 and λ_2 can be expressed approximately by

$$\lambda_2 \approx \frac{\lambda_1}{n_2} \quad (25)$$

The number of sampling points needed in the lower medium should be n_2 times that of the free space.

In the physics-based two-grid method, we use two grids with samplings per wavelength of n_{scg} (coarse grid) and n_{sdg} (dense grid), respectively. Let N_{scg} and N_{sdg} be, respectively, the total number of points on the dense grid and the coarse grid

$$N_{\text{sdg}} = \left(n_{\text{sdg}} \frac{L_x}{\lambda_1} \right) \left(n_{\text{sdg}} \frac{L_y}{\lambda_1} \right) \quad (26)$$

$$N_{\text{scg}} = \left(n_{\text{scg}} \frac{L_x}{\lambda_1} \right) \left(n_{\text{scg}} \frac{L_y}{\lambda_1} \right) \quad (27)$$

For example, $n_{\text{scg}} = 8$ and $n_{\text{sdg}} = 8n_2$. We first write (16) using the dense grid with $N = N_{\text{sdg}}$

$$\begin{aligned} & \sum_{n=1}^{N_{\text{sdg}}} [Z_{mn}^{p1} I_n^{(1)} + Z_{mn}^{p2} I_n^{(2)} + Z_{mn}^{p3} I_n^{(3)} \\ & + Z_{mn}^{p4} I_n^{(4)} + Z_{mn}^{p5} I_n^{(5)} + Z_{mn}^{p6} I_n^{(6)}] = I_m^{(p)\text{inc}} \end{aligned} \quad (28)$$

where the integer subscripts m and n denote indexing with the dense grid. Note that in the PBTG method, the surface fields on the dense grid are calculated. To reduce the calculation, we make the following three observations:

1. The Green function in the lower region is heavily attenuative. A medium with a large real part of dielectric constant is normally associated with a large imaginary part at high frequency because of the Kramer-Kronig relation. Let k_2'' be the imaginary part of k_2 . If $k_2'' r > C$, where C is a constant, then the field interaction between the m th and the n th points is vanishingly small. We can define a distance limit as dictated by dissipative loss

$$r_l = \frac{C}{k_2''} \quad (29)$$

outside of which the lower medium Green function can be set equal to zero. Comparisons with the results from SMCG, indicate that C is fixed at 1.5 in this article. Based on this observation, we calculate the left-hand sides of (28) for $p = 4, 5, 6$ as follows by approximating

$$Z_{mn}^{pq} \approx \tilde{Z}_{mn}^{pq} = \begin{cases} Z_{mn}^{pq} r, & r_{mn} \leq r_l \\ 0, & r_{mn} \geq r_l \end{cases} \quad (30)$$

where r_{mn} is the distance between the m th point and the n th points on the dense grid. Thus, \tilde{Z}_{mn}^{pq} ($p = 4, 5, 6$) are sparse matrices and (28) for $p = 4, 5, 6$ becomes

$$\sum_{n=1}^{N_{\text{sdg}}} [\tilde{Z}_{mn}^{p1} I_n^{(1)} + \tilde{Z}_{mn}^{p2} I_n^{(2)} + \tilde{Z}_{mn}^{p3} I_n^{(3)} + \tilde{Z}_{mn}^{p4} I_n^{(4)} + \tilde{Z}_{mn}^{p5} I_n^{(5)} + \tilde{Z}_{mn}^{p6} I_n^{(6)}] = 0 \quad (31)$$

- For non-near-field interaction, the Green function for the upper medium is slowly varying on the dense grid. Thus, when performing matrix-column vector multiplication on the dense grid, as indicated in (28), the Green function of the upper medium is essentially constant over an area of $n_2 \times n_2$ points on the dense grid. Thus, we can write

$$\begin{aligned} \sum_{n=1}^{n_2^2} Z_{(m+l')(n+l)}^{pq} I_{n+l}^{(q)} &\approx Z_{n_{mp}n_{np}}^{pq(q)} \sum_{l=1}^{n_2^2} I_{n+l}^{(q)} \\ &= n_2^2 Z_{n_{mp}n_{np}}^{pq} \left(\frac{1}{n_2^2} \sum_{l=1}^{n_2^2} I_{n+l}^{(q)} \right) \end{aligned} \quad (32)$$

where $l' = 1, 2, \dots, n_2^2$ and the points with indexes m_{mp} and n_{mp} are the central point of the n_2^2 dense grid points of $m + 1, m + 2, \dots, m + n_2^2$, and $n + 1, n + 2, \dots, n + n_2^2$, respectively. What is performed in (32) is that the surface fields on the dense grid are first averaged before being multiplied by the upper medium Green function.

- The slowly varying nature of the Green function of the upper medium applies only to non-near-field interaction. For near-field interaction, Green functions G_1 and G_2 have similar variation rates. Thus we separate out a distance, say, 1λ , outside of which G_2 is much more rapidly varying than G_1 . On the basis of the observations above, we decompose the upper medium Green function into near-field and non-near-field interactions

$$\sum_{n=1}^{N_{\text{sdg}}} Z_{mn}^{pq(s)} I_n^{(q)} = \sum_{n=1}^{N_{\text{sdg}}} Z_{mn}^{pq(q)} I_n^{(q)} + \sum_{n=1}^{N_{\text{sdg}}} Z_{mn}^{pq(ns)} I_n^{(q)} \quad (33)$$

where $Z_{mn}^{pq(s)}$ and $Z_{mn}^{pq(ns)}$ are determined by

$$Z_{mn}^{pq(s)} = \begin{cases} Z_{mn}^{pq}, & r_{mn} \leq r_f \\ 0, & r_{mn} \geq r_f \end{cases} \quad (34)$$

$$Z_{mn}^{pq(ns)} = \begin{cases} 0, & r_{mn} \leq r_f \\ Z_{mn}^{pq}, & r_{mn} \geq r_f \end{cases} \quad (35)$$

Thus, r_f is the distance outside which the Green function of the lower medium is rapidly varying compared with that of free space Green function. Let \tilde{m} and \tilde{n} denote the coarse grid indices. The coarse grid has surface unknowns $\tilde{I}_{\tilde{n}}^{(q)}$, which are averages of the dense grid surface unknowns. Thus, if $\tilde{r}_{\tilde{n}}$ is centered in the group of the n_2^2 dense grid-points of $n + 1, n + 2, \dots, n + n_2^2$, we have

$$\tilde{I}_{\tilde{n}}^{(q)} = \frac{I_{n+1}^{(q)} + I_{n+2}^{(q)} + \dots + I_{n+n_2^2}^{(q)}}{n_2^2} \quad (36)$$

The Green function of the upper medium on the coarse grid is represented by $\tilde{Z}_{\tilde{m}\tilde{n}}^{pq}$. Then (28) for $p = 1, 2, 3$ becomes

$$\begin{aligned} \sum_{q=1}^6 \sum_{n=1}^{N_{\text{sdg}}} Z_{mn}^{pq(s)} I_n^{(q)} \\ + \sum_{q=1}^6 \left[\sum_{\tilde{n}=1}^{N_{\text{scg}}} \tilde{Z}_{\tilde{m}\tilde{n}}^{pq(ns)} \tilde{I}_{\tilde{n}}^{(q)} \right]_{\text{int}p} = I_m^{(p)\text{inc}} \end{aligned} \quad (37)$$

Note in (37) that $\sum_{n=1}^{N_{\text{sdg}}} Z_{mn}^{pq(s)} I_n^{(q)}$ includes N_{sdg} values of $m = 1, 2, \dots, N_{\text{sdg}}$ on the dense grid, while $\sum_{\tilde{n}=1}^{N_{\text{scg}}} \tilde{Z}_{\tilde{m}\tilde{n}}^{pq(ns)} \tilde{I}_{\tilde{n}}^{(q)}$ only has N_{scg} values of $n = 1, 2, \dots, N_{\text{scg}}$ on the coarse grid. Thus, we first compute $\sum_{\tilde{n}=1}^{N_{\text{scg}}} \tilde{Z}_{\tilde{m}\tilde{n}}^{pq(ns)} \tilde{I}_{\tilde{n}}^{(q)}$. Then we use linear interpolation of $\sum_{\tilde{n}=1}^{N_{\text{scg}}} \tilde{Z}_{\tilde{m}\tilde{n}}^{pq(ns)} \tilde{I}_{\tilde{n}}^{(q)}$ on the coarse grid to find N_{sdg} values on the dense grid. In (37), we use subscript $\text{int}p$ to represent that interpolation. Thus the computational steps for matrix-vector multiplication are associated with the number of surface unknowns on the coarse grid. The algorithm is depicted in Fig. 1. Note that surface field is obtained with the dense grid but the CPU time depends on the coarse grid. The PBTG is also used in conjunction with the SMCG used previously used in computing scattering

Figure 1. Illustration of physics-based two-grid method.

from 2D rough surfaces. The computational complexity of the combined algorithm of PBTG/SMCG is $O(N_{\text{scg}} \log(N_{\text{scg}}))$.

2.1.3. Bistatic Scattering Coefficient and Emissivity. The numerical simulation results are presented in terms of the bistatic scattering coefficients normalized by the incident power. For an incident wave with a polarization N_{sdg} , we have

$$\gamma_{\alpha\beta}(\theta_s, \phi_s; \theta_i, \phi_i) = \frac{|E_{\alpha}^s|^2}{2\eta_1 P_{\beta}^{\text{inc}}} \quad (38)$$

The incident power is

$$P_{\beta}^{\text{inc}} = \frac{2\pi^2}{\eta} \int_{k_{\rho} < k} dk_x dk_y |E(k_x, k_y)|^2 \frac{k_z}{k} \quad (39)$$

where $k_{\rho} = \sqrt{k_x^2 + k_y^2}$. The horizontal and vertical polarized scattered components are E_{α}^s , respectively

$$\begin{aligned} E_h^s &= \frac{ik}{4\pi} \int_{ds'} dx' dy' \exp(-ik\beta') \\ &\quad \{ I_x(x', y') \cos \theta_s \cos \phi_s \\ &\quad + I_y(x', y') \cos \theta_s \sin \phi_s \\ &\quad - I_x(x', y') \frac{\partial f(x', y')}{\partial x'} \sin \theta_s \\ &\quad - I_y(x', y') \frac{\partial f(x', y')}{\partial y'} \sin \theta_s \\ &\quad - \eta [F_x(x', y') \sin \phi_s \\ &\quad - F_y(x', y') \cos \phi_s] \} \end{aligned} \quad (40)$$

$$\begin{aligned} E_v^s &= \frac{ik}{4\pi} \int_{ds'} dx' dy' \exp(-ik\beta') \\ &\quad \{ I_x(x', y') \sin \phi_s - I_y(x', y') \cos \phi_s \\ &\quad + \eta [F_x(x', y') \cos \theta_s \cos \phi_s \\ &\quad + F_y(x', y') \cos \theta_s \sin \phi_s \\ &\quad - F_x(x', y') \frac{\partial f(x', y')}{\partial x'} \sin \theta_s \\ &\quad - F_y(x', y') \frac{\partial f(x', y')}{\partial y'} \sin \theta_s \} \end{aligned} \quad (41)$$

where $\beta = x' \sin \theta_s \cos \phi_s + y' \sin \theta_s \sin \phi_s + f(x', y') \cos \theta_s$. For scattering by a dielectric surface, the emissivity of the rough surface at incident angle (θ, ϕ_i) based on energy conservation and reciprocity is

$$\begin{aligned} e_{\beta}(\theta_i, \phi_i) &= 1 - \frac{1}{4\pi} \iint [\gamma_{h\beta}(\theta_s, \phi_s; \theta_i, \phi_i) \\ &\quad + \gamma_{v\beta}(\theta_s, \phi_s; \theta_i, \phi_i)] \sin \theta_s d\theta_s d\phi_s \end{aligned} \quad (42)$$

The brightness temperature is

$$T_B(\theta_i, \phi_i) = e_{\beta}(\theta_i, \phi_i) T \quad (43)$$

where T is the physical temperature of the medium in degrees kelvin. In Section 3.1, we will present numerical simulations using this approach for active and passive microwave remote sensing.

2.2. The use of RWG Basis Functions and Combination with the SMCG Method for Scattering from Rough-Surface Simulation

As described in Section 2.1, using the pulse basis functions and point matching, we have combined with SMCG method for rough-surface scattering. Researchers have applied the method to simulations of emissivities in passive microwave remote sensing. Johnson et al. [11] studied the case of ocean emissivity at nadir incidence using 8 points per wavelength and attained the accuracy of the impedance matrix elements by using a large order of integration quadrature. The PBTG method in Section 2.1 was developed such that dense sampling could be used and maintained comparable to the CPU and memory requirements. The SMCG/PBTG method was used to study a soil surface that was assumed to be a Gaussian random process with a Gaussian correlation function [1,11–13]. The results were compared with the second-order SPM method, which give the same results as does the SSA method for emissivity [14,15]. It was found that the second-order SPM method gives poor results for cases when the RMS slope is large. In the past, the numerical solutions were restricted mostly to Gaussian random surfaces with Gaussian correlation function [12]. But the use of Gaussian correlation function is not appropriate for soil surfaces because the backscattering coefficients based on such surfaces are many decibels below that of measurements. The exponential correlation function is a more realistic choice for soil surface and can be used to match active remote sensing experimental data. The exponential correlation function gives a rough surface with much more fine-scale features than a Gaussian correlation function of the same RMS height and correlation length. However, the use of pulse basis functions was not able to provide accurate results of emissivity for the exponential correlation functions although they provide adequate results for backscattering coefficients in decibel scale [16]. For the exponential correlation functions, we have tried using pulse basis functions with 16 points per wavelength and 32 points per wavelength with a very high order of integration quadrature to calculate the impedance matrix elements. However, there was no convergence in emissivity and the energy conservation was poor. Recent emphases on microwave remote sensing of soil moistures are moving toward combined active and passive remote sensing, particularly in the planned HYDROS satellite mission. Thus it is important to have the same characterization (i.e., exponential correlation functions) in both active and passive remote sensing. In this section, we show that by using RWG basis functions, the accuracy of emissivities calculations are improved significantly for the case of exponential correlation functions. We implemented the SMCG method with the RWG basis functions [17] by projecting the triangular elements into the canonical grid. To implement the RWG basis functions, we use

the PMCHW formulation [18] (after Poggio, Miller, Chang, Harrington, and Wu). Energy conservation checks are provided.

2.2.1. General Formulations. Consider a tapered plane wave [1] \bar{E}^{inc} and \bar{H}^{inc} , with a time dependence of $e^{-i\omega t}$, impinging on a 2D dielectric rough surface with a random height profile $z = f(x, y)$. Incident electric and magnetic fields E^{inc} and H^{inc} create equivalent electric and magnetic surface currents $J(r)$ and $M(r)$ on the rough surface. In the following, $\epsilon_{1,2}$ and $\mu_{1,2}$ represent the permittivity and the permeability, respectively, of the upper and lower half-spaces. Also, $k_{1,2} = \omega(\epsilon_{1,2}\mu_{1,2})^{1/2}$, and $\eta_{1,2} = (\mu_{1,2}/\epsilon_{1,2})^{1/2}$. To implement the RWG basis functions, it is convenient to use the PMCHW formulation, which is summarized below. To obtain J and M , the PMCHW formulation enforces the continuity of the tangential electric and magnetic field components across S

$$\bar{E}^{\text{inc}}(\bar{r})|_{\text{tan}} = (L_1 + L_2)\bar{J}(\bar{r})|_{\text{tan}} - (K_1 + K_2)\bar{M}(\bar{r})|_{\text{tan}} \quad (44)$$

$$\begin{aligned} \bar{H}^{\text{inc}}(\bar{r})|_{\text{tan}} &= (K_1 + K_2)\bar{J}(\bar{r})|_{\text{tan}} \\ &+ \left(\frac{1}{\eta_1}L_1 + \frac{1}{\eta_2}L_2\right)\bar{M}(\bar{r})|_{\text{tan}} \end{aligned} \quad (45)$$

where the operators $L_{1,2}$ and $K_{1,2}$ are defined by

$$\begin{aligned} L_{1,2}\bar{X}(\bar{r}) &= \int_S ds' [-i\omega\mu_{1,2}\bar{X}(\bar{r}')] \\ &+ \frac{-i}{\omega\epsilon_{1,2}} \nabla\nabla' \cdot \bar{X}(\bar{r}') g_{1,2}(\bar{r}, \bar{r}') \end{aligned} \quad (46)$$

$$K_{1,2}\bar{X}(\bar{r}) = \int_S ds' \bar{X}(\bar{r}') \times \nabla g_{1,2}(\bar{r}, \bar{r}') \quad (47)$$

and $\nabla g_{1,2}(\bar{r}, \bar{r}')$ is the scalar Green function in region 1 (air) and region 2 (lossy dielectric medium)

$$g_{1,2}(\bar{r}, \bar{r}') = \frac{\exp(ik_{1,2}|\bar{r} - \bar{r}'|)}{4\pi|\bar{r} - \bar{r}'|} \quad (48)$$

2.2.1.1. Emissivity and Brightness Temperature. The solution of the PMCHW yields the electric and magnetic surface current densities $J(r)$ and $M(r)$. These current densities can be used to evaluate the scattering field required in the computation of the bistatic scattering coefficient. The normalized bistatic scattering coefficient defined by

$$\gamma_{\beta\alpha}(\theta_s, \phi_s; \theta_i, \phi_i) = \frac{|S_{\beta}(\hat{k}_s)|^2}{2\eta_1 P_{\alpha}^{\text{inc}}} \quad (49)$$

where α and β indicate the polarization of the incident and scattered waves, respectively, P_{α}^{inc} is the incident power, and the vertical and horizontal polarized scattered

components are, respectively

$$\begin{aligned} S_v(\hat{k}_s) &= \frac{ik_1}{4\pi} \int_S ds [\hat{v}_s \cdot \eta_1 \bar{J} \\ &+ \hat{h}_s \cdot \bar{M}] \exp(-ik_1 k_s \cdot \bar{r}') \end{aligned} \quad (50)$$

$$\begin{aligned} S_h(\hat{k}_s) &= \frac{ik_1}{4\pi} \int_S ds [\hat{h}_s \cdot \eta_1 \bar{J} \\ &- \hat{v}_s \cdot \bar{M}] \exp(-ik_1 k_s \cdot \bar{r}') \end{aligned} \quad (51)$$

with $\hat{k}_s = \sin \theta_s \cos \phi_s \hat{x} + \sin \theta_s \sin \phi_s \hat{y} + \cos \theta_s \hat{z}$, $\hat{v}_s = \cos \theta_s \cos \phi_s \hat{x} + \cos \theta_s \sin \phi_s \hat{y} - \sin \theta_s \hat{z}$, and $\hat{h}_s = -\sin \phi_s \hat{x} + \cos \phi_s \hat{y}$, for scattering by a dielectric surface.

2.2.1.2. Energy Conservation Verification. An energy conservation check is essential because emissivity is based on energy conservation. If the energy conservation check is such that transmissivity plus scattering is not equal to unity, then there is an ambiguity whether emissivity should be equal to transmissivity or equal to one minus scattering. For a penetrable medium, absorptivity $\alpha(\theta_i)$ is equal to transmissivity. The absorptivity and reflectivity $r(\theta_i)$ can be calculated in terms of the surface fields

$$\alpha(\theta_i) = \frac{P_x}{P_{\text{inc}}} = \frac{\int_S ds \hat{n} \cdot \frac{1}{2} \text{Re}[\bar{E} \times \bar{H}]}{P_{\text{inc}}} \quad (52)$$

$$r(\theta_i) = \frac{P_s}{P_{\text{inc}}} = \frac{\int_S ds \hat{n} \cdot \frac{1}{2} \text{Re}[\bar{E}_s \times \bar{H}_s]}{P_{\text{inc}}} \quad (53)$$

where \bar{E} and \bar{H} are the total electrical and magnetic surface fields, respectively, while \bar{E}_s and \bar{H}_s are the surface scattered fields. They are calculated as

$$\bar{E}_s = \bar{E} - \hat{n} \times \bar{E}^{\text{inc}} = -\bar{M} - \hat{n} \times \bar{E}^{\text{inc}} \quad (54)$$

$$\bar{H}_s = \bar{H} - \hat{n} \times \bar{H}^{\text{inc}} = +\bar{J} - \hat{n} \times \bar{H}^{\text{inc}} \quad (55)$$

Numerical energy conservation is carried out by calculating absorptivity $\alpha(\theta_i)$ and reflectivity $r(\theta_i)$ using (52) and (53), to determine whether $\alpha(\theta_i) + r(\theta_i)$ is equal to unity.

2.2.2. Numerical SMCG/RWG Method. To solve the PMCHW equation, the Galerkin procedure is used to obtain the impedance matrix. Applying the RWG basis to (44) and (45) produces the matrix equation

$$[Z]I = V \quad (56)$$

In the SMCG method, the matrix equations (44) and (45) are solved in an iterative manner (e.g., conjugate-gradient method). The impedance matrix is decomposed into the sum of a sparse matrix $[Z^w]$, denoting the *strong near interactions*, and a dense matrix $[Z^f]$, denoting the *weak far interactions*. For the near-field interactions, we take the numerical integration over both the basis and testing functions, using numerical quadrature of 7-point rule. When the integral is evaluated for the self-term, an analytic approach is employed [19]. Since the Green

Figure 2. RWG basis function.

functions are smooth over the integration domains of the impedance matrix elements integrals in the far-field interactions, we use only the one-point approximation. We choose a point $(\frac{1}{4}, \frac{1}{4})$ in the triangle instead of the centroid $(\frac{1}{3}, \frac{1}{3})$, as depicted in Fig. 2.

The points at $(\frac{1}{4}, \frac{1}{4})$ of triangles fall in the canonical grid, as shown in Fig. 3 by cross-points. By using this judicious procedure, we only need to make Taylor expansion vertically and not horizontally to translate to the canonical grid in the SMCG implementation [17]. Efficient evaluation of the far-interaction contributions in matrix-vector multiplication is reduced to efficient convolution between the Green function and current vector.

We choose r_d as the neighborhood distance (e.g. $r_d = 2\lambda$). Let

$$\rho_R = \sqrt{(x - x')^2 + (y - y')^2} \tag{57}$$

be the horizontal separation between two points on the rough surface $x,y,f(x,y)$ and $x',y',f(x',y')$. Since the

Figure 3. Projection of rough surface on the x - y plane and canonical grid depicted by cross-points.

weak-matrix elements satisfy the condition $\rho_R > r_d \gg |f(x,y) - f(x',y')|$, we can expand the Green function in a Taylor series about the flat surface. Thus, the Taylor-expanded Green function terms $g_{1,2}$ is

$$g_{1,2}(\bar{r} - \bar{r}') = \sum_{m=0}^M a_m^{(1,2)}(\rho_R) \left(\frac{z_d}{\rho_R} \right)^m \tag{58}$$

From $\nabla g = (\bar{r} - \bar{r}')G_{1,2}$, where $G_{1,2}(\bar{r} - \bar{r}') = [(ik_{1,2}|\bar{r} - \bar{r}'| - 1)] \exp(ik_{1,2}|\bar{r} - \bar{r}'|)/4\pi|\bar{r} - \bar{r}'|^3$, $G_{1,2}$ can be written as the form of Taylor expansion series

$$G_{1,2}(\bar{r} - \bar{r}') = \sum_{m=0}^M b_m^{(1,2)}(\rho_R) \left(\frac{z_d}{\rho_R} \right)^m \tag{59}$$

where $z_d = f(x,y) - f(x',y')$ and a_m and b_m are the coefficients of Taylor's series. Due to the translational invariable kernels in the Green functions, the weak-matrix vector multiplication can be efficiently performed via 2D fast Fourier transform (FFT). In this work, we use six terms of expansion series. Numerical results for passive and active microwave remote sensing will be described in Section 3.

2.3. An Efficient Algorithm for Electromagnetic Scattering from Rough Surfaces Using Single-Integral Equation and Multilevel SMCC Method

This is an algorithm presently being developed. The purpose of this algorithm is to reduce the number of surface unknowns by using the SIE. In this section, we present the efficient algorithm based on the SIE formulation in conjunction with a multilevel SMCG (MSMCG) method. The SIE method [20] needs only one unknown at each interior edge of the triangulated mesh, in contrast to using two or three unknowns by the coupling equations [21,22]. One advantage of using the SIE approach is the faster convergence for an iterative solution as revealed in Ref. 21. To extend the applicability of the original SMCG scheme [22,23] to rougher surfaces by using 3D FFT instead of 2D FFT, the MSMCG procedure [24,25] was proposed. By adjusting the expansion levels, the MSMCG scheme is applicable to surfaces with arbitrary roughness, while the number of terms of the Taylor series and the distance indicating whether the far interactions can be changed.

This section is organized as follows. In Section 2.3.1, formulations are provided for the method of moments using a single magnetic field integral equation along with the RWG basis functions. In Section 2.3.2, the solution procedure adopting the MSMCG method in solving the moment equations is outlined. In Section 2.3.3, a detailed description that the multiplication of the weak impedance matrices with a column vector can be calculated by means of FFT is illustrated. In Section 2.3.4, numerical examples are presented for bistatic scattering coefficients from surfaces with the Gaussian spectrum as well as wind-driven ocean spectrum. A short summary is given at the end.

2.3.1. Formulation by the Method of Moments. The time dependence adopted in this section is $e^{j\omega t}$. A dielectric random rough surface is depicted in Fig. 4. In the lower region, the fields may be expressed by a single *effective* surface current \mathbf{J}^{eff} beneath the interface as

$$\mathbf{E}_2 = L_2[\mathbf{J}^{\text{eff}}], \quad \mathbf{H}_2 = K_2[\mathbf{J}^{\text{eff}}] \quad (60)$$

where the operators are defined as

$$L_2[\mathbf{J}^{\text{eff}}] = -j\omega\mu_0 \int_S \left[G_2(R)\mathbf{J}^{\text{eff}}(\mathbf{r}') \right. \\ \left. + \frac{1}{k_2^2} \nabla G_2(R) \nabla' \cdot \mathbf{J}^{\text{eff}}(\mathbf{r}') \right] dS' \quad (61)$$

$$K_2[\mathbf{J}^{\text{eff}}] = \int_S [\nabla G_2(R) \times \mathbf{J}^{\text{eff}}(\mathbf{r}')] dS' \quad (62)$$

where $G_2 = e^{-jk_2 R} / 4\pi R$ is the Green function for the lower medium characterized by $(\epsilon_0 \epsilon_r, \mu_0)$. As an observer approaches the interface from the lower region, a pair of *equivalent* surface electric and magnetic currents can be defined as

$$\mathbf{J} = \hat{\mathbf{n}} \times \mathbf{H}_2 = \hat{\mathbf{n}} \times K_2[\mathbf{J}^{\text{eff}}] \\ = -\frac{1}{2} \mathbf{J}^{\text{eff}} + \hat{\mathbf{n}} \times (\text{PV})K_2[\mathbf{J}^{\text{eff}}] \quad (63)$$

$$-\mathbf{M} = \hat{\mathbf{n}} \times \mathbf{E}_2 = \hat{\mathbf{n}} \times L_2[\mathbf{J}^{\text{eff}}] \quad (64)$$

where $\hat{\mathbf{n}}$ is the normal upward and (PV) means the principal value integral with the singularity at $R=0$ removed. The scattering field in the air region may be found by

$$\mathbf{H}^{\text{s}} = \frac{1}{\eta_0} L_1[\mathbf{M}] + K_1[\mathbf{J}], \quad (65)$$

$$\eta_0 = \sqrt{\mu_0/\epsilon_0} \approx 377\Omega$$

where the operators L_1 and K_1 are the same as L_2 and K_2 but replacing the medium parameters $(\epsilon_0 \epsilon_r, \mu_0)$ with (ϵ_0, μ_0) and G_2 by G_1 (the air is seen as vacuum, and the permeability is assumed to be μ_0 for both regions). The total field in the air region is $\mathbf{H}_1 = \mathbf{H}^{\text{inc}} + \mathbf{H}^{\text{s}}$, where \mathbf{H}^{inc} is the

Figure 4. Configuration of a scattering problem from a random rough surface using a single-integral equation.

incident magnetic field. The boundary condition demands the continuity of the tangential magnetic field, that is, $\hat{\mathbf{n}} \times \mathbf{H}_2 = \hat{\mathbf{n}} \times \mathbf{H}_1$, which by (63) and (65) becomes

$$\mathbf{J} = \mathbf{J}^{\text{inc}} + \frac{1}{\eta_0} \hat{\mathbf{n}} \times L_1[\mathbf{M}] \\ + \frac{1}{2} \mathbf{J} + \hat{\mathbf{n}} \times (\text{PV})K_1[\mathbf{J}] \quad (66)$$

where $\mathbf{J}^{\text{inc}} = \hat{\mathbf{n}} \times \mathbf{H}^{\text{inc}}$ represents the equivalent incident electric current.

Using the method of moments with the RWG triangular basis functions [26], we can convert (63), (64), and (66) into linear equation sets

$$\left. \begin{aligned} [I^e] &= -\left(\frac{1}{2}[U] - [P_2]\right) \cdot [I^{\text{eff}}] \\ -[I^m] &= \eta_0 [Q_2] \cdot [I^{\text{eff}}] \end{aligned} \right\} \quad (67)$$

$$[I^e] = [I^{\text{inc}}] + \frac{1}{\eta_0} [Q_1] \cdot [I^m] + \left(\frac{1}{2}[U] + [P_1]\right) \cdot [I^e] \quad (68)$$

where $[U]$ is an identity matrix. Column vectors $[I^e]$, $[I^m]$, $[I^{\text{eff}}]$, $[I^{\text{inc}}]$ are the expansion coefficients of their corresponding vectors. For instance

$$\mathbf{J} = \sum_{n=1}^N I_n^e \mathbf{f}_n(\vec{r}), \quad (69a)$$

$$I_n^e \approx \frac{1}{l_n} \int_{l_n} (\hat{\mathbf{n}} \times \hat{l}_n) \cdot \mathbf{J} dl$$

$$\mathbf{M} = \sum_{n=1}^N I_n^m \mathbf{f}_n(\vec{r}), \quad (69b)$$

$$I_n^m \approx \frac{1}{l_n} \int_{l_n} (\hat{\mathbf{n}} \times \hat{l}_n) \cdot \mathbf{M} dl$$

where \mathbf{f}_n ($n=1, 2, \dots, N$) are the RWG basis functions associated with the N interior edges of the triangulated patches. The direction of the n th edge is labeled with \hat{l}_n , and $(\hat{\mathbf{n}} \times \hat{l}_n)$ defines the direction of the current flowing across the edge. The elements of $[P]$ and $[Q]$ are

$$P_i(m, n) = \frac{1}{l_m} \int_{l_m} \int_{l_n} [\hat{l}_m \cdot (\nabla G_i \times \mathbf{f}_n)] dS' dl \quad i=1, 2 \quad (70)$$

$$Q_i(m, n) = -jk_1 \frac{1}{l_m} \int_{l_m} \int_{l_n} \left[(\hat{l}_m \cdot \mathbf{f}_n) G_i \right. \\ \left. + \frac{1}{k_2^2} \frac{\partial G_i}{\partial l_m} (\nabla'_s \cdot \mathbf{f}_n) \right] dS' dl \quad i=1, 2 \quad (71)$$

Substituting (67) into (68), one obtains

$$[Z] \cdot [I^{\text{eff}}] = [I^{\text{inc}}] \quad (72)$$

$$[Z] = [Q_1] \cdot [Q_2] - \left(\frac{1}{2}[U] - [P_1]\right) \left(\frac{1}{2}[U] - [P_2]\right) \quad (73)$$

Solve (72) for $[I^{\text{eff}}]$, then restore $[I^e]$, $[I^m]$ via (67) and the equivalent currents by (69). Finally, instead of calculating the scattering fields by (65), we can compute the normalized bistatic scattering coefficients using the equivalent currents, which is defined by

$$\gamma_{ab}(\theta_s, \phi_s) = \lim_{r \rightarrow \infty} \frac{r^2 |E_a^s|^2}{2\eta_0 P_b^{\text{inc}}} = \frac{|S_a(\hat{\mathbf{k}}_s)|^2}{2\eta_0 P_b^{\text{inc}}} \quad (74)$$

where a and b indicate the polarization states of the scattering and incident waves, respectively, and P_b^{inc} is the power impinged on the surface. The scattering integral functions are

$$S_v(\hat{\mathbf{k}}_s) = -\frac{jk_1}{4\pi} \int_S (\hat{\mathbf{v}}_s \cdot \eta_0 \mathbf{J} + \hat{\mathbf{h}}_s \cdot \mathbf{M}) e^{jk_1 \hat{\mathbf{k}}_s \cdot \mathbf{r}'} dS' \quad (75)$$

$$S_h(\hat{\mathbf{k}}_s) = -\frac{jk_1}{4\pi} \int_S (\hat{\mathbf{h}}_s \cdot \eta_0 \mathbf{J} - \hat{\mathbf{v}}_s \cdot \mathbf{M}) e^{jk_1 \hat{\mathbf{k}}_s \cdot \mathbf{r}'} dS' \quad (76)$$

where $\hat{\mathbf{k}}_s = \sin \theta_s \cos \phi_s \hat{\mathbf{x}} + \sin \theta_s \sin \phi_s \hat{\mathbf{y}} + \cos \theta_s \hat{\mathbf{z}}$, $\hat{\mathbf{v}}_s = \hat{\mathbf{h}}_s \times \hat{\mathbf{k}}_s = \cos \theta_s \cos \phi_s \hat{\mathbf{x}} + \cos \theta_s \sin \phi_s \hat{\mathbf{y}} - \sin \theta_s \hat{\mathbf{z}}$, $\hat{\mathbf{h}}_s = \hat{\mathbf{z}} \times \hat{\mathbf{k}}_s / |\hat{\mathbf{z}} \times \hat{\mathbf{k}}_s| = -\sin \phi_s \hat{\mathbf{x}} + \cos \phi_s \hat{\mathbf{y}}$, where (θ_s, ϕ_s) is the scattering direction in spherical coordinate system.

2.3.2. Solution by the MSMCG Method. The SMCG method proved very successful in solving large-scale moment matrix equations encountered in analysis of rough-surface scattering. To use the method, we write each matrix as two parts, the strong part and the weak part:

$$[P_i] = [P_i^s] + [P_i^w], \quad [Q_i] = [Q_i^s] + [Q_i^w] \quad i = 1, 2 \quad (77)$$

Because the diagonal elements of $[P_i^s]$ are negligible with the singularity removed, it is possible to set $[P_i^s] = 0$ as long as the radius separating the far interactions is sufficiently small and the number of expansion levels is sufficiently large. Substituting (77) into (72), (73), one arrives at

$$[Z^s] \cdot [I^{\text{eff}}] = [I^{\text{inc}}] - [Z^w] \cdot [I^{\text{eff}}] \quad (78)$$

$$[Z^s] = [Q_1^s] \cdot [Q_2^s] - (\frac{1}{2}[U] - [P_1^s])(\frac{1}{2}[U] - [P_2^s]) \quad (79)$$

$$[Z^w] = [Z] - [Z^s] \quad (80)$$

Equation (78) will be solved by the conjugate-gradient method (CGM) on updating the right-hand side. Specifically, we assign $[I^{\text{eff}}] = [I_0^{\text{eff}}] = 0$ to the right-hand side of (78) and solve the equation using CGM for $[I^{\text{eff}}]$ to get $[I_1^{\text{eff}}]$. Then we assign $[I^{\text{eff}}] = [I_1^{\text{eff}}]$ to the right-hand side and solve for $[I^{\text{eff}}]$ to get $[I_2^{\text{eff}}]$. Convergence is admitted after k iterations if $\sqrt{\| [I_k^{\text{eff}}] - [I_{k-1}^{\text{eff}}] \| / \| [I^{\text{inc}}] \|} < 1\%$ is reached. For a small or mildly rough surface, the process converges rapidly. However, for very large or very rough surfaces, it may not converge through updating the right-hand side if the radius is not large enough. In this case, we move the last term back to the left-hand side. The resulting equation is again solved by CGM but using the

solution obtained in the last step of the updating approach as the initial solution.

In the SMCG method, the elements of the strong parts are calculated by exact numerical integration and stored in computer memory. However, the elements of the weak parts are not calculated and stored in common ways. Expand the Green function and its gradient as Taylor series about a three-dimensional cubic grid as shown in Fig. 5

$$G = \sum_{k=0}^K \frac{1}{k!} \frac{\partial^k G}{\partial \zeta^k} (\zeta - \zeta')^k = \sum_{k=0}^K C_k \sum_{l=0}^k \binom{k}{l} \zeta^l (-\zeta')^{k-l} \quad (81)$$

$$= \sum_{k=0}^K C_k \sum_{l=0}^k \kappa_{kl} \zeta^l (\zeta')^{k-l} \quad \nabla G = \sum_{k=0}^K \mathbf{D}_k \sum_{l=0}^k \kappa_{kl} \zeta^l (\zeta')^{k-l} \quad (82)$$

$$C_k = \frac{1}{k!} \left. \frac{\partial^k G}{\partial \zeta^k} \right|_{\zeta = \zeta' = 0},$$

$$\kappa_{kl} = (-1)^{k-l} \frac{k!}{l!(k-l)!},$$

$$\mathbf{D}_k = \hat{\mathbf{R}} \frac{1}{k!} \left. \frac{\partial^k}{\partial \zeta^k} \left(\frac{\partial G}{\partial \mathbf{R}} \right) \right|_{\zeta = \zeta' = 0}$$

where K truncates the number of terms of the Taylor series; C_k and \mathbf{D}_k are functions of the canonical grid coordinates. For instance, the expressions of the zeroth- and first-order terms are

$$C_0 = G(R_c), \quad C_1 = \frac{G'(R_c) z_c}{R_c}$$

$$\mathbf{D}_0 = G'(R_c) \hat{\mathbf{R}}_c, \quad \mathbf{D}_1 = \frac{z_c}{R_c}$$

$$\frac{G''(R_c) - G'(R_c)}{R_c} \hat{\mathbf{R}}_c + \frac{1}{R_c} G'(R_c) \hat{\mathbf{z}}$$

Inserting (81), (82) into (70), (71) and approximating the linear integration by the two-point rule (the endpoints of

Figure 5. Schematic diagram for the Taylor expansion of the Green functions on a 3D grid system for the use of the MSMCG method.

an edge) and the surface integration over a triangle by three-point rule (the midpoints of the three edges), we can show that the weak elements, say, $[Q_2^w]$, have a form such as

$$Q_2^w(m, n) = \sum_{k=0}^K \sum_{l=0}^k f_{kl}(m) U_k(m-n) g_{kl}(n) \quad (83)$$

where $f_{kl}(m)$ is associated with a testing edge and $g_{kl}(n)$, with a source triangle. The matrix $[U_k]$ has the Toeplitz structure that may be stored as a column vector. In Section 2.3.3, $[f_{kl}]$, $[g_{kl}]$, and $[U_k]$ will be described in detail. For a three-dimensional canonical grid system, the grid indices in (83) should be understood as $m = (m_x, m_y, m_z)$ and $m-n = (m_x - n_x, m_y - n_y, m_z - n_z)$. Note that (m, n) in (83) refers to the grid indices, which in (71) refers to the numbering of the edges. There exists a corresponding relation between them through an index transform, say, a grid coordinate (m_x, m_y, m_z) corresponding to a deterministic midpoint of the m th edge.

The reduction of memory storage requirement is achieved as follows illustrated using $[Q_2]$. The storage of the matrix $[Q_2]$ is on the order of $O(N^2)$ in common sense. However, the storage of $[Q_2^s]$ is proportional to $O(N)$ because at each observation point only a few nearby source elements within a given distance are taken into account; the storage of $[U_k]$ is on the order of $O(2N)$, and so is $[f_{kl}]$ and $[g_{kl}]$ with N zeros padded to each of them to make use of the FFT. Thus, the total storage of $([Q_2^s] + [Q_2^w])$ is scaled down to $O(CN)$, where C is a constant, typically a few tens. Reduction of the memory storage requirement is remarkable when we think that N could be as big as several millions.

Using CGM to solve (72), the computing burden is dominated by matrix-vector multiplications. Multiplications of the strong parts with a column vector takes a little time, as the strong matrices are very sparse. Because of the approximation (83), the multiplication of the weak parts with a column vector $[x]$ can be accelerated greatly using the FFT technique such as

$$[Q_2^w] \cdot [x] = \sum_{k=0}^K \sum_{l=0}^k [f_{kl}] \cdot \text{FFT}^{-1} \{ \text{FFT} \{ [U_k] \} \cdot \text{FFT} \{ [g_{kl}] \cdot [x] \} \} \quad (84)$$

where the products between two column vectors are affected between their corresponding elements. The complexity directly computing the left-hand side of (84) is on the order of $O(N^2)$. Because the complexity of the three FFTs is $3 \times (2N \log 2N)$ and that of the three column vector products is $3 \times (2N)$, the total manipulation of the right-hand side is only $O(\beta N)$, where $\beta = \frac{1}{2}(K+1)(K+2)$ ($6 \log 2N + 6$), which may be seen as a constant as $\log 2N$ varies very slowly with N . Thus, the saving in CPU time for an iterative solution is substantial as β is typically several hundreds while N could be on the order of millions.

Figure 6. Pair of triangular patches connecting to the n th edge where the source is considered and the m th edge where the equation is tested.

2.3.3. Multiplication of Matrices with a Vector Using

FFT. In this subsection, we give a detailed description to the form of (84) that favors the multiplication of (84) by the FFT technique using FFTW software [27]. Refer to Fig. 6, in which a pair of RWG triangles is depicted along with an edge where the equation is tested. If the distance between the triangle pair and the testing edge is sufficiently large, we can approximate the linear integration along the m th edge by a two-point rule (the endpoints) and the surface integration over each triangle connecting to the n th edge by a three-point rule (the midpoint of each side). This allows us to write (71) as

$$Q_i^w(m, n) = -\frac{jk_1}{12} \hat{l}_m \cdot \sum_{\alpha=1}^2 \sum_{\beta=1}^5 G_{\alpha\beta} \vec{A}_\beta + \frac{4}{k_i^2 l_m} \sum_{\alpha=1}^2 \sum_{\beta=1}^5 (-1)^\alpha \text{sign}(3-\beta) G_{\alpha\beta} l_n \quad (85)$$

where the subscript $\alpha=1,2$ indicates the endpoints of the m th edge, while $\beta=1,2,3,4,5$ indicates the midpoint of a triangle pair connecting to the n th edge; $G_{\alpha\beta} = G(R_{\alpha\beta})$ with $R_{\alpha\beta}$ the distance between an endpoint of the testing edge and a midpoint of the source triangle as indicated in the figure; $\text{sign}(3-\beta)$ equals 1 if $\beta < 3$, 0 if $\beta = 3$, and -1 if $\beta > 3$; and \vec{A}_β equals ρ_n^{c+} if $\beta < 3$, $\rho_n^{c+} + \rho_n^{c-}$ if $\beta = 3$, and ρ_n^{c-} if $\beta > 3$. The vectors of ρ_n^{c+} and ρ_n^{c-} are also shown in the figure.

Actually, (85) can be rewritten in a more compact form

$$Q_i^w(m, n) = \sum_{\alpha, \beta} \sum_{q=1}^4 w_q^\alpha(m) G_{\alpha\beta} u_q^\beta(n) \quad (86)$$

where $q=1,2,3$ counts the first term of (86) because of three components involved, and $q=4$ counts the last term of (85); $w_q^\alpha(m)$ is associated with the testing edge while $u_q^\beta(n)$ is associated with the source triangle. Specifically, $w_q^\alpha(m) = (-jk_1/12)(\hat{q} \cdot \hat{l}_m)$ and $u_q^\beta(n) = (\hat{q} \cdot \vec{A}_\beta) l_n$, where $\hat{q} = \hat{x}, \hat{y}, \hat{z}$ for $q=1,2,3$, respectively; $w_4^\alpha(m) = (-jk_1/12)(1/k_i^2 l_m)(-1)^\alpha$ and $u_4^\beta(n) = \text{sign}(3-\beta) l_n$. Substitution of

the expansion (81) into (86) leads to

$$Q_i^w(m, n) = \sum_{k=0}^K \sum_{l=0}^k \sum_{\alpha, \beta} \sum_{q=1}^4 w_q^\alpha(m) (\kappa_{kl} \zeta_m^l) C_k(m_x - n_x + \Delta_x^{\alpha\beta}, m_y - n_y + \Delta_y^{\alpha\beta}, m_z - n_z) \zeta_n^{k-l} u_q^\beta(n) \quad (87)$$

where $\Delta_x^{\alpha\beta}$ and $\Delta_y^{\alpha\beta}$ are integer or half-integer numbers, representing the displacements due to the integration points over a triangle chosen to be the midpoint of each side, which may not be the gridpoints. If we set

$$\begin{aligned} \tilde{f}_{kl}(m) &= w_q^\alpha(m) (\kappa_{kl} \zeta_m^l), \\ \tilde{g}_{kl}(n) &= \zeta_n^{k-l} u_q^\beta(n) \\ \tilde{U}_k(m-n) &= C_k(m_x - n_x + \Delta_x^{\alpha\beta}, m_y - n_y + \Delta_y^{\alpha\beta}, m_z - n_z) \end{aligned} \quad (88)$$

then (87) would have the same form as (83) except for a triple summation over the indices α , β , and q . Figure 7 shows the projection of a rough surface on the x - y plane and the ordering of the edges. The currents crossing the edges can be sorted into three types according to their directions— x , y , and 45° directions, which will be distinguished by introducing an index $s = 1, 2, 3$. The ranges of m_x and n_x in (88) are chosen to range from 1 to N_x , and the ranges of m_y and n_y from 1 to N_y . It can also be shown that $-\frac{3}{2} \leq \Delta_x^{\alpha\beta}, \Delta_y^{\alpha\beta} \leq 1$. Thus, for a pair of (n_x, n_y) there are three corresponding edges distinguished by s denoting the edge type. Keeping this in mind, we use (88), recasting (87) as

$$Q_i^w(m, n) = \sum_{k=0}^K \sum_{l=0}^k \sum_{q=1}^4 \sum_{\alpha, \beta} \tilde{f}_{kl}(m) \tilde{U}_k(m-n) \tilde{g}_{kl}(n) \quad \text{for } s, s' = 1, 2, 3 \quad (89)$$

Figure 7. Projection of the rough surface on the x - y plane, and the ordering of the edges. The grid indices in the x and y directions are from 0 to N_x and from 0 to N_y .

where $s, s' = 1, 2, 3$ means that given a field edge type such as $s = 1$ and a source edge type such as $s' = 2$, the grid indices on the right-hand side correspond to a unique edge ordering index on the left-hand side. For instance, if $s = 1$ and $s' = 2$, and $m_x = m_y = n_x = n_y = 1$ for the right-hand side, then $m = 1$ and $n = N_{xx} + 1$ for the left-hand side. Because the matrix elements can be written as (89), which is in the form of (83), matrix-column vector multiplication can be performed using FFT for each set of α , β , and q . In order to improve the computing efficiency, the triple summations over α , β , and q may be lifted in some sense, accomplished as follows. If we allow m_x and n_x to vary from 1 to $N_x + 1$, and m_y and n_y from 1 to $N_y + 1$, we will get an extended version of $\tilde{U}_k(m-n)$ to be denoted by $U_k(m-n)$. This means that for any combination of (α, β) and (s, s') in (88), $\tilde{U}_k(m-n)$ is a subset of $U_k(m-n)$. Thus we need only store $U_k(m-n)$ and perform its own FFT, and do not need to compute the FFT of $\tilde{U}_k(m-n)$ for various (α, β) and (s, s') . The storage requirement and computing complexity of $U_k(m-n)$ is on the same order as those of $\tilde{U}_k(m-n)$. Because $U_k(m-n)$ is not relevant to the index β , it can be taken out of the summation over β , so that the summation over β for $u_q^\beta(n)$ can be performed before FFT. This means that we need not compute the FFT of $[\tilde{g}_{kl}] \cdot [x]$ for each β , where $[x]$ is a column vector to be multiplied with the matrix, but only the FFT of $\sum_{\beta, s'} [\tilde{g}_{kl}] \cdot [x]$. Taking these strategies into consideration, (89) eventually becomes equivalent to (83), which means that both the storage requirement and computing complexity for $[f_{kl}]$, $[U_k]$, and $[g_{kl}]$ in (83) are on the same orders as $[f_{kl}]$, $[\tilde{U}_k]$, and $[\tilde{g}_{kl}]$ in (89). We remind the reader that, because a column vector $[x]$ represents the surface currents, we may set $x(n_x, n_y, n_z) = 0$ except for $n_z = h(n_x, n_y)$, where $h(n_x, n_y)$ is the level closest to the surface. This implies that the elements of the product column vector $[g_{kl}] \cdot [x]$ are nonzero only for $n_z = h(n_x, n_y)$. Similar calculation can be performed for the multiplication of $[P_i^w]$ with a column vector. Multiplication of the transposed conjugate matrices of $[P_i^w]$ and $[Q_i^w]$ with a column vector can also be performed using the FFT technique.

2.3.4. Numerical Results and Discussion. To simulate the scattering from a truncated area of a boundless surface, an incident wave with limited beamwidth is necessary to minimize the errors caused by the surface boundaries. The Gaussian tapered incident wave adopted in this section is [28]

$$E_B^{\text{inc}} = \iint_{k_x^2 + k_y^2 \leq k_1^2} \mathbf{S}_E(k_x, k_y) \Phi_B(k_x - k_{ix}, k_y - k_{iy}) e^{-j(k_x x + k_y y - k_z z)} dk_x dk_y \quad (90)$$

where $k_z = \sqrt{k_1^2 - k_x^2 - k_y^2}$, and $\mathbf{S}_E(k_x, k_y) = \hat{p}_i \cdot (\hat{v}\hat{v} + \hat{h}\hat{h})$, where \hat{p}_i is \hat{v}_i for vertically polarized (TM waves) or \hat{h}_i for horizontally polarized (TE waves) incidences. The definitions of \hat{h} and \hat{v} are $\hat{h} = \hat{z} \times \hat{k} / |\hat{z} \times \hat{k}|$ and $\hat{v} = \hat{h} \times \hat{k}$, respectively, so that $(\hat{v}, \hat{h}, \hat{k})$ forms an orthonormal system. The incident magnetic field is obtained by replacing \mathbf{S}_E with $\mathbf{S}_H = \hat{k} \times \mathbf{S}_E / \eta_0 = \hat{p}_i \cdot (\hat{v}\hat{h} - \hat{h}\hat{v}) / \eta_0$. The function Φ_B is

a Gaussian tapered spectrum with center incident direction in (k_{ix}, k_{iy}, k_{iz}) , where $k_{iz} = \sqrt{k_1^2 - k_{ix}^2 - k_{iy}^2}$

$$\Phi_{\mathbf{B}}(k_x - k_{ix}, k_y - k_{iy}) = \frac{B_x B_y}{4\pi} \exp\left\{-\frac{1}{4}[(k_x - k_{ix})^2 B_x^2 + (k_y - k_{iy})^2 B_y^2]\right\} \quad (91)$$

where B_x and B_y control the tapering or the beamwidths and are typically chosen to be $B_x = L_x/5$ and $B_y = L_y/5$, where L_x and L_y are the sizes of a square area to be simulated. This procedure consists of three steps:

1. As a first check, we use a Gaussian randomly rough surface as an example to verify the correctness and accuracy of the present method, comparing the results with those obtained by the original SMCG method. The surface size is $64\lambda^2$, with RMS height $\sigma = 0.2\lambda$ ($k_1\sigma = 1.257$) and correlation length 1λ . The relative permittivity of the lower space is chosen to be $15 - 15j$. Figure 8 compares the bistatic scatter-

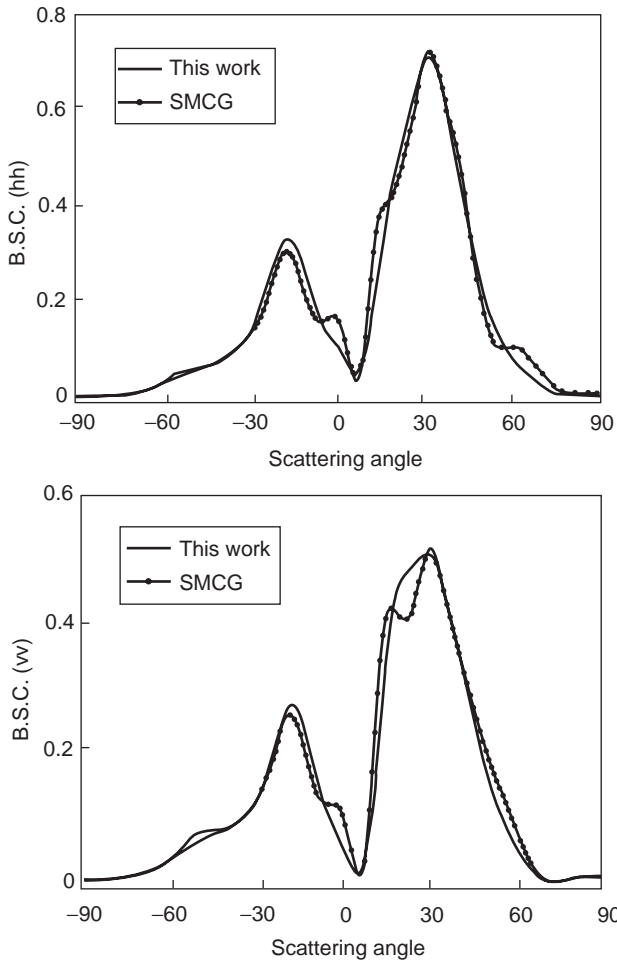

Figure 8. Comparison of the copolarized bistatic scattering coefficients (BSCs) from a $64\lambda^2$ surface area with RMS height 0.2λ using the original SMCG method and the present SMFIE-based MSMCG approach.

ing coefficients of copolarized components for a wave incident at -30° . Good agreement of the results demonstrates that both methods are reliable for predicting the bistatic scattering coefficients. The small discrepancy of the curves is understandable because of the difference between the two methods. The original SMCG method uses coupled equations with six unknowns per surface points, collocation method, and single-level expansion of the Green functions. The present method uses a single equation with one unknown per interior edge of the triangulated mesh representing the rough surface, RWG basis, and multilevel expansion. For this size and order of roughness surfaces, the overall iteration time using the present approach is around half that of the original SMCG method.

2. Next, to demonstrate the convergence of the proposed method for the large-RMS-height case, a very rough surface is analyzed. The simulated area is $256\lambda^2$ with RMS height $\sigma = 0.8\lambda$ ($k_1\sigma = 5.03$) and correlation lengths 1λ , and the relative permittivity of the lower region is set to be $8 - 4j$. The Green functions are expanded with 64 levels, and four Taylor series terms are retained. Figure 9 shows the simulation results of the bistatic scattering coefficients (BSCs) for a TE wave to z polarization incident at -30° . This example confirms that the present method converges to reasonable results as long as either the number of Taylor series terms or the number of expansion levels is sufficient. As a rule of thumb, the grid size in the z direction may be chosen to be $\Delta z \approx 1/|k_z|$. If the number of Taylor series terms is kept to be 4, the number of expansion levels is set to be around $(z_{\max} - z_{\min})/\Delta z$. If one more term of the Taylor series is added, the number of the expansion levels would be halved, and vice versa.
3. We perform some Monte Carlo simulations for bare soil surfaces over 50 realizations. A Gaussian spectrum is assumed, although an exponential spectrum may be more realistic. The permittivity of the wet soil is taken to be $25 - 3j$ at 1.5 GHz. The sizes of rough surfaces are 24×24 square wavelengths, with RMS height 0.25λ and correlation length 1λ . The results are shown in Fig. 10 for incidences at -30° .

In the following, we provide some results for wind-driven ocean surfaces. The ocean spectrum used is [29]

$$W(k, \phi) = \frac{1}{2\pi k} S(k) \Phi(k, \phi) \quad (92)$$

The spectral range used for simulations is $1 \leq k \leq 120 \text{ m}^{-1}$, and the surface sizes is chosen to be about 7.31 m by 7.31 m to sufficiently resolve the lower limit of the selected spectral range. At windspeed 10 m/s , the RMS height and slope are about 5 cm and 0.12 , respectively. At 1.5 GHz , the simulated area is about $36.6 \times 36.6\lambda^2$ with RMS roughness 0.25λ . The relative

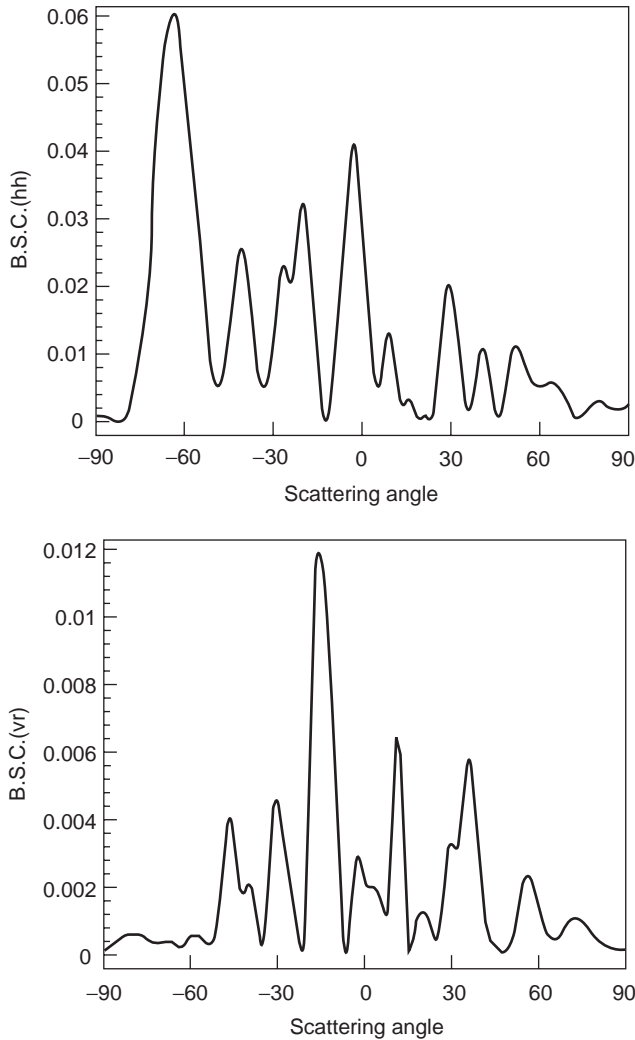

Figure 9. BSC from a $256\lambda^2$ rough surface area with RMS height 0.8λ for a TE wave incident at -30° .

permittivity of the seawater at the operating frequency is taken to be $74 - 61j$ at 15°C and 3.5% salinity.

First, it seems worth pointing out that (72) is a general and rigorous form, and some approximations may be made to speed up the computations within an acceptable loss of accuracy. If we set $[P_2]=[Q_2]=0$, then (67) would give $[I^m=0]$ and $[I^{\text{eff}}]=-2[I^e]$, and (72) would be reduced to the PEC (perfectly electric conducting) case. If only the diagonal elements are retained for $[Q_2]$ (the diagonal elements of $[P_2]$ are negligible with the singularity extracted), (72) would be commensurate with the impedance approximation method [30], and here we call it the *diagonal simplification method* (DSM). For a lossy half-space in which the Green function attenuates rapidly, it is always possible to discard the weak interactions in using the MSMCG scheme (i.e., letting $[P_2^w]=[Q_2^w]=0$), as long as the distance to distinguish the strong and weak interactions is appropriately large. This simplification, which would save nearly half of the CPU solution time, is referred to as the *neighborhood approximation method* (NAM). A comparison of the scattering coefficients for VV

Figure 10. Scattering coefficients versus scattering angles for wet-soil surfaces. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

components is shown in Fig. 11, which illustrates that both DSM and NAM can well capture the features of the scattering coefficients, although DSM is less accurate than NAM and tends to overestimate the results in all of our numerical experiments.

Next, some Monte Carlo simulations are performed over 50 realizations for incidences at -20° , and the results are shown in Fig. 12 for three azimuth angles of incidences relative to the wind direction. The peak in the specular scattering direction for a wave incident in the crosswind direction is slightly stronger than that in the downwind and deadwind directions. The peak is 8.1 dB for crosswind incidence but only 6.7 dB for downwind and deadwind cases. This implies that the anisotropy of a wind-driven ocean surface is identifiable from the data of scattering measurements. Compared with Fig. 10, it can be seen that the scattering properties from Gaussian surfaces and oceanlike surfaces are basically distinguishable.

Figure 11. Comparison of approximate results using DSM and NAM with exact results. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 12. Scattering coefficients against scattering angles for wind-driven ocean surfaces. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Finally, using the aforementioned NAM simplification, a very big oceanlike surface with sizes $128 \times 64\lambda^2$ is analyzed for which a permittivity of $45 - 30j$ has been used for the lower space [30]. The surface is modeled using 4,194,304 triangular patches, which results in a total of 6,288,384 unknowns for the *effective* surface electric currents using the single integral equation with the RWG basis functions. This number of unknowns would be doubled if two coupling integral equations were used. The results for incidence at -30° are shown in Fig. 13, which seems quite reasonable. The purpose of this example is to demonstrate the merits of our codes running on a newly constructed supercomputer that has 256 Alpha 800-MHz processors. The memory storage requirement for each processor is around 110 MB, and the total time is ~ 5 h for both polarizations combined. This efficiency is comparable with the Xia-Chan report [31] solving 10 million unknowns using 128 processors in 7 h.

2.4. Wave Scattering with UV Multilevel Partitioning Method: 3D Problem of Surface Scattering

We note that the SMCG method is limited by the RMS height. Also, when the RMS height is increased, the near-field neighborhood distance must be increased so that the number of terms in the Taylor series expansion can be limited. Furthermore, the PBTG requires an interpolation scheme. We have developed a multilevel UV method for rough-surface scattering. The basic of this method is described in this section.

Kapur and Long [32] proposed a QR decomposition method by using the property of the smoothness of the impedance matrix elements. The QR is applied to the matrix blocks with recursive partitioning and merging. The method has so far been demonstrated only for matrix block of moderate size in terms of wavelengths.

In this section, a UV method with multilevel partitioning (UV MLP) is developed to solve the wave scattering problem. The method consists of setting up a table of transmitting and receiving blocks of different sizes and separating them. For a specific scattering problem with given geometry, the scattering structure is partitioned into multilevel blocks. By looking up the rank in the static problem, the impedance matrix for a given transmitting and receiving block is expressed into a UV matrix product. In the method, we also apply the multilevel matrix partitioning (MLP) to partition the impedance matrix \bar{Z} . We demonstrate the technique for a 3D rough surface scattering problem. The surface area of the rough surface when projected onto the xy plane has a surface area up to 256 square wavelengths with the number of surface unknowns of 65,536. The RMS height is 0.5 wavelengths. In this case, the multilevel partitioning used is as done in the multilevel fast multipole method. Because the UV is applied independently to each level and each block, the procedure facilitates parallel implementation.

In Section 2.4.1, we describe the problem of independent rank determination. This is done for a flat surface and volume scattering. In Section 2.4.2, the formulation of the problem of wave impinging on a rough surface is given in terms of the surface integral equation, which is converted into a matrix equation using the method of moments (MoM). In Section 2.4.3, we describe the multilevel partitioning process, and in Section 2.4.4 we describe the UV method. In Section 2.4.5, the computational complexity of the proposed algorithm is derived.

2.4.1. Problem of Determination Independent Rank.

Consider a matrix \bar{Z} of dimension $N \times N$, which represents the interactions between two nonnear groups, each of which has N scatterers in the group, where the rank of \bar{Z} is r . We can use single-value decomposition (SVD) to determine rank. Let σ_1 be the largest singular value and the singular values be arranged in decreasing magnitude. Given a threshold ϵ , the rank r is such that $|\sigma_{r+1}/\sigma_1| \leq \epsilon$. The threshold used in the simulation is 1×10^{-5} in this article. Because of the smoothness of the matrix elements, the rank r is much less than the number of scatterers N . The rank r is determined mainly by the sizes of the

transmitting and receiving blocks and the separation distance between the two block centers.

Consider a transmitting block and a receiving block with N points in each block. The points are labeled \bar{r}_m , $m = 1, 2, \dots, N$ for the receiving block and \bar{r}_n , $n = 1, 2, \dots, N$, for the transmitting block. Then we have the matrix \bar{Z} of dimension $N \times N$ with elements

$$Z_{mn} = \frac{\exp(ik|\bar{r}_m - \bar{r}_n|)}{4\pi|\bar{r}_m - \bar{r}_n|} \quad (93)$$

For N , we assume 10 points per wavelength, which corresponds to 100 points per square wavelength and 1000 points per cubic wavelength.

The rank of the matrix can be determined. It is strongly dependent on the size of the transmitting and receiving blocks and the degree of separation between them.

2.4.1.1. Two Flat Sheets with Zero Vertical Separation.

Consider two flat sheets of sizes L_x and L_y placed on the same horizontal plane. The centers of the two planes are on the x axis, and R is the separation distance between the two centers. These requirements can be met for the problem of microstrip line and is usually assumed to be the current sheet. In the traditional method for determining the rank for such a problem, area sampling has to be used, which leads to a large number of sampling points and requires extensive CPU time and computer memory allocation. However, on the basis of Huygens principle, the equivalent sources are the boundary lines, which are the four sides of the sheet. Thus the radiation presumably originates from the enclosing boundary lines of the transmitting block to the boundary lines of the receiving block. We can actually use the boundary line sampling in the rank determination. Furthermore, due to the smoothness of Green function, we know that the rank is much less than the number of sampling points. Thus we can use coarse boundary sampling to further reduce the computational cost for the rank determination. In the Table 1, we list the ranks determined by these three methods, denoted as $L_z = 0$. For the area sampling, 100 points per square wavelength are used; for the boundary dense sampling, 10 points per wavelength are used. For the boundary coarse sampling, 4 points per wavelength are used. The ranks determined through them are comparable for the given physical sizes of the problem. Note that the ranks are substantially smaller than the block size N .

2.4.1.2. Volumetric Blocks and Enclosing Boundary Radiation. Next we consider volumetric blocks of sizes $L_x \times L_y \times L_z$. The centers of the blocks are placed on the x axis and separated by a distance R .

We also used three methods to determine the ranks for a given physical size of the problem: volume sampling, boundary dense sampling, and boundary coarse sampling. For the *boundary sampling*, the equivalent sources are now the boundary surfaces, which are the six sides of the block. Thus the radiation can be considered as radiation from the enclosing boundary surface of the transmitting block to the boundary surface of the receiving block. The

^fBoundary (surface) coarse sampling (16 points per square wavelength).

^gNA = not available because of the limitation of computer resource.

ranks are also given in Table 1. For *volume sampling*, 1000 points per cubic wavelength are used. For *boundary dense sampling*, 100 points per square wavelength are used. For boundary coarse sampling, 16 points per square wavelength are used. Note that for the $4\lambda \times 4\lambda \times 4\lambda$, the number of points for volume sampling is 64,000, while for boundary coarse sampling the number of sampling points is only 1536. This will speed up the rank determination greatly for this case. We note that for the case of the $4\lambda \times 4\lambda \times 4\lambda$ with the $R = 8\lambda$ case, the number of points is $n = 40 \times 40 \times 40 = 64,000$. The rank from this case is only 116, meaning that significant matrix compression is possible. The table also shows that coarse sampling gives essentially the same rank as dense sampling. The rank can be determined quickly using coarse-coarse sampling.

2.4.1.3. Small Overestimation of Rank. In the SVD method, the rank determination is based on a threshold. Thus there is built in variation of rank due to variations in threshold. Furthermore, in applications as illustrated in this article, the exact rank is not required. Thus we usually are on the safe side using 10–20% above the “actual” rank.

We note that the block selection is dependent on the type of problem. However, once the static rank table is determined, the rank table can be applied to all cases within the same type of problem.

2.4.2. Wave Scattering Formulation. Consider a tapered scalar plane wave $\psi_{\text{inc}}(x, y, z)$ (Eq. 6.1.1 in Ref. 15) impinging on a 2D random rough surface with Dirichlet boundary condition and a random height profile $z=f(x, y)$. A Fredholm integral equation of the first kind can be formed. Let $\bar{r}' = \hat{x}x' + \hat{y}y' + \hat{z}f(x', y')$ denote a field point and $\bar{r} = \hat{x}x + \hat{y}y + \hat{z}f(x, y)$ denote a source point on the rough surface. Then the surface integral equation is [14]

$$0 = \psi_{\text{inc}}(\bar{r}) - \iint dx dy G_0(x, y, f(x, y); x', y', f(x', y')) U(x, y) \quad (94)$$

where $G_0 = [\exp(ik|\bar{r} - \bar{r}'|)] / (4\pi|\bar{r} - \bar{r}'|)$ is the free-space Green function and the unknown surface field is $U(x, y)$.

The method of moments (MoM) is used to discretize the integral equation. We use the pulse basis function and point matching method. The resulting matrix equation is

$$\bar{\bar{Z}} \cdot \bar{u} = \bar{b} \quad (95)$$

2.4.3. Multilevel Partitioning Process. Assuming that we have a square area as shown in Fig. 14a, we first split into four blocks as shown in Fig. 14b. Each of these four blocks is a subgroup at the P th level, which has the maximum group size. Then we split each subblock into another four small groups as shown in Fig. 14c. This splitting process is continued until we reach the smallest group size, which is at the first level. We decompose the full impedance matrix in Eq. (96) as the sum of P sparse matrixes as follows:

$$\bar{\bar{Z}} = \bar{\bar{Z}}^{(0)} + \bar{\bar{Z}}^{(1)} + \bar{\bar{Z}}^{(2)} + \dots + \bar{\bar{Z}}^{(P-1)} \quad (96)$$

Matrix $\bar{\bar{Z}}^{(0)}$ includes all the interactions among neighboring groups (including the self-group) at the first level. Matrix $\bar{\bar{Z}}^{(1)}$ includes all the interactions among neighboring groups at the second level. It consists of blocks at the

Figure 14. Illustration of multilevel partitioning process.

first level. Similarly, matrix $\bar{\bar{Z}}^{(i)}$ includes all the interactions among neighboring groups at the $(i+1)$ th level, but these consist of blocks at the i th level.

To facilitate understanding of the multilevel partitioning process, we give an example that has 64 subgroups at the first level. Assume that each group has M elements. For this example, the highest level is $P=3$. Thus $\bar{\bar{Z}} = \bar{\bar{Z}}^{(0)} + \bar{\bar{Z}}^{(1)} + \bar{\bar{Z}}^{(2)}$ and the impedance matrix of $\bar{\bar{Z}}$ is $64M \times 64M$ with $4096M \times M$ blocks.

In Fig. 15a, the 64 subgroups at the first level are denoted $1_1, 2_1, \dots, 64_1$. In Fig. 15b, the level 2 groups are denoted as $1_2, 2_2, \dots, 16_2$. Each of the level 2 groups has four level 1 groups. For example, group 3_2 has four groups of $5_1, 6_1, 13_1$, and 14_1 . In Fig. 15c, the level 3 groups are denoted as $1_3, 2_3, 3_3$, and 4_3 . Each of the level 3 groups has four level 2 groups. For example, group 2_3 has four groups of $3_2, 4_2, 7_2$, and 8_2 .

We use m_i to represent the group m of the level i . Then matrix $\bar{\bar{Z}}_{m_i, n_i}$ represents the interactions between the receiving group m and the transmitting group n of the i th level. Since the four level 1 groups form a level 2 group

and four level 2 groups form a level 3 group, we have

$$\bar{\bar{Z}}_{m_1 n_1} = \text{dimension of } M \times M$$

$$\bar{\bar{Z}}_{m_2 n_2} = \text{dimension of } 4M \times 4M$$

Examples are

$$\bar{\bar{Z}}_{3_2 5_2} = \begin{bmatrix} \bar{\bar{Z}}_{5_1 17_1} & \bar{\bar{Z}}_{5_1 18_1} & \bar{\bar{Z}}_{5_1 25_1} & \bar{\bar{Z}}_{5_1 26_1} \\ \bar{\bar{Z}}_{6_1 17_1} & \bar{\bar{Z}}_{6_1 18_1} & \bar{\bar{Z}}_{6_1 25_1} & \bar{\bar{Z}}_{6_1 26_1} \\ \bar{\bar{Z}}_{13_1 17_1} & \bar{\bar{Z}}_{13_1 18_1} & \bar{\bar{Z}}_{13_1 25_1} & \bar{\bar{Z}}_{13_1 26_1} \\ \bar{\bar{Z}}_{14_1 17_1} & \bar{\bar{Z}}_{14_1 18_1} & \bar{\bar{Z}}_{14_1 25_1} & \bar{\bar{Z}}_{14_1 26_1} \end{bmatrix} \quad (97)$$

$$\bar{\bar{Z}}_{6_2 5_2} = \begin{bmatrix} \bar{\bar{Z}}_{19_1 17_1} & \bar{\bar{Z}}_{19_1 18_1} & \bar{\bar{Z}}_{19_1 25_1} & \bar{\bar{Z}}_{19_1 26_1} \\ \bar{\bar{Z}}_{20_1 17_1} & \bar{\bar{Z}}_{20_1 18_1} & \bar{\bar{Z}}_{20_1 25_1} & \bar{\bar{Z}}_{20_1 26_1} \\ \bar{\bar{Z}}_{27_1 17_1} & \bar{\bar{Z}}_{27_1 18_1} & \bar{\bar{Z}}_{27_1 25_1} & \bar{\bar{Z}}_{27_1 26_1} \\ \bar{\bar{Z}}_{28_1 17_1} & \bar{\bar{Z}}_{28_1 18_1} & \bar{\bar{Z}}_{28_1 25_1} & \bar{\bar{Z}}_{28_1 26_1} \end{bmatrix} \quad (98)$$

$$\bar{\bar{Z}}_{1_3 2_3} = \begin{bmatrix} \bar{\bar{Z}}_{1_2 3_2} & \bar{\bar{Z}}_{1_2 4_2} & \bar{\bar{Z}}_{1_2 7_2} & \bar{\bar{Z}}_{1_2 8_2} \\ \bar{\bar{Z}}_{2_2 3_2} & \bar{\bar{Z}}_{2_2 4_2} & \bar{\bar{Z}}_{2_2 7_2} & \bar{\bar{Z}}_{2_2 8_2} \\ \bar{\bar{Z}}_{5_2 3_2} & \bar{\bar{Z}}_{5_2 4_2} & \bar{\bar{Z}}_{5_2 7_2} & \bar{\bar{Z}}_{5_2 8_2} \\ \bar{\bar{Z}}_{6_2 3_2} & \bar{\bar{Z}}_{6_2 4_2} & \bar{\bar{Z}}_{6_2 7_2} & \bar{\bar{Z}}_{6_2 8_2} \end{bmatrix} \quad (99)$$

There are three sets of blocks:

1. *The Blocks in $\bar{\bar{Z}}^{(0)}$.* In $\bar{\bar{Z}}^{(0)}$, we select interactions of the level 1 group with their nearest neighbors. For example, 20_1 have eight neighbors of 11_1 , 12_1 , 13_1 , 19_1 , 21_1 , 27_1 , 28_1 , and 29_1 . Thus $\bar{\bar{Z}}^{(0)}$ includes $\bar{\bar{Z}}_{11_1 20_1}$, $\bar{\bar{Z}}_{12_1 20_1}$, $\bar{\bar{Z}}_{13_1 20_1}$, $\bar{\bar{Z}}_{19_1 20_1}$, $\bar{\bar{Z}}_{20_1 20_1}$, $\bar{\bar{Z}}_{21_1 20_1}$, $\bar{\bar{Z}}_{27_1 20_1}$, $\bar{\bar{Z}}_{28_1 20_1}$, and $\bar{\bar{Z}}_{29_1 20_1}$, a total of nine matrices. Note that self-interaction is also included in here. We note that (a) block size of $\bar{\bar{Z}}_{m_1 n_1}$ is $M \times M$; (b) there are 36 interior level 1 groups of 9 blocks = $36 \times 9 = 324$ ($M \times M$) blocks; (c) 24 edge level 1 groups of 6 blocks = $24 \times 6 = 144$ ($M \times M$) blocks; (d) four corner level 1 groups of 4 blocks = $4 \times 4 = 16$ ($M \times M$) blocks. Thus $\bar{\bar{Z}}^{(0)}$ has a total of $324 + 144 + 16 = 484$ ($M \times M$) blocks.
2. *The Blocks in $\bar{\bar{Z}}^{(1)}$.* In $\bar{\bar{Z}}^{(1)}$, we select the interactions between level 2 groups and their nearest neighbors. For example, we need to include $\bar{\bar{Z}}_{6_2 5_2}$. However, we need to exclude those that have been included in $\bar{\bar{Z}}^{(0)}$. We define the impedance matrix primes

$$\bar{\bar{Z}}'_{6_2 5_2} = \begin{bmatrix} \bar{\bar{Z}}_{19_1 17_1} & \bar{0}_1 & \bar{\bar{Z}}_{19_1 25_1} & \bar{0}_1 \\ \bar{\bar{Z}}_{20_1 17_1} & \bar{\bar{Z}}_{20_1 18_1} & \bar{\bar{Z}}_{20_1 25_1} & \bar{\bar{Z}}_{20_1 26_1} \\ \bar{\bar{Z}}_{27_1 17_1} & \bar{0}_1 & \bar{\bar{Z}}_{27_1 25_1} & \bar{0}_1 \\ \bar{\bar{Z}}_{28_1 17_1} & \bar{\bar{Z}}_{28_1 18_1} & \bar{\bar{Z}}_{28_1 25_1} & \bar{\bar{Z}}_{28_1 26_1} \end{bmatrix} \quad (100)$$

where $\bar{0}_1$ is the zero matrix of dimension ($M \times M$).

Thus the $\bar{\bar{Z}}^{(1)}$, include all the $\bar{\bar{Z}}'_{m_2 n_2}$, where m_2 and n_2 are neighbors. As shown in Eq. (101), we note that the matrix $\bar{\bar{Z}}'_{m_2 n_2}$ (a) consists of blocks with size of $M \times M$, (b) each block consists of a transmitting region and a receiving region that are not neighbors of each other (e.g., in $\bar{\bar{Z}}'_{19_1 17_1}$, the receiving region is 19_1 and the transmitting region is 17_1 and the two are not neighbors of each other), and (c) the separation R between the transmitting and the receiving regions is at a minimum of $2S$ for $\bar{\bar{Z}}'_{19_1 17_1}$, where S is the block size. It is at a maximum of $R = 3\sqrt{2}S$ for $\bar{\bar{Z}}'_{44_1 17_1}$, which is in $\bar{\bar{Z}}'_{10_2 5_2}$. Thus $\bar{\bar{Z}}^{(1)}$ includes

3. Four interior level 2 groups that have eight neighbors, four of which have 12 blocks and four of which have 15 blocks. The total number of blocks is $4 \times (4 \times 12 + 4 \times 15) = 432$.
4. Eight edge level 2 groups that have five neighbors, three of which have 12 blocks and two of which have 15 blocks. The total number of blocks is $8 \times (3 \times 12 + 2 \times 15) = 528$.
5. Four corner level 2 groups, that have three neighbors, two of which have 12 blocks and one of which has 15 blocks. The total number of blocks is $4 \times (2 \times 12 + 1 \times 15) = 156$.
6. Thus matrix $\bar{\bar{Z}}^{(1)}$ includes $432 + 528 + 156 = 1116$ ($M \times M$) blocks.
7. *The Blocks in $\bar{\bar{Z}}^{(2)}$.* In $\bar{\bar{Z}}^{(2)}$, we select the interactions between level 3 groups and their nearest neighbors. For example, we need to include $\bar{\bar{Z}}'_{1_3 2_3}$. However, some of the interactions have already been included in $\bar{\bar{Z}}^{(0)}$ and $\bar{\bar{Z}}^{(1)}$ and need to be excluded. We define the prime impedance matrices

$$\bar{\bar{Z}}'_{1_3 2_3} = \begin{bmatrix} \bar{\bar{Z}}_{1_2 3_2} & \bar{\bar{Z}}_{1_2 4_2} & \bar{\bar{Z}}_{1_2 7_2} & \bar{\bar{Z}}_{1_2 8_2} \\ \bar{0}_2 & \bar{\bar{Z}}_{2_2 4_2} & \bar{0}_2 & \bar{\bar{Z}}_{2_2 8_2} \\ \bar{\bar{Z}}_{5_2 3_2} & \bar{\bar{Z}}_{5_2 4_2} & \bar{\bar{Z}}_{5_2 7_2} & \bar{\bar{Z}}_{5_2 8_2} \\ \bar{0}_2 & \bar{\bar{Z}}_{6_2 4_2} & \bar{0}_2 & \bar{\bar{Z}}_{6_2 8_2} \end{bmatrix} \quad (101)$$

Note that the building blocks of $\bar{\bar{Z}}'_{1_3 2_3}$ are level 2 blocks and are of size of $(4M \times 4M) = 16M \times M$. This is important that as the level increases, there will be a fourfold growth in block size as we go up each level. We have four level 3 groups, each of which has two neighbors with 12 level 2 blocks and one neighbor with 15 level 2 blocks. Thus, we have $4 \times (2 \times 12 + 1 \times 15) = 156$ level 2 blocks. Since each level 2 blocks has 16 level 1 blocks. Thus we have a total of $16 \times 156 = 2496$ level 1 block in $\bar{\bar{Z}}^{(2)}$.

Thus the total count is $484 + 1116 + 2496 = 4096$, and all the level 1 blocks are counted exactly once. To summarize, the block size in $\bar{\bar{Z}}^{(0)}$ is $M \times M$, in $\bar{\bar{Z}}^{(1)}$ is $M \times M$, and in $\bar{\bar{Z}}^{(2)}$ $4M \times 4M$. In applying UV decomposition, the UV

matrix is applied to each block for that level. Each block consists of a transmitting region and a receiving region that are not neighbors of each other. However, their separations are within a restricted range as indicated before.

2.4.4. UV Method Based on Interpolation Technique.

The matrix $\bar{\bar{Z}}_{m_i n_i}$, which represents the interactions between two nonneighbor groups' m_i and n_i , can be represented by UV decomposition. The matrix $\bar{\bar{Z}}_{m_i n_i}$ is of dimensions $4^{(i-1)}M \times 4^{(i-1)}M$. The rank of $\bar{\bar{Z}}_{m_i n_i}$, r , is much smaller than $4^{(i-1)}M$. For simpler notation, we denote $\bar{\bar{Z}}_{m_i n_i}$ by $\bar{\bar{A}}$, which has dimension of $N \times N$ and rank of r with $r \ll N$. Decomposition of $\bar{\bar{A}}$ by the SVD and Gram-Schmidt processes will consume CPU time because N is large. Note that in Section 3, we apply the SVD to find r . But because of coarse sampling, the selected matrices are roughly of dimension $r \times r$ only.

Let the column of $\bar{\bar{A}}$ be denoted by \bar{a}_l , where $l = 1, 2, \dots, N$; then $A_{mn} = (\bar{a}_n)_m$. The element A_{mn} is the m th element of the column vector \bar{a}_n . However, there are only r independent columns. In the transmitting region, we select r points from the N points. The r points must be uniformly distributed in the transmitting region.

We compute the r columns \bar{u}_l , $l = 1, 2, \dots, r$. Each column is of dimension of N and coincides with a column of $\bar{\bar{A}}$:

$$U_{ml} = (\bar{u}_l)_m = A_{mp(l)}, \quad m = 1, 2, \dots, N \quad (102)$$

where $p(l)$ is a column index of $\bar{\bar{A}}$ that depends on l . Note that to get U_{ml} , we need to go through all the N points in the receiving region. Thus the matrix \bar{U} has $N \times r$ elements.

Because of linear independence, any general column \bar{a}_m of $\bar{\bar{A}}$ is a linear combination of \bar{u}_l , that is

$$\bar{a}_m = \sum_{l=1}^r v_{lm} \bar{u}_l, \quad m = 1, 2, \dots, N \quad (103)$$

where v_{lm} are the coefficients to be determined.

We pick r rows of $\bar{\bar{A}}$ which has total of $N \times r$ elements. The r rows correspond to r points in the receiving group. The r points must be uniformly distributed in the receiving group. We first put these rows in a matrix of \bar{R} :

$$R_{m_a p} = A_{m(m_a)p}, \quad p = 1, 2, \dots, N \quad \text{and} \quad m_a = 1, 2, \dots, r \quad (104)$$

We pick the m_a rows in \bar{u}_l , $l = 1, 2, \dots, r$. That will give us a $r \times r$ matrix, which we will call \bar{U} , and we have $\bar{U}_{m_a n_a} = (\bar{u}_{n_a})_{m(m_a)}$. Then we set

$$R_{m_a l} = \sum_{n_a=1}^r \bar{U}_{m_a n_a} v_{n_a l}, \quad l = 1, 2, \dots, N \quad (105)$$

In matrix notation, $\bar{\bar{V}} = r \times N$, $\bar{\bar{R}} = r \times N$, $\bar{\bar{U}} = r \times r$, $\bar{\bar{R}} = \bar{\bar{U}} \bar{\bar{V}}$, and $\bar{\bar{V}} = (\bar{\bar{U}})^{-1} \bar{\bar{R}}$. This completes the UV decomposition:

$$\bar{\bar{A}} = \bar{\bar{U}} \bar{\bar{V}} \quad (106)$$

To summarize, we take r columns of $\bar{\bar{A}}$ and then r rows of N , which constitutes a total of $2r \times N$ elements. We need to

take the inverse of an $r \times r$ matrix $\bar{\bar{U}}$ and a matrix multiplication of the $r \times r$ matrix times a $r \times N$ matrix. The computational and memory efficiency is achieved when $r \ll N$.

2.4.5. Computational Complexity Analysis

2.4.5.1. Multilevel Group Sizes and Number of Groups. A rough surface is generated in a square area with \sqrt{N} points in x direction and \sqrt{N} points in y direction, so the total number of patches is N . We use various subgroup sizes at P level to partition the whole area as follows:

1. At P th level, we split the whole area as four groups. Each group has $N/4$ elements:

$$L_P = 4 = 2^{2(P-P+1)} \quad (107)$$

$$M_P = N/4 = \frac{N}{L_P} \quad (108)$$

2. where L_P is the number of groups and M_P is the number of elements of each group at P th level.
3. We split each group into four subgroups and continue this partitioning; at i th level, we have

$$L_i = 2^{2(P-i+1)} \quad (109)$$

$$M_i = \frac{N}{L_i} \quad (110)$$

4. At the first level, we have

$$L_1 = 2^{2P} \quad (111)$$

$$M_1 = \frac{N}{L_1} \quad (112)$$

2.4.5.2. Cost Function at i th Level. In $\bar{\bar{Z}}^{(i)}$, we select the interactions between level $(i+1)$ groups and their nearest neighbors. However, some of the interactions have already been included in the lower-level groups and must be excluded here. There are two kinds of neighboring groups: (1) that sharing only one common point and (2) that sharing one common edge.

1. *Sharing Only One Common Point.* For the neighboring groups of $m_{(i+1)}$ and $n_{(i+1)}$ shown in Fig. 16a, only one common point is shared between them. The impedance matrix that will be calculated is

$$\bar{\bar{Z}}_{m_{(i+1)} n_{(i+1)}} = \begin{bmatrix} \bar{\bar{Z}}_{m_i^{(1)} n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(1)} n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(1)} n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(1)} n_i^{(4)}} \\ \bar{\bar{Z}}_{m_i^{(2)} n_i^{(1)}} & \bar{0}_i & \bar{\bar{Z}}_{m_i^{(2)} n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(2)} n_i^{(4)}} \\ \bar{\bar{Z}}_{m_i^{(3)} n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(3)} n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(3)} n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(3)} n_i^{(4)}} \\ \bar{\bar{Z}}_{m_i^{(4)} n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(4)} n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(4)} n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(4)} n_i^{(4)}} \end{bmatrix} \quad (113)$$

The dimension of matrix $\bar{\bar{Z}}_{m_i n_i}$ is $M_i \times M_i$. The computational steps for $\bar{\bar{Z}}_{m_i n_i} \cdot \bar{b}_{M_i}$ through the UV is $2M_i r_i$, where r_i is the rank of $\bar{\bar{Z}}_{m_i n_i}$. In here we

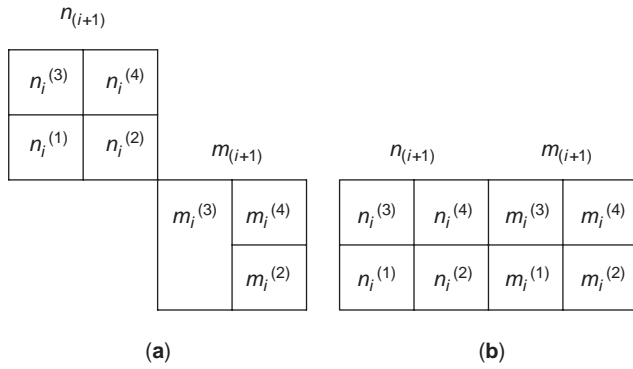

Figure 16. Illustration of block interactions at the i th level.

assume that the rank r_i of $\bar{\bar{Z}}_{m_i n_i}$ is same for all block interactions at the same level. There are 15 nonzero matrices of $\bar{\bar{Z}}_{m_i n_i}$ in the $\bar{\bar{Z}}'_{m_{i+1} n_{i+1}}$. The total computational steps for $\bar{\bar{Z}}'_{m_{i+1} n_{i+1}} \cdot \bar{b}'_{M_{i+1}}$ are $30M_i r_i$.

2. *Sharing One Common Edge.* For the neighboring groups of m_{i+1} and n_{i+1} shown in Fig. 16b, one common edge is shared between them. The impedance matrix that will be calculated is

$$\bar{\bar{Z}}'_{m_{i+1} n_{i+1}} = \begin{bmatrix} \bar{\bar{Z}}_{m_i^{(1)} n_i^{(1)}} & \bar{0}_i & \bar{\bar{Z}}_{m_i^{(1)} n_i^{(3)}} & \bar{0}_i \\ \bar{\bar{Z}}_{m_i^{(2)} n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(2)} n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(2)} n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(2)} n_i^{(4)}} \\ \bar{\bar{Z}}_{m_i^{(3)} n_i^{(1)}} & \bar{0}_i & \bar{\bar{Z}}_{m_i^{(3)} n_i^{(3)}} & \bar{0}_i \\ \bar{\bar{Z}}_{m_i^{(4)} n_i^{(1)}} & \bar{\bar{Z}}_{m_i^{(4)} n_i^{(2)}} & \bar{\bar{Z}}_{m_i^{(4)} n_i^{(3)}} & \bar{\bar{Z}}_{m_i^{(4)} n_i^{(4)}} \end{bmatrix} \quad (114)$$

There are 12 nonzero matrices of $\bar{\bar{Z}}_{m_i n_i}$ in the $\bar{\bar{Z}}'_{m_{i+1} n_{i+1}}$. The total computational steps for $\bar{\bar{Z}}'_{m_{i+1} n_{i+1}} \cdot \bar{b}'_{M_{i+1}}$ are $24M_i r_i$.

3. *Interior Groups.* The interior groups have eight neighbors, four of which share only one common point and four of which share one common edge. There are $(L_{i+1}^{1/2} - 2)^2$ interior groups at the $(i+1)$ th level. Thus the computational steps for the interior groups at the i th level are

$$\begin{aligned} & (L_{i+1}^{1/2} - 2)^2 (4 * 30M_i r_i + 4 * 24M_i r_i) \\ & = 216(L_{i+1}^{1/2} - 2)^2 M_i r_i \end{aligned} \quad (115)$$

4. *Edge Groups.* The edge groups have five neighbors, two of which share only one common point and three of which share one common edge. There are $4(L_{i+1}^{1/2} - 2)$ edge groups at the $(i+1)$ th level. Thus computational steps for the edge groups at the i th level are

$$\begin{aligned} & 4(L_{i+1}^{1/2} - 2)(2 * 30M_i r_i + 3 * 24M_i r_i) \\ & = 528(L_{i+1}^{1/2} - 2)M_i r_i \end{aligned} \quad (116)$$

5. *Corner Groups.* The corner groups have three neighbors. One of them shares only one common point, and two of them share one common edge. There are four corner groups at the $(i+1)$ th level. Thus computational steps for the corner groups at the i th level are

$$4(1 * 30M_i r_i + 2 * 24M_i r_i) = 312M_i r_i \quad (117)$$

6. *Total Computational Steps at i th Level:*

$$\begin{aligned} & 216(L_{i+1}^{1/2} - 2)^2 M_i r_i \\ & + 528(L_{i+1}^{1/2} - 2)M_i r_i + 312M_i r_i \\ & = 2M_i r_i (108L_{i+1} \\ & - 168L_{i+1}^{1/2} + 60) \end{aligned} \quad (118)$$

2.4.5.3. Cost Function for the Multilevel UV Method (nonnear). The total computational steps for nonneighbor block interactions through the multilevel UV decomposition are then

$$\sum_{i=1}^{P-1} 2r_i M_i [108L_{i+1} - 168L_{i+1}^{1/2} + 60] \quad (119)$$

Generally speaking, the rank of each block level will increase with increase in block size. For simplicity, we assume $r_i = \text{constant} = r$ here, and incorporating this r into Eq. (119), we have

$$27rN \log_2 \left(\frac{N}{M_1} \right) + 60rN - 120rM_1 \quad (120)$$

2.4.5.4. Cost Function for Near-Field Interactions in $\bar{\bar{Z}}^{(0)}$. All the near-field interactions are included in the matrix $\bar{\bar{Z}}^{(0)}$, which is computed directly as the original impedance matrix. The block size in $\bar{\bar{Z}}^{(0)}$ is of dimension of $M_1 \times M_1$. The computational steps for the block and block interaction are M_1^2 :

1. The interior group has nine blocks (including self-interaction). There are $(L_1^{1/2} - 2)^2$ interior groups at the first level. Thus computational steps for the interior groups at the first level are $9(L_1^{1/2} - 2)^2 M_1^2$.
2. The edge group has six blocks (including self-interaction). There are $4(L_1^{1/2} - 2)$ edge groups at the first level. Thus computational steps for the edge groups at the first level are $6(L_1^{1/2} - 2)M_1^2$.
3. The corner group has four blocks (including self-interaction). There are four corner groups at the first level. Thus the computational steps for the corner groups at level 1 are $4M_1^2$.

4. The total number of computational steps for near-field interaction is then

$$\begin{aligned} &9(L_1^{1/2} - 2)^2 M_1^2 + 6(L_1^{1/2} - 2)M_1^2 + 4M_1^2 \\ &= (9NM_1 - 12N^{1/2}M_1^{3/2} + 4M_1^2) \end{aligned} \quad (121)$$

2.4.6. Cost Function. The total computational steps for multilevel partitioning UV is the sum of the near and nonnear interactions and is given by

$$\begin{aligned} &27rN \log_2 \frac{N}{M_1} + 60rN \\ &- 120rM_1 + (9NM_1 \\ &- 12N^{1/2}M_1^{3/2} + 4M_1^2) \end{aligned} \quad (122)$$

2.4.7. Numerical Results and Discussion. The numerical simulation results are presented in terms of the bistatic scattering coefficients normalized by the incident power. Simulations are based on Gaussian random rough surfaces with Gaussian correlation functions. The computer used in the simulations is a Pentium single processor of 2.6 GHz with 2 GB memory. We have implemented both the SVD-based QR method and the UV method. First, we will illustrate the rank for the rough surface.

2.4.7.1. Rank Determination for Random Rough Surface.

For the rough-surface scattering problem, the difficulty is that the vertical sizes of the blocks are always changed because of the randomness of surface height. Thus we have to use the coarse-coarse area sampling to determine the rank. In the simulation, 16 (instead of 100) points per square wavelength are used for rank determination. In Table 2, we show the ranks as functions of the horizontal size, vertical size, and distance between two group centers. The vertical size is defined as the maximum height of the surface minus the minimum height of the surface in the same block. The results are obtained through one realization of rough-surface profiles with the given RMS height of 0.5λ and correlation length of 0.707λ .

2.4.7.2. CPU for the UV . In Table 3, we list the CPU time based on the UV method for different number of surface unknowns. The RMS height and correlation

Table 2. Rank Table of Rough Surface^a

$L_x = L_y$ (λ)	Points in Square	Distance (λ)	L_z (λ)	Rank
1.0	64	2.00	1.402	15
2.0	256	4.00	1.824	25(29)
4.0	1,024	8.00	3.219	35(44)

^aFrom one realization of rough surfaces with RMS height of 0.5λ and correlation length of 0.707λ . Surface area is 16×16 square wavelengths, 64 points per square wavelength are used in generating the rough surface. For rank determination, 16 points per square wavelength are taken uniformly from the rough surfaces.

Table 3. CPU for the UV Method

Number of Unknowns	Preprocessing(s)	Conjugate Gradient(s)	Total CPU(s)
4,096	$6^a + 5^b$	14	25
16,384	291 + 54	170	515
65,536	291 + 500	1220	2011

^aCPU for rank determination with coarse-coarse sampling.

^bCPU for building UV matrix.

length of the rough surface for all cases is 0.5λ and 0.707λ , respectively. The preprocessing time of the UV method is time used to find the rank on the basis of coarse-coarse sampling and the time to construct the UV matrix. The CPU time for CG means the CPU time spent for solving the matrix equation after the matrix filling and preprocessing is finished. For the case of 65,536 surface unknowns, it takes about 34 min for the total CPU.

2.4.7.3. Comparison of Bistatic Scattering Coefficients Simulated from Different Methods for Single Realization.

In Fig. 17, we plot the bistatic scattering coefficients as a function of the scattering angles. The RMS height and correlation length are 0.5λ and 0.707λ , respectively. The incidence angle is 20° . The surface lengths are 8×8 wavelengths, and we use 64 points per square wavelength to generate the rough surface. The results simulated from three methods are shown, which are the exact solution of the matrix equation, the solution based on the SVD-based QR method, and the solution of the UV method. All of them are in good agreement.

In Fig. 18a, we plot the same results except that the surface lengths are extended to 16×16 wavelengths. Because of the limitation of computer memory, we cannot

Figure 17. Comparisons of the bistatic scattering coefficients between numerical simulations from three approaches of exact solution, SVD-based QR method, and UV method. The RMS height and correlation length of the rough surface are 0.5λ and 0.707λ , respectively. The surface area is 8×8 squared wavelengths. The incident angle is 20° . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

solve the matrix equation with the exact solution. We only show the simulation results from the SVD-based QR and the *UV* method. The two results are in good agreement.

To demonstrate that the proposed algorithm can be used also for a large number of surface unknowns, we plot the simulation results for the case of RMS height of 0.5λ and correlation length of 0.707λ at an incidence angle of 20° in Fig. 18b. The surface lengths are 16×16 wavelengths, but we use 256 points per square wavelength to sample the rough surface. Again, very good agreement is observed at all scattering angles between the simulation results from the SVD-based QR method and the *UV*.

Figure 18. Comparisons of the bistatic scattering coefficients between the numerical simulations from two approaches of the SVD-based QR method and the *UV* method. The RMS height and correlation length of rough surface are 0.5λ and 0.707λ , respectively. Surface area is 16×16 squared wavelengths, with 64 points per square wavelength (a) and 256 points per square wavelength (b) used in the rough surface sampling. The incident angle is 20° . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

3. APPLICATIONS IN MICROWAVE REMOTE SENSING

Soil surface roughness is a major problem in land surface sensing. However, effects of vegetation cover are equally, if not more, important since very few land surfaces are not vegetation-covered. This article addresses roughness effects. We include both volume and surface scattering by considering a volume scattering layer above the rough surface; this is done using the NMM3D rough-surface results as a boundary condition for radiative transfer theory [33]. The model will be applied to vegetation effects over rough soil surface in a future paper.

Measurements of soil and ocean surface thermal emission at microwave frequency can provide the means to predict soil moisture and ocean wind velocity. In active microwave remote sensing, the radar backscattering response of soil surface at microwave frequencies is measured to evaluate the soil moisture and surface roughness parameters. The study of frequency, polarimetric, and angular dependence of the backscattering coefficients of rough surface is essential for retrieving soil moisture. In this section, we illustrate the numerical results from the NMM3D in active and passive remote sensing. In Section 3.1, NMM3D applications in active remote sensing will be described; in Section 3.2, we describe applications in passive remote sensing.

3.1. Application of NMM3D with Pulse Basis Function and Point-Matching Method in Active Remote Sensing

The backscattering coefficients of wet soil surfaces are studied with the three-dimensional Monte Carlo simulations using the Stratton–Chu formulation, pulse basis functions, and point matching. The method was described earlier in this article. The simulation results are compared with the experimental measurements for backscattering coefficients at L and C frequency bands and at multi-incidence angles. Fairly good agreements are obtained for the same physical surface roughness parameters at both frequency bands. The Monte Carlo simulation results of bistatic scattering from random rough surface in this section are averaged over 30 realizations.

The experimental data are taken from Oh et al. [34]. We choose these data because (1) they cover a wide range of surface roughness from smooth to very rough, (2) the RMS heights and correlation lengths of each field are given, (3) measurements are made for both dry and wet soils, and (4) the measurements are performed at three frequency bands of L, C, and X and incidence angles of 10 – 70° . There are four total surface fields used in the measurements. Fields 1 and 2 have similar surface roughness parameters and soil moisture levels, and they are very smooth. Field 3 is rough, and the field 4 is very rough. We will show the simulation results and their comparisons with the measurements for fields 1 and 3. For convenience, we list the measured rough surface parameters and relative permittivities of soil given by Oh et al. [34] and in Table 4. It was reported that these two rough-surface profiles are closer to an exponential correlation function

Table 4. Measured Surface Roughness Parameters and Relative Permittivities of Soil

Field	RMS Height (cm)	Correlation Length (cm)	Relative Permittivity			
			Wet Soil		Dry Soil	
			At 1.5 GHz	At 4.75 GHz	At 1.5 GHz	At 4.75 GHz
1	0.4	8.4	15.57 + i3.71	15.42 + i2.15	7.99 + i2.02	8.77 + i1.04
3	1.12	8.4	15.34 + i3.66	15.23 + i2.12	7.70 + i1.95	8.50 + i1.00

[34], so the numerical simulations of rough-surface scattering are conducted for the Gaussian rough surface with an exponential correlation function. The exponential correlation function is given by

$$C(x,y) = h^2 \exp - \frac{\sqrt{x^2 + y^2}}{l} \tag{123}$$

and its corresponding spectrum is

$$W(k) = \frac{h^2 l^2}{2\pi [1 + (kl)^2]^{3/2}} \tag{124}$$

where parameter h is RMS height and l is correlation length.

3.1.1. Comparison of Backscattering Coefficients for Wet and Dry Soils for Rough Surface of Field 3. In Figs. 19 and 20, we illustrate the results respectively for wet and dry soils. We show the backscattering coefficients obtained from the Monte Carlo simulations as a function of incidence angles and the comparisons with the experimental measurements for field 3. The surface roughness parameters and permittivities of soil are taken from the measurements given by Oh et al. [34]. The RMS height and correlation length of the measured soil surface are 1.12 cm and 8.4 cm, respectively. The relative permittivities of wet and dry soils are $15.34 + i3.66$ and $7.70 + i1.95$ at L band and $15.23 + i2.12$ and $8.50 + i1.0$ at C band. Figure 19 is simulated from wet-soil conditions and Fig. 20, from dry-soil conditions. Figures 19a and 20a

are for L band and Figs. 19b and 20b, for C band. Figure 20a gives the best match between the simulations and measurements; other figures (Figs. 19a,b, 20b) also show the fairly good agreement between the simulations and the measurements.

3.1.2. Comparison of Backscattering Coefficients for Wet and Dry Soils for Slightly Rough Surface of Field 1. In Figs. 21 and 22, we illustrate the results respectively for wet and dry soils of field 1. The field 1 is smoother than the field 3. The physical RMS height and correlation length are only 0.4 and 8.4 cm, respectively. There are also two sets of soil moisture conditions, wet and dry, similar to those for field 3. The relative permittivities of wet and dry soils are $15.57 + i3.71$ and $7.99 + i2.02$ at L band and 15.42

+ $i2.15$, and $8.77 + i1.04$ at C band. Figure 21 shows numerical simulation results and their comparisons with the measurements for wet soil, Fig. 22 is for dry soil surface. Figures 21a and 22a are results at C band and Figs. 21b and 22b, at L band. For C-band results, both vertical and horizontal polarizations are in good agreement with the measurements at both wet and dry soil conditions. However, for L-band results, only those of vertical polarization are comparable with the experimental measurements at the full range of incident angles. For the horizontal polarization, the simulation results are consistent with the measurements at small incident angles, while at large incidence angle, some of the backscattering coefficients of horizontal polarization exceed those of vertical polarization. This is because a higher number of realizations is needed in the numerical simulations for the horizontal polarization to converge.

However, a major limitation of the simulations listed in Table 5 is that the surface has to be much larger than the wavelength so that the tapered wave can be used to approximate a plane wave. With limited computer resources, the present surface area is 8×8 wavelengths. With a finite surface area, the incident wave is not a plane wave in a single direction. It actually has an angular spectrum about the direction with the angular width roughly equal to the wavelength divided by the surface length. This means an incident angle of 40° actually has an angular spread of $\sim 40^\circ$. Thus the simulations will not be able to simulate the true results if there are large angular variations of backscattering. We have put the results of backscattering in tabulated form in Table 5. The table shows that the simulations do reveal dependence on soil moisture, although not as drastically as for the VV polarization in the experimental measurements.

3.2. Application in Passive Remote Sensing

In the NMM3D of rough-surface scattering, we solve Maxwell equations in three dimensions to calculate emis-

sivities for applications in passive microwave remote sensing of soil and ocean surfaces.

3.2.1. Application of NMM with Pulse Basis Function and Point Matching Method. In this section, we illustrate the numerical simulation results of emissivities of wet soils with a 2D rough surface (3D problem). Simulations are based on Gaussian random rough surfaces with Gaussian correlation functions. In the numerical results, the surface area used is 64 square wavelengths. We use 64 points per square wavelength as a coarse grid and 256 points per square wavelength as a dense grid, which leads to totally 98,304 surface unknowns. In our experiences of simulations for 1D lossy dielectric rough surfaces [6] within the range of relative permittivity, we found that 16 points per wavelength (256 points per square wavelength) can give accurate results for the emissivity for each single realization. For rough surfaces with an RMS height of 0.3λ , correlation length of 1.0λ , and relative permittivity of 17, the total CPUs for a single dense grid with SMCG are ~ 45 h for a TE wave and 49 h for a TM wave, respectively, on a DEC 3000/700 workstation. By using the PBTG with SMCG, the CPUs are about 8.5 h for TE and 9.0 h for TM, respectively, for the same case. We have shown that the SMCG is with the computational complexity of $O(N \log(N))$ in Refs. 35 and 36. The permittivities of wet soil by weight of the soil moisture at L band (1.4 GHz) [37] are listed in Table 6. The relative permittivity values of soil moisture in volumetric water content (cm³/cm³) [38,39] for L and C bands are given in Table 7. The C band is at 5 GHz. All cases were computed at an observation angle of 50°. In Tables 8–12, emissivities calculated are tabulated for interested readers. We also illustrate the brightness temperatures in Figs. 23 and 24. The physical temperature is taken as 300 K for all cases.

The brightness temperatures in passive microwave remote sensing are measured at L and C bands; thus it is useful to compare the brightness temperatures of soils at L and C bands using the same physical parameters of

Table 12. Calculated Emissivities^a

^aParameters: RMS height = 0.73 cm, correlation length = 35.5 cm, observation angle = 50°; L band— $F = 1.4$ GHz, C Band— $F = 5.0$ GHz.

(a)

(b)

Figure 23. Variation of brightness temperatures with the soil moistures in volumetric water content at L and C bands using the permittivities in Table 7. The physical rough surface parameters are RMS height of 2.45 cm and correlation length of 8.0 cm (a) and RMS height of 0.73 cm and correlation length of 3.5 cm (b). The observation angle is 50°. The solid and dashed lines represent horizontal and vertical polarizations, respectively, at L band; circles and stars indicate horizontal and vertical polarizations, respectively, at C band.

roughness and soil moisture. In Fig. 23a, we plot the brightness temperatures as a function of soil moisture in volumetric water content at both L and C bands. The corresponding permittivities are taken from Table 7. The physical parameters are that the RMS height is 2.45 cm and correlation length is 8.0 cm. We can see that the brightness temperatures are higher at C band than at L band for horizontal polarization and lower at C band than at L band for vertical polarization. Since the permittivities between L and C bands are comparable, the results indicate that roughness has a greater effect on C band

Figure 24. Brightness temperature of Monte Carlo simulations averaged over five realizations as a function of correlation length and comparisons with those from the second-order small-perturbation method, and from the PBTG/pulse. The case is for RMS height 0.1λ, relative permittivity 17 + 2i, and physical temperature of 283 K at observation angle 50°. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 25. Comparison of the bistatic scattering coefficients between the SMCG/RWG and the SMCG/pulse for the TE wave incidence of copolarization. The case is for RMS height 0.1λ, correlation length of 1.0λ, and relative permittivity 17 + 2i at observation angle 50°. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

than at L band. In Fig. 23b, the results are shown with different rough-surface parameters. The RMS height is 0.73 cm, and the correlation length is 3.5 cm in this figure. Comparing the results of Figs. 23a and 23b indicates that as roughness decreases, the brightness temperatures of L and C bands are closer to each other.

3.2.2. With RWG Basis Function and Galerkin Method. In this section, we illustrate the numerical simulation

Figure 26. The profiles of surface side views by exponential and Gaussian correlation functions. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

results using the RWG basis functions and SMCG. Three types of random rough surfaces are studied: (1) Gaussian rough surfaces with Gaussian correlation function, (2) the exponential correlation function, and (3) the ocean spectrum. Surface area is 8×8 square wavelengths. As many as 96,266 current basis functions are used. Results are computed using parallel computations with the near interaction set at 2.1λ . We use $T = 283$ K as the physical temperature. Besides plotting the results, we also tabulate the results of emissivities so that the accuracies can be ascertained and to facilitate future comparisons for readers. Energy conservation checks are given by adding $a(\theta_i)$ and $r(\theta_i)$. We have gained extensive experience in our course of numerical simulations. On one hand, passive remote sensing requires great accuracy in energy conservation, which is not required in active remote sensing. On the other hand, passive remote sensing is easier than active remote sensing in other ways. For example, in active remote sensing, the results fluctuate from realization to realization because of speckle. However, in passive remote sensing, the emissivity requires an integration of bistatic scattering cross sections over solid angles over the hemisphere. The integration smooths out the fluctuations that exist in the bistatic coefficients. Our experience indicates that passive remote sensing requires for fewer realizations than does active remote sensing. Tests of convergence with realizations have also been done in the past. Five realizations were used for the results reported in this section. Checks have been used for selected cases using five or more realizations.

In the past, extensive studies have also been done with sample size varying from $8\lambda \times 8\lambda$ to $16\lambda \times 16\lambda$, and so on. The physical meaning is that the coherent interaction of waves is limited in extent. Thus if coherent interaction is limited to 8×8 square wavelengths, then incoherent

superposition can be exercised beyond 8×8 wavelengths. Numerical solutions of Maxwell equations need to be done for an area of 8×8 square wavelengths. Because of our previous experience in varying sample sizes, an $8\lambda \times 8\lambda$ area was used in this section. The surface length of 8λ is much larger than the correlation lengths.

The results of emissivities are tabulated. Energy conservation test for each case is given. Thus the accuracy of the emissivities values should be judged in relation to the test of energy conservation.

3.2.2.1. Emissivities and Bistatic Scattering Cross Sections of Gaussian Surfaces with Gaussian Correlation Function.

We compare the brightness temperature results of rough surfaces with Gaussian correlation function using three methods: SMCG with pulse basis functions (SMCG/pulse), SMCG with RWG basis functions (SMCG/RWG), and SPM. By *SPM*, we mean the common second-order SPM result of emissivity, which is computing the coherent field to second order and incoherent field to first order [40]. In Fig. 24, the brightness temperatures are shown as functions of correlation length from 0.3λ to 1.2λ with a fixed value of RMS height at 0.1λ , for both TE and TM waves. The observation angle is 50° , and the relative permittivity

Table 13. Measured Surface Roughness Parameters and Relative Permittivities of Wet Soil

The brightness temperature of Monte Carlo simulation averaged over five realizations as a function of observation angles and comparisons with those from the second-order small-perturbation method for field III with RMS height 1.12 cm, correlation length 8.4 cm in L band (a) and in C band (b). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

is $17 + i2.0$. It is shown that the results for the three approaches agree very well for the case of TM wave incidence. The exception for the TM case is the deviation from the numerical solutions by SPM at a correlation length of 0.3λ . In the case of TE wave incidence, SMCG/pulse gives lower results than does SMCG/RWG by about 5 K for a large RMS slope. SPM gives good comparison for small slopes but becomes inaccurate by as much as 20 K for large slopes.

In Fig. 25, the bistatic scattering coefficients of the same surfaces are compared between the SMCG/RWG and SMCG/pulse for the TE wave incidence at the incident angle of 50° . The RMS height and correlation length of

Gaussian surface are 0.1λ and 1.0λ , and the relative permittivity is $17 + 2i$. The results are for a single realization. The comparison in Fig. 25 shows good agreement between two approaches. This shows that pulse basis functions can give accurate results for bistatic scattering coefficients but less accurate results for passive remote sensing. We plot the surface profiles with the exponential correlation function, Gaussian correlation function, and ocean spectrum in Figs. 26 and 27. Figure 26 shows the fine irregular features that exist in exponential correlation function. This is the cause of the large emissivity differences between Gaussian correlation function and exponential correlation function. Figure 27 shows those new features of irregularity in the roughness profiles when the upper limit of ocean spectrum is increased. It is apparent that surfaces with exponential correlation function and ocean spectrum can have fine-scale features with large RMS slope. Although the Gaussian correlation function is inappropriate for soil surface, soil surface characterization remains an important problem. Exponential correlation function is just one better choice than the Gaussian correlation function. It is to be noted that the exponential correlation function does not have RMS slopes if the roughness spectrum upper limit is set at infinity. However, in actual implementation in this section, 16 points per wavelength is used to generate the roughness profile. This corresponds to setting an upper limit on the roughness spectrum.

Table 18. Comparison of Numerical Results (NMM) with Experimental Brightness Temperature Measurements (Surface RMS Height $\sigma = 2.6$ cm)

Dataset	Correlation Length (cm)	Relative Permittivity	Physical Temperature (K)	Flat Surface T_B (K)	NMM T_B (K)	Experiment

3.2.2.2. Soil Surfaces. The experimental results are from Oh et al. [34]. The physical surface parameters, based on the exponential correlation function, are the same for both L and C bands. Field I is smooth, and field III is rough. The measured rough surface parameters and relative permittivities of wet soil are listed in Table 13. The upper limits of wavenumber in the spectrum are 3.55 and 11.24 cm^{-1} , respectively, in L and C bands. The numerical results are presented with various incident angles and compared with those from SPM.

In Figs. 28a and 28b, we illustrate the brightness temperature results in L and C bands, respectively, for the smooth field I with RMS height 0.4 cm and correlation length 8.4 cm. The dashed-dotted curves are results of calculations from the Fresnel equations. It is shown that surface roughness increases the brightness temperature over flat surfaces for both horizontal and vertical polarizations. The difference of brightness temperature between rough surface and flat surface is larger in C band than in L band; this can be observed from both numerical results and SPM. In this case, the results from SPM are comparable to the numerical results. The numerical values of emissivities of field I are also tabulated in Tables 14 and 15, respectively, for L and C bands.

As the surface slope increases, the SPM cannot give the correct results of brightness temperature. We can see that from results for field III, which has RMS height of 1.12 cm and correlation length of 8.4 cm. In Figs. 29a and 29b, the brightness temperature results are illustrated for L and C bands, respectively. In this case, the SPM results are much higher than the numerical results. This means that the SPM is used beyond the limit of validity. We also see that the deviation of SPM results from numerical results is worse in C band than in L band. The numerical values of emissivities of field III are also tabulated in Tables 16 and 17, respectively, for L and C bands.

3.2.2.2.1. Comparison with Experimental Data. Numerical results are compared with measurements of soil surfaces [41]. The measurements were conducted at Texas

A&M University [42,43] for 16 profiles of soil moisture and temperatures. The brightness temperatures were measured at nadir incidence of $\lambda = 21$ cm. Ground truth measurements of soil moisture and temperature were taken at several depths down to 15 cm. The standard deviation of height σ was also measured and was 2.6 cm. The permittivities are calculated by using the mixing formula at a wavelength of 21 cm [44], based on soil moisture measurements in each layer. Then, they are averaged from the soil depth of 0–2 cm. The weighted physical temperature, based on measurements, was used for each profile. Since there was no measurement of the horizontal correlation length, the correlation length within a reasonable range was chosen to match the data. In Table 18 we list the results for 4 of the 16 profiles; these 4 cases are with large permittivities.

In performing numerical simulations, the exponential correlation function with an upper wavenumber limit of 3.38/cm is employed to generate rough surfaces. The correlation length l is the same as that used in Ref. 41. As shown in Table 18, the numerical results are in agreement with the experiments data. The difference between them is no more than 3 K. Since the brightness temperature of rough surfaces with high permittivities can be more than 40 K higher than that of smooth surfaces, the discrepancy of 3 K between numerical results and measurements is acceptable.

3.2.3. Ocean Surfaces. To describe the wind-induced ocean surfaces, we use the semiempirical Durden–Vesecky spectrum [45], which was found to predict much of the observed dependence of the radar cross section on frequency, polarization, angle of incidence, and wind velocity [46–48]. In the model, a_0 is the absolute magnitude of the spectrum. Since a parametric analysis has been carried out showing that $a_0 = 0.008$ gives the best agreement with experiment data [46], a_0 of 0.008 is used for calculations in this section. The wavenumber cutoffs k_L and k_U are the key parameters in the spectrum, corresponding to the low and high frequency limits of the ocean spectrum, respectively. The quantities k_L and k_U can be selected to control the RMS height and fine-scale structures [46]. The physical temperature is 283 K. The permittivities of the seawater at 19 GHz are $28.9541 + i36.8340$.

For the sake of illustration, we show the results for hypothetical situations of windspeed 10 m/s and 20 m/s. It is to be noted that 20 m/s is closer to gale-force winds under hurricane conditions. With such high winds the ocean surface tends to have white capping and may not be simply represented by an ocean spectrum. In Fig. 27, the

ocean surfaces are generated at a windspeed 20 m/s with various k_U values, while k_L is equal to 100 rad/m. For larger values of k_U , there are more fine-scale structures. The corresponding results of emissivities and brightness temperature at incident angle of 50° are listed in Table 19, where k_U is chosen to be 400 rad/m, 1000 rad/m, and 4000 rad/m with fixed $k_L = 100$ rad/m. The roughness parameters k_σ for these three cases were 0.4263, 0.4415, and 0.4715, respectively. It is shown that the difference in brightness temperature between rough and flat surfaces increases with increase in k_U . This means that fine-scale structure plays an important role in calculating emissivities. Figure 30a illustrates the case for windspeed 10 m/s with corresponding $k_\sigma = 0.3156$, $k_L = 100$ rad/m, and $k_U = 4000$ rad/m. Brightness temperature values are also tabulated in Table 20. We can see that the numerical results agree well with the results from SPM for both horizontal and vertical polarizations. For windspeed of 20 m/s with $k_\sigma = 0.4715$, the brightness temperatures are plotted in Fig. 30b and listed in Table 21. The SPM results are in good agreement with numerical results for horizontal polarization, but are higher for vertical polarization.

SATELLITE ANTENNAS

R. B. DYBDAL
The Aerospace Corporation

Antennas for satellite systems have developed and increased in performance since the 1950s and greatly contribute to satellite capabilities. The preponderance of this antenna development has been for communication systems, and other development has been for remote sensing applications. Early satellite systems provided not only proof of concept but also a useful initial operating capability. The payload constraints of early satellites together with primitive attitude control systems limited antennas to simple narrow-bandwidth, broad-coverage designs, a far cry from today's sophisticated antenna systems with substantial throughput capabilities. Similarly, early users needed large ground terminal antennas to achieve the required link performance, and terrestrial links were provided to other system users. Today, systems are being developed to communicate to individual users with handheld terminals [1].

Both spaceborne and user antenna systems have requirements and development issues that are unique to satellite systems. In addition, satellite system antennas have testing requirements and objectives that differ from other antenna applications. Antenna technology, requirements and development issues, and test methods and objectives are described.

1. SPACE SEGMENT ANTENNAS

Spaceborne antennas have unique requirements and development issues. Like all satellite subsystems, much design attention is paid to three important parameters: weight, power, and volume. Likewise, reliability is a key requirement because an anticipated lifetime exceeding 10 years is expected without the possibility of repair or servicing. Spaceborne antenna designs must be sufficiently rugged to survive the rigors of launch environments. In addition to these physical requirements, the RF requirements differ from common antenna specifications. Spaceborne antennas provide performance over prescribed coverage areas containing the user segment; the pattern of the antenna projected on Earth's surface is referred to as its *footprint*. Antenna systems are specified by their minimum performance within the specified coverage area rather than their peak performance levels. This discussion uses different coverage area requirements to describe space segment antennas.

1.1. Earth Coverage Antennas

The simplest spaceborne antenna design is one that matches its coverage area with the available field of view from the satellite. These antennas are generally re-

ferred to as Earth coverage designs, and their beamwidth subtends the field of view plus the angular uncertainties of the satellite's attitude stability. Early satellite attitude control systems had both limited attitude control and uncertain reliability, so simple antenna designs with broad coverage were used. However, today's attitude control systems provide stabilities on the order of one-tenth of a degree, so that Earth coverage antennas can be essentially matched to the field of view. Thus, for geosynchronous satellites, an antenna with an 18° beamwidth is required; lower altitude LEO and MEO satellites require a correspondingly larger beamwidth for their larger field of view.

A typical Earth coverage design for geosynchronous altitudes is a corrugated horn antenna [2], which can be easily constructed and has a rotationally symmetric, low-sidelobe pattern for an efficient fit to the design coverage area. These horns are typically wide-flare designs chosen to maintain the same beamwidth and coverage over a wide bandwidth. Thus, a single horn together with a diplexer to isolate the receiver and transmitter can be used for both uplink and downlink frequencies. A design alternative at higher EHF frequencies is separate uplink and downlink horn antennas because these horns are very small and lightweight. Since the uplink and downlink frequencies are widely separated at EHF, the transmit diplexing filter is inherent because the transmit waveguide is cutoff at the receive frequencies and a modest physical separation may provide adequate isolation to meet the receive diplexing filter requirement of avoiding receiver saturation at the transmit frequency. Thus, the weight of a second horn antenna is offset because a diplexer is not required and performance is not degraded by the insertion loss of the diplexer.

At lower LEO and MEO altitudes, the broader field of view requirements can be met with an open-ended waveguide surrounded by corrugations to produce low sidelobes and beam symmetry. At these lower altitudes, the range differences between the subsatellite point and the edge of the earth become more significant and thus users at the edge of the coverage experience less sensitivity from the satellite antenna. In these cases, a shaped beam that provides more gain at the edge of Earth than the subsatellite point may be desired. Such shaped-beam antennas can be realized by an array of horns with properly selected excitation to meet the beamshaping requirement. However, such shaped-beam designs have more design complexity than a simple horn, and weight and volume are important satellite parameters. A well-known example of shaped beam designs is the array antenna used by the GPS satellites to broadcast navigational information. The GPS satellites are in a 12-h orbit, and the antenna array [3] is designed to deliver a uniform flux density to users within the earth's field of view.

1.2. Tracking, Telemetry, and Command Antennas

Every satellite requires a TT&C (tracking, telemetry, and command) subsystem to assist in determining the

satellite's orbital position, reporting the satellite's health and status to the ground-based satellite control segment, and providing a means to command and validate changes to the satellite's operation. The TT&C antennas have two distinct coverage requirements. One requirement is to provide complete spatial coverage during launch operations so that corrective commands or, in the worst case, a command for destruction can be delivered irrespective of the satellite's orientation. The second requirement is to provide coverage over Earth's field of view once on-orbit so that different terminals within the ground-control network can access the satellite. TT&C antennas must be both simple in design and highly reliable since the control of satellite operation is critical.

The broad coverage requirements of the TT&C antennas provide several design challenges. Aside from the impossibility of an ideal isotropic antenna with uniform sensitivity in all directions, the presence of the spacecraft blocks the antenna coverage. As a result, two antennas that strive for hemispheric coverage are used with one hemisphere being Earth facing and the other hemisphere facing away from Earth. During launch operations, the antenna having the higher signal strength is used and once the satellite is stable in its orbital position, the Earth facing antenna is used. In principle, somewhat better on-orbit performance could be achieved with an Earth coverage antenna, but the additional antenna and required switching increase weight and volume and add switch reliability risks. Since TT&C data rate requirements are low, ample link performance is readily achieved by ground-based control terminals.

Achieving and quantifying the performance of hemispheric coverage antenna elements remain challenges. Satellites have irregular shapes and appendages such as solar arrays whose positions vary to *sun-track* and maximize their power output. The hemispheric coverage required by TT&C antennas is degraded by blockage and diffraction effects from the satellite structure. Controlling wide-angle sidelobes and backlobes of a simple, electrically and physically small antenna is difficult to do but is needed to minimize antenna interactions with satellite structure. Extending the antenna from the spacecraft to reduce interactions results in deployment risk. Analytic projections of the antenna coverage in the presence of the spacecraft are challenged by the design complexity and the wide variety of satellite designs. Measurements of the antenna performance have all the problems of testing broad coverage antenna designs. Certainly, measurements using flight hardware not only have practical limitations such as the inability to deploy solar arrays but also moving and positioning flight hardware for the measurements have unacceptable risks. Generally, these problems are addressed by a combination of selecting a satellite antenna location with a clear field of view, analytic estimates of the effects of nearby satellite structure, scale model measurements, and ample margin in the ground segment.

Typically, TT&C systems operate at the lower microwave frequencies. Generally, a single uplink/downlink antenna is used to minimize weight and volume and avoid mutual blockage. The difference between uplink and

downlink frequencies often spans a significant percentage bandwidth. These considerations typically result in selecting a frequency independent antenna design such as a spiral to achieve the broad coverage requirements.

1.3. Spot Coverage Antennas

Spot coverage antennas service only a portion of the available field of view. These antenna designs provide higher gain levels than Earth coverage antennas because of their narrower beamwidths. This higher gain performance may be traded for higher data rate transfer, reduced user antenna dimensions, or increased link margin. In addition, spot beam antenna designs can provide coverage that is confined to geographic areas [4] and avoid worldwide licensing requirements. Thus, these designs are widely used to serve national or regional requirements. Several different design implementations have been developed to satisfy these needs.

The easiest design solution is to select a sufficiently large antenna so that its beamwidth matches the required coverage area and any variations caused by attitude uncertainty. Such a design might consist of a reflector whose size is selected to meet the desired beamwidth and a single feed horn, a simple design approach. In such a design, any variations in coverage requirements during the satellite lifetime can be accomplished by mechanically repositioning the antenna to serve a different coverage area. Such a capability is commonly used in military satellites so that coverage to different geographic areas within the field of view can be provided to service changing political needs.

A wide variety of designs has been developed to service more irregular coverage areas. These coverage areas may be bounded by geopolitical borders, different time zones, and other delineations. A standard means of providing such coverage is to synthesize the coverage area by combining different beams generated by a cluster of feed elements in the focal region of a reflector antenna. Each feed has its own pointing direction, and the collection of beams subtends the desired coverage area. The individual beams being combined are required to have a common phase center so that grating lobes do not degrade coverage characteristics. Thus, the collection of beams is generated by a common aperture. The arrangement of individual beams and their corresponding feed elements mimic the desired coverage area. The reflector antenna size is much larger than that needed to provide coverage over the composite area. When active devices are used in the feed elements prior to combining, design attention must be paid to their amplitude and phase tracking. The precision of fitting to the design coverage area can be increased by using a larger number of beams at the expense of design complexity and a larger overall aperture size.

In addition to the complexity of the additional number of feeds and the larger reflector required by this approach, the design complexity also increases because the individual feeds are no longer located at the focal point of the reflector but instead are distributed within the focal region. The off-axis feeds are not ideally focused, and suffer gain loss and pattern degradation. These problems are shared with multiple beam designs and, as will be

discussed, result in dual reflector designs to limit beam degradation when a large number of beam are combined.

Another design approach has developed to provide coverage over irregular areas. This design uses a single feed, and the irregular coverage area is generated by deforming the reflector surface [5]. Synthesis procedures have been developed [6] to specify the required deformation of the reflector surface. This design approach has the advantage of a simple feed design rather than a cluster of feed elements and combining, but requires developing and maintaining controlled reflector surface distortion. If the coverage requirements change, a new surface deformation is required. This approach also precludes changing the coverage areas on-orbit by using beam switching techniques.

A final design alternative for spot coverage is an adaptive uplink antenna. The pattern within the coverage area is adaptively controlled to service desired users within the design coverage area to the extent practical while reducing received interference by forming pattern nulls in the direction of interference sources. This capability is principally required for military systems whose users desire protection from intentional interference. When interference is not present, a quiescent pattern provides coverage over the design region. When interference is initiated, the antenna responds under adaptive control to form pattern nulls.

Adaptive antennas require a means to distinguish desired signals from interference, to detect the initiation of interference, and to determine a set of complex weighting values that combine antenna elements to satisfy an optimization criteria. Several different discriminates have been employed to distinguish desired signals from interference: spectral characteristics, power levels, and signal arrival directions. When systems also use spread spectrum modulation for additional interference protection, the properties of the spread-spectrum codes provide a basis to distinguish interference from desired signals. Interference initiation can be detected by increased received power levels that do not have spread spectrum modulation components; correlation processes are normally used to indicate interference power. An optimization criterion such as maximum SINR (signal-to-interference-plus noise ratio) is used to establish complex weighting coefficients to combine antenna elements. Generally, a recursion relation based on measured correlation values and the optimization criteria is derived to form a control algorithm. The combination of the complex weighted antenna elements produces a pattern containing null in the direction of interference, and equivalently, the received interference power is minimized.

Two types of antenna designs have been investigated for these adaptive systems [7,8]. One approach uses a thinned array where the elements are combined to generate pattern nulls when interference is present and a set of weighting coefficients for interference-free cases. The potential advantage of this approach is that the resolution between desired users and interference is enhanced by increasing the array element spacing. However, the separation between array elements produces additional nulls within the coverage area referred to as grating nulls that

degrade coverage characteristics. The separation of the array elements results in the inherent frequency scanning properties of an array creating dispersion that limits cancellation performance over the required bandwidth. In addition, the coverage of the array elements generally extends beyond the desired coverage area, resulting in susceptibility to interference beyond the coverage area. Finally, the thinned array design generally results in reduced G/T performance within the coverage area.

The second design approach uses an offset reflector with a cluster of feeds in the focal region. In interference-free conditions, a set of quiescent weighting values for the individual feeds maintains performance over the design coverage area. The initiation of interference produces correlation products associated with the interference that are used to derive complex weighting values. The advantage of this design approach is that all beams generated by the feed cluster have the same phase center location so that the dispersion inherent in array designs is not present and broad bandwidth cancellation performance is achieved. The resolution between interference and desired signals is limited by the beamwidth of the individual beams. This resolution depends on the amount of G/T margin that the user can sacrifice and the interference source's location on the earth, as illustrated in Fig. 1. A comparison between the performance of a thinned array design and a multiple feed design is presented in Fig. 2. The grating nulls are apparent in the thinned array contours, which reduces the coverage available to users.

Several performance measures are used with adaptive antenna designs. The threshold SNIR establishes a bound for acceptable communication performance that can be measured using BER (bit error rate) values by injecting both desired signals and residual interference into the receiver. The null depth performance and its variation over the required bandwidth as measured between the quiescent pattern and the pattern after adaption are sometimes used to judge nulling performance. The amount of time the adaptive process takes to convert the quiescent pattern to the nulled pattern is referred to as the convergence time and measures the transient performance of the system. Finally, for this uplink application, the amount of the design coverage area that exceeds the threshold SNIR value is another measure for space segment antennas. These performance measures depend on the number of interference sources and their locations, and their power levels and spectral characteristics; this description of the interference is referred to as a scenario. Adaptive systems are commonly developed using a simulation that varies the scenario parameters on a Monte Carlo basis to provide statistical measures of the performance parameters. The simulation is then validated by using hardware measurements on a limited number of scenario cases in order to avoid the impractical amount of time required to test on a Monte Carlo basis.

1.4. Multiple-Beam Antennas

Multiple-beam antenna systems (MBA) [9] greatly increase the on-orbit satellite capabilities. These antennas simultaneously produce more than one antenna beam

Figure 1. Adaptive antenna resolution (after Ref. 8).

from a single aperture. For space applications, a single aperture is a significant savings in space required on the satellite and the overall weight compared with multiple aperture alternatives. When the coverage area is subdivided by different beams, the gain available to users increases, permitting higher data rates or reduced user terminal performance. A further advantage of multiple beam antennas is that beams directed to different geographic locations are isolated by their spatial separation. Thus, the same frequency bands can be used simultaneously at both beam locations increasing the information that can be transferred by a single satellite. These advantages are the reasons for the wide application of multiple-beam antennas.

The antenna design has several different requirements. Independent beams must be efficiently generated with high pattern fidelity and minimal gain degradation over the required field of view. Isolation between different beams must be maintained so that signals using the same frequency subband are not degraded by cochannel interference. Beamforming networks that combine signals from the antenna beam outputs to and from the satellite transponder must be developed. The transponder must provide a means to map the uplink information in each beam position to the downlink beam positions.

One design issue is to efficiently generate independent beams with high pattern fidelity over the required field of view. When optical designs (i.e., reflector and lens antennas) are used, each feed produces an independent beam in a different direction, but not all of the feeds are ideally focused. As a consequence, some of the feeds experience phase distortions that degrade the pattern characteristics and reduce the gain compared to the feeds that are well focused [10]. Several different techniques in the design of the optics are used to minimize the degradation. One technique is to select a long f/D ratio to reduce off-axis phase distortions. The popularity of dual-reflector designs in these applications results in part from their increase of

the effective f/D , and careful attention to the optics can produce excellent results [11,12]. The dual-reflector designs in an offset configuration also provide the ability to achieve very good polarization purity. Other techniques have been applied to selecting lens surface contours [13].

In addition to achieving good pattern and gain performance over the required field of view for an individual feed, another set of design challenges exists with the cluster of feeds. The problem is a conflict among beam isolation, the crossover level between adjacent beams, the sidelobe levels of the beams, and the antenna efficiency. On the one hand, low sidelobe patterns are desired to enhance the beam isolation, which requires the feed to produce an amplitude taper over the aperture, resulting in a relatively large feed. The physical interference between large adjacent feeds results in a relatively low tangential crossover level (the pattern level relative to the beam boresight at an equal distance between beam centers) between beams. The consequence of the low crossover level is that the minimum gain within the field of view is reduced. On the other hand, high beam crossover levels result a higher minimum gain level within the field of view, but beam patterns with high sidelobes having reduced beam isolation. High beam crossover levels also result in beam coupling loss [14], which degrades antenna efficiency.

These conflicts have resulted in several different design approaches. One technique is to couple signal samples from adjacent feed elements [15] to achieve high crossover levels, low sidelobe patterns, and reasonable antenna efficiency. Another technique [16] uses a underilluminated aperture with the feeds displaced from the focal region. This approach requires a somewhat larger reflector than in the focused case, but at EHF frequencies where compact antennas result from the small wavelength, the size increase may be unimportant.

The required isolation between beams depends on the susceptibility of the signal modulation to cochannel interference and the dynamic range of the system users. Thus,

(a) Multiple beam contours

(b) Thinned array contours

Figure 2. Comparison of multiple-beam antennas and thinned array performance (after Ref. 8).

the required isolation level must be derived for each application. Isolation between adjacent beams can be achieved in two ways. One way, referred to as frequency reuse, divides the allotted bandwidth into subbands. A frequency plan is devised to adequately separate the beams using the same subband to meet the isolation requirement. Since the same frequency subband is simultaneously used in different beam positions, the plan is referred to as a frequency reuse plan.

A second way of increasing isolation referred to as polarization reuse uses orthogonal polarizations together with frequency subbands in applications requiring high isolation. Orthogonal polarization is also used in applications demanding as much capacity as possible because the same beam position can transfer twice the information.

These techniques require antennas with high polarization purity; a typical requirement is to suppress cross polarization levels at least 27 dB lower than the principal polarization. Generally, satellite systems use circular polarization so that the user does not have to align to a linear polarization. However, inclement weather can cause coupling between polarizations, reducing the isolation. This effect is less severe for linear polarization, so that orthogonal linear polarization is sometimes used. This combination of polarization and frequency reuse is commonly used by commercial systems to obtain as much capacity as possible from a single satellite.

Multiple-beam antennas are generally considered as designs covering the available field of view. As the beamwidth of the individual beams decreases, the required number of beams greatly increases as shown in Fig. 3, larger aperture sizes are required and the complexity of beam routing increases. In some applications, multiple beams are used in a limited geographical region [4,17]. The Ka-band multiple-beam system described in Ref. 17 has such small beamwidths that active tracking of a ground beacon is required to compensate for satellite attitude variations.

Figure 3. Number of beams to cover FV (after Ref. 9).

The ability to process and direct the information on the collection of multiple beams requires beamforming networks that separate information on the uplink beams and combine information on the downlink beams. A wide variety of beamforming networks have been developed. The simplest design is a fixed beamformer network that simply combines beams in a fixed pattern. This beamformer, together with transponder channelization, maps the uplink beam patterns into the downlink patterns. Other beamformer designs use cascaded networks on switches or variable power dividers so that the beam patterns can be changed on-orbit. Still other beamformers use adaptive processing on the uplink beamformer to negate interference. Yet other systems route the uplink information to a terminal on the ground, referred to as a *gateway*, where the uplink beams are mapped into the downlink collection.

The beamformers have different requirements for the uplink beams and downlink beams. The system noise temperature on the uplink can be established by preamplifiers that are followed by the beamformers. In this way the system sensitivity is not degraded by the insertion loss of the beamformers, and lightweight networks and diode switching can be used in the beamformer implementation. The downlink beamformer network must be placed between the transmitters and the beam ports, so that power handling and insertion loss are important design parameters. In addition, switching for redundant transmitters is also required. These requirements depend on the application.

The development of multiple-beam antenna systems has been pursued principally for geosynchronous satellites, and future design challenges exist to develop multiple-beam designs for LEO and MEO (low- and medium-Earth orbit) satellites. While offset reflector antennas are commonly used in geosynchronous satellites, these antennas are examples of limited scan antennas [14], which are not appropriate for the wider field of view at the lower altitudes. These lower altitudes also need wider beamwidths than geosynchronous designs to maintain reasonable footprint dimensions, and thus the overall antenna size is electrically smaller. Array antennas are commonly used to meet performance requirements for these orbits. With their smaller electrical size compared with geosynchronous designs, a reasonable number of array elements is required.

The trend toward using digital technology in the transponder also naturally leads to considering digital beamforming techniques in the array design. On the uplink, the received signal at each element is preamplified, downconverted to baseband, and transformed into the digital domain by an analog-to-digital converter (ADC). Digital samples from each array element are combined using a complex matrix multiplier containing the complex coefficients that perform the beamsteering. Parallel complex multipliers are required to form multiple beams. The same constraints on beam isolation exist for multiple beam operation. The downlink antenna follows the same procedure in reverse. The input digital datastream is complex-matrix-multiplied to obtain the properly weighted samples for each array element for the beamsteering, and a digital-to-analog converter (DAC) provides

conversion to the analog domain. This analog baseband is upconverted to the transmit frequency and suitably amplified to the required element power level. Experience with digital array designs is described in Ref. 18; an adaptive array using digital technology to increase beam isolation is described in Ref. 19.

The downlink array designs for multiple-beam operation also present challenges in transmit power control. The element transmit power is shared with each of the beams transmitted by the array. The relative amplitude and phase between the array elements must be maintained to achieve the desired downlink pattern. In addition, the total power in the array elements must be maintained near saturation to achieve the design ERP performance and maximum power efficiency. However, the total power must not extend into the transmitter's non-linear region, which would degrade performance by producing intermodulation products and signal suppression. The challenge is to maintain the required amplitude and phase excitation for each beam while allotting each beam an equitable share of the downlink transmit power.

1.5. Remote Sensing Antennas

Satellite antennas also include designs for remote sensing applications. Two types of sensors are used: active, or radar, and passive, or radiometric, sensors. These systems are used in low-orbiting satellites to provide both global coverage and high resolution of terrain features.

Radar sensitivity is commonly measured by the power aperture product of the design, and thus, in addition to high peak power levels, a physically large aperture size is required [20]. Antenna designs for active applications generally require deployment to achieve the required aperture size. A conflict exists in these designs. Large apertures can be obtained from low-frequency arrays where a reasonable number of elements are required and the mechanical tolerance is not overly stringent, but the resolution of these systems is lower than higher-frequency designs. The better resolution of the higher-frequency designs is accompanied by the requirements of additional array elements and more stringent mechanical tolerance. The size, weight, and prime power requirements for these sensors make their development an ambitious effort, but future systems designs, particularly those using synthetic aperture processing, can be anticipated.

Passive sensors are commonly used for both meteorological and terrain remote sensing [21]. Two types of antenna designs are used in these applications. One type of antenna, generally an offset reflector, is mechanically rotated at a constant angle from the satellite's nadir to generate a conical trace on the ground at a constant elevation angle. As the satellite proceeds in its orbit, a swath on the ground is swept out. The requirements for these antennas include design attention to minimize insertion loss to achieve high sensitivity, good polarization purity to discern the radiometric contrast for oblique incidence angles used by these sensors, low sidelobes so that the emission received by the mainbeam is not degraded by sidelobe returns, and a narrow beamwidth to obtain good resolution

of terrain features. Commonly, these antennas are specified by their solid beam efficiency performance. This parameter is defined by the power received for the specified polarization over a required angular region to the total power received from all space assuming the antenna is uniformly illuminated from all directions. This parameter is defined to provide a means to quantify the degree to which the power received by the sensor is isolated to its specified coverage area. This system design commonly operates at several different frequency bands using the same aperture.

A second type of antenna has a much simpler design and is used in sensors referred to as *sounders*. In this design, the antenna boresight is aligned with the satellite nadir. These designs operate at frequencies selected from peak of molecular absorption resonances, which occur at EHF frequencies. Several different IF bandwidths are used in these designs. As the bandwidth straddles more of the molecular resonance, the absorption toward the bandwidth edges reduces from the peak value at the resonant frequency. This reduced absorption at the bandwidth edges permits the sensor to view emission closer to Earth's surface. Thus, by examining the emission received at different IF bandwidths, a profile for different altitudes may be observed. The antennas used in these sounder designs are generally corrugated horn designs selected for their low insertion loss and rotationally symmetric, low sidelobe patterns.

2. USER SEGMENT ANTENNAS

User segment antennas also have requirements specific to satellite applications. In addition to meeting G/T and ERP requirements for link closure, the user antennas generally need to align their mainbeams with the appropriate satellite. Other design issues include the control of interference to and the reduction of interference from other systems. With the increased number of satellite users, terminal costs including the antenna, transportability to alternative locations, and in future personal communication systems, techniques to reduce interactions with the surrounding environment form the principal development issues.

2.1. Radiofrequency Issues

The most common user antenna is a reflector design capable of reasonable RF performance with a modest cost. Other antenna technologies, such as phased arrays, have more complexity which results in higher manufacturing costs, and therefore are used when compelling reasons exist for their design. For example, aerodynamic constraints for high-performance aircraft may dictate the development of conformal array designs.

The trend toward increased numbers of users results in the terminal costs having a significant fraction of the total system costs. This trend in turn requires sufficient performance from the satellite to minimize terminal performance requirements. An excellent example is provided by direct-broadcast satellite TV services where both the user terminal size and costs have dramatically shrunk.

More generally, the present development of systems for VSATs (very-small-aperture terminals) illustrates this trend. A very important part of system planning is to insure that adequate satellite performance is available to minimize user performance requirements, and thereby control the total system cost as well as provide a minimum amount of equipment, particularly for those users with mobility requirements.

The increased number of satellites in orbit has also resulted in additional requirements for the antennas. Concern regarding interference to and from satellites that are closely spaced in orbit has resulted in sidelobe envelope requirements to reduce interference levels. These requirements are mandated on antenna manufacturers. A typical example of these requirements has been levied by the CCIR [International Radio Consultative Committee, technical branch of International Telecommunication Union (ITU)] [22], which results in a sidelobe envelope constraint that depends on the electrical size of the antenna.

Sidelobe control is one antenna technique that reduces interference for both reception and transmission. Another technique for reducing received interference is to construct an adaptive cancellation system. A typical design for ground terminal applications called a *sidelobe canceler* [23] assumes the desired signal is received by the main-beam and that the interference arrives through the antenna sidelobes. The antenna hardware consists of a main reflector antenna and a set of auxiliary antenna elements that are combined with complex weighting values with the main reflector antenna to cancel interference. The principal issue for this design approach is the dispersion inherent in the main reflector's sidelobe response. The sidelobe response of reflector antenna includes radiation from edge diffraction, direct feed radiation and spillover, scattering and blockage contributions, and leakage from the panels composing the reflector surface. The complex sum of these individual radiation mechanisms varies over the operating bandwidth so that effective cancellation requires frequency-dependent weighting values. Such frequency-independent weighting values can be achieved by adaptive equalization circuitry using a transversal filter with adaptive weighting coefficients at each time-delay tap. An example of this interference reduction approach may be found in Ref. 24, which describes the design and the measured results of a demonstration of cancellation capabilities.

The trend toward increased microwave users and systems extends beyond satellite applications. This trend also increases the possibility of interference to user terminals from nearby terrestrial systems. A particular concern is the possibility of out-of-band receiver compression from high-level pulse systems such as radars that suppresses desired signal levels and creates intermodulation products degrading receiver performance. Design attention must be paid to the receiver's dynamic range and RF filtering to protect the receiver from high-level interference. However, RF filtering, while necessary has insertion loss, which degrades sensitivity by reducing the received signal and increasing the system temperature.

Inexpensive, low noise receiver front ends and relatively low sky temperature values [25] provide the potential of

low system temperatures that increase system performance and reduce the required antenna size. Controlling antenna spillover and wide-angle sidelobe levels by both efficient rotationally symmetric feed designs and reflector geometry choice produces low antenna temperature values [26]. Low antenna temperature values also require minimizing feed and transmission line losses. Filter loss even in a high- Q medium becomes the dominant insertion loss, but such receiver protection is necessary. These steps permit development of terminals that meet the required G/T with a minimum size antenna. These factors result in the popularity of offset reflector antennas for user applications. The efficiency of offset reflectors is enhanced by the absence of feed blockage; their high-level spillover lobes are directed toward the lower sky temperature instead of the ambient Earth temperature, and their low sidelobe levels minimize the antenna temperature while also complying with sidelobe envelope requirements.

User antennas for future personnel communication systems face additional challenges. These antennas must provide broad coverage so that antenna pointing is not required, particularly since the LEO and MEO orbits used in these systems produce ever-changing angular positions between the user and the satellite. One problem inherent in broad-coverage antennas, as previously discussed for TT&C antennas, is the sensitivity of the antenna performance to the environment surrounding the antenna. For the personal communication application, there exists a wide variety of environments with varying degrees of multipath (i.e., scattering from human-made and terrain features). In addition, link performance can be degraded by foliage attenuation and blockage from terrain features. These development issues are being actively pursued for both satellite systems and terrestrial cellular networks that operate at somewhat lower frequencies. Development of techniques to mitigate these degradations is also being actively pursued; techniques such as RAKE receivers, which provide adaptive diversity combining and equalization are being evaluated.

2.2. Antenna Pointing Techniques

User antennas must also be aligned with the desired satellites for signal reception. The satellite's orbital position is specified by its ephemeris which describes the satellite's altitude, eccentricity of orbit, inclination, longitude of ascension, and time of epoch. The satellite ephemeris and the user location are required to determine the antenna pointing angles. Typically, this information is transferred to the antenna control unit where the required pointing angles are computed and the necessary commands to the antenna positioner are issued. The requirements for antenna pointing depend on the antenna beamwidth, the uncertainty in the satellite's location, and the orbital dynamics. For communication applications, a pointing accuracy of one-tenth of a beamwidth is typically specified to minimize signal loss caused by pointing errors.

In some cases, antenna pointing is trivial. For example, the antennas for personal communication systems are purposely designed with broad coverage antennas, so that the user has no pointing requirements. Another com-

mon example is a small user antenna for direct-broadcast satellite reception from geosynchronous satellites. These antennas are roughly aligned using the user's geographic location, verified by signal peaking techniques, and rigidly secured. The combination of the relatively wide beamwidth from the small antenna and the stationary position of the geosynchronous satellite and its station keeping results in a fixed pointing requirement.

In other applications where satellites have inclined orbits or orbits that are not geosynchronous, the satellite undergoes dynamic motion with respect to the user, and a means must be provided to follow the satellite in orbit. For users with relatively broad beamwidths compared to the orbital uncertainty, the knowledge of the satellite ephemeris and the user location may be adequate to simply command the user's antenna position. This open-loop procedure is commonly referred to as *program tracking*.

If some uncertainty exists in the antenna pointing, such as ephemeris data that are not current, another open-loop technique referred to as *step track* is commonly used to verify correct alignment with the satellite's position. The user's antenna is pointed at the nominal position of the satellite as might be obtained from program track. The antenna is then commanded to move in equal and opposite angular positions from this nominal pointing direction. If the antenna is correctly aligned with the satellite, the received signal level should be reduced by the same amount at both angular offsets. If the signal levels at both positions are not identical, the difference in the power level provides the angular correction to the nominal position. This process is repeated in the orthogonal plane to properly position the antenna in two angular coordinates.

These two open-loop antenna pointing techniques are commonly used together. The step track procedure is periodically exercised to validate the correctness of the program track pointing. A significant advantage of these techniques is that minimal equipment is required. The antenna positioner is required and simple software commanding is needed to execute the angular offsets. The power measurements at the different angular offsets may be obtained from a simple measurement of the receiver's automatic gain control (AGC) voltage with the appropriate calibration and linearity verification.

When user antennas have beamwidths that approach 10 times the uncertainty in satellite position or a significant amount of orbital dynamics exist, closed-loop tracking techniques are required. These techniques are commonly used in radar systems to locate targets and are referred to as *monopulse* designs. This term is derived from radar applications because the tracking information is obtained from each radar pulse. In radar applications, the received signal level varies as the target changes aspect angle and typically has a significant dynamic range. Thus, tracking information is derived from each radar pulse so that the dynamics of the target return do not degrade antenna pointing performance. Monopulse systems for communication applications have requirements easier than those for radar systems. The received signal level has a relatively constant amplitude, so that the monopulse signals can be sequentially sampled, reducing hardware

requirements. The antenna pointing accuracy depends on aligning the antenna with sufficient accuracy to minimize signal loss as compared to locating a radar target with the maximum precision practical.

Monopulse systems operate by forming two types of antenna beamshapes: a sum beam, which receives the desired signal; and a difference beam, which has a null on the antenna boresight axis. The signal power in the sum beam is maximized by positioning the antenna to the null of the difference pattern. The ratio of the signal levels in the sum and difference beams is independent of the power density of the received signal, and provides a measure of the angular displacement from the antenna's axis. This ratio can be used in a closed loop system so that the antenna will align to the received signal and will follow any variations in the signal location.

Two different types of feed designs are commonly used to generate the sum and difference beams. One feed design [27] uses a conventional feed for the sum beam and an additional four small feed elements to produce the difference beam. The second design [28] uses a higher-order waveguide mode to produce the difference beam, which is sampled by couplers. In both cases, the difference beam outputs are coupled into the sum channel and switched sequentially. The resulting AM modulation on the sum signal is processed to derive the antenna pointing measurements.

3. SATELLITE ANTENNA TESTING

While antenna testing is widely developed for many applications, satellite antenna systems pose some unique testing challenges. Rigorous testing is required for spaceborne antenna systems because of their reliability requirements and the inability to service on-orbit antennas. This discussion illustrates the trends toward increased integration of antennas with payload electronics, and testing where the antenna performance depends on both the antenna hardware and system electronics further increases testing complexity. The user segment also follows the trend of increased integration with terminal requirements. Finally, the demands for capacity also result in more stringent than normal testing requirements, such as validating the polarization purity requirements for systems using polarization reuse.

Spaceborne antenna testing generally has three distinct phases:

Development testing that demonstrates design compliance with system specifications

Qualification testing that ensures flight hardware not only meets the RF performance demonstrated in development testing but also is capable of surviving the launch and on-orbit environments and meets weight and power requirements

On-orbit testing that validates system compliance with system specifications and provides diagnostic evaluation of system shortfalls during the orbital lifetime

These three test phases have a scope that greatly exceeds the normal testing to define the component level performance of antennas. This situation is particularly true with the trend toward incorporating payload electronics into the antenna system, which results in antenna system performance that depends on not only the antenna components but also the electronics performance.

The development testing has the objective to demonstrate the designs fully comply with the system specifications. The testing in this phase of the program is most closely related to conventional antenna testing and quantifies gain values, pattern characteristics, polarization purity, impedance properties, bandwidth variations, and so on, as is typically performed. These RF characteristics can generally be performed using conventional RF test facilities and general-purpose instrumentation. The antenna components are designed on a prototype or engineering model basis, so that weight projections and compliance with thermal and mechanical requirements for launch can also be evaluated.

The qualification testing has the objective of determining whether the flight hardware is capable of the performance established for the design whose compliance has been demonstrated in the development testing. An important part of the program test planning is a requirements' flowdown that identifies the testing necessary to demonstrate overall system compliance and assurance of flight-worthiness. The principal concern in this phase of the testing is how to perform the testing without risk to flight hardware. Moving flight hardware to conventional antenna test facilities poses an unacceptable risk in many cases. Testing very lightweight antenna designs may be precluded because they can be destroyed by wind or become contaminated and the effects of gravity can degrade the ability to project on-orbit performance. The development of portable near-field test facilities is viewed as a need to permit detailed antenna testing in payload assembly areas. Another important part of the test planning in the early part of the program is the identification of test ports for system evaluation and the required development and calibration of any specialized test fixture. Qualification testing must also evaluate performance variations in the thermal variations and vacuum conditions, and the ability to survive the shock and vibration levels experienced during launch. Other issues such as the reliability of deployment mechanisms, if used, must be demonstrated.

On-orbit testing is conducted using specialized test terminals, which are often a part of the satellite control networks. The testing at this phase is generally conducted shortly after the satellite arrives at its orbital location. This testing generally concentrates on system-level performance parameters, such as uplink G/T, downlink ERP, and payload antenna pointing alignment, to establish overall performance compliance. After this initial performance evaluation, these test facilities are used to periodically assess on-orbit performance, and together with the telemetry information provide a means for on-orbit diagnostics. An important part of the test planning is an examination of the adequacy of the telemetry and test terminal information for identifying failed components

and their potential substitution with redundant components.

Satellite systems also have some specialized testing requirements peculiar to their environment. One problem with satellite systems is the static charging of components on-orbit. Typically, this charging occurs on dielectric materials used for thermal protection not only for the antenna but also for other satellite subsystems. The charge builds up on these components until discharge occurs. This phenomenon is referred to as ESD (electrostatic discharge), and the spectral components of the discharge may have sufficient intensity to interfere with payload receivers. The ESD spectral content is typically measured by embedding a sample of the material in an electron beam and using a pickup probe antenna and a spectrum analyzer or very wide bandwidth oscilloscope.

Another problem that results from high power operation in vacuum conditions is multipaction. In this case, the RF energy may be sufficient to strip electrons from the surfaces of materials exposed to the high power, which will damage the component. The potential for multipaction is typically evaluated by testing the components associated with high power in an evacuated bell jar and using a spectrum analyzer to observe any RF noise associated with multipaction. Such testing can also evaluate any power-handling and microarcing limitations of the components by examining the components after the test for damage. Temperature increases from high-power operation can also be measured.

A third problem is also associated with high-power operation and is referred to as PIM (passive intermodulation). This problem results from exposing junctions with high power. Dissimilar metals or contamination forms weak diode junctions whose nonlinearity generates intermodulation products. Such junctions can occur in transmission-line components, filters and diplexers, and joints within the antenna structure. Those components exposed to high power are tested by injecting two tones at high-power levels (higher-power transmitters than the operational ones are sometimes used to insure the observed intermodulation does not result from products generated by a saturated transmitter) and observing any intermodulation products generated by the components under test with a spectrum analyzer.

User antenna testing also has some unique issues for satellite systems [29]. One problem results from testing on ground terminal antennas, where the physical size of the antenna precludes testing in conventional antenna test facilities. A test technique using the emission from astronomical sources is used to measure the G/T [30]. The flux density of these emissions has been well established, and a variety of sources exist. The emission from the sun has a high level, but the angular width of the solar disk limits this technique to relatively wide beamwidths. Other sources such as the moon and radio stars such as Cassiopeia A are used for narrower beamwidths. The positions of these sources are also well known, and thus, the opportunity to validate the accuracy of the antenna positioning systems is also available. The antenna gain in the transmit bandwidth can also be established by connecting a

low-noise preamplifier in place of the transmitter, measuring the G/T, separately measuring the system temperature, and multiplying to obtain the transmit antenna gain. While this technique was developed for large ground terminal antennas [31] with the available low-noise preamplifiers, useful measurements can be made on much smaller antennas. This technique is particularly useful for those antennas that follow the trend of integrating the antenna feed and receiver front end without connectors for test purposes.

Other electromagnetic measurements are required in the development of both user and spaceborne systems to validate EMI/EMC (electromagnetic interference/electromagnetic compatibility) issues. Part of the system planning for satellite systems involves frequency planning to avoid such problems; measurements at the assembly level are performed to ensure that on-orbit performance will not be degraded by interference between subsystems. User terminal designs are also evaluated to insure the design is not susceptible to outside interference as well as not creating interference to other systems that may be located nearby.

4. SUMMARY

Satellite antenna development is a significant part of present-day antenna technology. Much progress in antenna systems for both the space and user segments has been made. However, future requirements such as the development of satellite systems for personal use provide a rich opportunity for further development and challenges to meet the increased performance levels demanded in future systems and applications.

SCHOTTKY BARRIER DIODES AND THEIR APPLICATIONS

W. ALAN DAVIS

The University of Texas at
Arlington

1. INTRODUCTION

The original point contact diodes were made by pressing a tungsten wire onto a semiconductor such as Ge or Si. These early forms of the Schottky barrier diode were used as detectors and mixers in radar systems. Although times have changed, the Schottky barrier diode remains an important component in many systems because of its unique features. They act in some ways like the pn junction, but they also have some important differences. In particular, the Schottky barrier diode is a majority carrier device, so they lack the diffusion capacitance associated with the minority carrier storage effects, which makes them ideal for fast switching and high-frequency mixer applications. The discussion will first focus on the origin of the energy bands and their relationship to the Fermi level. The simple theory is later modified by the barrier-lowering effect and the presence of surface states. The reverse bias depletion capacitance and, subsequently, the forward current characteristics are determined. Equivalent circuit models are discussed that are useful for circuit design. Finally, some comments are made about recent progress in wide bandgap Schottky barrier diodes. The applications sections emphasize mixer design, as this seems to be the predominant use of Schottky devices.

2. ENERGY LEVELS IN A METAL AND SEMICONDUCTOR

Conceptually, two materials, one a metal and the other a semiconductor, can be initially far removed from one another and then brought together into intimate contact. The electrons in both materials obey the Pauli exclusion principle, and hence their energy levels can be described in terms of the Fermi-Dirac distribution function. For both the metal and the semiconductor, these distributions functions are:

$$f_{Dm}(\mathcal{E}) = \frac{1}{1 + \exp[(\mathcal{E} - \mathcal{E}_{Fm})/kT]} \quad (1)$$

$$f_{Ds}(\mathcal{E}) = \frac{1}{1 + \exp[(\mathcal{E} - \mathcal{E}_{Fs})/kT]} \quad (2)$$

Thus the probability that an electron is located either above or below the Fermi level, \mathcal{E}_F , is $1/2$ when $\mathcal{E} = \mathcal{E}_F$.

The total allowed energy states is $g(\mathcal{E})$, the total number of filled states is $n(\mathcal{E})$, and the total number of empty states is $v(\mathcal{E})$. For both the metal and the semiconductor, the number of filled states is the product of the total number of available states and the probability that it is full, whereas the total number of vacant states is what is left

over.

$$n(\mathcal{E}) = g(\mathcal{E}) \cdot f_D(\mathcal{E}) \tag{3}$$

$$v(\mathcal{E}) = g(\mathcal{E}) \cdot [1 - f_D(\mathcal{E})] \tag{4}$$

Thus, at $\mathcal{E} = \mathcal{E}_F$, the energy state has equal probability of being full or empty. In a metal, the Fermi level lies within the conduction band, whereas for a typical semiconductor, the Fermi level lies inside the forbidden energy gap. Figure 1 shows the energy levels for a metal and a semiconductor when the two are separated far enough apart so that their energy levels do not interact with one another. Shown are diagrams for both n- and p-type semiconductors. Another energy level located above the conduction band may be identified as the vacuum or free electron energy level, \mathcal{E}_0 , which is the minimum energy required to remove an electron from the surface of the metal or semiconductor. The difference between this and the Fermi level is called the *work function*, ϕ .

$$q\phi = \mathcal{E}_0 - \mathcal{E}_F \tag{5}$$

In a semiconductor, this is a function of the doping density, because \mathcal{E}_F varies with doping density. For an n-type semiconductor, \mathcal{E}_F is closer to the conduction band, and for a p-type semiconductor, \mathcal{E}_F is closer to the valence band. However, the *electron affinity*, χ , is the difference between the vacuum energy, \mathcal{E}_0 and the conduction band energy, \mathcal{E}_C , which does not vary with doping concentration.

$$q\chi = \mathcal{E}_0 - \mathcal{E}_C \tag{6}$$

These parameters are useful in giving an explanation of the behavior of a metal semiconductor junction described in Section 3.

3. FUNDAMENTALS OF THE IDEAL METAL-SEMICONDUCTOR JUNCTION

Assume that the metal and semiconductor materials are brought into contact so that electrons can flow between them [1]. The flow of charge from the metal to the semiconductor is proportional to the number of filled states in the metal, $n_m(\mathcal{E})$, and is also proportional to the number of empty states in the semiconductor, $v_s(\mathcal{E})$. On the other hand, the amount of charge flowing from the semiconductor to the metal is proportional to the number of filled

states in the semiconductor, $n_s(\mathcal{E})$, and the number of empty states in the metal ready to receive the charge, $v_m(\mathcal{E})$. At equilibrium, the charge flow between the semiconductor and metal is equal in both directions.

$$n_m(\mathcal{E})v_s(\mathcal{E}) = n_s(\mathcal{E})v_m(\mathcal{E}) \tag{7}$$

When this equation is written in terms of the Fermi–Dirac distribution functions, it is found that the Fermi energies of both materials are equal to one another. Substituting Eqs. (3) and (4) into Eq. (7) demonstrates this statement.

$$g_m f_{Dm} \cdot g_s (1 - f_{Ds}) = g_s f_{Ds} \cdot g_m (1 - f_{Dm}) \tag{8}$$

$$g_m f_{Dm} g_s = g_s g_m f_{Ds} \tag{9}$$

which is true if

$$\mathcal{E}_{Fm} = \mathcal{E}_{Fs} \tag{10}$$

The Fermi levels of the two materials line up at their junction.

Three principles can be used to draw the energy level diagram for the metal semiconductor junction: (1) the equality of the Fermi levels on both sides of the junction, (2) the constancy of the electron affinity in all regions of the materials, and (3) the continuity of the free electron energy levels. In regard to the last principle, a discontinuity of \mathcal{E}_0 would be a violation of energy conservation. Figure 2 shows how the energy bands bend in the transition from metal to semiconductor. In the choice of materials illustrated in Fig. 2, the work function in the metal is larger than that for the semiconductor.

$$q\phi_m > q\phi_s \tag{11}$$

$$\mathcal{E}_{Fs} > \mathcal{E}_{Fm} \tag{12}$$

The abrupt shift of the energy bands in the semiconductor near the junction is the barrier potential. For an n-type semiconductor, this is given by

$$q\phi_{Bn} = q(\phi_m - \chi) \tag{13}$$

When $\phi_m > \phi_s$, as assumed in Fig. 2(a), the average energy of the electrons is greater in the semiconductor than in the metal. Electrons will flow from the semiconductor into the metal. The higher values of \mathcal{E}_C and \mathcal{E}_V near the junction

Figure 1. The energy bands of a metal and semiconductor when separated: (a) n-type semiconductor, and (b) p-type semiconductor.

(a)

(b)

Figure 2. The energy bands of a metal and semiconductor when brought into contact with one another: (a) n-type semiconductor, and (b) p-type semiconductor.

are a result of the charge transfer to the metal. An electric field is formed that increases the net energy of the electrons in this vicinity. The electrons left behind in the semiconductor have a higher average energy, and thus the distance between the conduction band and the Fermi level increases (Fig. 2(a)). The barrier height between a metal and p-type semiconductor is illustrated in Fig 2(b). If the energy gap between the conduction band and valence band is \mathcal{E}_G , then the barrier height is

$$q\phi_{Bp} = \mathcal{E}_G - q(\phi_m - \chi) \quad (14)$$

The electric field, the potential, and finally the capacitance resulting from this charge motion can now be described. The approximation is made that all mobile charges are removed from the region of the semiconductor near the junction up to a distance, x_d , the depletion, or space charge region. What is left is the bound charge associated with the ionized atoms. The maximum electric field at the metal-semiconductor interface is found from $\nabla \cdot \mathbf{D} = \rho$.

$$E_m = \frac{-qN_D x_d}{\epsilon_s} \quad (15)$$

In this equation, ϵ_s is the semiconductor permittivity, q is the electron charge, and N_D is the donor concentration for the n-type semiconductor. The built-in potential, V_{bi} , is the voltage across the depletion region. It is the amount the conduction band goes up inside the n-type semiconductor from the semiconductor bulk to the junction. In the p-type semiconductor, it is the amount the conduction band shifts downward between the semiconductor bulk and the junction. The built-in potential is the integral of the electric field between the junction and the edge of the depletion region, x_d , in the semiconductor bulk.

$$V_{bi} = - \int_0^{x_d} E dx = \frac{1}{2} \frac{qN_D x_d^2}{\epsilon_s} \quad (16)$$

The immobile space charge in this region with cross-sectional area, A , is

$$\begin{aligned} Q_s &= AN_D q x_d \\ &= A \sqrt{2q\epsilon_s N_D V_{bi}} \end{aligned} \quad (17)$$

or when an applied external voltage, V_a , is applied,

$$Q_s = A \sqrt{2q\epsilon_s N_D (V_{bi} - V_a)} \quad (18)$$

The stored charge results in a depletion junction capacitance.

$$C = - \frac{\partial Q_s}{\partial V_a} \quad (19)$$

$$= A \sqrt{\frac{q\epsilon_s N_D}{2(V_{bi} - V_a)}} \quad (20)$$

$$= \frac{C_0}{(1 - V_a/V_{bi})^{3/2}} \quad (21)$$

This equation is similar in form to that of an abrupt junction pn diode where $\gamma = 1/2$. Sign confusion is reduced if Eq. (21) is written the way it is shown above with a negative sign. If the diode is reverse biased at, for example, $V_a = -5$ V, then the denominator of Eq. (21) is $(1 + 5/V_{bi})^{3/2}$.

4. BARRIER LOWERING

The analysis in Section 3 assumed that the barrier potential, ϕ_B , is independent of an applied voltage. However, there is some reduction in ϕ_B that is proportional to fourth root of the applied voltage, which is known as the Schottky effect. When a negative charge is placed a certain distance, x , from a conducting plane, it will induce a positive charge on that plane and be attracted to it. The forces on the charge would be unchanged if the conducting plane were replaced with a positive charge of the same magnitude but a distance x on the opposite side of the plane. The force on the actual charge in the semiconductor with a dielectric constant, ϵ_s , can easily be found from Coulomb's law.

$$F(x) = \frac{-q^2}{4\pi\epsilon_s (2x)^2} \quad (22)$$

The energy required to bring the charge to a distance x away from the metal is found by integrating

Figure 3. The barrier lowering effect caused by the image force on electrons in the semiconductor but close to the metal.

from $x = \infty$ to x .

$$\mathcal{E} = \int_{\infty}^x F(x) dx = \frac{q^2}{16\pi\epsilon_s x} \quad (23)$$

which represents the energy of the charge associated with its image force. In the presence of an electric field, E , the total potential energy is measured downward relative to the x -axis in Fig. 3 where the reference energy is $q\phi_B(V_a = 0)$ above the Fermi level.

$$PE(x) = \frac{q}{16\pi\epsilon_s x} + qEx \quad (24)$$

The position, x_m , where the maximum potential occurs, results from setting the derivative of Eq. (24) to zero.

$$x_m = \sqrt{\frac{q}{16\pi\epsilon_s E}} \quad (25)$$

The potential energy at this position is the amount the potential barrier is reduced as a result of an applied electric field.

$$PE(x_m) = q\Delta\phi = q\sqrt{\frac{qE}{4\pi\epsilon_s}} \quad (26)$$

when for example, in a metal-silicon interface, where $\epsilon_s = 11.7 \cdot \epsilon_0$, $E = 10^5$ V/cm, the values for $x_m = 17.54$ Å and $\Delta\phi = 3.51 \cdot 10^{-2}$ V.

The variation of the current from the metal into the semiconductor changes with the field-dependent value of $\Delta\phi$. The current, at room temperature, will obey the Maxwell-Boltzmann distribution.

$$J = J_0 \exp\left(\frac{\sqrt{q^3 E / 4\pi\epsilon_s}}{kT}\right) \quad (27)$$

If x_d is eliminated between Eq. (15) and Eq. (16) and the built-in voltage, V_{bi} , is modified by the applied voltage, $V_{bi} - V_a$, then the field is seen to be proportional to the

square root of the applied voltage.

$$E = \sqrt{\frac{2qN_D(V_{bi} - V_a)}{\epsilon_s}} \quad (28)$$

Consequently, the current under reverse bias depends only on the fourth root of the applied voltage.

5. SURFACE STATES

The barrier height, as seen from Eq. (13), is determined by the metal work function. In addition, surface states that develop from imperfections and discontinuities at the junction can play an important role. The interfacial states cause a surface charge layer that is so thin that it does not impede the flow of electrons, but they can modify the voltage drop across the junction. The analysis of the effect of the surface states was carried out by Crowley and Sze [3]. The energy level at the surface of the semiconductor is designated as $q\phi_0$. Before joining the semiconductor with the metal, it would be

$$q\phi_0 = \mathcal{E}_F - \mathcal{E}_V \quad (29)$$

which specifies that all states below $q\phi_0$ must be filled. As a result of the presence of surface states when the metal and semiconductor are joined (Fig. 2), $q\phi_0$ reaches from \mathcal{E}_V to somewhere below the Fermi level. If the density of surface states is D_s states/cm²/eV, then the barrier potential can be found for two extreme states [3]. When $D_s \rightarrow \infty$, the barrier height for an n-type semiconductor is

$$q\phi_{Bn} = (\mathcal{E}_G - q\phi_0) - q\Delta\phi \quad (30)$$

and when $D_s \rightarrow 0$

$$q\phi_{Bn} = q(\phi_m - \chi) - q\Delta\phi \quad (31)$$

When there is a large number of surface states, the barrier potential is independent of the metal work function. A least squares fit for a variety of semiconductor-metal systems has been developed. A summary of these relations is given in Table 1. The large scatter in data for CdS makes the expression for this material less certain.

Table 1. Empirical Expressions for the Barrier Height [3]

Semiconductor	ϕ_{Bn} (eV)	Slope Error	Intercept Error (eV)
Si	$0.27\phi_m - 0.55$	± 0.05	± 0.22
GaP	$0.27\phi_m - 0.01$	± 0.05	± 0.13
GaAs	$0.074\phi_m + 0.49$	± 0.05	± 0.24
CdS	$0.38\phi_m - 1.20$	± 0.16	± 0.77

6. FORWARD BIAS CURRENT-VOLTAGE CHARACTERISTICS

Two basic mechanisms exist for the flow of current when the Schottky barrier is forward biased: thermionic emission and diffusion [2]. In both cases, the result is in the form of the Shockley diode equation where the externally applied voltage is V_a .

$$J = J_s(e^{qV_a/kT} - 1) \quad (32)$$

Of the two theories, thermionic emission is seen to prevail at room temperatures for Ge, Si, and GaAs with electric fields in the 10^4 to 10^5 V/cm range. The thermionic emission theory shows that J_s is especially dependent on the temperature, and the diffusion theory shows that J_s is more strongly dependent on the applied voltage.

6.1. Thermionic Emission

The thermionic emission theory, which was first developed by Bethe [4] and reviewed by Sze [2], was based on the assumptions that (1) $q\phi_{Bn} \gg kT$, (2) thermal equilibrium exists at the junction, and (3) superposition of forward and reverse currents is accurate.

First, the current from the semiconductor to the metal, $J_{s \rightarrow m}$, is found, which is the current that develops from the electrons that have sufficient energy to overcome the barrier potential.

$$J_{s \rightarrow m} = \int_{\mathcal{E}_F + q\phi_{Bn}}^{\infty} qv_x dn \quad (33)$$

The carrier velocity in the semiconductor is v_x , and the number density of electrons is n . The incremental number of electrons is the number of available states for the electrons and the probability of them being filled [5].

$$dn = N(\mathcal{E})f_D(\mathcal{E})d\mathcal{E} \quad (34)$$

$$= \frac{8\pi p^2 dp}{h^3} f_D(\mathcal{E}) \quad (35)$$

$$= 4\pi \left(\frac{2m_n^*}{h^2} \right)^{3/2} (\mathcal{E} - \mathcal{E}_C)^{1/2} f_D(\mathcal{E}) d\mathcal{E} \quad (36)$$

The incremental momentum from p to $p + dp$ is found by determining the change in the spherical volume in momentum space and recognition that the crystal momentum is $p_x = h/\lambda$. An extra factor of 2 is included to account for electron spin. The kinetic energy expressed in terms of momentum, p , is expressed in terms of energy in Eq. (36). When $\mathcal{E} > 3kT$ above or below the Fermi level, the Fermi-Dirac distribution can be approximated by the Maxwell-Boltzmann distribution. Under this condition, the incremental change in the electron density is

$$dn = 4\pi \left(\frac{2m_n^*}{h^2} \right)^{3/2} (\mathcal{E} - \mathcal{E}_C)^{1/2} \exp[-(\mathcal{E} - \mathcal{E}_F)/kT] d\mathcal{E} \quad (37)$$

If all the electron energy above the conduction band is kinetic energy, so that

$$\mathcal{E} - \mathcal{E}_C = \frac{m_n^* v^2}{2} \quad (38)$$

$$d\mathcal{E} = m_n^* v dv \quad (39)$$

then

$$dn = 2 \left(\frac{m_n^*}{h} \right)^3 e^{(\mathcal{E} - \mathcal{E}_F)/kT} \cdot e^{m_n^* v^2 / 2kT} \quad (40)$$

The velocity is decomposed into its three Cartesian coordinates.

$$v^2 = v_x^2 + v_y^2 + v_z^2 \quad (41)$$

$$dv_x dv_y dv_z = v^2 \sin \theta dv d\theta d\phi = 4\pi v^2 dv \quad (42)$$

which is used to integrate Eq. (33). It should be noted that the integrals in the v_y and v_z directions are of the form $\int_{-\infty}^{\infty} r e^{-ar^2} dr = \sqrt{\pi/a}$. The lower limit on the integral in the x -directed velocity is v_{ox} , which is the minimum electron velocity needed to overcome the barrier. As a result, the current going from the semiconductor to the metal is given below.

$$J_{s \rightarrow m} = 2q \left(\frac{m_n^*}{h} \right)^3 e^{(\mathcal{E}_C - \mathcal{E}_F)/kT} \cdot \frac{1}{2} \left(\frac{2kT}{m_n^*} \right) e^{-m_n^* v_{ox}^2 / 2kT} \sqrt{\frac{\pi 2kT}{m_n^*}} \cdot \sqrt{\frac{\pi 2kT}{m_n^*}} \quad (43)$$

The minimum energy

$$\frac{m_n^* v_{ox}^2}{2} = qV_{bi} - V_a \quad (44)$$

and the barrier height

$$q\phi_{Bn} = qV_{bi} + (\mathcal{E}_C - \mathcal{E}_F) \quad (45)$$

are substituted into Eq. (43). The thermionic current density is thus given in terms of the Richardson constant, A^* ,

$$J_{s \rightarrow m} = A^* T^2 e^{q\phi_{Bn}/kT} \cdot e^{-qV_a/\eta kT} \quad (46)$$

where

$$A^* = \frac{4\pi q m_n^* k^2}{h^3} \quad (47)$$

The only parameter in A^* that will vary from one material to another is the effective electron mass, m_n^* . Values for these can be found in [6]. The ideality factor, η , in a pn junction is 1 when diffusion current dominates and is 2 when recombination current dominates. For many Schottky barrier devices, $\eta \approx 1.08$ for either Si or GaAs.

When the applied voltage $V_a = 0$, thermal equilibrium occurs and

$$J_{m \rightarrow s} = J_{s \rightarrow m} = -A^* T^2 e^{-q\phi_{Bn}/kT} \quad (48)$$

As this does not change with applied voltage, the total current with an applied voltage is the total electron current.

$$\begin{aligned} J_n &= J_{s \rightarrow m} + J_{m \rightarrow s} \\ &= \left(A^* T^2 e^{-q\phi_{Bn}/kT} \right) \cdot \left(e^{qV_a/\eta kT} - 1 \right) \end{aligned} \quad (49)$$

6.2. Diffusion Theory

The diffusion theory is based on balancing the diffusion current with the conduction current in the diode [1].

$$\begin{aligned} J_n &= \frac{q^2 D_n N_c}{kT} \left[\frac{2q(V_{bi} - V_a) N_D}{\epsilon_s} \right]^{1/2} \\ &\quad \times e^{-q\phi_{Bn}/kT} \cdot \left(e^{qV_a/\eta kT} - 1 \right) \end{aligned} \quad (50)$$

The diffusion theory predicts that the saturation current varies with the $\sqrt{V_a}$ and is inversely proportional to temperature, which is in contrast with the thermionic theory where the saturation current is proportional to T^2 . Both theories have been incorporated into one to highlight the predominance of the thermionic mechanism at room temperature [2]. The effective thermal velocity and the diffusion velocity are respectively

$$\begin{aligned} v_R &= \frac{A^* T^2}{q N_C} \\ \frac{1}{v_D} &= \int_{x_m}^W \frac{q}{\mu kT} \exp \left[-\frac{q\psi(x)}{kT} \right] dx \end{aligned} \quad (51)$$

where ψ is the electron potential energy difference between the top of the barrier and the bottom of the conduction band in the semiconductor as a function of position, x , x_m is the point where the electron potential energy is maximum, and μ is the mobility. Neglecting optical phonon scattering and quantum-mechanical reflection of electrons, the revised ‘‘Richardson constant’’ is designated as A^{**} .

$$A^{**} = \frac{A^*}{1 + v_R/v_D} \quad (52)$$

7. SCHOTTKY BARRIER DEVICE CIRCUIT MODEL

The simplest model for a Schottky barrier diode is a voltage variable resistance. In addition, the depletion capacitance exists when the diode is in reverse or slightly

Figure 4. The Schottky diode circuit model with additional inductance necessary to fit data [7].

forward bias. The analysis in [7] shows the importance of the parasitic inductance in predicting the waveshape for the junction voltage, v (Fig. 4). One practical consequence is the discovery that burnout is associated with an over voltage rather than too much power, and this is only obvious after including the parasitic inductance in the calculations. As a reference point, the device parameters used in [7] at 9 GHz are $R_s = 8.5 \Omega$, $C_o = 0.08 \text{ nF}$, $L_s = 1.7 \text{ nH}$, $n = 1.1$, $I_s = 10^{-13} A^{**}$, $V_{bi} = 0.9 \text{ V}$, and $R_g = 50 \Omega$.

Applications for Schottky barrier diodes at millimeter and sub-millimeter frequencies have required that the diode model take into consideration skin effect, carrier inertia, and displacement current [8]. If the device radius is b and the contact radius is a , then clearly $a < b$. When $a \ll b$, the total diode impedance is the sum of the spreading and skin effects.

$$Z = Z_{sp} + Z_{skin} \quad (53)$$

$$Z_{sp} = \frac{1}{4\sigma a} \left[\frac{1}{1 + j(\omega/\omega_s)} + j(\omega/\omega_d) \right]^{-1} \quad (54)$$

$$\begin{aligned} Z_{skin} &= \left[\frac{\ln(b/a)}{2\pi} \right] \sqrt{\frac{j\omega\mu_0}{\sigma}} \\ &\quad \times \left[\frac{1}{1 + j(\omega/\omega_s)} + j(\omega/\omega_d) \right]^{-1/2} \end{aligned} \quad (55)$$

The definition of the dielectric relaxation frequency and scattering frequency are defined as

$$\omega_d = \frac{\sigma}{\epsilon} \quad (56)$$

$$\omega_s = \frac{q}{m^* \mu} \quad (57)$$

In these expressions, σ is the semiconductor conductivity, q is the charge of an electron, m^* is the effective mass of the carrier in the semiconductor, and μ is the carrier mobility. The equivalent circuit for the impedance, Eq. (53), is shown in Fig. 5 where the inertial inductance is

Figure 5. The Schottky diode circuit model incorporating spreading resistance, displacement capacitance, and inertial inductance [8].

$L_s = R_s / \omega_s$, the DC spreading resistance is R_s , and the displacement capacitance is $C_s = 1/R_s \omega_d$. The classic definition for the cutoff frequency is

$$\omega_c = \frac{1}{R_s C(v)} \Big|_{v=0} \quad (58)$$

but should now be found from the expression.

$$0 = \Re\{Z_{skin}\} + \Re\{Z_{sp}(\omega_c)\} - \frac{1}{\omega_c C(v=0)} \quad (59)$$

The cutoff frequency for an n-type GaAs Schottky barrier diode is as much as six times lower than what is predicted by Eq. (58), whereas for n-type Si, the results from Eq. (58) and Eq. (59) are quite close [8]. In any case, the theory shows that the smaller the contact radius, a , the higher the cutoff frequency.

The topology assumed by both [8,9] is a circular contact. An attempt was made in [10] to determine if alternative contact geometries might produce higher cutoff frequency devices. The finite element analysis of various geometries showed that for a given constant contact area, the skin effect resistance, R_{skin} , is minimized for a rectangular shape.

The analytical understanding of mixer and multiplier design will require simplification of the model described above. If the Schottky diode can be expressed as a nonlinear conductance based on Eq. (32), where J_s is

independent of voltage, then the conductance is

$$G(V_a) = \frac{dJA}{dV_a} = \frac{J_s}{V_T} A e^{V_a/V_T} \approx \frac{J(V_a)A}{V_T} \quad (60)$$

For a sinusoidal excitation given by

$$V_a = V_{dc} + V_1 \cos \omega t \quad (61)$$

the conductance can be expressed in terms of the modified Bessel functions.

$$G(t) = \frac{J_s A}{V_T} e^{V_{dc}/V_T} \left[I_0(V_1/V_T) + \sum_{n=1}^{\infty} I_n(V_1/V_T) \cos n\omega t \right] \quad (62)$$

In this expression, $V_T = kT/q$. The assumed sinusoidal excitation is a simplification of the analysis given in [7].

8. RECENT SiC SCHOTTKY BARRIER DESIGNS

The crystal structure of silicon carbide can take on a wide variety of stacking sequences with the same chemical composition. The stack can be viewed as alternating hexagonal planes of carbon and silicon atoms. Every silicon atom is bonded to four nearest neighbor carbon atoms, and each carbon atom is bonded to four nearest neighbor silicon atoms. The number of layers of SiC couples in the repeating sequence is designated by an integer. The most important values for a periodic stacking sequence in SiC are 3, 4, or 6. In addition, the crystal shapes of the material is designated as C for cubic, H for hexagonal, and R for rhombohedral. The published values for the number of polytypes have ranged from 170 to 250. Technologically, the most important polytypes of silicon carbide are designated as 3C-SiC, 4H-SiC, or 6H-SiC. Approximate values for some important properties of these materials are compared with those of Si in Table 2.

The wide bandgap of SiC (≈ 3 eV) compared with that of Si (≈ 1.1 eV) and GaAs (≈ 1.43 eV) makes this material ideal for high-power, high-temperature, and radiation-resistant applications. Silicon carbide also has high thermal conductivity and high saturated electron velocities. The most obvious difference between Si and SiC is the value for the intrinsic carrier concentration. The lower value for n_i in SiC makes the thermally generated leakage currents orders of magnitude smaller than that found for Si, thereby allowing much higher operating temperatures [12].

The choice of the metal used in the diode determines the tradeoff between low forward voltage drop and low reverse saturation current. A low barrier Schottky diode gives small forward voltage but a large reverse current. A high barrier Schottky gives a large forward voltage drop but a low reverse current. For mixer applications, a low forward voltage drop improves conversion loss.

Table 2. Physical Properties of SiC [1,11]

Parameter	Symbol	Units	Silicon	3C-SiC	4H-SiC	6H-SiC
Bandgap Energy	\mathcal{E}_G	eV	1.12	2.37	3.25	3.0
Intrinsic carrier concn.(300 K)	n_i	cm^{-3}	$1.45 \cdot 10^{10}$	–	$2 \cdot 10^{-8}$	$2 \cdot 10^{-6}$
Breakdown Field	E_C	V/cm	$3 \cdot 10^5$	$1.8 \cdot 10^6$	$1.5 - 4 \cdot 10^6$	$1.5 - 4 \cdot 10^6$
Electron mobility	μ_n	cm^2/Vs	1350	900	–	–
to c-axis			–	–	1050	100
⊥ to c-axis			–	–	800	375
Saturation velocity	v_s	cm/s	$1 \cdot 10^7$	$2 \cdot 10^7$	$2.2 \cdot 10^7$	$1.9 \cdot 10^7$
Thermal conductivity	κ	W/(cm K)	1.412	3.3	3.3	3.3

Nitrogen has been used for n-type doping in both the 4H- and 6H- materials with concentrations as high as $5 \cdot 10^{18} \text{ cm}^{-3}$. Both aluminum and boron have been used as p-type dopants for SiC, but Al gives the lowest resistivity and can have carrier concentrations as high as 10^{21} cm^{-3} . The design of a Schottky device not only involves determining the barrier potential at the Schottky junction, but also the design of the Ohmic contact on the other side of the semiconductor. The Ohmic contact for 6C-SiC is more difficult to form than for 3C-SiC. Both the barrier height and the Ohmic contact are heavily influenced by the polytype [11, p. 212].

A small-signal and large-signal model for a SiC microwave Schottky barrier diode was given in [13] using the basic topology given in Fig. 4, where L_s was not used. The saturation current was found from Eq. (49) where the Richardson constant was found to be $A^* = 151 \text{ A} \cdot \text{cm}^{-2} \text{ K}^{-2}$. Careful accounting of mobility, junction reverse capacitance, forward current density, reverse biased tunneling current, and barrier-lowering effect caused by the image force, resulted in a diode model that predicted both forward and reverse current with reasonable accuracy. The cutoff frequency available from SiC, however, still falls short of what can be achieved with GaAs Schottky barrier diodes [13].

Examination of the properties of SiC can be illustrated by the requirements for a mixer design. The desired mixer properties include achieving good linearity, high dynamic range, low conversion loss, low noise (especially $1/f$ noise), and low local oscillator power requirements. A measure of the linearity is the third-order intercept point, IP_3 , which is defined as the point on the IF output power vs. RF input power curves where the desired IF power and the third-order product intersect. Basically, the larger the IP_3 , the better. Schottky barrier diodes made with SiC offer some unique characteristics in regard to these parameters. Both the linearity and the conversion loss of the mixer may be enhanced by increasing the LO power. By sacrificing the low local oscillator power, conversion loss can vary from 26 dB to 5.2 dB as the local oscillator power changes from 0 dBm to 30 dBm [13]. At the same time, the IP_3 varied from 13 dBm to 31 dBm as the local oscillator power varied from 10 to 30 dBm. Similar results were obtained independently for local oscillator power levels up to 19 dBm

[14]. The improved conversion loss of the mixer is qualitatively the same as found by Torrey and Whitmer [9, p. 157]. The increase in linearity and the decrease in conversion loss comes at the cost of larger local oscillator power requirements. In absolute terms, wide bandgap Schottky barrier single ended mixer can achieve similar values for intermodulation distortion than a more complex resistance loaded, multiple device per branch double balanced Si mixer [14].

Low frequency $1/f$ noise properties of the Schottky barrier device become important in receiver designs. A variety of mechanisms have been suggested for the existence of this noise in Schottky barrier devices: Fluctuations in the number of charge carriers associated generation-recombination noise in the depletion region and trapping of carriers in a multistep tunneling process. However, for a Si Schottky barrier the spectral short circuit current is

$$S_I \propto \frac{I_F^\beta}{A^\gamma f^\delta} \quad (63)$$

where I_F is the forward current, A is the diode area, and f is the frequency. Typically, β and δ are near unity. However, the fluctuation in the number of charge carriers model would give $\beta \approx 2$. For this to correlate with Eq. (63), the low-frequency noise mechanism would have to be caused by fluctuations in the mobilities of the free carriers [15]. It was verified that the thermionic emission model for Richardson's equation was valid as given in Eqs. (46), (47). However, these equations do not contain mobility, so that $1/f$ noise is not present in ideal diodes. However, the modified Richardson's constant, A^{**} , is dependent on mobility, which does lead to the conclusion that mobility fluctuations results in current fluctuations [15]. A similar explanation for $1/f$ noise was found experimentally for 6H-SiC Ti Schottky diodes. For a wide bandgap material, the generation-recombination of carriers is much lower than in a Si device [16].

Other wide bandgap materials that have received considerable interest are AlN, InN, GaN, and AlGaIn, with the most attention for high-frequency devices centered on the latter two. The GaN material has an energy bandgap of 3.4 eV and a saturation velocity of $2 \cdot 10^7 \text{ cm/s}$, which is

similar to that found in SiC. All three materials, SiC, GaN, and AlGaIn, will probably play a much greater role in high-speed electronic devices in the near future.

9. MIXERS

Schottky diodes are the predominant diode type for microwave and millimeter wave mixers. Silicon diode ring and star connections of four diodes are readily available for use in double balanced mixers. GaAs offers improved conversion loss and noise performance over what is possible for silicon [17]. The saturation current is much higher in silicon than GaAs, and this leads to increased shot noise in silicon. The nonlinear conductance given in Eq. (60) is primarily responsible for the mixing properties of the Schottky barrier diode.

The conversion loss of a mixer along with its noise figure are the primary figures-of-merit for a mixer. The mixer is usually placed in the first or second stage of a receiver where it receives a low power signal. The theory on mixers was first developed based on the assumption of a sinusoidal voltage local oscillator waveform across the diode junction. As shown in [18], the waveform can be more accurately taken as a rectangular pulse. Nevertheless, the theory based on the sinusoidal waveform gives clearer analytical insight into mixer design and will be used here even though it may be less accurate.

9.1. Volt–Ampere Relationship for Mixing Frequencies

If the total voltage and current can be expressed as the sum of local oscillator values (v_p and i_p) and all the rest of the small signal components, then

$$v_t = v_p + v'_s \quad (64)$$

$$i_t = i_p + i'_s \quad (65)$$

The v'_s and i'_s are the sum of the RF input signal and all the rest of the sideband components. It is assumed from the outset that the RF input signal voltage is much less than the local oscillator pump voltage, so that the only frequencies generated are $m\omega_p \pm \omega_s$. The pumped conductance can be expressed in terms of a Fourier series.

$$G(v_p) = \sum_{m=-\infty}^{\infty} G_m e^{jm\omega_p t} \quad (66)$$

This equation multiplied by the small-signal sideband voltages,

$$v'_s = \sum_{m=-\infty}^{\infty} V_{np+s} e^{j(n\omega_p + \omega_s)t} + \sum_{n=-\infty}^{\infty} V_{np-s} e^{j(n\omega_p - \omega_s)t} \quad (67)$$

will give the current sidebands.

$$\begin{aligned} i'_s &= \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} V_{np+s} e^{j(n\omega_p + \omega_s)t} G_m e^{jm\omega_p t} \\ &+ \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} V_{np-s} e^{j(n\omega_p - \omega_s)t} G_m e^{jm\omega_p t} \end{aligned} \quad (68)$$

As each of the summations extend to $\pm\infty$, no change in the sum occurs if a finite shift in m exists. Hence, with m replaced by $m - n$, the sideband currents can be found.

$$\begin{aligned} i'_s &= \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} V_{np+s} G_{m-n} e^{j(m\omega_p + \omega_s)t} \\ &+ \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} V_{np-s} G_{m-n} e^{j(m\omega_p - \omega_s)t} \end{aligned} \quad (69)$$

The sideband current components can be expressed individually for a given m .

$$I_{mp+s} = \sum_{n=-\infty}^{\infty} V_{np+s} G_{m-n} \quad (70)$$

$$I_{mp-s} = \sum_{n=-\infty}^{\infty} V_{np-s} G_{m-n} \quad (71)$$

The goal now is to find an appropriate finite matrix that will describe the current–voltage characteristics of the device based on Eqs. (70) and (71). For example, if $m = 0$, the current at the signal frequency is seen to be the result of voltages at a variety of sideband frequencies.

$$\begin{aligned} I_s &= \cdots + V_{-3p+s} G_3 + V_{-2p+s} G_2 + V_{-p+s} G_1 + V_s G_0 \\ &+ V_{p+s} G_{-1} + V_{2p+s} G_{-2} + V_{3p+s} G_{-3} + \cdots \end{aligned} \quad (72)$$

$$\begin{aligned} I_{-s} &= \cdots + V_{-3p-s} G_3 + V_{-2p-s} G_2 + V_{-p-s} G_1 + V_{-s} G_0 \\ &+ V_{p-s} G_{-1} + V_{2p-s} G_{-2} + V_{3p-s} G_{-3} + \cdots \end{aligned} \quad (73)$$

If the voltages and current in Eqs. (70) and (71) are expressed in trigonometric form, then clearly the coefficients of the sine and cosine terms would be real, which implies that the coefficients of the exponential series on either side of zero are complex conjugates.

$$\begin{aligned} V_{-x} &= V_x^* \\ I_{-x} &= I_x^* \end{aligned} \quad (74)$$

Furthermore, the G_{m-n} coefficients are real. As a result, Eqs. (70) and (71) produce twice as many equations as necessary because one can be written as the complex conjugate of the other. Equations (70) and (71) can be expanded like Eqs. (72) and (73) for other values of m to give

a truncated matrix representation of the mixer.

$$\begin{bmatrix} I_s \\ I_{p-s}^* \\ I_{p+s} \\ I_{2p-s}^* \\ \vdots \end{bmatrix} = \begin{bmatrix} G_0 & G_1 & G_{-1} & G_2 & \dots \\ G_{-1} & G_0 & G_{-2} & G_1 & \dots \\ G_1 & G_2 & G_0 & G_3 & \dots \\ G_{-2} & G_{-1} & G_{-3} & G_0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} V_s \\ V_{p-s}^* \\ V_{p+s} \\ V_{2p-s}^* \\ \vdots \end{bmatrix} \quad (75)$$

This matrix relates currents to voltages at different frequencies and thus differs from the usual conductance matrix.

A similar matrix can be found for the current-voltage relation resulting from the pumped capacitance.

$$\begin{bmatrix} I_s \\ I_{p-s}^* \\ I_{p+s} \\ I_{2p-s}^* \\ \vdots \end{bmatrix} = \begin{bmatrix} j\omega_s C_0 & j\omega_{p-s} C_1 & j\omega_{p+s} C_1 & j\omega_{2p-s} C_2 & \dots \\ j\omega_s C_{-1} & j\omega_{p-s} C_0 & j\omega_{p+s} C_{-2} & j\omega_{2p-s} C_1 & \dots \\ j\omega_s C_1 & j\omega_{p-s} C_2 & j\omega_{p+s} C_0 & j\omega_{2p-s} C_3 & \dots \\ j\omega_s C_{-2} & j\omega_{p-s} C_{-1} & j\omega_{p+s} C_{-3} & j\omega_{2p-s} C_0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix} \times \begin{bmatrix} V_s \\ V_{p-s}^* \\ V_{p+s} \\ V_{2p-s}^* \\ \vdots \end{bmatrix} \quad (76)$$

The classic theory for the mixer is based on Eq. (75) and, for parametric amplifiers and upconverters, on Eq. (76). When both the nonlinear conductance and nonlinear capacitance are significant, the two effects can be added together. Physically, the generated frequencies are

$n\omega_p \pm \omega_s$, but only those frequencies shown in Fig. 6 are used to arrive at Eq. (75).

9.2. Mixer Conversion Loss

The typical mixer (Fig. 7) will have an RF small signal coming from the receive antenna, a large amplitude local oscillator of frequency ω_p , and the difference frequency called the intermediate or IF frequency. The customary notation for these frequencies, and other higher order terms, is given by the relationship

$$\omega_n = \omega_0 + n\omega_p \quad (77)$$

Figure 6 shows these frequencies where the RF signal, $\omega_1 > \omega_p$. The IF frequency is then ω_0 . For synthesis purposes, Eq. (75) is truncated to include only ω_0, ω_1 , and the image frequency ω_{-1} . Based on these three frequencies, the conversion loss and the optimum input conductance can be determined [9]. The conversion loss has been defined by [9] as the ratio of the input and output available powers. The theory based on this definition has been well developed.

The available power from the signal generator and from the IF output of the mixer is given below.

$$P_G = \frac{I_G^2}{8G_G} \quad (78)$$

$$P_0 = \frac{I_0^2}{8G_{out}} \quad (79)$$

In order to make the conversion loss a positive number when expressed in dB, it is defined as the reciprocal of the available gain.

$$L_a = \frac{P_G}{P_0} \quad (80)$$

The different frequency terms can be expressed in the way used in Eq. (70) and Eq. (71), or they can be expressed in the more usual mixer notation of Eq. (77). Some simplifying assumptions can now be made to the conductance matrix representing the mixer diode. First, only the RF, IF, and image voltages are nonzero. These correspond to the currents (applying the notational shift) $I_{p+s} = I_1, I_s = I_0$, and $I_{p-s}^* = I_{-1}^*$, respectively. In the former notation, I_s was considered the low-frequency input, but in typical mixer application, the lowest frequency is the IF. In short, the "s" does not really stand for the RF signal frequency anymore.

Figure 6. The spectrum of frequencies necessary to analyze the nonlinear conductance of a Schottky diode mixer.

The effect of the local oscillator voltage is to pump the diode, so this does not need to be further considered in the small signal analysis of the mixer other than through $G(v_p)$.

Equation (75) can be truncated still further to retain only the RF signal, IF output, and the image frequencies. Using the above revised notation, Eq. (75) is written as

$$\begin{bmatrix} I_1 \\ I_0 \\ I_{-1}^* \end{bmatrix} = \begin{bmatrix} G_0 & G_1 & G_2 \\ G_{-1} & G_0 & G_1 \\ G_{-2} & G_1 & G_0 \end{bmatrix} \begin{bmatrix} V_1 \\ V_0 \\ V_{-1}^* \end{bmatrix} \quad (81)$$

$$= \begin{bmatrix} y_{11} & y_{12} & y_{13} \\ y_{21} & y_{22} & y_{23} \\ y_{31} & y_{32} & y_{33} \end{bmatrix} \begin{bmatrix} V_1 \\ V_0 \\ V_{-1}^* \end{bmatrix} \quad (82)$$

Second, certain approximations can often be made in Eq. (81) or Eq. (82) that makes the analysis simpler. As the image and RF frequencies are typically close together, and the mixer is typically a broad-band circuit, it can be assumed that the external loads, $G_{image} = G_G$, and that conversion from the RF port to another port will be the same as the conversion from the image port to that same port (Fig. 7). Consequently,

$$y_{32} = y_{12}^* = G_{-1} = G_1 \quad (83)$$

$$y_{23} = y_{21}^* = G_1 = G_{-1} \quad (84)$$

$$y_{31} = y_{13}^* = G_{-2} = G_2 \quad (85)$$

$$g_{33} = y_{11}^* = G_0 = G_0 \quad (86)$$

so that for real matrix elements

$$\begin{bmatrix} I_1 \\ I_0 \\ I_{-1}^* \end{bmatrix} = \begin{bmatrix} g_{11} & g_{12} & g_{13} \\ g_{21} & g_{22} & g_{21} \\ g_{13} & g_{12} & g_{11} \end{bmatrix} \begin{bmatrix} V_1 \\ V_0 \\ V_{-1}^* \end{bmatrix} \quad (87)$$

Figure 7. Mixer circuit that includes terminations at the RF input signal, the IF output signal, and the image frequency.

If I_1 is replaced by $-G_G V_1$, I_0 is replaced by $+G_{out} V_0$ and I_{-1}^* is replaced by $-G_G V_{-1}^*$, then Eq. (88) becomes singular and only can be solved when the determinate is 0, which results in an equation that can be solved for G_{out} , the IF output admittance.

$$\begin{aligned} G_{out} &= g_{22} + \frac{2g_{12}g_{21}[g_{13} - (g_{11} + G_G)]}{(g_{11} + G_G)^2 - g_{13}^2} \\ &= g_{22} - \frac{2g_{12}g_{21}}{g_{13} + g_{11} + G_G} \end{aligned} \quad (88)$$

If in the IF port, $G_L = \infty$, then the IF voltage $V_0 = 0$. The current entering the RF port is $I_G - G_G V_1$, and the current entering the image port (where $G_{image} = G_G$) is $-G_G V_{-1}^*$. Solution of Eq. (87) for this condition leads to an expression for I_G and I_0 in terms of the RF voltage V_1 .

$$I_G = (g_{11} + G_G)V_1 - \frac{g_{13}g_{31}}{g_{11} + G_G}V_1 \quad (89)$$

$$I_0 = \left(g_{21} - \frac{g_{21}g_{13}}{g_{11} + G_G} \right) V_1 \quad (90)$$

By eliminating V_1 between these two expressions, I_0 can be related to I_G .

$$I_0 = \frac{g_{21}I_G}{g_{11} + G_G + g_{13}} \quad (91)$$

The conversion loss can be found now from Eqs. (78)–(80).

$$\begin{aligned} L_a &= \frac{P_G}{P_0} \\ &= \frac{G_{out}(g_{11} + G_G + g_{13})^2}{G_G g_{21}^2} \end{aligned} \quad (92)$$

The value for G_{out} in Eq. (88) is substituted into Eq. (92) to give the conversion loss in terms of the mixer diode properties and G_G only.

$$L_a = \frac{g_{12}}{g_{21}} \frac{(g_{11} + g_{13} + G_G)[g_{22}(g_{11} + g_{13} + G_G) - 2g_{12}g_{21}]}{G_G g_{21} g_{12}} \quad (93)$$

At this point, Torrey and Whitmer [9] normalized conductances in Eq. (93) with respect to g_{11} . If

$$\begin{aligned} x &= \frac{G_G}{g_{11}} \\ a &= 1 + \frac{g_{13}}{g_{11}} \\ b &= \frac{2g_{12}g_{21}}{g_{11}g_{22}} \end{aligned}$$

then

$$L_a = \frac{2g_{21}g_{11}}{g_{12}} \cdot f(x) \quad (94)$$

where $f(x)$ is defined as

$$f(x) = \frac{(a+x)(a+x-b)}{bx} \quad (95)$$

The value of $x = x_o$ that minimizes $f(x)$ is found by taking a derivative.

$$x_o = \sqrt{a(a-b)} \quad (96)$$

Substituting this result back into Eq. (95) gives the value for $f(x)$ that minimizes the conversion loss.

$$L_{a-min} = \frac{2g_{21}}{g_{12}} \frac{1 + \sqrt{1 - b/a}}{1 - \sqrt{1 - b/a}} \quad (97)$$

where

$$\frac{b}{a} = \frac{2g_{12}g_{21}}{g_{22}(g_{11} + g_{13})} \quad (98)$$

The optimum conductance for the RF port is found from $x_o g_{11}$.

$$\begin{aligned} G_{G-opt} &= g_{11} a \sqrt{1 - b/a} \\ &= (g_{11} + g_{13}) \sqrt{1 - b/a} \end{aligned} \quad (99)$$

and the optimum conductance for the IF port is found from Eq. (88).

$$G_{out-opt} = g_{22} \sqrt{1 - b/a} \quad (100)$$

Equations (97)–(100) can now be written in terms of the pumped conductance parameters Eqs. (83)–(86).

$$\frac{b}{a} = \frac{2G_1^2}{G_0(G_0 + G_2)} \quad (101)$$

$$L_{a-min} = 2 \frac{1 + \sqrt{1 - b/a}}{1 - \sqrt{1 - b/a}} \quad (102)$$

$$G_{G-opt} = (G_0 + G_2) \sqrt{1 - b/a} \quad (103)$$

$$G_{out-opt} = G_0 \sqrt{1 - b/a} \quad (104)$$

Values for G_0 , G_1 , G_2 , etc., are best obtained experimentally.

For a known mixer diode, Eqs. (103)–(105) and Eq. (102) give the design procedure and a predicted value for the minimum conversion loss. These are, as mentioned earlier, based on the assumption of a sinusoidal pump voltage at the diode terminals.

An alternative definition for conversion loss is the reciprocal of the transducer power gain, which is defined as the power available from the source to the IF power delivered to the load [17]. The 3×3 matrix Eq. (81) is converted to a 2×2 matrix, and the resulting matrix elements are used in the standard transducer power gain equation [18, p. 131].

Barber [19] determined the mixer conversion loss, noise figure, optimum G_G , and G_{out} as a function of the pulse duty ratio for three conditions: $G_{image} = G_G$, $G_{image} = \infty$, and $G_{image} = 0$. The pulse duty ratio is the ratio, t/T , where t is the time the local oscillator pulse is on and T is the total period of the local oscillator pulse generator, which is seen to be more accurate than an assumed sinusoidal voltage on the diode junction. It was found that the conversion loss was smallest when $t/T \rightarrow 0$. The minimum theoretical conversion loss (and noise figure) was shown to be 3 dB when $G_{image} = G_G$ and 0 dB when $G_{image} = \infty$ or 0.

9.3. Mixer Noise

The source of noise in a Schottky barrier diode can be considered to be from $1/f$ flicker noise at low frequencies, from shot noise at intermediate frequencies (which is essentially white noise), and noise associated with electron transit time effects at high frequencies. The transit time noise component was the subject emphasized in [20] for Si devices.

Achieving the lowest possible noise figure in a mixer requires cooling the devices to cryogenic temperatures. A double sideband (DSB) receiver noise temperature of 62 K was achieved at 100 GHz when the mixer was cooled to 20 K [21]. Their data also show an average DSB noise temperature of 75 K over the frequency range of 80 to 115 GHz. Single sideband noise temperature would be 124 K because the input signal is twice as large in the DSB measurement.

The shot noise component was addressed in [19] by associating the nonlinear conductance terms of the diode with the current components that gives rise to the shot noise, which implies that the mixer gain and noise are functions of the single variable, the AC input signal amplitude. Formulas given in [19] show noise figure for the three cases when the image conductance is infinite, is zero, and is equal to the source conductance.

The noise characteristics of Schottky barrier diodes become very important for mixer design for radio astronomy applications or millimeter-wave sensors. High-frequency devices require small areas to reduce capacitance, but small areas have been known to exhibit noise temperatures much greater than what would be predicted at cryogenic temperatures. The larger than expected noise has been seen to be the result of interfacial stress between the GaAs device and the SiO_2 , where the latter material is used to define the location and size of the metal contact on the GaAs [22]. The large difference in the expansion coefficients of the materials seems to produce stress, which in turn was responsible for higher than expected noise.

10. FREQUENCY MULTIPLIERS

The nonlinearity available in the Schottky barrier diode can also be used in frequency multipliers. In the Schottky barrier diode, both the forward conduction current, which provides nonlinear conductance, and the reverse biased charge storage in the depletion capacitance can contribute to the frequency multiplication process, which is in

contrast to the pn junction varactor that uses only the nonlinear capacitance (but might include diffusion capacitance). The varactor multipliers are more efficient and less noisy than Schottky diode resistive multipliers, but they are more sensitive to circuit tuning. Schottky barrier diodes used in broad-band frequency multipliers are more easily tuned and have fewer unwanted frequencies than their varactor counterpart. A discussion of combining $G(v)$ and $C(v)$ is found in [23], with regard to a mixer application.

The Manley–Rowe equations [24,25], which are basically a statement of energy conservation, show that the lossless varactor multiplier output power is proportional to the output to input frequency ratio, n , which is good news when the output frequency is higher than the input frequency, and bad news when the output frequency is lower. In contrast, for the resistive multiplier, the power at $n\omega_1$ is

$$P_n \leq \frac{P_1}{n^2} \quad (105)$$

and the remaining power is converted to DC.

$$P_{DC} \geq (n^2 - 1)P_1 \quad (106)$$

SCHOTTKY BARRIERS

S. ASHOK
The Pennsylvania State
University
University Park, Pennsylvania

The Schottky barrier, one of the earliest and simplest semiconductor interfaces studied, consists of a metal in contact with a semiconductor. It is named after Walter Schottky, who in the 1930s developed a comprehensive theory of such contacts, and traced their properties to the electrical barrier that forms at the metal-semiconductor (MS) interface. If the barrier height is relatively large, the current–voltage (I – V) characteristics exhibit an asymmetric rectifying behavior, while a symmetric linear I – V response results from a low barrier. The rectifying MS

contact is called the *Schottky diode*, whereas the nonrectifying device is simply referred to as an *ohmic contact*.

The first observation of asymmetric conduction in solids was made by Ferdinand Braun in 1874, when he studied the properties of metal contacts to metallic sulfides (later identified as semiconductors). The subsequent advent and rapid growth of radiocommunication led to widespread use of these contacts as “point contact” diode detectors. These naturally occurring semiconducting minerals suffered from high levels and variable distribution of impurities, which made the devices rather unreliable. Reproducible, high-quality MS interfaces had to await the post-World War II development of synthesized semiconductors of extremely high purity (such as Ge and Si) and the use of vacuum deposition techniques. Exhaustive studies of an enormous assortment of metal–semiconductor contacts have led to a better—although still incomplete—understanding of the mechanism of barrier formation. Other phenomena (such as carrier transport) are well understood, and Schottky contact technologies may be considered mature for most semiconductors.

Because of its inherent high speed, the Schottky diode is widely used in micro- and millimeter-wave detection and mixing, while the Schottky interface itself is a key element in important amplifying devices such as the *metal semiconductor field-effect transistors* (MESFETs) and the more recent heterostructure FET (HFET), as well as in a variety of radiation detectors. Commonly used metals generally form high barriers on n-type semiconductors, and this is also the usually desired situation in devices because of the higher mobility of electrons. The ohmic contact with negligible voltage drop across itself is essential for all external and internal connections to the elements of semiconductor devices; the theory of the Schottky barrier is also of relevance to the choice of metals for ohmic contacts.

1. THEORY OF SCHOTTKY BARRIER FORMATION

It is important to distinguish between two different types of MS interfaces: (1) those prepared on semiconductor surfaces freshly formed (by cleaving, or sputtering and annealing, or in situ epitaxy) in ultrahigh vacuum (UHV, with pressures $< 10^{-10}$ torr) and, hence, unexposed to the ambient; and (2) those prepared on chemically etched surfaces with the metallization done under simple high vacuum (pressure $\approx 10^{-6}$ torr). The former are of great importance in basic studies of Schottky barrier formation. These involve mono- and submonolayer coverage of the metal on freshly cleaved semiconductor surfaces and in situ evaluation of the barrier height as well as microscopic interactions between the metal and the semiconductor through sophisticated surface analytical tools. All practical Schottky barriers are formed on chemically etched surfaces and result in extremely reproducible electrical characteristics. Regardless of the specific MS interface, it turns out that the same physical models generally apply. This is true even for the special case of reacted metal–semiconductor contacts such as between metallic silicides and silicon. The silicide Schottky barriers are of interest from both fundamental and practical viewpoints, as the

MS interface here is buried inside the semiconductor bulk, thus obviating the deleterious influence of surface oxides and other contamination.

We will consider here two basic models, the earlier one due to Schottky and the later one inspired by Bardeen’s postulation of the surface states. Exhaustive reviews of the physical models and experimental data on the Schottky barrier may be found in Refs. 1–3.

2. THE INTIMATE SCHOTTKY CONTACT MODEL

This model, originally proposed by Schottky as well as Mott, assumes an intimate interface between the metal and the semiconductor with no interfacial layer between the two. Consider a metal with workfunction ϕ_m greater than the electron affinity χ_s of an n-type semiconductor. Figure 1a shows the electron energy lineup in the metal and the semiconductor before contact. When the contact is made (Fig. 1b), the workfunction (or, equivalently, electronegativity) difference forces a momentary net flow of electrons from the semiconductor to the metal until the MS system as a whole reaches thermal equilibrium with a single constant Fermi energy E_F . The consequences of this process are twofold: (1) an energy barrier ϕ_b separating the electrons in the metal from the empty conduction band states of the semiconductor at the interface and (2) a space

Figure 1. Electron energy band diagram of a metal and an n-type semiconductor under thermal equilibrium before (a) and after (b) contact. The workfunction of the metal ϕ_m is assumed to be greater than the semiconductor electron affinity χ_s .

charge or depletion region of width W on the semiconductor side of the interface. The electrical properties of the Schottky barrier arise principally from this space charge layer. The positive charge in the latter (Q_{sc}), consisting of ionized donors, compensates the negative electron charge in the metal (Q_m). Correspondingly, the space charge region develops a band bending qV_d in a manner similar to that in a p-n junction. From Fig. 1, the Schottky barrier height ϕ_b^n and (zero-bias) band bending qV_d or diffusion potential V_d are readily shown to be

$$\phi_b^n = \phi_m - \chi_s \quad (1)$$

$$qV_d = \phi_m - \phi_s \quad (2)$$

The space region width W is given by

$$W = \left[\frac{2\epsilon_s V_d}{qN_D} \right]^{1/2} \quad (3)$$

where ϵ_s is the dielectric permittivity of the semiconductor, q the electron charge, V_d the diffusion potential, and N_D the bulk donor concentration.

It is possible to form Schottky barriers on p-type semiconductors also, in which case we need $\phi_m < \phi_s$, and the Schottky barrier height ϕ_b^p (for holes, measured from E_{Fm} to E_v at the interface) becomes

$$\phi_b^p = E_g + \chi_s - \phi_m \quad (4)$$

Equations (1) and (4) predict a linear dependence of barrier height on metal workfunction, with a slope parameter $S_\phi = |d\phi_b/d\phi_m|$ equal to unity. However, experimental values of S_ϕ are significantly less than unity for most semiconductors, thus requiring a more elaborate model postulating the presence of an interfacial layer *and* interfacial charge. The first proposal for the interfacial charge was made by Bardeen, who recognized that the discontinuity of the crystal lattice at the surface would give rise to surface states or traps located physically at the semiconductor surface and energetically within the bandgap.

Addition of Eqs. (1) and (4) yields the relation

$$\phi_b^n + \phi_b^p = E_g \quad (5)$$

for any metal–semiconductor combination. While Eqs. (1) and (4) invariably fail to describe experimental results on Schottky barriers, the Schottky barrier heights of similarly prepared contacts on n-type and p-type semiconductors often add up to the bandgap as given by Eq. (5) for a variety of semiconductors and metals.

2.1. The MIS Schottky Contact Model

The MIS Schottky model incorporates the following changes to the intimate Schottky contact model: (1) an (ultrathin, tunnelable) interfacial layer (I) of thickness δ between the metal and the semiconductor and (2) interface traps of density D_{it} ($\text{cm}^{-2} \text{eV}^{-1}$) located at the IS interface and with occupancy controlled by the metal Fermi energy E_{Fm} . By Gauss' law, a surface charge density Q_{it} in

the interface traps would give rise to a potential (Δ/q) across the I layer as shown in Fig. 2. The resulting realignment of the semiconductor band bending then alters the barrier height, making it less dependent on the metal workfunction. In view of the electrical transparency of the I layer, note that the Schottky barrier height is still given by the difference between the semiconductor conduction band edge at the surface and the Fermi energy in the metal. With the additional source of charge, the charge neutrality condition becomes

$$Q_m + Q_{it} + Q_{sc} = 0 \quad (6)$$

It is convenient to define a “neutral level” ϕ_0 for the interface traps, such that the net interface trap charge Q_{it} is zero when E_{Fm} lies at ϕ_0 . From the band diagram of Fig. 2, using Gauss' law and a few simplifying assumptions, it can be shown (see Ref. 2, p. 20) that

$$\phi_b^n = \gamma(\phi_m - \chi_s) + (1 - \gamma)(E_g - \phi_0) \quad (7)$$

where $\gamma = \epsilon_i / (\epsilon_i + q\delta D_{it})$. Now the slope parameter $S_\phi = \gamma < 1$, and decreases monotonically with increase in the interface trap density D_{it} and interface layer thickness δ . In the extreme case when $(\delta D_{it}) \rightarrow \infty$, $\phi_b^n = (E_g - \phi_0) = \text{constant}$, independent of the metal workfunction ϕ_m —the so-called Bardeen limit. This situation is also referred to as (surface) Fermi level pinning, because E_{Fn} is now pinned

Figure 2. Electron energy band diagram for the MIS Schottky model under thermal equilibrium, with an ultrathin, tunnelable interfacial layer I .

to the neutral level ϕ_0 of the interface traps. If, on the other hand, $(\delta D_{it}) \rightarrow 0$, then Eq. (4) reduces to Eq. (1), which applies to the (intimate) Schottky limit.

If we use an upper limit of $\delta = 20 \text{ \AA}$ for a good Schottky diode and assume an $\varepsilon = 4\varepsilon_0$, the Bardeen limit is approached for $D_{it} \gtrsim 10^{13} \text{ cm}^{-2} \text{ eV}^{-1}$. Using a surface atomic density of 10^{15} cm^{-2} for a solid, this corresponds to about one interface trap for every 100 surface atoms. Such a high level of interface trap density contrasts with $D_{it} < 10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$ obtained for the high-quality thermal SiO_2/Si interface used in Si MOS technology.

Experimental verification of Eq. (7) requires deposition of metals of widely differing workfunction on identically prepared samples, rather than compiling data reported by different authors in the literature. Such studies on Si have yielded a γ in the range 0.15–0.22 depending, evidently, on surface preparation [4]. However, phenomena such as metal–semiconductor reaction, interfacial strain, and aging effects could profoundly influence the MS interface, so strict adherence of relations such as Eq. (7) should not be expected for all metal–semiconductor combinations. The principal success of the model is in explaining semiquantitatively those trends observed in measurements.

An expression similar to that in Eq. (7) can be derived for the MIS Schottky barrier on a p-type semiconductor, and again ϕ_b^n and ϕ_b^p add up to the bandgap E_g of the semiconductor as with the intimate Schottky model [see Eq. (5)]. Experimental data on a number of semiconductors confirm this trend (Ref. 2, Sec. 2). Thus a high barrier height on an n-type semiconductor implies a low barrier on the p-type. A practical conclusion from the MIS Schottky model, as with the intimate Schottky model, is that high barrier heights require metals of large workfunction for n-type materials and small workfunction metals for p-type materials. Measured barrier heights are typically in the range 0.6–0.8 eV for n-type Si, and 0.75–0.95 eV for n-type GaAs. Clearly, the higher the bandgap E_g , the higher will be the expected Schottky barrier height.

The stipulation of the I layer in this model is a logical one for Schottky barriers formed on chemically etched semiconductor surfaces. Most semiconductors form a native insulating oxide, 10–20 Å thick, on inevitable exposure to room ambient before the samples are introduced into the vacuum chamber for metallization. The MIS model, however, could also be applied to UHV-prepared intimate contacts because an atomic level separation between Q_m and Q_{it} is all that is needed to simulate the I layer; here the two sheet charges essentially constitute an atomic dipole.

The origin of the interface traps has been a subject of some controversy over the years, with at least two distinct schools of thought: (1) the unified defect model, where the surface Fermi level is pinned at discrete acceptor- and donorlike defect states induced by the metal deposition and (2) the continuum metal-induced gap states (MIGSs) that arise from the decay of the metal electron wavefunctions into the semiconductor, as originally proposed by Heine in 1965. More recent studies of both UHV and chemically etched samples appear to favor the MIGS theory although some anomalies persist, requiring an additional secondary

mechanism of metal deposition-induced defect states. These issues have been reviewed at length by Mönch [3,5].

The MIS Schottky model is most effective in giving a qualitative explanation for the observed weak dependence of barrier height on the metal workfunction. Quantitative, predictive interpretations using Eq. (7) are beset not merely by second-order phenomena, such as metal–semiconductor interdiffusion, but the more basic problem of choosing the right value for the workfunction ϕ_m . The workfunction of a solid contains surface as well as volume contributions, and both the intimate and MIS Schottky models tacitly assume that ϕ_m and χ_s do not change (at least differentially) when the metal and the semiconductor are brought into contact. This may not be true in practice, so other parameters of the metal such as electronegativity have been proposed over the years for correlating to barrier height. Other empirical correlations studied include the heat of formation of silicides, effective workfunction, and the interfacial crystal structure. Detailed discussions of these aspects can be found in an article by Werner and Rao [4] on silicon, and in the review by Brillson [6] on other types of semiconductors.

3. CARRIER TRANSPORT

The current flow across the Schottky barrier may be visualized as an extension of electron emission from a metal to vacuum. As seen in Fig. 1a, the energy barrier for this process is the metal workfunction ϕ_m , which constitutes the activation energy for over-the-barrier thermionic emission current [proportional to $\exp -(\phi_m/kT)$]. With the metal in contact with the semiconductor (Fig. 1b or 2), the effective barrier for electron emission changes to the Schottky barrier height ϕ_b , as empty states are available in the conduction band of the semiconductors to receive the emitted electrons. Further, unlike vacuum, the semiconductor is also a source of electrons for emission back into the metal. Most importantly, we can control this latter flow by applying a voltage V of proper polarity—the so-called forward bias where the n-type semiconductor is negatively biased—that raises the conduction (and valence) band edge upward by an amount qV relative to thermal equilibrium. As shown in Fig. 3, the energy barrier for electrons in the semiconductor reduces from qV_d to $q(V_d - V)$, which results in an exponential increase of current with the applied voltage. The path for this over-the-barrier-thermionic emission is shown as (a) in Fig. 3.

The current–voltage (I – V) characteristics of a Schottky barrier are then dominated by the thermionic emission process, with the following expression for current:

$$I = I_0 \left(\frac{\exp qV}{nkT} - 1 \right) \quad (8)$$

I_0 is the so-called saturation current given by

$$I_0 = A \cdot A^{**} \cdot T^2 \exp -\frac{\phi_b}{kT} \quad (9)$$

Figure 3. The band diagram of a metal/n-type semiconductor interface under an applied forward bias voltage V , displaying the various carrier transport mechanisms.

where A is the area of the Schottky contact; A^{**} is the modified Richardson constant, which is dependent on the semiconductor band structure; k is Boltzmann's constant; and T is the temperature in kelvins. Equation (8) also contains the so-called ideality factor n , which has a value slightly greater than unity. This n factor is a consequence of second-order effects such as the image force reduction of the Schottky barrier height, and the presence of any interfacial layer that drops part of the applied voltage and thus reduces the voltage across the semiconductor. High-quality, intimate Schottky barriers made on moderately doped semiconductors can have $n \leq 1.01$, while increased doping and presence of I layers can raise the value to as high as 1.1.

According to Eq. (8), the log I - V plot should be linear for $V \geq 3 kT$, with the zero-voltage extrapolation giving the saturation current I_0 . Using Eq. (9) and assuming the value of A^{**} ($112 \text{ A cm}^{-2} \text{ K}^{-2}$ for n -Si and $4.4 \text{ A cm}^{-2} \text{ K}^{-2}$ for n -GaAs), one can then extract the value of the Schottky barrier height ϕ_b . In the reverse direction, that is, for $V < 0$, the current will remain constant at the saturation value I_0 (typical range 10^{-10} – 10^{-6} A/cm^2) until the junction breaks down under large reverse bias. It is evident that Eq. (8) represents highly asymmetric I - V characteristics, leading to the use of the Schottky barrier as a rectifier in the Schottky diode.

Thermionic emission is the dominant transport mechanism at room temperature and above for Schottky barriers formed on moderately doped, single-crystal semiconductors, but a number of other mechanisms are also simultaneously present. Most of these are parallel processes and are illustrated in Fig. 3, where process b represents the thermionic field emission or thermally assisted tunneling process, where the electron climbs part way up the barrier thermally and tunnels through the rest; process c is field emission or direct tunneling across

the entire barrier; process d is recombination in the depletion region; and process e is recombination in the semiconductor bulk of injected minority holes.

Thermionic field emission and field emission become important as the dopant concentration is increased [with corresponding reduction in depletion width W , Eq. (3)] or temperature is reduced, and they have I - V relations similar in form to Eq. (8), but with an n factor increasing substantially above unity. In the extreme case of field emission, the (nT) product becomes a constant, giving a temperature-independent slope for the log I - V plots. In highly defective or disordered materials such as amorphous and polycrystalline semiconductors, one sometimes observes nonthermionic characteristics even at room temperature and at doping levels where direct field or thermionic field emission is impossible. These are attributed to "multistep" tunneling through impurity and defect levels in the depletion region.

Recombination in the depletion region (process d) and hole injection (process e) are identical to the phenomena that occur in a p-n junction. The former gives an additional current component similar to Eq. (8), but with an ideality factor n that is usually close to 2. If the corresponding I_0 is larger than that for thermionic emission, this component will show up as a shoulder in the log I - V plots under low forward bias. The (minority) hole injection component has a form similar to that in Eq. (8), but with $n = 1$. As the corresponding I_0 is invariably orders of magnitude lower than that for the majority electron thermionic emission, minority carrier injection into the semiconductor is only rarely observed in Schottky barriers, corresponding to unusually large barrier heights and high forward bias. Note that the electrons injected from the n-type semiconductor into the metal are still majority carriers in the metal, unlike those injected from the n- to the p-side of a p-n junction. Thus there is no minority-carrier storage in the Schottky diode, making it an extremely fast switching device.

All the current flow mechanisms identified in the preceding text are parallel processes. However, the thermionic emission process itself is in series with diffusion of majority electrons from the bulk towards the interface. Nevertheless, except in some very low mobility semiconductors, the rate-limiting step is thermionic emission, not diffusion. Thermionic emission and diffusion limits in a Schottky barrier are analogous to water flow in a pipe limited by the orifice and internal bulk friction, respectively. Further details of current flow in a semiconductor may be found in Ref. 2.

4. BARRIER HEIGHT MEASUREMENTS

The most commonly used technique for measuring the Schottky barrier height is the I - V measurement. As noted earlier, extrapolation of the forward log I - V plot yields I_0 , which is related to ϕ_b through Eq. (9). A simple room-temperature I - V measurement will suffice here if the value of A^{**} is assumed. However, the barrier height measured includes the effect of image force, a reduction on the order of 0.01–0.04 eV depending on the material and

doping. The error due to uncertainties in the value of A^{**} (due to the interfacial layer, etc.) is small (<0.02 eV for a factor of 2 change in A^{**}) due to its logarithmic influence on ϕ_b . For any meaningful interpretation of the log I - V data using the thermionic emission theory, it is important to verify that the linear region extends over at least two decades of current and that the n factor is less than 1.1.

An added degree of freedom in Schottky barrier measurement can be gained if the I - V measurements are made at different temperatures, typically at room temperature and above where thermionic emission is likely to dominate. Then an activation energy plot of $\log(I/T^2)$ versus $1/T$ should yield a straight line, whose slope gives the barrier height and the y -axis intercept yields the value of A^{**} . This approach hence does not require any knowledge of the Richardson's constant, and is particularly effective for the assessment of Schottky barriers containing intentionally introduced I layers for barrier height control.

Another frequently used electrical measurement is based on the depletion capacitance $C = \epsilon_s (A/W)$, which is a function of applied voltage V through Eq. (3) [modified by replacing V_d with $(V_d - V)$ under bias]. To avert the influence of strong conduction under forward bias, the capacitance-voltage (C - V) measurement is usually done under reverse bias (i.e., $V < 0$). Assuming that the dopant concentration is constant, a plot of $[1/C^2]$ versus V will then give a straight line with an x -axis intercept at V_d . Figures 1 and 2 show the relation between V_d and ϕ_b ; however, by including the effect of carriers at the depletion region edge through a correction term kT , one obtains the relation

$$\phi_b = qV_d + \zeta + kT \quad (10)$$

For intimate Schottky contacts on uniformly doped substrates, the agreement between I - V - and C - V -determined barrier height is quite close. However, the C - V technique fails to yield the correct barrier height with I layers of substantial thickness and interface traps that may respond to the AC measurement signal. Incidentally, the slope of the $1/C^2$ plot gives the doping concentration N_D , which turns out to be valid even for nonuniform doping. A convenient way of obtaining the doping profile of a semiconductor wafer is to use a mercury contact as a temporary Schottky barrier.

One of the most direct measurements of Schottky barrier height involves photoexciting the electrons in the metal over the barrier. This *internal* photoemission process requires photons of energy $h\nu$ lying between ϕ_b and E_g to avert fundamental absorption in the semiconductor. The photoyield Y (photoelectron per absorbed photon) is given approximately by

$$Y \simeq B[h\nu - \phi_b]^2$$

where B is a constant. A plot of $Y^{1/2}$ versus $h\nu$ gives a straight line with an x -axis intercept at ϕ_b . As with I - V measurements, this barrier height includes the image force reduction effect. The variable wavelength illumination needed for this measurement may be obtained using a

high-intensity white-light source and a monochromator. If the illumination is on the metal side, the thickness of the metal should be small ($\approx 100 \text{ \AA}$) because otherwise the photoexcited, *hot* electron with its limited mean free path cannot reach the interface.

5. MATERIAL SYSTEMS

Schottky barriers may be formed on literally any semiconductor, and in most cases it is easier to obtain a high barrier on n-type than on p-type material. There are exceptions such as InP, where the barrier height on n-type material is very low, seriously limiting the application potential of this important optoelectronic semiconductor in MESFETs. Most practical applications of Schottky contacts require a high barrier to minimize the leakage current I_0 , and this, coupled with the higher electron mobility, makes n-type semiconductors the preferred choice for Schottky-based devices.

The choice of the metal is also based on metallurgical considerations involving interfacial stability. Metal-semiconductor interdiffusion may occur at high operating temperatures and current densities, so practical contacts may involve multilayers, and refractory and other metals and their alloys. Metallic silicides (e.g., PtSi, Co_2Si) are particularly attractive Schottky contact materials for Si as well as compound semiconductors and are widely used.

The technique of metal deposition is also crucial in determining the barrier height. Thermal evaporation in high vacuum ($<10^{-6}$ torr) is the most innocuous method for Schottky barrier formation, while sputtering and related ion-beam/plasma techniques introduce defects close to the MS interface and significantly modify the Schottky barrier height [7].

6. SCHOTTKY BARRIER MODIFICATION

Modification and control of the Schottky interface have been the subject of intense interest since the 1970s, from both fundamental and practical viewpoints. The interest in basic studies stems from the possibility of "passivating" the interface traps with suitable chemical treatment so that one may achieve the Schottky limit. Studies have also focused on introducing insulating as well as semiconducting nanoscale interlayers (e.g., Al/Si/GaInP, Metal/ Si_3N_4 /Si) to form deliberate MIS structures for barrier modification [8]. Interface doping can also be used to alter ϕ_b . An elegant practical technique is that proposed by Shannon [9]. By using a very shallow ($\approx 100 \text{ \AA}$) implanted layer between the metal and the semiconductor, the shape of the barrier is altered, thereby changing the effective barrier height. If the implanted species are of the same conductivity type as the substrate, the increased electric field and thinning of the barrier near the top causes carrier tunneling. This effectively reduces barrier height. With an implant of the opposite conductivity type, the dopant compensation causes electric field reversal near the top, thereby increasing barrier height.

More recent contributions to the understanding of Schottky barriers have come about from the study of

epitaxial silicide/Si interfaces where the crystallographic effects are very much in evidence. A very interesting result is the difference in barrier height of 0.13 eV between NiSi₂ and Si(111) depending on whether both have the same orientation or are rotated 180° about the $\langle 111 \rangle$ direction.

A closer inspection of the electrical and structural properties has also forced one to consider the inherent inhomogeneities at Schottky interfaces. The spatial potential fluctuations effectively yield a distributed system of parallel Schottky barriers of varying barrier heights. Hence, the net carrier transport can be profoundly influenced through the exponential dependence of current on ϕ_b [see Eqs. (8), (9)]. These issues are discussed at length in Ref. 4.

1. INTRODUCTION

The characteristic properties of semiconductor materials play a key role for the performance of the fabricated electronic devices. In this respect, silicon carbide (SiC) devices offer great advantages to overcome the physical device limitations in silicon (Si) devices set by the materials

Figure 1. Figures of merit for various semiconductors. All values are normalized with respect to Si, including Johnson's figure of merit (FoM) (JFM in diagram) for basic limits on the device performance (high power and frequency) and Keyes' FoM (KFM in diagram) for the switching speed of transistor. Quality factors QF1–3 take thermal properties into consideration (QF1) for the heatsink material and the active-device area in power devices. QF2 assumes a perfect heatsink. QF3 is based on no heatsink nor geometric factors. Baliga's FoM (BFM in diagram) can be used for evaluation of high-frequency application.

properties in Si. The theoretical performances of SiC can be compared to Si and other common semiconductors using appropriate figures of merit [1] (see Fig. 1).

Si devices are generally used below a maximum junction temperature of $\sim 200^\circ\text{C}$ and confined to blocking voltages of a few kilovolts. Because of its large bandgap, SiC possesses a very high breakdown field and low intrinsic carrier concentration, which consequently makes high voltage and high temperature operation possible. SiC is also suitable for high-frequency device applications, because of the high saturation drift velocity and low permittivity. The material quality and the diameter of silicon carbide wafers have steadily been improved and the micropipe densities have been reduced to $\sim 10\text{ cm}^{-2}$ at production level ($\sim 0.9\text{ cm}^{-2}$ for a 50-mm 4H SiC wafer in research stage) [2,3]. This is promising for future fabrication of larger than millimeter-sized devices. Presently, 6H and 4H SiC wafers of n and p types with a diameter of 75 mm are commercially available, while wafers of 100 mm diameter are shown as viable demonstrators expected to be in production within a few years. Most of the key SiC process technologies including doping, dry etching, oxide growth, and Schottky and Ohmic contacts, and are relatively mature and compatible to those in Si processing. However, some key processing issues that are critical must still be overcome for device commercialization. In this article, the progress and the current status of SiC device technologies are discussed.

2. PROCESS TECHNOLOGY

A good feature with SiC is the excellent behavior to be thermally oxidized to form SiO₂, which is crucial in both fabricating devices with MOS structures as well as passivation of surfaces. SiC is normally oxidized at higher

temperatures ($> \sim 1150^\circ\text{C}$) and at slower rate, due to the stronger Si–C bonds compared to Si–Si bonds [4]. The interface properties of SiO_2/SiC have recently been improved by H_2 treatment prior to the oxidation or by postoxidation annealing in NO or N_2O [5]. A serious problem with oxidation of SiC is the low MOS channel mobility. The highest values reported for the n-channel inversion mobility in $6H$ SiC is $70\text{--}100\text{ cm}^2/\text{V}\cdot\text{s}$, whereas values of $1\text{--}20\text{ cm}^2/\text{V}\cdot\text{s}$ are commonly found for the inversion channel mobility in $4H$ SiC [6].

High-voltage termination technique is crucial to high power devices. Most passivation techniques in Si devices are also applicable to SiC, which includes guard rings, field plate termination, and junction termination extensions (JTEs). Other passivation techniques suggested are the high-dose implantation of inert ions (either Ar or B) forming a high-resistivity region or to create a beveled surface region by etching. Power switching devices appear to perform well with these passivation treatments even though the inadequate passivation affects the subthreshold or the microwave characteristics of JFETs [7] and MESFETs [8].

Whereas the large Si–C bonding energy makes silicon carbide attractive for applications in harsh environments, it becomes problematic in etching SiC. Because of the high bond energies between silicon and carbon, the conventional wet chemical etching is not possible at practical process temperatures. Hence plasma-based dry etching plays a crucial role in SiC for the device pattern transfer process. Plasma etching is used for junction termination in mesa structures, devices with various structures such as U-MOSFETs, buried-gate JFETs, BJTs, or via-hole etching in SiC. Plasma etching of SiC in F-based chemistry has been proved to work well [9]. Etch rates as high as $1.35\text{ }\mu\text{m}/\text{min}$ in helicon reactor and $970\text{ nm}/\text{min}$ by inductively coupled plasma reactive ion etching in a SF_6/O_2 plasma have been reported. Electrical properties of Schottky and Ohmic contacts on etch damaged surfaces are of interest, and more recent studies show that the damage from a low-energy etched $4H$ SiC can be recovered by a sacrificial oxidation annealing [10].

All devices need good low-Ohmic contacts. They are particularly important for applications using high current densities that result in large voltage drops across even small resistances. The specific contact resistance to n- and p-type SiC is normally in the range of $10^{-4}\text{--}10^{-6}\text{ }\Omega\text{ cm}^2$ and $10^{-3}\text{--}10^{-5}\text{ }\Omega\cdot\text{cm}^2$, respectively, and are highly dependent on the surface doping concentration, choice of the metal, sample preparation, and the postmetallization heat treatment. The surface of SiC can be terminated by either Si or C and will greatly affect the contact properties. Normally contacts are made to Si-surface-oriented device structures, which has proved to yield reliable properties. Ohmic contacts to n-type SiC seem to be acceptable for device applications. However, because of the higher barrier height, it is yet more difficult to obtain lower specific contact resistance (ρ_c) for p-type SiC. Generally, Ni-based and aluminum-based contacts have been widely used for n-type and p-type SiC, respectively. The lowest contact resistivities yet reported for p-type SiC is in the $5 \times 10^{-6}\text{ }\Omega\cdot\text{cm}^2$ range using CoSi_2 by sequential evaporation

of Co and Si on $6H$ SiC [11]. Various interesting approaches can be found in the literature. Epitaxially grown TiC on $4H$ SiC has shown good Ohmic contact properties (5×10^{-6} and $3 \times 10^{-5}\text{ }\Omega\cdot\text{cm}^2$ for n- and p-type $4H$ SiC epilayers) by using coevaporation with an e-beam for Ti and a Knudsen cell for C60 in a UHV system, which required an annealing temperature of only $\sim 500^\circ\text{C}$ [12].

3. DEVICE APPLICATIONS

3.1. High-Voltage Devices

SiC offers a high voltage capability that can be realized on much thinner drift layers than in Si or GaAs. High breakdown voltage with lower on-state resistance can be achieved because of the high critical electric field of SiC. Schottky diodes are approaching the unipolar limit of $4H$ SiC and are today commercially produced by Infineon and Cree Inc. with voltage ratings up to 600 V. The SiC Schottky diodes are free from reverse recovery, and this reduces switching power losses, thus allowing higher switching frequencies in converter circuits. In the development and research laboratories, several Schottky prototypes approaching 2000 V have been demonstrated. SiC junction barrier Schottky (JBS) diodes are interesting candidates to Schottky diodes in the 600–3300 V blocking voltage regime. JBS diodes [11] combine the excellent switching behavior of Schottky diodes with a low leakage current approaching that of PN diodes. The process technology of JBS diodes is, on the other hand, more complex than for Schottky diodes. Figure 2 shows a performance comparison between Schottky and JBS diodes [13].

PN diodes become advantageous for voltages above $\sim 3\text{--}4\text{ kV}$ because of their lower on resistance obtained through conductivity modulation. Cree Inc. have reported the highest breakdown voltage for a PN diode [14] to date with $\sim 19.2\text{ kV}$ and a low forward voltage drop of 4.9 V at $100\text{ A}/\text{cm}^{-2}$ that clearly indicates conductivity modulation. This type of very-high-voltage diode has potential

Figure 2. Performance comparison between Schottky and JBS diodes.

application with substantial system benefits, for instance, in high-voltage DC power transmission. Very-high-voltage diodes are, however, interesting mainly for applications with high currents of 100 A and more. This requires chip sizes in the range of 1 cm^2 , and a commercially viable production of such diodes therefore requires significant improvements regarding crystal imperfections such as micropipes, screw and edge dislocations, and low-angle grain boundaries. Another problem that needs to be solved is the long-term degradation of bipolar SiC devices caused by recombination assisted defect generation and motion discovered in 2002 [15].

Among switching power devices, MOSFETs, JFETs, bipolar junction transistors, and thyristors have been experimentally demonstrated. In $4H$ SiC MOSFETs, the measured ON-state resistance is relatively poor due to a low effective channel mobility. More recently, however, MOSFETs fabricated on $6H$ and $15R$ SiC as well as on the $(11\bar{2}0)$ or $(03\bar{3}8)$ surface of $4H$ SiC showed impressive performances. Double-implanted MOSFETs in $6H$ SiC showed properties exceeding 30 times the Si theoretical limit with V_B of 1.8 kV and R_{ON} of $46 \text{ m}\Omega \cdot \text{cm}^2$ [16]. Static channel expansion MOSFETs with 5.0 kV and R_{ON} of $88 \text{ m}\Omega \cdot \text{cm}^2$ have been demonstrated in $4H$ SiC, using an accumulated MOS gate and a pn-junction gate [17,18]. Additionally, the highest blocking voltage for a SiC switching device (6.5 kV) was obtained with an accumulation-mode MOS gated device [19]. Technological challenges for SiC MOSFETs are improvements regarding channel mobility and oxide reliability.

JFETs, which are unipolar devices without any Schottky or MOS interface, have advantages due to the built in potential and inherent stability of the pn-junction gate and do not suffer from the low channel mobility of the MOSFETs. Thus they are suitable for applications in which the normally ON characteristic is not a severe disadvantage. The best performance published to date in a SiC majority-carrier active switch was in a vertical JFET with R_{ON} of $26 \text{ m}\Omega \cdot \text{cm}^2$ for devices with 3.5 kV breakdown voltage [20]. Those types of JFETs are connected with Si MOSFETs in a cascode configuration to obtain a module with normally OFF characteristics. SiC JFETs combine low ON-state resistance with fast switching and excellent short-circuit withstand times in the range of milliseconds.

Progress has been made in development of SiC bipolar junction transistors (BJTs) with an ON-state resistance of only $10.8 \text{ m}\Omega \cdot \text{cm}^2$ for a device blocking 1.8 kV [21]. The BJTs combine a very low ON-state resistance with fast switching, thanks to the thin drift layer needed for SiC devices. Most of the reported SiC BJTs have epitaxially grown emitter regions and common-emitter current gains in the range of 10–50. Increased complexity in drive circuitry and the low current gains are drawbacks of BJTs compared to FETs, whereas normally OFF characteristics are an advantage compared to the JFET.

Promising results have been reported also for thyristors with a gate turnoff GTO thyristor capable of blocking 2.6 kV and turning off 12 A [28]. Thyristors are, however, like PN diodes, mainly interesting in large chip sizes and therefore depend on improvements in material quality for a potential commercialization.

Table 1. Summary of High-Voltage SiC Devices

Device (Polytype)	V_{BD} (kV)	R_{ON} ($\text{m}\Omega \cdot \text{cm}^2$)	V_{BD}^2/R_{ON} (MW/cm^2)	Ref
PIN diode ($4H$)	19.5	65	5850	14
PIN diode ($4H$)	4.5	42	482	20
JBS diode ($4H$)	2.8	8	980	11
Schottky diode ($4H$)	4.9	43	558	22
DMOSFET ($4H$)	2.4	42	137	23
SIAFET ($4H$)	6.1	732	51	19
SEMOSFET ($4H$)	5	88	284	17

JFET ($4H$)	5.5	218	139	25
VJFET ($4H$)	2	70	57	26
VJFET ($4H$)	3.5	25	490	20
VJFET ($4H$)	1.7	3.6	802	47
BJT ($4H$)	1.8	10.8	300	21
BJT ($4H$)	1	17	59	27
BJT ($4H$)	1.3	8	211	29

The breakdown voltage squared over the ON-state resistance (V_{BD}^2/R_{ON}) is compared in general, as shown in Table 1. In Fig. 3, the results are plotted with the ideal ON-state resistance of Si, $6H$ SiC, and $4H$ SiC devices. As can be seen, diodes have been more successful so far, and are very close to the ideal R_{ON} . To calculate the forward voltage drop, the R_{ON} should be multiplied by the current density. For the bipolar devices there is an additional voltage drop because of the built-in voltage of the pn junction, around 0.7 V for Si and 2.5 V for SiC. For the MOSFETs in Table 1 and Fig. 3, the ON-state resistance is, to a large extent, the channel resistance, since the mobility of the inversion channel is still a problem.

3.2. RF Power Devices

SiC devices have shown considerable improvement and superior RF power performance compared to those

Figure 3. ON-state resistance versus blocking voltage performances for reported SiC devices.

Table 2. Summary of High-Frequency SiC Devices

Device (Polytype)	Frequency (GHz)	Power Density (W/mm)	Ref.
IMPATT diode (4H)	9.9	300 mW (pulsed)	30
IMPATT diode (4H)	7.2	9 kA/cm ² (pulsed)	31
MESFET (4H)	3.5	5.2 (pulsed, total 62 W)	32,33

MODFET (GaAs)	2.16	2.22 (pulsed, total 200 W)	43

available from Si or GaAs devices. Better high frequency figures of merits are attributed to improved materials properties such as bandgap, critical electric field, and thermal conductivity as well as the saturation electron velocity, and also to a reduced capacitance from decreased device area. The most recent results demonstrated on SiC RF power devices are listed in Table 2. The RF power available from an impact ionization avalanche transit time (IMPATT) diode in SiC is ~ 100 times higher than in Si or GaAs. Promising devices have been demonstrated for IMPATT diodes with X-band operation and microwave power of 300 mW [30].

SiC MESFETs are developed as power transistors for operating frequencies in the 1–10 GHz range (from UHF through X band). Cree Inc. is marketing MESFETs with a best performance of 5.2 W/mm at 3.5 GHz and 63% power-added efficiency (PAE) for a $0.7\text{ }\mu\text{m} \times 48\text{-mm}$ device and monolithic microwave IC (MMIC) amplifiers based on these devices are also demonstrated with a power 36.3 W, associated gain of 0.5 dB, and PAE of 20.6% [33].

Static induction transistors (SITs) are also unipolar devices with a pn junction or a Schottky controlled gate. Normally, a SIT has a vertical channel structure for higher power density but is restricted to lower frequencies (UHF to C band) compared to MESFET with a lateral channel.

High-electron-mobility transistors (HEMTs) based on the AlGaN/GaN heterostructure show very promising device operation at frequencies of 10 GHz and higher. In this structure, a 5-times-higher two-dimensional electron gas (2DEG) than in the AlGaAs/GaAs structures allows a higher current capability. However, conventional GaN devices on sapphire substrates are not well suited because of a poor lattice match between GaN and sapphire ($\sim 13\%$) and thus high defect density ($\sim 10^8/\text{cm}^2$). By using a SiC substrate, the lattice mismatch can be decreased and the efficient heatsink is considerably better because of higher thermal conductivity in SiC.

There are several figures for comparing high-frequency devices, such as maximum operating frequency (f_T) or maximum frequency of oscillation (f_{max}). It is common to scale the output power with the gate width when compar-

ing devices with different dimensions at the operating frequency. Any device used in a circuit to measure the output power needs an f_T and f_{max} about 5–10 times higher than the operating frequency as a rule of thumb (see Fig. 4).

There are other aspects to consider when designing high-frequency devices. One is impedance matching, which influences linearity and bandwidth of an amplifier. The RF power devices in silicon today have output impedances in the order of $2\text{ }\Omega$, requiring complicated frequency-dependent matching circuits. The wide-bandgap materials have an advantage here in terms of breakdown voltage. Due to high critical fields, the devices in the GHz range can have breakdown voltages in the order of 200 V, which is necessary for high power delivery directly to a $50\text{-}\Omega$ load. For example, 30 W of power delivered to such a load requires a voltage swing of 55 V, and a device with a breakdown voltage safely above twice this value. However, in order to utilize this advantage the parasitic

Figure 4. Output power density versus operating frequency for some more recent high-frequency devices.

Figure 5. (a) A SEM image and (b) a schematic cross section of the 4H SiC ferroelectric FET in SiC.

elements have to be controlled, since higher output impedances are more sensitive to parasitics. Output impedances for 1-mm²-sized 4H SiC MESFETs are between 20 and 40 Ω.

3.3. Other Application Areas

A SiC application very close to commercial use is catalytic gas sensors. The basic principle is to use a catalytic metal (Pt, Pa, Ir, etc.) as gate on a metal–oxide–semiconductor (MOS) structure. Some gases will crack or decompose on the catalytic metal, and hydrogen ions can be sensed on the gate by the shift in flatband voltage that the extra charge incurs. Several devices based on this principle have been demonstrated in several different sensor applications for combustion processes [44].

More recently, the structural and electrical properties of ferroelectric PZT/Al₂O₃/4H SiC diode structures are proved to be promising for device applications [45], and the experimental results in the ferroelectric FETs (FeFET) in SiC showed nonvolatile operations (see Fig. 5). As shown in Fig. 6, it can be clearly seen that I_D – V_G characteristics exhibited memory effect; depending on the sweep direction, two different values of I_D can be measured for the same gate voltage [46]. The results are promising for other smart sensing applications utilizing high-temperature and high-frequency properties of ferroelectrics.

Figure 6. Static drain current versus drain voltage characteristics of a typical SiC ferroelectric FET after different V_G of +12 and –12 V has been applied.

4. SUMMARY

A discussion of the advantageous physical material properties of SiC that allows for high power, high frequency, and high temperature applications was presented. An updated review of the state-of-the-art performance was given for high-voltage as well as RF power devices. Although serious defect problems still remain to be overcome before large-area devices can be economically viable, the development of fabrication processes for SiC is at a relatively advanced stage and superior to most other wide-bandgap semiconductors. New emerging device applications such as the FeFET were presented.

SIGNAL FADING IN RADIOCOMMUNICATIONS

RAMAKRISHNA JANASWAMY
University of Massachusetts
Amherst, Massachusetts

1. INTRODUCTION

THE term *fading* generally refers to the fluctuation of a radiofrequency (RF) signal with respect to time due to wave interference associated with time-varying propagation multipath. Multipath may be caused by reflections, refractions, diffractions, or scattering of the radio signals by obstacles dispersed around the transmitter and receiver. Time variation is caused by the motion of the transmitter, or the receiver, or the multipath environment, or combinations thereof. Depending on the time scales of variation, fading is characterized either as short-term (also referred to as *fast fading*) or long-term (also referred to as *slow fading*). Long-term variations are usually associated with obstacles causing shadowing and blockage of signals, and these influence the attenuation of the mean signal level. Examples are large buildings, trees, and solar or meteorological influences, all extending over at least a few tens of wavelengths of the RF signal. In terrestrial mobile communications, the long-term timescales can vary from few tenths of a second to a few seconds depending on the mobile speed and the angle of arrival of the multipath waves. In HF communications, timescales can range from a few minutes to a even a few hours depending on solar activity and meteorological influences; in many cases the long-term variation includes components that are diurnal, seasonal, or annual, or even involve the 11-year sunspot cycle. The availability of a channel in a wireless communication system is determined by long-term fading, whereas short-term fading variations affect the details of received waveform structure and system performance parameters such as the error rate. Because of the complexity and variety of the multipath environment, one often resorts to a statistical description of long-term and short-term fading. In most wireless systems, long-term fading and short-term fading coexist, and these variations

are superimposed on the gross variation of signal strength resulting from wave spreading in space. However, it is reasonable to assume that the long-term variability is sufficiently slow such that the short-term fading statistics are locally stationary; thus the channel statistics of the latter can be regarded fixed over an interval of interest. This assumption facilitates independent handling of the two statistics and greatly simplifies system analysis. Section 5 of this article describes short-term fading and the parameters of interest in a system design. Section 5 describes long-term fading and its effect on the determination of a cell size in a cellular type of system. Section 5 discusses current work and research topics in the area.

2. SHORT-TERM FADING

Short-term fading is a direct consequence of multipath and motion. When the radio environment consists of many scatterers, multiple copies of the transmitted signal waveform appear at the receiver, and this phenomenon is termed *multipath*. In addition, if there is motion at the transmitter or receiver, or in the environment, the received signal time and frequency characteristics are altered as a result of constructive and destructive interference of the multipath wave components. In the general case, the propagation channel can be conveniently treated as a time-varying linear system. However, it is instructive to discuss the narrowband case and the wideband case separately to gain a better understanding of the fading phenomena.

When a pure tone of frequency f_c and amplitude A_c is transmitted through a time-varying discrete multipath channel, the latter imposes amplitude and phase fluctuations on the carrier. One consequence of this is that the frequency of the carrier experiences a *Doppler shift*, whose maximum value, f_{dM} , depends on the transmitted wavelength λ and the maximum speed of motion v_0 :

$$f_{dM} = \frac{v_0}{\lambda} = 1.4815 f_{\text{GHz}} v_{0\text{mph}} \quad (1)$$

where the frequency f_{GHz} in the latter is expressed in GHz (gigahertz) and the speed of motion $v_{0\text{mph}}$ is expressed in miles per hour. For example, if the frequency of operation is 1 GHz and the receiver moves at a speed of 100 mph, the maximum Doppler shift is 148.15 Hz. The reciprocal of the maximum Doppler shift defines a timescale of variation of short time fading. In the example above, we say that radio channel has a variability over timescales of the order of 6.75 ms. More precise parameters such as the Doppler spread B_D , the level crossing rate N_A , and the average fade duration τ_A will be defined later. When a pure tone experiences fading, signal fluctuations of 40 dB or more about the mean level are not uncommon, with successive minima occurring every half-wavelength or so at the carrier frequency. In the design of digital systems, the data rate must be chosen so that there is no loss of coherence over the symbol as received. A rule of thumb is to choose the symbol rate to be at least two orders of magnitude greater than the maximum Doppler frequency.

When an electromagnetic wave of certain polarization enters a medium consisting of arbitrarily oriented scatterers, its polarization gets altered as a result of multiple scattering. One may expect to receive power from all polarizations even though it may be dominant in one polarization. For the sake of simplicity, we ignore polarization aspects and treat only scalar wave propagation here. Assuming a discrete multipath model, the complex envelope¹ of the total received signal could be written as

$$z(t) = A_c \sum_{n=1}^N a_n e^{j(2\pi\nu_n t + \phi_n)} \quad (2)$$

The time-varying equivalent lowpass transfer function $H(t)$ of the channel is thus

$$H(t) = \sum_{n=1}^N a_n e^{j(2\pi\nu_n t + \phi_n)} \triangleq a(t) e^{j\varphi(t)} \triangleq X(t) + jY(t) \quad (3)$$

The Doppler frequency ν_n depends not only on ν_0 and λ , but also on the angles of arrival (θ_n, ϕ_n) of the n th multipath wave relative to the direction of motion. Also, the amplitude a_n , the phase ϕ_n , and the number of independently varying multipath components N can all be treated as random numbers changing from location to location. It is seen from (2) that the time variation of the channel is a consequence of the Doppler shift experienced by the carrier. If the number of multipath components is large enough (typically $N \geq 5$), then, by the central-limit theorem, $H(t)$ will converge to a complex Gaussian random process, namely, the in-phase component $X(t)$ and the quadrature phase component $Y(t)$ of the complex envelope $H(t)$ will be independently distributed Gaussian random processes, or equivalently, the actual envelope $a(t) = \sqrt{X^2(t) + Y^2(t)}$ will be Rayleigh distributed and the phase $\varphi(t) = \text{atan}(Y(t)/X(t))$ will be uniformly distributed. Denoting the instantaneous signal power received with $A_c = 1$ as $S = \frac{1}{2}|H(t)|^2$ and its mean as $\sigma_S^2 = \langle S \rangle$, where angle brackets denote statistical expectation, the probability density functions (pdf's) for the phase envelope, and power are given by

$$p(\varphi) = \frac{1}{2\pi}, \quad 0 \leq \varphi \leq 2\pi \quad (\text{uniform distribution}) \quad (4)$$

$$p(a) = \frac{a}{\sigma_S^2} e^{-a^2/2\sigma_S^2}, \quad 0 \leq a < \infty \quad (5)$$

(Rayleigh distribution)

$$p(S) = \frac{1}{\sigma_S^2} e^{-S/2\sigma_S^2}, \quad 0 \leq S < \infty \quad (6)$$

(exponential distribution)

¹The complex envelope $u(t)$ of a real signal $s(t)$ relative to a nominal frequency f_c is defined as $s(t) = \Re[u(t)e^{j2\pi f_c t}]$, where \Re denotes *real part*. For a linear filter the impulse response $g(t)$ is related to the equivalent lowpass complex impulse response $h(t)$ as $g(t) = 2\Re[h(t)e^{j2\pi f_c t}]$.

For the Rayleigh distribution, the mean envelope level is $\bar{a} = \sqrt{\pi/2}\sigma_S$. Other distributions have been proposed in the literature, which purportedly match better with measured results around the mean or median signal level. For example, the Nakagami- m distribution for the envelope a given by

$$p_m(a) = \frac{2}{\Gamma(m)} \left(\frac{m}{2\sigma_S^2} \right)^m a^{2m-1} e^{-ma^2/2\sigma_S^2}, \quad a > 0, \quad (7)$$

$$m \geq \frac{1}{2} \quad (\text{Nakagami-}m \text{ distribution})$$

$$p_m(a) = \frac{2}{\Gamma(m)} \left(\frac{m}{2\sigma_S^2} \right)^m a^{2m-1} e^{-ma^2/2\sigma_S^2}, \quad a < 0,$$

$$m \geq \frac{1}{2} \quad (\text{Nakagami-}m \text{ distribution})$$

where $\Gamma(\cdot)$ is the gamma function, has been suggested by some researchers as a better model for describing the fluctuating signal. Note that $m = 1$ recovers the Rayleigh distribution. The corresponding distribution for power $S = a^2/2$ transforms to a gamma distribution:

$$p_m(S) = \frac{m^m S^{m-1} e^{-(mS/\sigma_S^2)}}{\Gamma(m)\sigma_S^{2m}} \quad (\text{gamma distribution}). \quad (8)$$

Once again $m = 1$ recovers the exponential power distribution (6) corresponding to the Rayleigh envelope (5).

Note that the characterizations in (2) and (3) assume that all the multipath components are random and that there is no steady component. If a steady component with mean power S_0 exists along with the random components, the distribution of the phase and envelope will be modified to

$$p(\varphi) = \frac{e^{-K} \left[1 + \sqrt{\pi K} \cos \varphi e^{K \cos^2 \varphi} \right] \left[1 + \text{erf} \left(\sqrt{K} \cos \varphi \right) \right]}{2\pi},$$

$$0 \leq \varphi \leq 2\pi \quad (9)$$

$$p(a) = \frac{a}{\sigma_S^2} e^{-a^2/2\sigma_S^2} e^{-K} I_0 \left(a\sqrt{2K}/\sigma_S \right),$$

$$0 \leq a < \infty \quad (\text{Ricean distribution}) \quad (10)$$

where $I_0(\cdot)$ is the modified Bessel function of the first kind of order zero and $K = S_0/\sigma_S^2$, known as the *Ricean K factor*, is the ratio of the power contained in the steady component to that contained in the random part. It is seen that the phase of the signal will no longer be uniformly distributed, but will peak around the phase of the steady component. Furthermore, the amount of fluctuations experienced under Rayleigh fading will be more severe than that under Ricean fading; consequently most system designers are concerned with evaluating system performance under Rayleigh fading.

Second-order statistical functions such as the autocorrelation and the autocovariance functions define the rate of variation of the fading signal. Assuming that the short-term fading is wide-sense stationary, the autocorrelation and the autocovariance functions of the envelope are defined as $\mu_a(\tau) = \langle a(t+\tau)a(t) \rangle$ and $v_a(\tau) = \mu_a(\tau) - \langle a(t) \rangle \langle a(t+\tau) \rangle$, respectively. The normalized envelope correlation coefficient is defined as

$$\rho_a(\tau) = \frac{v_a(\tau)}{[(\langle a^2(t) \rangle) - |\langle a(t) \rangle|^2]} \approx |e^{-j[\omega_{\text{dM}}\tau \cos(\gamma_0 - \phi) \sin \theta]}|^2 \quad (11)$$

where $\omega_{\text{dM}} = 2\pi f_{\text{dM}}$, (θ, ϕ) are the angles of arrival (random) of the incoming waves, and γ_0 is the azimuth angle of motion of the receiver. It is seen that the correlation properties of the signal will depend on the angular spectrum of arriving waves and are proportional to the Fourier transform of the angular spectrum. The signals received at two different time instants will be more correlated in the case when waves arrive through a narrower angular extent than when they arrive through wider angles. Using $x = v_0\tau$, Eq. (11) can also be used to describe the spatial correlation of the received envelope as a function of distance x . From the distribution of angles of arrival, related parameters such as the mean angle (first moment of the angular pdf) and rms angular spread (variance of the angular pdf) can be defined both for the azimuth angle and the elevation angle. A simple model, known as *Clarke's 2D model*, is where the waves are assumed to propagate in a two-dimensional plane (azimuth plane) and arrive with equal likelihood from all angles. For the Clarke's 2D model, the envelope correlation can be found as

$$\rho_a(\tau) = J_0^2(\omega_{\text{dM}}\tau) = J_0^2(k_0x) \triangleq \rho_e(x) \quad (12)$$

where $k_0 = 2\pi/\lambda$ is the wavenumber and $J_0(\cdot)$ is the zeroth-order Bessel function of the first kind. In general, the envelope correlation will decrease as τ or x are increased. As a rule of thumb, the signals at 2 times separated by time lag $f_{\text{dM}}\tau$ (or spatial points separated by k_0x) are considered to be correlated if $\rho_e(\tau) \leq 0.7$. For the Clarke's 2D model, the demarcation between correlated and uncorrelated signal occurs at $f_{\text{dM}}\tau = k_0x = 0.825$. Thus signals at two points separated by more than 0.13λ will be uncorrelated. Conversely, the correlation between two points separated more than 0.13λ will be less than 0.7. For example, the spatial correlation coefficient between two points separated by $\lambda/2$ is equal to $J_0^2(\pi) \approx 0.1$. If waves arrive uniformly from all angles in three dimensions (Clarke's 3D model), then the envelope correlation can be found using the second of (11) as

$$\rho_a(\tau) = \left[\frac{\sin(\omega_{\text{dM}}\tau)}{\omega_{\text{dM}}\tau} \right]^2 \quad (13)$$

To indicate the rate and severity of the fading signal, system parameters such as the level crossing rate and the average fade duration can also be extracted from the second-order statistics of the received signal. The *level cross-*

ing rate N_A (in Hertz) is the expected rate at which the envelope of the received signal crosses a specified level A in the positive-going (or negative-going) direction. The *average fade duration* τ_A (in seconds) below a specified level $a = A$ is the average of all durations for which the envelope is below that level. For Clarke's 2D model, the level crossing rate and the average fade duration can be shown to be

$$N_A = \frac{\sqrt{\pi}f_{\text{dM}}A}{\sigma_S} e^{-A^2/2\sigma_S^2} \quad (14)$$

$$\tau_A = \frac{1}{N_A} [1 - e^{-A^2/2\sigma_S^2}] \quad (15)$$

The level crossing rate is small at small and large values of A . Its maximum value occurs at $A = \sigma_S$ and is equal to $\sqrt{\pi}/e f_{\text{dM}} \approx 1.075f_{\text{dM}}$. The average fade duration increases with increasing values of A . Since the time taken to travel one wavelength is $\lambda/v_0 = 1/f_{\text{dM}}$, dividing N_A by f_{dM} and multiplying τ_A by f_{dM} gives, respectively, the number of crossings per wavelength and the average fade duration in wavelengths. As an example, using $f = 1$ GHz, $v_0 = 60$ mph, $A = \sigma_S$ yields $N_A = 96.75$ per second or 1.075 positive-going crossings per wavelength, and $\tau_A \approx 4.1$ ms or 0.37 wavelength. In order to capture fades at the level $A = \sigma_S$, the envelope must be sampled every 4.1 ms or every 0.37 wavelength. In actual wireless systems, the correlation properties of the received signal will also be influenced by electromagnetic mutual coupling, and this needs to be considered as well in system design.

For a general time-varying linear system representing the radio channel, the impulse response $g(\tau; t)$ is related to the equivalent lowpass impulse response $h(\tau; t)$ as

$$g(\tau; t) = 2\Re\{h(\tau; t) e^{j2\pi f_c \tau}\} \quad (16)$$

where the variable t represents the time variation of the channel due to Doppler frequency and the variable τ represents the propagation delay variable. The impulse response $h(\tau; t)$ represents the complex response of the channel at time t for an impulse applied τ seconds in the past. For a channel comprised of discrete multipath waves, the complex impulse response can be written as

$$h(\tau; t) = \sum_{n=1}^N a_n \delta(\tau - t_n) e^{j2\pi[v_n t - f_c t_n] + j\psi_n} \quad (17)$$

where the random quantities (a_n, v_n, ψ_n, t_n) respectively are the amplitude, Doppler shift, phase, and delay associated with the n th multipath wave. The phase $2\pi f_c t_n$ could be combined with ψ_n to define a new phase $\varphi_n = \psi_n - 2\pi f_c t_n$. A Fourier transformation of (17) with respect to the delay variable \mathcal{F}_τ results in the frequency-selective channel transfer function $H(f; t)$

$$H(f; t) = \int_{-\infty}^{\infty} h(\tau; t) e^{-j2\pi f \tau} d\tau \triangleq \mathcal{F}_\tau[h(\tau; t)] \quad (18)$$

where the frequency f represents translation relative to the nominal frequency f_c . At each frequency denoted by f ,

$H(f; t)$ represents the *time-varying* envelope and phase received with a single tone transmitted at that frequency. As described previously, as a result of the central-limit theorem, this is characterized by a zero-mean complex Gaussian random process. If the transmitted signal has a complex envelope $u(t)$ and a corresponding frequency spectrum $U(f)$, the received signal will have a complex envelope

$$z(t) = \int_{-\infty}^{\infty} h(t - \tau; t) u(\tau) d\tau = \int_{-\infty}^{\infty} H(f; t) U(f) e^{j2\pi f t} df \quad (19)$$

where it has been assumed that multipath returns at all delays will be observed. For the discrete multipath model of (17), the received complex envelope could be written as

$$z(t) = \sum_{n=1}^N a_n u(t - t_n) e^{j[2\pi\nu_n t + \phi_n]} \quad (20)$$

For a bandlimited transmitted signal $u(t)$, the multipath components cannot be resolved with infinite precision as can be done with impulse type of signals. All those delays arriving within a time duration much less than the reciprocal of the bandwidth W of $u(t)$ will appear together. The set of t_n s can be partitioned into L disjoint sets A_ℓ , $\ell = 1, 2, \dots, L$ and a representative delay τ_ℓ is associated with each set A_ℓ such that $t_n \in A_\ell$ if $u(t - t_n) \approx u(t - \tau_\ell)$. This will be true if the differences $\tau_\ell - t_n$ are much smaller than the reciprocal bandwidth of $u(t)$. Assuming single-bounce scattering, multipath components with a fixed delay τ_ℓ will appear to arrive from points distributed on an ellipsoid drawn in space such that the total pathlength traveled from the transmitter to the receiver via the ellipsoid is equal to $c\tau_\ell$, where c is the speed of light. The thickness of the sheath around the ellipsoid is of the order of the reciprocal bandwidth of $u(t)$ and will contribute to the set A_ℓ . With this approximation

$$z(t) = \sum_{\ell=1}^L u(t - \tau_\ell) \sum_{n_\ell} a_n e^{j[2\pi\nu_n t + \phi_n]} \quad (21)$$

where n_ℓ is the set of integers such that $t_n \in A_\ell$. Writing $\sum_{n_\ell} a_n \exp(j[2\pi\nu_n t + \phi_n]) = \alpha_\ell(t)$ and taking the Fourier transform on both sides of (21) with respect to the delay variable while treating $\alpha_n(t)$ terms as constants, the frequency-selective multipath description of fading channels

$$Z(f; t) = U(f) \sum_{\ell=1}^L \alpha_\ell(t) e^{j2\pi f \tau_\ell} \quad (22)$$

with the transfer function

$$H(f; t) = \sum_{\ell=1}^L \alpha_\ell(t) e^{j2\pi f \tau_\ell} \quad (23)$$

is obtained. The coefficient $\alpha_\ell(t)$ is a complex random quantity, and if n_ℓ is a sufficiently large, the sum defining it will contain different random terms. Moreover, note that we

Figure 1. Tapped delay-line model for a frequency-selective channel. Note that $\tau_{\ell+1} - \tau_\ell \approx 1/W$.

have treated them as being constants while taking the Consequently, from the central-limit theorem, the $\alpha_\ell(t)$ terms, $\ell = 1, \dots, L$ can be regarded as i.i.d. (independent, identically distributed) complex, zero-mean, Gaussian random variables. The phase of $\alpha_\ell(t)$ will be uniformly distributed in $[0, 2\pi]$, and the envelope $|\alpha_\ell(t)|$ will be Rayleigh distributed. A tapped delay-line model derived from (22) is frequently employed for a frequency-selective channel and is shown in Fig. 1. When only a single tone is transmitted, then $u(t) = A_c$ and (20) reduces to (2). In situations where the duration of the symbol transmitted is very small in comparison to the inverse of f_{DM} , there will be negligible change in the structure of the transfer function over one symbol duration, and one may regard the spectrum of the received signal to be $Z(f; t) = U(f)H(f; t)$. Thus the channel imposes multiplicative fading on the transmitted spectrum at each frequency.

To characterize the behavior of the transfer function at different frequencies and at different times, we define the following correlation functions

$$R_h(\tau_1, \tau_2; t_1, t_2) = \langle h(\tau_1; t_1) h^*(\tau_2; t_2) \rangle \quad (24)$$

$$R_H(f_1, f_2; t_1, t_2) = \langle H(f_1; t_1) H^*(f_2; t_2) \rangle \quad (25)$$

$$R_T(f_1, f_2; \nu_1, \nu_2) = \langle T(f_1; \nu_1) T^*(f_2; \nu_2) \rangle \quad (26)$$

$$R_S(\tau_1, \tau_2; \nu_1, \nu_2) = \langle S(\tau_1; \nu_1) S^*(\tau_2; \nu_2) \rangle \quad (27)$$

where $T(f; \nu)$ and $S(\tau; \nu)$ are the Fourier transform of $H(f; t)$ and $h(\tau; t)$, respectively, with respect to t . The relationships between the various system functions are shown in Fig. 2 and between the various correlation functions, in Fig. 3.

For a wide-sense stationary (WSS) random process, the correlation functions depend only on the timelag $\Delta t = t_2 - t_1$. This also implies that the returns at different Doppler frequencies will be uncorrelated. Likewise, if the channel is wide-sense stationary in the frequency variable, the correlation functions will depend only on the frequency difference $\Delta f = f_2 - f_1$. This assumption is also known as *uncorrelated scattering* (US) for it implies that the returns arriving from different delays will be uncorrelated. The

Figure 2. Relationships between the various system functions. \mathcal{F}_x denotes Fourier transformation with respect to the variable x .

US assumption has been derived for tropospheric scattering where multiple scattering phenomena are negligible. For terrestrial wireless multipath channels, the wave can be multiply scattered before arriving at the receiver. However, the US assumption has continued to be adopted by the wireless community owing to its simplicity. For a WSSUS channel, then, the various correlation functions simplify to

$$R_h(\tau_1, \tau_2; t_1, t_2) = \delta(\tau_2 - \tau_1) P_h(\tau_1; \Delta t) \quad (28)$$

$$R_H(f_1, f_2; t_1, t_2) = R_H(\Delta f; \Delta t) \quad (29)$$

$$R_T(f_1, f_2; \nu_1, \nu_2) = \delta(\nu_2 - \nu_1) P_T(\Delta f; \nu_1) \quad (30)$$

$$R_S(\tau_1, \tau_2; \nu_1, \nu_2) = \delta(\tau_2 - \tau_1) \delta(\nu_2 - \nu_1) P_S(\tau_1; \nu_1) \quad (31)$$

where $\delta(\cdot)$ is the delta function. The US assumption in the model is evident from the presence of $\delta(\tau_2 - \tau_1)$ in Eqs. (28) and (31). The quantity $P_S(\tau_1; \nu_1)$ is known as the *delay-Doppler channel scattering function* and describes the power spectral density of scattered waves arriving from delay τ_1 and Doppler shift ν_1 . The frequency selectivity of fading is characterized by $R_H(\Delta f; 0)$. In general, a wireless channel is frequency-selective. However, over a transmission bandwidth B for which $R_H(\Delta f; 0) \approx R_H(0; 0)$, all signal components fade together and $H(f; t)$ in effect acts like an allpass filter with a transfer function approximately equal

Figure 3. Relationships between the various correlation functions. $\mathcal{D}\mathcal{F}_{xy}$ denotes double Fourier transformation with respect to the variables x and y .

Figure 4. Relationships between the various correlation functions in a WSSUS channel.

to $H(0; t)$. Such a case is termed *frequency-nonselective fading or flat fading*. From Eq. (19), it is seen that the received complex envelope in such a case reduces to $z(t) = u(t)H(0; t)$, in a form similar to fading of a pure tone with a multiplicative channel gain. The relationships between the various correlation functions in a WSSUS channel are shown in Fig. 4.

It is useful to characterize the timescales over which fading can be treated as being essentially nonvarying. To determine this, we express the autocorrelation function of the received signal in terms of the transmitted signal $u(t)$ and $P_S(\tau, \nu)$:

$$R_z(t_1, t_2) = \langle z(t_1) z^*(t_2) \rangle = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} u(t_1 - \tau) u^* \times (t_2 - \tau) P_S(\tau; \nu) e^{-j2\pi\nu(t_2 - t_1)} d\tau d\nu \quad (32)$$

If a pure tone with unit amplitude is transmitted, then $u(t) = 1$, and writing $\Delta t = t_2 - t_1$, we get

$$R_z(\Delta t) = \int_{-\infty}^{\infty} \left[\int_{-\infty}^{\infty} P_S(\tau; \nu) d\tau \right] e^{-j2\pi\nu\Delta t} d\nu \triangleq \int_{-\infty}^{\infty} P_0(\nu) e^{-j2\pi\nu\Delta t} d\nu \quad (33)$$

where $P_0(\nu)$, known as the *Doppler spectrum*, is the observed power spectrum, equal to the sum of spectra contributed by all delays. The nominal width of this power spectrum is termed the *Doppler spread* B_D and is defined as

$$B_D = \left[\frac{\int_{-\infty}^{\infty} \nu^2 P_0(\nu) d\nu}{\int_{-\infty}^{\infty} P_0(\nu) d\nu} \right]^{1/2} \quad (34)$$

The fade rate at the median envelope level can be shown to be equal to $1.475 B_D$. For Clarke's 2D model, whose Doppler spectrum is the Fourier transform of $J_0(\omega_{dM}\tau)$, it can be shown that $B_D = f_{dM}/\sqrt{2}$. Thus, as mentioned earlier, the maximum Doppler shift f_{dM} is a measure of the fading rate of the channel. For a pure tone transmitted, we can also show that $R_z(\Delta t) = R_H(0; \Delta t)$. Hence, for a pure tone transmitted, coherent integration in reception is

possible only over timespans Δt for which the autocorrelation function $R_H(0;\Delta t)$ remains constant. The width Δt of $R_H(0;\Delta t)$ is known as the *channel coherence time* and is approximately equal to the reciprocal of the Doppler spread B_D . The channel Doppler spread is an important parameter and plays a key role in system design. In coherent systems the channel must be estimated at least one order of magnitude faster than the symbol rate, and we assert that the symbol duration $T \ll 1/B_D$. In adaptive systems (filters or antennas), the adaptive weights must be updated at least two orders of magnitude faster than the Doppler spread.

The value $P_h(\tau;0) = P_h(\tau)$ is the mean intensity of the channel in the delay variable and describes the dispersive behavior of the channel. This is known as the *power delay profile*. In terms of the function $P_h(\tau)$, the correlation function of the received complex envelope for zero timelag can be expressed as

$$R_z(t,t) = \int_{-\infty}^{\infty} |u(t-\tau)|^2 P_h(\tau) d\tau \approx P_h(t) \quad (35)$$

where the latter approximation is valid when the time duration of the transmitted symbol is much smaller than the spread of $P_h(t)$ and when its energy has been normalized to unity. The parameters of practical interest are the *mean delay* $\bar{\tau}$ and the root-mean-square (RMS) *delay spread* τ_{RMS} :

$$\bar{\tau} = \frac{\int \tau P_h(\tau) d\tau}{\int P_h(\tau) d\tau} \quad (36)$$

$$\tau_{\text{RMS}}^2 = \frac{\int (\tau - \bar{\tau})^2 P_h(\tau) d\tau}{\int P_h(\tau) d\tau} \quad (37)$$

For frequency-nonselctive fading we require the delay spread to be a small fraction of the symbol duration: $\tau_{\text{RMS}} \ll T$. This is also the requirement to avoid intersymbol interference. The requirement for coherent detection of symbols using matched filters is that $\tau_{\text{RMS}} \ll T \ll 1/B_D \Rightarrow \tau_{\text{RMS}} B_D \ll TB_D \ll 1$. A reasonable symbol time that satisfies both limits is to pick it to be the geometric mean of the two limits: $T \simeq \sqrt{\tau_{\text{RMS}}/B_D}$ or a symbol rate of $\sqrt{B_D/\tau_{\text{RMS}}}$. The quantity $\tau_{\text{RMS}} B_D$ is known as the *spread factor* of the wireless channel, and it is desirable to keep it less than unity for coherent detection. The spread factor depends on the RF frequency, speed of motion, angular spectrum of arriving waves, and buildup of the multipath environment.

Typical values of RMS delay spread vary from a few hundred nanoseconds for rural environments to few tens of microseconds for hilly terrain in terrestrial mobile communications. In HF skywave communication, delay spread arises due to multiple hops, electron density variation with height, from magnetoionic effects causing polarization-dependent paths (ordinary and extraordinary waves) and from inhomogeneities of the ionosphere. Typical values of τ_{RMS} due to multiple hops are 20–40 μs , and those due to electron density variation and magnetoionic effects vary from 100–200 μs . Typical values of Doppler

spread are less than 1–2 Hz, resulting in a spread factor of about 0.1 or less. In troposcatter links, the delay spread remains below 100–200 ns and the Doppler spread is in the range 0.1–10 Hz. In Earth–satellite links, fading (also referred to as *scintillation*) depends on the orbital radius as well as whether the terrestrial link is fixed or mobile on an airplane. Typical delay spreads are less than 10 ns, while the fade rates are in the range of fractional hertz to a few hertz. In underwater acoustic communication links with ranges within 10–100 mi, delay spreads range from a few seconds, while the Doppler spread often exceeds 1 Hz. Thus the channel is generally overspread, requiring non-coherent waveform processing.

For a WSSUS radio channel, the autocorrelation function $R_H(\Delta f;\Delta t)$ and $P_h(\tau;\Delta t)$ are related through the Fourier transform relationship as indicated in Fig. 4. As in the case of power delay profile, it is customary to consider zero timelag $\Delta t = 0$ and drop the second argument from the autocorrelation function. The resulting function, $R_H(\Delta f)$, is known as the *frequency correlation function* and is related to the power density profile through

$$R_H(\Delta f) = \int_{-\infty}^{\infty} P_h(\tau) e^{-j2\pi\Delta f\tau} d\tau \quad (38)$$

The *coherence bandwidth* B_{coh} is the nominal width of this function about $\Delta f = 0$. A common definition is to take B_{coh} as the smallest value for which the correlation falls to a prescribed value, say, –5 dB below the peak. The coherence bandwidth will be inversely proportional to the RMS delay spread and it is usual to assume $B_{\text{coh}} \approx 0.5/\tau_{\text{RMS}}$.

Having described the statistics of short term fading, we can easily ascertain its effects on the performance of a communication system. As an example, the bit error rate of BPSK in the presence of additive white Gaussian noise is equal to

$$P_e(\gamma) = \frac{1}{2} \text{erfc}(\sqrt{\gamma}) \quad (39)$$

where $\text{erfc}(\cdot)$ is the complementary error function and γ is the SNR per bit. In the presence of Rayleigh fading, γ will vary randomly, and the probability of error $P_b(\Gamma)$ will be obtained by considering (39) as a conditional probability, conditioned on the instantaneous SNR γ and writing

$$P_b(\Gamma) = \int_0^{\infty} P_e(\gamma) p(\gamma) d\gamma = \frac{1}{2} \left(1 - \sqrt{\frac{\Gamma}{1+\Gamma}} \right) \quad (40)$$

where $p(\gamma)$ is the pdf of γ and equal to [following from Eq. (6)]

$$p(\gamma) = \frac{1}{\Gamma} e^{-\gamma/\Gamma} \quad (41)$$

and Γ is the mean SNR per bit. The effect of fading is to drastically increase the bit error rates relative to those achieved in free space.

3. LONG-TERM FADING

Long-term fading generally occurs over spatial scales of the order of tens of wavelengths at the RF frequency and is attributed to blocking or shadowing by large obstacles. It is also known as *shadow fading*. It is obtained from the received signal by removing short-term fading after performing an average over spatial scales of the order of a few wavelengths or so. In terrestrial mobile communications, shadow fading is typically found to exhibit *lognormal distribution*; specifically, the sector averaged received signal power expressed on a decibel (dB) scale follows a Gaussian distribution. A lognormal distribution in built-up areas can be conceived from the central-limit theorem if the signal *sequentially* passes features of the environment that impart independent random fluctuations to its amplitude. Such features include random variation in building heights, gaps between buildings, variation in building design and construction material, and the presence of trees. In mobile communications, the standard deviation $\sigma_d = 20 \log(\bar{\sigma})$ of lognormal distribution has been found to lie in the range $6 \leq \sigma_d \leq 12$ dB. If $\bar{a}_d = 20 \log(\bar{a})$ is the mean envelope level in dB, where \bar{a} is the mean envelope level as a fraction, and $\bar{\mu}_d = 20 \log(\bar{\mu})$ is the area mean in dB, then the lognormal distribution can be expressed as

$$\begin{aligned} p(\bar{a}_d) &= \frac{1}{\sqrt{2\pi}\sigma_d} \exp\left[-\frac{(\bar{a}_d - \bar{\mu}_d)^2}{2\sigma_d^2}\right] \\ &= \frac{1}{\sqrt{2\pi}\sigma_d} \exp\left[-\frac{1}{2}\left(\frac{\ln[\bar{a}/\bar{\mu}]}{\ln(\bar{\sigma})}\right)^2\right] \text{ (lognormal distribution)} \end{aligned} \quad (42)$$

The instantaneous power received at a distance r from the transmitter for a signal undergoing lognormal fading with standard deviation σ_d (dB) can be expressed as

$$P_r(r) = \bar{P}_r(r) + \tilde{X} \quad (\text{dBW}) \quad (43)$$

where $\bar{P}_r(r)$ is the mean power received at r and \tilde{X} is a zero mean, Gaussian random variable with standard deviation σ_d . The mean signal power $\bar{P}_r(r)$ generally obeys the relation

$$\bar{P}_r(r) = \bar{P}_r(r_0) - 10\gamma \log \frac{r}{r_0} \quad (44)$$

where $\bar{P}_r(r_0)$ is the mean power received at some reference distance r_0 from the transmitter and γ is known as the *path loss exponent*. In terrestrial mobile communications, its value can range from 1.5 to 6. Given that the instantaneous power received can vary about the mean power, it is apt to ask the question ‘‘What is the probability $P_{X_0}(r)$ that the signal received at r falls below some threshold power X_0 [dBW]?’’ Using the pdf for a Gaussian random

variable, it is easy to see that

$$\begin{aligned} P_{X_0}(r) &= \int_{-\infty}^{X_0} \frac{1}{\sqrt{2\pi}\sigma_d} e^{-[x - \bar{P}_r(r)]^2 / 2\sigma_d^2} dx \\ &= \frac{1}{2} \operatorname{erfc}\left(\frac{\bar{P}_r(r_0) - 10\gamma \log(r/r_0) - X_0}{\sqrt{2}\sigma_d}\right) \end{aligned} \quad (45)$$

Given the parameters γ , σ_d , X_0 , $\bar{P}_r(r_0)$, and r_0 , Eq. (45) can be used to determine the radius of a cell $r = R$ about the transmitter such that the signal level on its boundary falls below the threshold for only a fraction β of the time. Hence

$$\log \frac{R}{r_0} = \frac{\bar{P}_r(r_0) - X_0 - \sqrt{2}\sigma_d \operatorname{erfc}^{-1}(2\beta)}{10\gamma} \quad (46)$$

As an example, if $\beta = 0.25$, $X_0 = -100$ dBm, $\sigma_d = 9$ dB, $\gamma = 4.8$, $r_0 = 1$ mi, $\bar{P}_r(r_0) = -77$ dBm (at 850 MHz), then $R = 3.6$ km.

4. COMBINED SHORT- AND LONG-TERM FADINGS

It is possible to combine the short-term distributions with long-term distributions and come up with a single model for the composite variation of the signal. For example, the statistics of a non-line-of-sight (NLoS) signal can be treated as a mixture of Rayleigh distribution whose mean power varies lognormally, resulting in what is known as *Suzuki distribution* for the envelope:

$$\begin{aligned} P_s(a; \sigma_d, \mu_d) &= \int_0^\infty \frac{a}{\sigma^2} e^{-a^2/2\sigma^2} \Big|_{\sigma = \bar{a}\sqrt{2/\pi}} \cdot \frac{1}{\sqrt{2\pi}\sigma_d} \\ &\quad \times \exp\left[-\frac{1}{2}\left(\frac{\ln[\bar{a}/\bar{\mu}]}{\ln(\bar{\sigma})}\right)^2\right] d\bar{a} \end{aligned} \quad (47)$$

Although Suzuki distribution is sound on physical grounds, it has limited practical utility as no closed-form expression is available for the integral given above. A similar mixture can also be defined for LoS situations where Ricean distribution is used instead of the Rayleigh distribution for short-term fading.

5. CURRENT WORK AND RESEARCH TOPICS

With the advent of antenna arrays for interference reduction (smart antennas), mitigation of fading (spatial or polarization diversity antennas), exploitation of multipath fading itself to increase system capacity [multiple-input/multiple-output (MIMO) systems], and position location (direction finding systems), it becomes necessary to develop more advanced models than the ones based on uniform angles of arrival in 2D or 3D space as were assumed in the previous sections. It has already been demonstrated in (11) that even though the statistics of fluctuation (i.e., pdf of fluctuations) may remain the same, the temporal or spatial correlation of the signal in a dynamic multipath

environment depends on the angular spectrum of the arriving waves at the receiver. Furthermore, when electromagnetic waves strike arbitrarily oriented, finite obstacles, there will be transfer of power from copolar components to the cross-polar components. Geometric scattering models, introduced during the era of troposcatter communications, are now being used to simulate various wireless environments. In these models, waves are singly scattered from point scatterers and arrive at the receiver. Various models exist that all differ in the distribution of scatter density to simulate either multipath around base stations, multipath around mobile stations, or combinations of both. Using these models it is possible to get the PDF in the angles and times of arrival as well as the power spectra in angles and delay. Other quantities such as the envelope correlation can be obtained from these statistics. Janaswamy compares the various geometric models with each other as well as with measurements. As an example, the Gaussian scatter density model gives the following expression for the spatial correlation, ρ , between two points separated by a distance d

$$\rho \approx \exp(jk_0 d \cos \bar{\phi}) \exp \left[-\frac{1}{2} \left(\frac{k_0 d \sigma_s \sin \bar{\phi}}{D} \right)^2 \right], \quad (48)$$

$$\sigma_s \ll D,$$

where D is the distance between the mobile station (MS) and the base station (BS), $\bar{\phi}$ is the angle between the line joining the two spatial points and the line joining BS and MS, and σ_s is a measure of the effective radius of scatterers about the MS. The envelope correlation is equal to $|\rho|^2$. All the existing geometric scattering models are scalar in nature. An empirical polarimetric model for fixed wireless applications is described by Oestges et al. With the introduction of MIMO systems, there is certainly a need to develop full polarimetric models that also take into account multiple scattering of waves. Jensen and Wallace give a good summary of the antenna and propagation issues for MIMO systems.

6. CONCLUSION

In this article we have described the mathematical models of short-term and long-term fading. Statistical distributions for signal fading such as Rayleigh distribution, Ricean distribution, lognormal distribution, and models for wide-band channel characterization have been introduced. Various propagation parameters, including Doppler spread, delay spread, angular spread, spatial correlation, have been discussed. The effect of short-term fading on system performance and the effect of long-term fading on the design of a wireless cell size has been demonstrated. Finally, topics of current research in fading have been discussed.

SILICON-GERMANIUM

HERMANN SCHUMACHER
University of Ulm
Ulm, Germany

1. INTRODUCTION

By a wide margin, Silicon is the most used semiconductor material in electronics today. Its main advantages are its abundant supply (it is fabricated from SiO₂, which is as abundant as sand on a beach), its mechanical robustness (which allows very large wafers to be fabricated, currently up to 300 mm in diameter), its high thermal conductivity (which not only allows power semiconductor devices to be fabricated, but also is a prerequisite for the integration of millions of transistors on one chip), and most importantly, its highly stable native oxide, SiO₂. The most common transistor device technology in use today, the metal-oxide-semiconductor field-effect transistor, or MOSFET, uses this native oxide extensively both in the fabrication process and in the completed device.

Compared with other semiconductor materials—Silicon (Si), Germanium (Ge), or Gallium-Arsenide (GaAs)—the semiconducting alloy Silicon-Germanium (SiGe) has been a late arrival on the stage of high-speed electronics. SiGe layers are never used alone, but always in combination

with Si layers, and they allow significant enhancement of electronic device performance in a variety of ways.

- Si/SiGe heterostructure bipolar transistors (HBTs) have been commercially available since 1998. SiGe is being used in the base layer in two different ways.
 - A graded $\text{Si}_{1-x}\text{Ge}_x$ layer with a low Ge content x near the emitter and a higher Ge content near the collector of a bipolar transistor creates a strong electric field in the base and significantly increases the speed of electrons traversing the base, increasing the current-gain cutoff frequency f_T .
 - In another concept, the Ge content is already substantial at the emitter-base junction, creating an energy barrier for the unwanted injection of holes from the base into the emitter, which allows significant increase of the base doping concentration, leading to a much reduced base resistance, and increases primarily the microwave power gain of these transistors.
- Si/SiGe heterostructures can also be advantageously used to confine charge carriers in the channel of a field-effect transistor (FET). The primary goal of this confinement (forming a two-dimensional electron or hole gas) is an improvement in the charge carriers' mobility, which in turn increases the device speed. At the time of this writing (2004), no Si/SiGe heterostructure FET processes are commercially available, but the area is experiencing intense research.
- The fact that the introduction of Ge into the Silicon crystal lattice also increases the lattice constant can be used to fabricate Silicon films with a built-in tensile strain, which can equally increase the charge carrier mobility. Such "strained-Si" channels are one of the options for next-generation metal-oxide-semiconductor field-effect transistors (MOSFETs), holding great promise for an increase in the speed of operation of highly integrated digital and analog integrated circuits.

The large interest in Si/SiGe heterostructure devices is caused by the fact that they fully exploit the vast body of technological advances in Silicon semiconductor processing in general. The concept of "bandgap engineering," the modification of the semiconductor energy band structure, introduces new degrees of freedom in the design of advanced devices, yet requires only minor modifications to existing processes.

By combining bandgap engineering for the vertical layer sequence of a semiconductor device with the deep sub- μm lateral scaling made possible by advances in Silicon processing, SiGe HBTs (the most mature Si/SiGe device concept) have shown dramatic improvements in their cutoff frequencies: a record transit frequency $f_T = 350$ GHz characterizes the state-of-the-art today in laboratory experiments [1], whereas more readily available devices show both f_T and the maximum frequency of oscillation f_{max} in the 100–200 GHz range. The demonstrated Si/SiGe HBT performance enables monolithic microwave integrated circuits (MMICs) with good performance well into the

upper microwave and lower millimeter-wave range. The mature Silicon fabrication processes into which the SiGe devices are being embedded allow for high-complexity designs. Device cutoff frequencies have progressed to a point where raw device speed is no longer the bottleneck in the design of Si-based MMICs, but rather passive circuit element performance and layout issues. Additionally, breakdown voltages of Si/SiGe HBTs optimized for high cutoff frequencies are too low for some higher power applications.

Although circuits using Si/SiGe heterostructure devices are making inroads into areas traditionally held by GaAs technologies, such as short-range radar sensors, it is evident that they will not replace these technologies entirely. Demanding applications in terms of either low receiver noise figure or significant radio frequency (RF) output power at elevated frequencies will continue to use GaAs-based heterostructure technologies.

Si/SiGe ICs are best when

- large market volumes can be expected
- the specific application benefits from multifunctional, high-complexity monolithic ICs
- optimum RF performance is not required, but rather low cost.

2. A CLOSER LOOK

Commonly, electronic devices are fabricated in a crystal lattice that consists of one semiconductor only—Silicon, which has a chemical composition made up from only one atom. Other mono-element semiconductors are Ge, or C in its crystalline form—diamond.

2.1. Compound Semiconductors and Bandgap Engineering

Other semiconductor materials, such as GaAs, are composed of two or more chemical elements—they are compound semiconductors. Semiconducting alloys may have several advantages over mono-element semiconductors, like strong electro-luminescence (conversion of an electric current into light), or high electron mobility.

Most important, however, is the added degree of freedom in device design obtained by the ability to change the chemical composition of the lattice within a single crystal. Such a structure with varied stoichiometry within a single semiconducting crystal is called a semiconductor heterostructure.

In solid-state physics terms, the most striking feature of any semiconductor is the band structure, characterized by a valence band energy E_V (which is the highest energy of bound electrons at absolute temperature $T = 0$ K), a conduction band energy E_C (which is the lowest energy of a free electron—free to move about in the lattice), and the forbidden energy range in between, which does not contain any allowed energy states an electron can occupy. This forbidden energy region is called the bandgap.

The exact band structure depends strongly on the chemical composition of the semiconductor material: By modifying the chemical structure, we can tailor the band

structure according to our needs—we perform bandgap engineering. In 1982, Herbert Kroemer formulated the central design principle of semiconductor heterostructures, saying; “Heterostructures modify the distribution and flow of charge carriers in semiconductors” [2].

Most compound semiconductor materials are formed by combining elements of the third and fourth column of the periodic table of elements, like Gallium (3rd column) and Arsenic (5th column). These compounds are called “three-five semiconductors.”

2.1.1. The Silicon-Germanium Compound Heterostructure. Silicon and Germanium are both elements from the fourth column of the periodic table of elements. Their alloy, $\text{Si}_{1-x}\text{Ge}_x$, is also a semiconductor whose properties can be modified by changing the Germanium mole fraction x .

An important observation is that when we modify the chemical composition of a semiconducting crystal, we not only modify the energy band structure, but also the geometry of the lattice, characterized by the lattice constant. Both effects are typically represented in a graph similar to Fig. 1. Note that for the ternary compound semiconductor formed by the alloy of GaAs and AlAs— $\text{Al}_x\text{Ga}_{1-x}\text{As}$ —the bandgap can be varied in a wide range by an appropriate Al mole fraction x , whereas the lattice constant remains essentially unchanged. In $\text{Si}_{1-x}\text{Ge}_x$, not only the bandgap but also the lattice constant is being significantly modified by the Ge mole fraction. The corresponding change in the geometry of the lattice will lead to strong mechanical strain in the crystal, which will eventually cause crystallographic defects, which restricts the modification of chemical composition to very thin layers where the mechanical energy can be stored by elastic deformation of the lattice; the strained layer has to be thinner than a critical layer thickness, which is a function of the material composition of the layers forming the heterostructure.

Current semiconductor devices employing $\text{Si}/\text{Si}_{1-x}\text{Ge}_x$ heterostructures exploit the ability to modify the bandgap. The change in lattice constant is a complicating side effect. SiGe heterostructures are being used in two different ways.

Figure 1. Lattice constant (horizontal axis) and bandgap (vertical axis) of important compound semiconductor structures.

Figure 2. Abrupt n-Si/p-SiGe heterostructure: hole-blocking barrier in the valence band.

1. Abrupt Si/SiGe junctions can be used to construct energy barriers, e.g., for holes in the valence band, see Fig. 2. The situation shown is found in the “wide-gap emitter” concept of heterostructure bipolar transistors (HBTs) and will be described in more detail below. Another application of abrupt Si/SiGe heterostructures is the formation of confining energy barriers for the channel region of field-effect transistors. Figure 3 shows the concept for the case of a hole channel.
2. Graded Si/SiGe heterostructures can be used to create a built-in electric field through a variation of the bandedge, for one carrier species only, see Fig. 4. This concept is being used in Si/SiGe drift transistors, where electrons in the base of an npn bipolar transistors experience a significant reduction in base transit time by the additional drift field.

In all of these applications, the effect of mechanical strain has to be carefully observed. Crystallographic defects have to be avoided by choosing the thickness of the strained layer to be lower than a critical thickness d_{crit} . Figure 5 shows the most common case, a thin strained $\text{Si}_{1-x}\text{Ge}_x$ layer on relaxed Si [3]. Note that two different definitions of the critical thickness exist: The lower curve is the

Figure 3. Two abrupt Si/SiGe heterostructures provide confinement for holes in a p-channel field-effect transistor.

Figure 4. Creation of a built-in drift field acting on electrons only, through a gradual variation of the Ge concentration x in a p-doped $\text{Si}_{1-x}\text{Ge}_x$ layer.

equilibrium limit. Layers with combinations of Ge content and layer thickness below this line can be considered stable even at elevated processing temperatures. The upper line is an empirical fit to published data on strained SiGe layers. Layers with Ge content and layer thickness combinations above this line will most likely result in plastic deformation of the lattice and crystallographic defect formation. The medium range is called the metastable regime. Layers in the metastable regime can be defect-free, provided that the thermal budget of process steps after the SiGe film deposition is being carefully monitored.

In an elastically strained SiGe film, the strain will affect the band structure. Here, we need to take a closer look at the three fundamentally different ways in which the conduction and valence bands in a semiconductor heterostructure can line up.

- In a “type I” heterostructure, the valence band of the material with the wider gap is below, and the

conduction band is above, the respective band in the material with the smaller bandgap, or in other words, the forbidden gap of the material with the smaller bandgap is completely within the forbidden gap of the material with the larger bandgap.

- In a “type II” heterostructure, both the valence band and the conduction band of one material are below the respective bands in the other material, leading to a staircase-like impression.
- In a “type III” heterostructure, the conduction band of one material is energetically below the valence band of the other material.

Elastically deformed Si/SiGe heterostructures can have a type I or a type II band lineup, depending on the strain built into the lattice. Figure 6 shows a chart, published by Schäffler [4], which allows determination of the conduction band (ΔE_C) and valence band (ΔE_V) discontinuities of abrupt SiGe/Si heterostructures.

2.2. The Si/SiGe/Si Heterostructure Bipolar Transistor

To understand the central design dilemma of the bipolar transistor, addressed by the introduction of heterostructures, consider the way in which the collector current is controlled by the base-emitter voltage. We will restrict our discussion to npn-type transistors, where the emitter is n-doped, the base p-doped, and the collector again n-doped. Equal arguments can be found for the pnp-type transistor by considering holes instead of electrons.

The base of a bipolar transistor is hence bordered by two pn-junctions: one, the emitter-base diode, is forward biased in active operation, whereas the other, the base-collector diode, is reverse biased. Through the forward bias $V_{BE} > 0$ across the emitter-base diode, the minority carrier density (here, the electron density in the p-doped base, n_p) in the base layer at $y = 0$ (the base-side edge of the emitter-base space charge region) is increased.

$$n_p(y=0) = n_{p0} \exp\left(\frac{V_{BE}}{V_T}\right) = \frac{n_{i,B}^2}{N_{AB}} \exp\left(\frac{V_{BE}}{V_T}\right) \quad (1)$$

where $n_{i,B}$ is the intrinsic carrier concentration in the base layer, N_{AB} is the acceptor doping concentration, and $V_T = kT/q$ is the thermal voltage (approximately 26 meV at room temperature). We are assuming that all acceptors have been ionized.

The reverse bias $V_{CB} > 0$ across the collector-base junction lowers the minority carrier concentration at $y = W_B$, the base-side edge of the collector-base space charge region

$$n_p(y=W_B) = n_{p0} \exp\left(\frac{-V_{BC}}{V_T}\right) = \frac{n_{i,B}^2}{N_{AB}} \exp\left(\frac{-V_{BC}}{V_T}\right) \approx 0 \quad (2)$$

in the active forward regime, as $n_p(W_B)$ can be neglected vs. $n_p(0)$.

The base layer is so thin that recombination can be neglected across the base (short-base diode). In this case, the minority carrier concentration is a linear function of the

Figure 5. Critical thickness of strained $\text{Si}_{1-x}\text{Ge}_x$ layers on Si, vs. Ge mole fraction x , after [3].

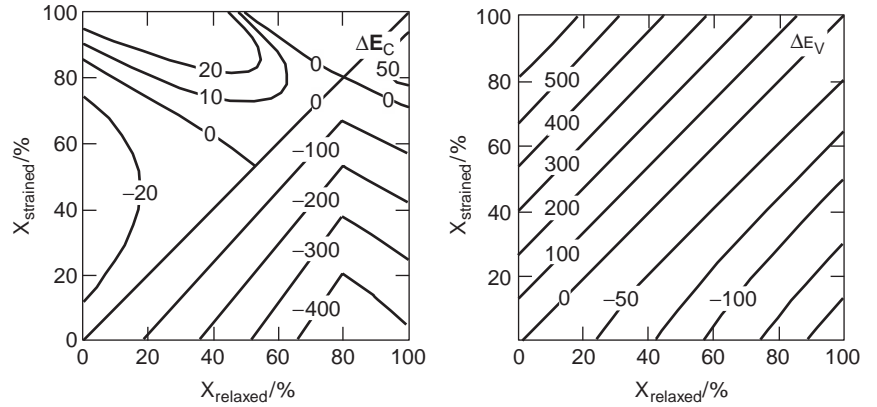

Figure 6. Conduction band and valence band discontinuities of Si/SiGe heterostructures as a function of the composition of the relaxed layer and the strained layer, after [4].

coordinate y

$$n_p(y) = n_p(0) - \frac{n_p(0) - n_p(W_B)}{W_B} y \approx n_p(0) \times \left(1 - \frac{y}{W_B}\right) \text{ for } 0 < y < W_B \quad (3)$$

Neglecting any potential difference across the neutral base layer (the voltages drop across the space charge regions), the electrons move across the base driven by diffusion only and the collector current density J_C is proportional to the minority carrier gradient

$$J_C = qD_{n,B} \frac{dn_p(y)}{dy} \approx -qn_{p0} \frac{D_{n,B}}{W_B} = -q \frac{D_{n,B}n_{i,B}^2}{W_B N_{AB}} \exp\left(\frac{V_{BE}}{V_T}\right) \text{ for } 0 < y < W_B \quad (4)$$

Here, q is the electron charge and $D_{n,B}$ is the diffusion constant of electrons in the base.

Likewise, we consider the emitter region as a short-base diode bordered by the base emitter at $y = -d_{BE}$ and an ideal recombination contact at $y = -W_E$, which forces $p_n(-W_E) = 0$. We further assume that the thickness of the base-emitter space charge region d_{BE} is much smaller than the emitter width W_E . The forward-biased emitter-base junction injects holes from the base to the emitter, leading to a base current density J_B

$$J_B = -qD_{p,E} \frac{dp_n}{dy} = -q \frac{D_{p,E}n_{i,E}^2}{W_E N_{DE}} \exp\left(\frac{V_{BE}}{V_T}\right) \text{ for } -W_E < y < -d_{BE} \quad (5)$$

where $n_{i,E}$ is the intrinsic carrier concentration in the emitter layer and N_{DE} the donor doping concentration there. Equations (4) and (5) allow us to find the common

emitter current gain of the bipolar transistor

$$B = \frac{J_C}{J_B} = \frac{D_{n,B}}{D_{p,E}} \frac{W_E}{W_B} \frac{N_{DE}}{N_{AB}} \frac{n_{i,B}^2}{n_{i,E}^2} \quad (6)$$

In a conventional homojunction bipolar transistor, where emitter and base layers are composed of the same material, the intrinsic carrier concentrations in the emitter $n_{i,E}$ and the base $n_{i,B}$ will be identical (neglecting small differences because of doping-dependent bandgap narrowing effects), so the last term in Eq. (6) is close to one. The ratio of diffusion constants in the base and the emitter (the first term) reflects the ratio of electron and hole mobilities, which in Silicon is a little less than three. The emitter and base width (the layer thicknesses, in the third term) will be comparable, as the emitter width cannot be increased without a significant increase in emitter resistance. Hence, a current gain $B \gg 1$ will require $N_{DE} \gg N_{AB}$.

This requirement now constitutes the central design dilemma of the bipolar transistor. The base resistance R_B is an important element in the high-frequency performance of the bipolar transistor—an increased R_B :

- lowers the maximum frequency of oscillation according to the approximation

$$f_{\max} = \left(\frac{f_T}{8\pi R_B C_{BC}}\right)^{\frac{1}{2}} \quad (7)$$

where f_T is the transit frequency and C_{BC} the base-collector capacitance

- increases the noise figure F and the equivalent noise resistance R_n , see, e.g., [5]
- leads to an inhomogeneous current density distribution over the emitter-base junction area (displacement of the current toward the emitter edge, see, e.g., [6])

The base resistance scales with base width and base doping concentration as

$$R_B \sim (W_B N_{AB})^{-1} \quad (8)$$

On the other hand, the base transit time, a crucial factor determining f_T , scales with the square of the base width. In a homogeneously doped base, the electrons will move across the neutral base by diffusion only

$$\tau_B = \frac{W_B^2}{D_{n,B}} \quad (9)$$

Optimizing a bipolar transistor for f_T by lowering W_B will hence come at the price of an increased R_B , deteriorating f_{\max} and noise performance, while trying to avoid the R_B increase by increasing N_{AB} will lower the current gain B.

Possible solutions can be found by examining Eqs. (6) and (9) again.

In Eq. (6), the last term, the ratio of intrinsic carrier concentrations in the base and the emitter, $n_{i,E}$ could be made much smaller than $n_{i,B}$ if a material with a higher bandgap energy E_G was chosen, because

$$n_i = (N_C N_V)^{1/2} \exp\left(\frac{-E_G}{2kT}\right) \quad (10)$$

where N_C and N_V are the conduction and valence band densities of states, k is Boltzmann's constant, and T is the absolute temperature.

Equation (6) can now be rewritten as

$$B = \frac{J_C}{J_B} = \frac{D_{n,B}}{D_{p,E}} \frac{W_E}{W_B} \frac{N_{DE}}{N_{AB}} \frac{N_{C,B}}{N_{C,E}} \frac{N_{V,B}}{N_{V,E}} \exp\left(\frac{E_{G,E}}{E_{G,B}}\right) \quad (11)$$

The important term here is the exponential one. The possible vast improvement in current gain B will be used to drastically increase N_{AB} (and lower N_{DE}), opening the way to reduced R_B despite thinner base layers W_B .

This approach, the "wide-gap emitter structure" has already been described shortly after the invention of the bipolar transistor [7], yet technological problems prevented the creation of the necessary semiconductor heterostructures at the time.

A different optimization strategy can be found by examining the assumptions leading to Eq. (9). We assumed that the minority carriers in the neutral base move by virtue of diffusion only, without the assistance of an electrical field. If we now allow a built-in drift field E_{bi} in the neutral base, the base transit time expression becomes [8]

$$\tau_B = \frac{W_B^2}{2 \left(1 + \left(q \frac{E_{bi} W_B}{kT} \right)^{3/2} \right) D_{n,B}} \quad (12)$$

The built-in field can be realized through a doping variation in the base (higher N_A at the base-emitter junctions than at the base-collector junction), but it is much more efficiently implemented using a bandgap variation across

the base (larger bandgap at the base-emitter junction than at the base-collector junction), and without the otherwise inevitable reduction in the average base doping concentration.

Both strategies can be pursued using a Silicon-Germanium alloy in the base layer.

2.2.1. The Si/SiGe/Si Wide-Gap Emitter Structure. The concept of the Si/SiGe/Si wide-gap emitter HBT is identical to that of HBTs fabricated from compound semiconductors of the third and fifth column of the periodic table of elements and has been pursued primarily by DaimlerChrysler [9] and, more recently, Atmel [10].

The base is fabricated from a $\text{Si}_{1-x}\text{Ge}_x$ alloy with a fixed Ge mole fraction x , with typically $x = 0.2$. The SiGe layer is elastically strained between unstrained Si layers (emitter and collector), so turning to Fig. 6, we find that for $x = 0.2$, the conduction band discontinuity is negligible at slightly less than -20 meV, whereas the valence band discontinuity is substantial at 150 meV. The large valence band and negligible conduction band discontinuity is ideal for npn-type transistors, as it avoids the conduction band parasitic barrier found, for example, in abrupt AlGaAs/GaAs heterojunctions. Figure 7 shows a qualitative representation of the band structure at thermodynamic equilibrium. Note that a valence band discontinuity exists both at the emitter-base and base-collector junction; the first is desired. The latter is because of the fact that the SiGe layer has to be thin because of the lattice mismatch, and hence the collector has to be fabricated from Si, leading necessarily to a double heterostructure. It will have a detrimental effect on high-current operation, as will be explained later.

The exponential factor in Eq. (11) is 1.18×10^4 at room temperature and allows the emitter and base doping concentration ratio to be reversed, i.e., the higher doping concentration is now in the base, whereas the emitter doping concentration immediately adjacent to the emitter-base junction is lowered to prevent tunneling. To control the emitter series resistance, the low-doped emitter region is narrow and the doping is increased in the top part of the emitter, see Fig. 8.

Figure 7. Qualitative band diagram of a Si/SiGe/Si wide-gap emitter bipolar transistor.

Figure 8. Schematic representation of Ge mole fraction and doping concentrations in a Si/SiGe/Si wide-gap emitter HBT.

The combination of $x_{Ge}=0.2$ and typical base thicknesses of 30–50 nm places these structures into the metastable regime of Fig. 5. The built-in strain of the base is substantial, precluding high-temperature processing steps after deposition of the SiGe layer. Still, both dedicated bipolar and BiCMOS processes have been realized using this concept and are commercially available. Its prime advantage is the very low base sheet resistance possible using this concept, which allows high cutoff frequencies without aggressive lateral scaling of the emitter, e.g., 80 GHz f_T and f_{max} with 0.5 μm minimum feature size [11]. There are no known reliability concerns in normal mode of operation stemming from the high built-in strain in the base.

2.2.2. The Si/SiGe/Si Graded Base Structure. Full compatibility with CMOS processing temperatures, even after the deposition of the SiGe layer, requires a substantially lower Ge concentration in the base; the combination of Ge mole fraction and layer thickness needs to be below the equilibrium limit in Fig. 5. As this simultaneously decreases the valence band discontinuity, see again Fig. 6, the wide-gap emitter concept becomes less powerful.

Instead, the optimization strategy suggested by Eq. (12) is being pursued; the Ge mole fraction at the emitter-base junction is zero or very low and gradually increases toward the base-collector junction, where it is reduced to zero again for the collector layer. As Fig. 9 shows, the conduction band in the neutral base is tilted toward the collector now and creates a very strong built-in field for electrons only, whereas the conduction band is essentially unchanged (except for the effect of the changing density of states in the valence band with the Ge mole fraction, neglected here for simplicity).

This concept has been introduced by IBM [12]. Typical maximum Ge mole fractions (at the base-collector inter-

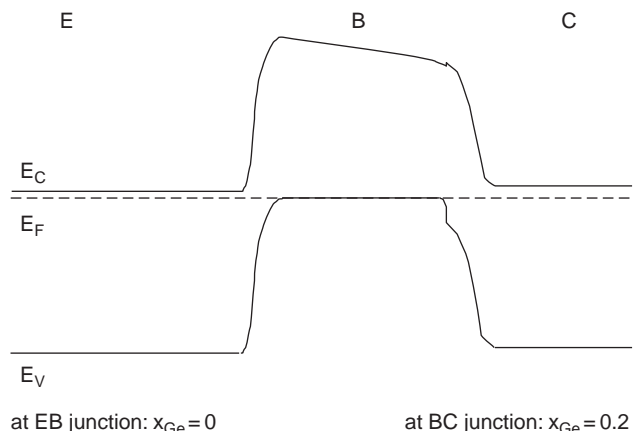

Figure 9. Qualitative band diagram of a Si/SiGe/Si graded-base bipolar transistor.

face) are $x = 0.15\text{--}0.20$, leading to an average mole fraction of 7.5–10%, resulting in a substantially lower built-in strain in the base.

Note that here, too, a valence band discontinuity exists at the base-collector junction.

Figure 10 shows the doping and Ge mole fraction profile for the graded-base structure. The lack of an emitter-base bandgap difference requires a emitter-base doping ratio that is similar to a conventional bipolar transistor. The base sheet resistance is thus higher than in the wide-gap emitter concept; the required low-base resistance has to be realized here by a more aggressive lateral scaling of the emitter width, e.g., a production technology with $f_T = 72$ GHz and $f_{max} = 75$ GHz has a feature size of 0.35 μm [13].

Figure 10. Schematic representation of Ge mole fraction and doping concentrations in a Si/SiGe/Si graded-base HBT.

2.2.3. The Base-Collector Heterostructure Effect. As pointed out, the severe lattice mismatch between practical SiGe layers and the embedding Si forces SiGe heterostructure bipolar transistors to have a second heterostructure at or near the base-collector junction.

Generally, this heterostructure is undesirable as it might introduce a conduction band energy barrier (“spike”) that negatively affects the collection of base minority carriers (electrons in npn transistors) by the collector. In the special case of S/SiGe/Si HBTs, no noticeable conduction band spike will occur as the conduction band discontinuity for strained SiGe layers versus unstrained Si is negligible (see again Fig. 6).

The situation changes when higher collector current densities are present, but shows an onset prior to that of the Kirk effect. In the classic Kirk effect, the injected minority carriers from the base have a sufficient density to effectively neutralize the fixed charge in the collector space-charge region. The space charge will disappear at the base-collector junction, the neutral base will extend into the base (“base push-out”). As a consequence, the effective base width will increase, the current gain decrease [see Eq. (6)], and the base transit time will increase drastically, see Eq. (9).

In the case of the double heterostructure, as pointed out by Tiwari in 1988 [14], partial compensation of the collector space charge will lead to the appearance of an electron barrier in the conduction band, which can be intuitively understood when considering that in a conventional bipolar transistor, the weakening of the space charge will lead to a decreased potential barrier not only for electrons, but also for holes. If the base-collector junction is replaced by a heterojunction with a significant valence band discontinuity, the increasing injection of holes from the base into the collector is blocked. Holes will instead accumulate against the barrier, their increased density pushes the valence and conduction bands upward, leading to the observed decrease in current gain B and transit frequency f_T , which is much more pronounced than what is observed in homojunction bipolar transistors. It is significant because in high-speed operation, bipolar transistors need to be operated at or close to the collector current density for maximum f_T . Large-signal CAD models for SiGe HBTs will hence have to predict the high-current rolloff very accurately, which will occur immediately beyond the optimum f_T bias point.

In SiGe HBTs, the effect of this base-collector heterostructure effect can be lessened by introducing a retrograde SiGe profile extending into the collector layer, by slightly displacing the SiGe/Si heterojunction into the collector, or by increasing the collector doping concentration immediately adjacent to the base [15]. In the first two cases, the increased strain because of the lattice mismatch has to be observed, whereas the latter solution will compromise the maximum frequency of oscillation (through an increase in the base-collector capacitance) and the collector-base breakdown voltage.

2.2.4. Carbon Codoping in the SiGe Base Layer. As pointed out, the main attractions of introducing an SiGe heterostructure into Si bipolar transistors is the possible

decrease in the base resistance by increasing the base doping concentration. Simultaneously, the vertical base thickness is decreased to reduce the base transit time. This technological development leads invariably to very steep doping profiles in the base layer.

Very steep doping gradients, in turn, increase the risk of dopant outdiffusion from the base layer into the emitter and collector regions, with very detrimental effects.

- Especially in wide-gap emitter structures, outdiffusion into the emitter places the emitter-base pn junction into the emitter and the heterojunction into the base. The hole-blocking valence band discontinuity is no longer effective, whereas the heterostructure inside the p-doped region will lead to a conduction band barrier decreasing electron injection from the emitter into the base. As a result, the current gain B will be dramatically decreased.
- The base-collector heterostructure will be placed into the base layer as the p-dopant diffuses into the collector, displacing the pn junction. Again, this will cause a conduction band barrier for electrons and particularly worsen the high-current base-collector heterostructure effect discussed in Section 2.2.3.

Traditionally, base dopant outdiffusion has been anticipated through the introduction of undoped setback layers in the base, which absorbed the outdiffusing base dopant and placed the pn junctions in the proper place [16]. However, as the vertical base width is decreased, these setback layers have to be scaled down or eliminated. Also, the necessity to accurately predict the amount of outdiffusion makes the processing windows for the epitaxial growth much smaller.

As the lateral transistor sizes are scaled down, the fact that the dopant not only diffuses vertically, but also laterally, becomes visible. The problem is that in many processes, the extrinsic base is doped highly by ion implantation (usually with BF_2). The resulting crystallographic damage creates a significant density of interstitial defects that enhances the outdiffusion of the predominant base dopant, Boron. Similar defect-induced enhanced diffusion effects can occur because of high-level emitter implant doses.

Rather than anticipating dopant outdiffusion through setback layers and relaxed lateral scaling rules, it is better to reduce the diffusivity of the dopant. A very efficient way of doing this is the use of Carbon codoping [17]. Codoping denotes the incorporation of low ($< 10^{20} \text{ cm}^{-3}$) concentrations of Carbon, as opposed to ternary SiGeC compounds, which are under investigation to reduce the lattice mismatch toward Si. The codoped Carbon atoms are electrically inactive, but dramatically reduce the transient enhanced diffusion (TED) of Boron [18], enabling steep Boron gradients without doping setbacks, and simultaneously enabling the aggressive lateral scaling that has made transit frequencies in excess of 300 GHz possible in SiGe HBTs.

2.2.5. State of the Art. The performance of Si/SiGe HBTs rivals that of its competitors from III-V compound

Figure 11. Cross-section of a state-of-the-art box-shaped SiGe HBT, after [19].

semiconductors. The combination of bandgap engineering in the base and drastic reductions in base and collector layer thicknesses with aggressive lateral scaling made possible by advances in modern CMOS processing resulted in record transit frequencies of $f_T = 350$ GHz in 2002 [19], or a total emitter-to-collector transit time $\tau_{EC} = 0.45$ ps. The base has a Ge mole fraction of 25%, with a Boron sheet concentration of $5 \times 10^{13} \text{ cm}^{-3}$. The lateral emitter width has been scaled down to 120 nm. Although the intrinsic base resistance benefits from the high Boron dose, the extrinsic base resistance has been lowered using raised base contact layers, which have been grown in a self-aligned fashion.

The box-like transistor cross section, shown in Fig. 11, reduces particularly the base-collector capacitance. For the f_T -optimized design, the authors reported a maximum frequency of oscillation, determined from Mason's unilateral gain, of 170 GHz. In this design, the radical reduction of base and collector layer thicknesses increases R_B and C_{BC} , respectively, leading to the rather low f_{max} compared with f_T .

Optimizing the device in a more practical way, for similar f_T and f_{max} , the authors obtained $f_T = 270$ GHz and $f_{max} = 260$ GHz. The peak f_T in these transistors occurs at a high collector current density of $17 \text{ mA}/\mu\text{m}^2$.

The negative aspect of the lateral scaling, especially of the collector layer, is the reduction in breakdown voltage. For the record device, the open-base collector-emitter breakdown voltage BV_{CEO} is only 1.4 V, in part because of the very high current gain of 2300. The more practical device design with 260 GHz f_T has $BV_{CEO} = 1.6$ V. As the authors point out, the product of breakdown voltage and f_T is 490 V GHz and 416 V GHz, respectively, and much beyond the commonly assumed Johnson limit of 200 V GHz, and the breakdown voltages for short-circuited base terminal (BV_{CBO}) are 5 V and 5.5 V, respectively, but still the low breakdown voltages present significant challenges in practical micro- and millimeter-wave applications of ad-

vanced SiGe HBTs. The general trend in breakdown voltages in HBTs using Si/SiGe can be found in Fig. 12.

The inferiority of Si/SiGe HBTs versus its III-V competitors in terms of breakdown voltage for a given f_T is because of

- the higher electric field at the onset of avalanche breakdown in GaAs and InP
- the lower average carrier velocity in Si at moderate electric fields

In essence, devices with an Si collector will pay a higher price in breakdown voltage reduction when the collector is being scaled for a given collector transit time τ_C .

It can be argued that for practical micro- and millimeter-wave applications requiring at least moderate power levels (1 V_{p-p} amplitude corresponds to only 4 dBm into a 50 Ω load), the low breakdown voltage is now the most

Figure 12. Comparison of breakdown voltage trends in Si-, GaAs-, and InP-based HBTs, vs. transit frequency f_T . The dashed curve is the often-quoted "Johnson limit" of 200 GHz V for the product of f_T and the open-base breakdown voltage BV_{CEO} (data partly from the SiGe Microsystems website).

significant challenge in the development of SiGe HBTs, not the cutoff frequencies.

2.3. The Si/SiGe/Si Heterostructure Field-Effect Transistor

2.3.1. Quantum-Well Channels for Electrons and Holes.

The use of Si/SiGe heterostructures in field-effect transistors has not yet (in 2004) reached the commercialization stage, but is, after slow beginnings, gaining momentum in research, as it holds promise for advances in high-speed CMOS beyond those offered by geometry scaling. The reasons for the slower market introduction of SiGe heterostructure field-effect transistors, compared with SiGe HBTs, is not only the significant performance improvement that has been experienced in scaled Si CMOS, but also the fact that, as we will see, high-performance SiGe HFETs need strain-relaxed SiGe buffer layers (“quasisubstrates” with a larger lattice constant than Si), making process integration not as straightforward as in SiGe HBTs.

When comparing Silicon with III-V compound semiconductors, it cannot be overlooked that III-V semiconductors, like GaAs and especially InGaAs, have significant advantages in terms of the low-field electron mobility μ_n . The hole low-field mobility μ_p in Si is larger than in GaAs or InGaAs, but still significantly lower than μ_n . The following challenges therefore develop, for which SiGe heterostructures promise potential solutions:

- Increase the electron mobility μ_n —in III-V semiconductors, an often used solution is the reduction of electrostatic interaction (Coulomb scattering) between free charge carriers (here, electrons) and fixed charge stemming from ionized doping atoms (here, positively charged donors), which is the concept of the high electron mobility transistor, or HEMT, and requires the physical separation of dopants and free charge. The physical separation can be created by confining the free charge to a quantum well apart from the fully depleted supply layer and requires a heterostructure.
- Increase the hole mobility μ_p ; here, reduction of Coulomb scattering will help as well, but the observation of a significantly higher hole mobility in Ge as compared with Si points into a different direction: Increase the Ge mole fraction in a SiGe hole channel.

The formation of a quantum-well channel with separation of free holes and fixed ionized acceptors, useful for p-channel FETs, is quite straightforward and can use the heterostructure system discussed for Si/SiGe HBTs. Figure 13 (a) shows a suitable layer structure. The supply layers are 20 nm thick Si, doped with Boron to $p = 10^{19} \text{ cm}^{-3}$. The quantum well is formed in a $\text{Si}_{0.85}\text{Ge}_{0.15}$ layer of 40 nm thickness. Two 2 nm wide undoped Si spacer layers create the physical separation of free holes and fixed ionized acceptor charge. Two two-dimension hole gas channels form at the Si/SiGe heterointerfaces in this structure [20]. Figure 13 (b) demonstrates the difference in low-field hole mobility between the cases of doped and undoped SiGe well; a factor of 2 at room temperature, increasing to

Figure 13. (a) Si/SiGe/Si heterostructure with formation of a two-dimensional hole gas (2DHG). (b) Low-field hole mobility μ_p for doped and undoped wells (after [20]).

a factor of almost 12 at 77 K, where the limitation because of phonon scattering is less pronounced.

Even higher gains in hole mobility are possible if the Ge concentration in the well is increased. Figure 14 provides a survey of literature values [21]; the index x demotes the Ge mole fraction in the $\text{Si}_{1-x}\text{Ge}_x$ channel, whereas y is the Ge mole fraction in the underlying $\text{Si}_{1-y}\text{Ge}_y$ quasisubstrate, which will be explained below. Almost a factor of 10 can be gained when moving from $\text{Si}_{0.85}\text{Ge}_{0.15}$ to a pure Ge channel ($x = 1$).

Also note that the hole mobility can even be improved when straining a pure Si channel ($x = 0$) by an underlying SiGe film (here, $y = 0.25$), which has a larger lattice constant and hence provides a tensile strain to the Si layer, which is the concept pursued in “strained-Si” CMOS, which will not be treated here any further.

Figure 14. Effective hole mobilities in SiGe heterostructures, vs. electric field, after [21]. DC = DaimlerChrysler, ETH = ETH Zurich, Si = Siemens, Warwick = University of Warwick, Berkeley = University of California, Berkeley.

Referring back to Fig. 5, we readily notice that high Ge mole fractions will lead to extremely small critical thickness values. The resulting very thin quantum wells will no longer provide an effective confinement to the holes and lead to an increase of Coulomb scattering. Practical high-Ge channels therefore need a SiGe substrate with significant Ge content.

Such SiGe quasisubstrates are realized on Si substrates by growing layers that are deliberately unstrained (relaxed). The challenge is to provide strain-relaxed buffer layers that are ideally free of defects at the top (where the device structure will be grown) and as thin as possible.

First experiments to produce strain-relaxed virtual substrate layers involved the growth of thick (2–5 μm) graded Si_{1-x}Ge_x layers, starting with x=0–0.05 at the the Si substrate and ending in typically x=0.3–0.4 at the top of the layer.

A reduced thickness will improve the integrability of the technology, but even more importantly, it will reduce the overall thermal resistance. It has been reported [22] that Si_{0.6}Ge_{0.4} has an 18-fold lower thermal resistance than Si. A reduction of the relaxed buffer thickness from 5 μm to 0.5 μm led to a reduction of the overall thermal resistance seen by the FET structure by a factor of 3.

The growth of thin strain-relaxed quasisubstrates with low defect density generally requires the restriction of dislocations to certain parts of the layer, using various growth methods, e.g., low-energy plasma-enhanced chemical vapor deposition (LEPECVD, [23]), very low temper-

ature epitaxy (VLTE, [24]), or by postdeposition relaxation through He implantation and annealing (HELAX, [25]).

An example for a SiGe-channel p-MOSFET is shown in Fig. 15. A strain-relaxed Si_{0.7}Ge_{0.3} buffer is grown onto Si and forms the quasisubstrate. The channel region itself has a Ge concentration of 0.7 and is therefore experiencing tensile strain. Figure 6 predicts a negligible conduction band discontinuity of 5 meV and a significant valence band discontinuity of 300 meV, the desired situation. Figure 15 also provides the qualitative band diagram of the structure, indicating the location of the buried hole channel. The Silicon cap layer between the Si_{0.3}Ge_{0.7} well and the oxide serves two purposes.

1. It improves the quality of the gate oxide; a direct oxidation of the SiGe compound should be avoided.
2. It removes the free carriers from the oxide interface, which further improves the mobility.

Note the second valence band maximum at the oxide-Si interface. A parasitic surface channel with lower mobility

Figure 15. (a) Cross section of a SiGe-channel p-MOSFET (after [26]) (b) corresponding band diagram under the gate.

may form here if the device is strongly forward biased, which has to be avoided by proper device design.

Aside from MOSFET structures with charge control through an MOS diode, MODFET structures with channel control through a Schottky gate (as in III-V HEMTs) have also been realized, see, e.g., [27].

The use of SiGe heterostructures for n-channel FETs is less obvious; the heterostructures considered so far all had significant valence band offsets, yet negligible conduction band discontinuities and were therefore unable to provide confinement in a conduction band well. However, consider the case of a strained Si film on unstrained $\text{Si}_{1-x}\text{Ge}_x$ (e.g., for $x=0.3$). Figure 6 gives a valence band offset of -55 meV and a conduction band offset of -160 meV . The negative sign denotes that the conduction band in the strained Si is below the conduction band in the unstrained SiGe; this is a type II heterostructure. An efficient electron confinement is now possible in the strained Si layer.

Figure 16 provides a synopsis of low-field mobility data. The significant improvement over the universal electron mobility curve is clearly visible, especially for buried channel structures, where an up to eight-fold improvement is observed.

Figure 17 shows the layer structure of an n-channel SiGe MODFET [28]. The electron channel forms in the 9 nm thick Si layer, which is sandwiched between two $\text{Si}_{0.6}\text{Ge}_{0.4}$ spacer layers (undoped, 3 resp. 4 nm thick). A double-doped MODFET structure is adopted here, with 5 nm thick Sb-doped supply layers above ($2 \times 10^{19}\text{ cm}^{-3}$) and below ($2 \times 10^{18}\text{ cm}^{-3}$) the channel. The Schottky gate sits on top of a 3.5 nm thick Si cap layer; the authors report that an increased gate leakage current was noticed, which is likely because of the bandgap lowering in the strained Si. The quasisubstrate is provided by a 240 nm thick strain-relaxed buffer ($\text{Si}_{0.6}\text{Ge}_{0.4}$) grown by VLTE. With a T-gate and a gate length of $L_G = 0.1\ \mu\text{m}$, the devices showed peak $f_T = 43\text{ GHz}$ and $f_{\text{max}} = 95\text{ GHz}$.

It is interesting to note that p-channel devices (channel in SiGe) and n-channel devices (channel in Si) can use the

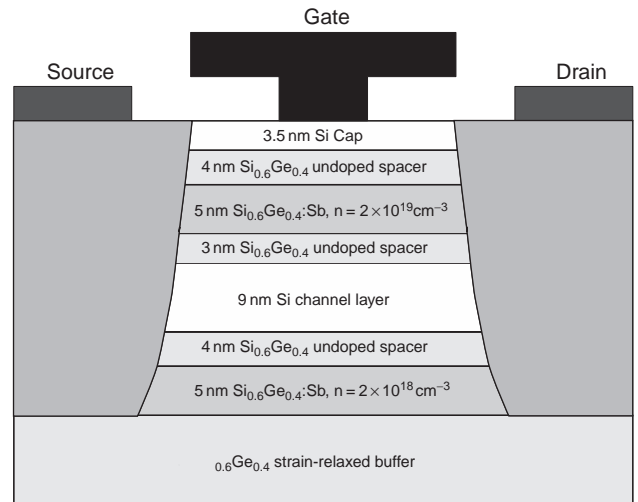

Figure 17. Cross section of an n-channel Si/SiGe heterostructure MODFET, after [28].

same SiGe quasisubstrate, opening the way to complementary Si/SiGe MOSFET technologies [29].

As SiGe heterostructure MOSFETs and MODFETs all provide significantly increased low-field mobilities through the combination of strain, high Ge content in the channel (for p-channel devices), reduction of Coulomb scattering (in MODFET structures), and suppression of oxide interface scattering (in MOSFET structures, through the buried channel), they will be particularly suitable in providing low-noise amplification at microwave frequencies [30].

2.3.2. SiGe HFETs: State of the Art. Using gate lengths down to 90 nm, transit frequencies up to 90 GHz have been demonstrated in n-channel Si/SiGe MODFETs [31]. The f_T still scaled well with the inverse gate length. A technological problem that remains to be solved is the high source access resistance, which lowers the extrinsic transconductance and hence the f_T . With this problem solved, and with gate lengths comparable with experimental Si NMOS technologies (down to 40 nm), f_T values significantly in excess of 200 GHz can be predicted.

Owing to the metal gates and also a low output conductance, Si/SiGe HFETs already show impressive maximum frequencies of oscillation, reported up to 188 GHz [32]. Figure 18 shows a comparison of values reported in the literature. It is obvious that Si/SiGe HFET structures have most pronounced advantages for p-channel devices, where they now have comparable properties with current Si NMOS, holding great promise for high-speed fully complementary circuits.

Also obvious, however, is that SiGe HBTs offer 100 GHz f_{max} values at much relaxed lateral scaling requirements.

2.3.3. Microwave and Millimeter-Wave Circuits Using SiGe HBTs and HFETs. The motivation to use Si/SiGe heterostructure devices lies not in their properties as discrete devices, but in their ability to be easily integrated

Figure 16. Effective electron mobilities in SiGe heterostructures, vs. electric field, after [21].

Figure 18. Comparison of literature values for the maximum frequency of oscillation for various classes of Si-based high-speed devices, after [21].

into mature Silicon IC processes. A brief look at microwave and millimeter-wave ICs (MMICs) realized using Si/SiGe heterostructures shall therefore conclude this chapter.

Significant differences exist between Si-based MMICs and their counterparts realized from III-V compound semiconductors, in terms of circuit complexity, the density of active elements on chip, and in the total chip size.

Traditionally, MMICs have been borrowing heavily from hybrid microwave circuit design, using transmission line segments to realize reactances and for impedance transformations. GaAs substrates in MMIC fabrication are semiinsulating, with resistivities $> 10^7 \Omega\text{cm}$, and hence suitable for circuit design techniques originally conceived for non-semiconducting substrates such as alumina, sapphire, or PTFE. Si-based MMICs may use high-resistivity substrates (e.g., $1000 \Omega\text{cm}$), but are more often realized on medium-to-low resistivity substrates (e.g., $20 \Omega\text{cm}$).

Distributed passive structures are hence in danger of suffering from prohibitive substrate losses and have to be avoided in Si MMIC design. Instead, quas lumped passive circuit elements are being used even at millimeter-wave frequencies, such as spiral inductors and metal-insulator-metal (MIM) capacitors. The necessary compact layout techniques have the added benefit of resulting in very compact chips, adding to the cost benefit of Si/SiGe ICs.

The lossy nature of the Silicon substrates will have to be accounted for in various ways. Transmission line segments can be described as lossy-backplane thin film microstrip lines or coplanar waveguides backed by a lossy backplane [33], depending on the geometry. Such lines show pronounced dispersion in the form of slow-wave effects at low frequencies, which disappear at higher frequencies (typically above 2–3 GHz), see Fig. 19. Thin film microstrip lines can also be placed in higher metalization layers, using the first metalization layer as a backplane, providing shielding from the substrate. Such lines no longer suffer from substrate effects, but the thin dielectric

Figure 19. Measured attenuation and slowing factor for $4.2 \mu\text{m}$ wide microstrip (MSL—dashed curves) and coplanar transmission lines (CPW—solid curves) on $20 \Omega\text{cm}$ Silicon substrate, after [33].

layer makes signal lines very narrow, leading to nonnegligible Ohmic metalization losses.

Spiral inductor models on conducting substrates need to take Eddy currents in the substrate into account, at least at lower frequencies where necessary self-inductance and hence geometric size are large [34]. Eddy currents will lower the inductance of the planar coil and reduce the quality factor. At millimeter-wave frequencies, with typical inductances of less than 1 nH, the modeling of spiral inductors simplifies as the skin-effect metalization losses dominate over substrate effects. Ground shields (either in the lowest metalization layer or using a buried highly doped semiconductor layer) are sometimes used to reduce substrate losses, but under inductors they have to be slotted to avoid excessive Eddy current effects. Ground-coupled noise can be a significant problem in applications such as low-noise amplifiers and can be addressed equally by ground shields.

Integration density and the high yield of mature Silicon processes make MMICs with a high number of integrated functions possible. As an example, refer to Fig. 20, which shows a fully integrated downconverter IC for the 24 GHz ISM band [35]. The IC contains all necessary circuit blocks: a three-stage preamplifier (lower left), a voltage-controlled oscillator using an active inductance concept, a

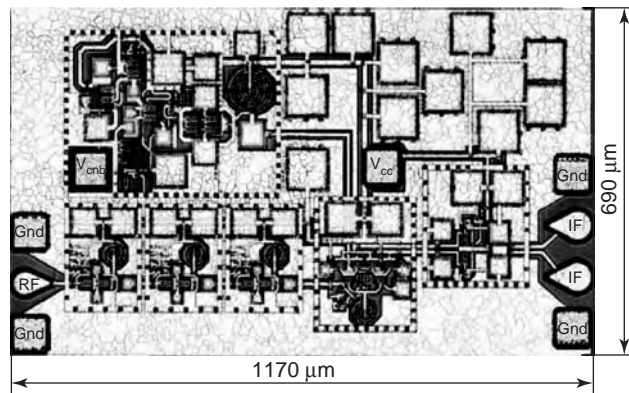

Figure 20. Chip photograph of a fully integrated 24 GHz receiver IC using Si/SiGe HBT technology, after [35].

Figure 21. Chip photo of an 8 channel phased-array receiver for 24 GHz in a SiGe BiCMOS technology, after [36].

Gilbert cell mixer, and IF output buffers (lower right). The circuit has been realized in the Atmel SiGe1 technology, which, as a first-generation SiGe HBT technology, has f_T and f_{max} of 50 GHz and is at its limits at 24 GHz. Still, the receiver is fully functional and provides a conversion gain of 16 dB. Circuits for the 24 GHz ISM band have also been realized in Si/SiGe BiCMOS processes, where they can take advantage of the excellent microwave properties of the npn Si/SiGe HBTs and realize lower frequency high-complexity circuit blocks in CMOS. Hashemi et al. [36] realized the highly complex 8 channel receiver chip for 24 GHz phased-array systems shown in Fig. 21. An interesting research topic will be the efficient testing of such RF systems-on-a-chip in production lines, however.

Using state-of-the-art SiGe HBT technologies, ICs can be realized with frequencies of operation in excess of 100 GHz. Figure cc shows the concept and the sensitivity of a dynamic frequency divider realized using an SiGe HBT technology with $f_T = 200$ GHz [37]. In a dynamic divider, whose concept is shown in Fig. 22 (a), any spectral component at one-half f_1 at port 1 of the mixer is sufficient to produce $f_1 \pm$ one-half f_1 at port 3. The active mixer has a low-pass characteristic that suppresses the higher frequency component and passes the one-half f_1 spectral component, which is amplified and fed back to the mixer in a regenerative fashion. The useful input sensitivity in this circuit extended beyond 110 GHz, the highest measurement frequency, see Fig. 22 (b). The circuit consumed 310 mW from a 5 V power supply.

Micro- and millimeter-wave circuit applications of Si/SiGe HFETs are still quite rare as of this writing (2004), reflecting the fact that most of the research is still in fundamental issues such as optimized thin quasisubstrate layers. A first ultra-wideband MMIC amplifier structure has been realized using an n-channel MODFET technology described in [38].

The transistors are characterized by a transconductance $g_m = 175$ mS/mm, a transit frequency f_T of 52 GHz, and a maximum frequency of oscillation $f_{max} = 148$ GHz extracted from Mason’s unilateral gain U. The transistors used in the circuit design had a gate length of 0.1 μ m and a

total gate width of 100 μ m. Models for the coplanar transmission lines on the virtual SiGe substrate were developed using test structures on similar wafers and fitting the parameter set for coplanar transmission lines in Agilent ADS, which was also used for the complete circuit design.

The distributed amplifier realized in this technology has six identical stages [39]. The gate transmission line has segments of 450 μ m length with a center conductor width of 20 μ m and signal-to-ground gaps of 60 μ m, whereas the drain transmission line has segments of 530 μ m length, with a center conductor width of 20 μ m and gaps of 40 μ m. Figure 23 shows a chip photograph.

of 20 μm and signal-to-ground gaps of 60 μm , whereas the drain transmission line has segments of 530 μm length, with a center conductor width of 20 μm and gaps of 40 μm . The circuit draws 45.7 mA from a 2.3 V supply, the gate bias is held at $V_{\text{GS}} = -0.16$ V. At this bias point, the amplifier exhibits a power gain of 5.5 dB \pm 0.8 dB up to 32 GHz.

3. CONCLUSIONS

Si/SiGe heterostructure devices introduce the advantages of bandgap engineering to Si-based microelectronics and open up options for the optimization of RF performance that go beyond lateral and vertical geometric scaling. The significant lattice mismatch between Si and Ge introduces a high mechanical strain into Si/SiGe heterostructures that needs to be carefully observed. As a consequence, SiGe alloy layers need to be very thin, or strain-relaxed buffer layers (quasisubstrates with a larger lattice constant than Si) need to be used.

SiGe heterojunction bipolar transistors are firmly established in commercial production and have provided impressive circuit results, both in terms of circuit complexity and in terms of frequency of operation, which surpasses 100 GHz in special cases.

SiGe heterostructure field-effect transistors are still at a research stage, but demonstrate an equally impressive performance potential.

The most significant challenge in the design of Si-based micro- and millimeter-wave circuits is no longer the raw speed of the active devices, but rather the control of substrate losses, and the very low breakdown voltages of high- f_T SiGe HBTs.

1. INTRODUCTION

A *software-defined radio* (SDR) is a radio in which the operating parameters, including the frequency range, modulation type, and maximum radiated or conducted output power can be altered by making a change in software without making any hardware changes.

The essence of an SDR is the ability, without introducing new hardware, to change operating characteristics by changing software programs executing in processing resources. In SDR, operating parameters are determined for the most part by software. This enables a single wireless device to be reprogrammed to allow different modulation schemes, coding, and access protocols. SDR allows more efficient use of spectrum by facilitating spectrum sharing and allowing equipment to be reprogrammed for various modulation schemes. The ability of SDR to be programmed also enhances interoperability between different radio services. Figure 1 shows a block diagram of an ideal SDR. Broadband RF signals are converted to baseband and fed to high-speed A/D converter (ADC) and programmable digital filter or channel decoder to select the desired channel signal such that demodulation means of RF signals with various bandwidths, transmission rates and modulation schemes are readily programmed. The hardware for this procedure requires downconversion to baseband of the entire bandwidth for various mobile standards and different frequency bands. This baseband signal is digitized, and all the subsequent processing is implemented in software [1–4].

SDR has been identified as a potential method to enhance flexible wireless communication systems. The operation speed of an analog/digital converter (ADC) and processing ability of digital signal processors (DSPs) and chips are key factors in the development of SDR for useful commercial applications. More recent advances in semiconductor processing technology and the development of reconfigurable devices such as digital signal processors (DSP) and field-programmable gate arrays (FPGA) reduce the development time of commercial products. SDR in conjunction with six-port receivers has promising

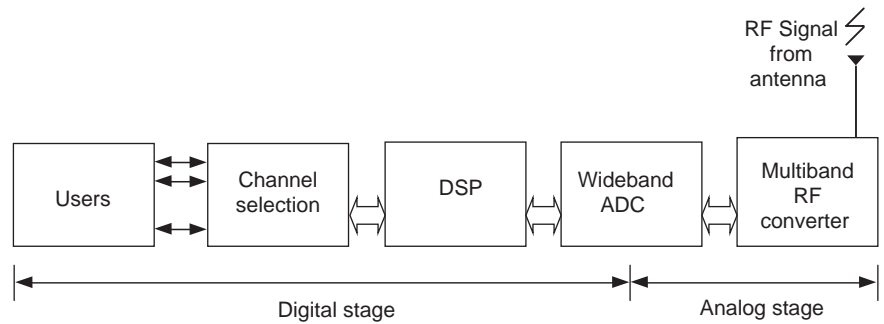

Figure 1. Block diagram of an Ideal Software Defined Radio Receiver.

applications for use in wireless LANs, audio and television broadcasting, and interoperability between different radio services, as seen by new studies on the use of six-port technology [5] in various design aspects of a new SDR receiver. The objective is to realize an application of SDR to provide a multichannel, multimode wireless direct digital receiver. The combination of SDR and six-port technology provides great flexibility in system configuration, significant reduction in hardware cost, particularly at millimeter-wave frequencies, and potential for software reuse. Different types of six-port circuits have been designed, with center frequencies at 2.4, 5.8, 24, and 28 GHz [6–9], operating over large frequency bands. Some six-port circuits are based on microstrip structures, fabricated with hybrid microwave integrated circuit (MHMIC) or monolithic microwave integrated circuit (MMIC) technology at both microwave and millimeter-wave frequencies. Other circuits use a novel substrate-integrated waveguide (SIW) structure [10], which allows integration of planar integrated circuit structure with waveguide structure. The performances of these six-port circuits in digital receivers are reported in relation to signal modulation schemes, noise performance analysis calibration, and coding. Bit error rate simulation and measurement results obtained with demodulation algorithms are given for QPSK and QAM-16 signals under a variety of operating conditions [11]. It is shown that this type of receiver can provide bit error rates as low as 1×10^{-6} for E_b/N_0 of 11 dB (for QPSK) and 15 dB (for QAM-16). Initial results show promising applications of six-port technology for direct digital conversion demodulation reception, needed in future low-cost SDR communication systems [11]. Measurement and

simulated demodulation results obtained with coding algorithms are also given in Section 7.

The six-port receiver approach offers wideband accommodation to ever-changing communication specifications required in a SDR as much of its functionality is defined in software and it can offer widebands from 2 to 2200 MHz [12].

SDR can be considered to be an information transfer system (ITS) combining technology from historically separate fields of computers and radios. Emerging from military applications, SDR has received much attention by researchers investigating wireless communications, and several Websites are providing detailed information [13–15]. An SDR is a radio in which the operating parameters, including the frequency range, modulation type, and maximum radiated or conducted output power can be altered by changes in software without need to make hardware changes [1]. Taking advantage of state-of-the-art digital signal processing technology, the performances of SDR systems depend more on DSPs with low-cost RF hardware. Of course, this goal can be achieved by less stringent requirements for expensive RF circuit fabrication and more flexibility for diverse communication systems.

The ideal SDR receivers must be wideband with high-speed ADCs and effective operating algorithms. Data signals from antenna are converted from analog to digital, and remaining tasks are processed in the DSP. Limited by the ability of current ADC and reprogramming device, present SDR receiver systems convert signals from analog to digital after downconversion to baseband. A block diagram of a typical superheterodyne receiver with double-stage downconversion is shown in Fig. 2; a typical direct

Figure 2. Block diagram of a typical double-stage downconversion superheterodyne digital receiver.

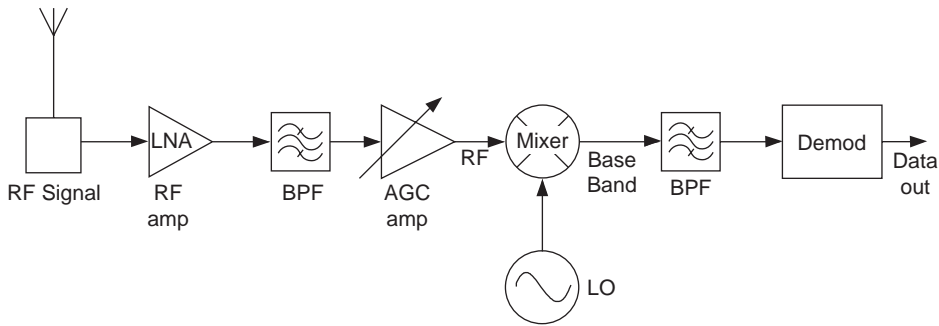

Figure 3. Block diagram of a typical direct digital receiver.

digital receiver is shown in Fig. 3, and a typical six-port receiver is shown in Fig. 4.

In all three receiver types the phases and amplitudes are measured to determine I,Q data by signal processing means. However, the conversion of data from RF signal to baseband signal is quite different and more simple by using six-port circuit approach (Fig. 4) in conjunction with integrated circuits, SIW, and wideband operational six-port circuits.

In general, digital receivers used in RF communication systems can be divided into two categories: superheterodyne receivers and direct-conversion receivers. Figure 2, as mentioned, illustrates a simplified block diagram of a typical superheterodyne digital receiver. The received RF signal is amplified first and then converted into a lower frequency (intermediate frequency). The desired signal is filtered to eliminate noise and interference and a succeeding high-gain AGC amplifier stabilizes the output signal level as the input RF signal level may vary because of a fading transmission channel. The superheterodyne receiver offers advantages such as high sensitivity and high frequency selectivity, and it has been the de facto standard configuration in most communication systems. However, this receiver uses many components, including several bandpass filters and IF amplifiers, and it is less suited for high-level circuit integration fabrication means needed to satisfy SDR mass production markets.

On the other hand, Fig. 3 shows the block diagram of a typical direct digital receiver. The received RF signal is converted with a mixer directly from RF to baseband. The direct-conversion receiver offers several advantages; it is simpler and less costly than superheterodyne receiver, since there is no IF amplifier, IF bandpass filter, or IF local oscillator required for final downconversion. Therefore,

the overall configuration of the direct receiver is expected to be much simpler than superheterodyne receiver, leading to a potentially cost-effective solution. Another important advantage of direct conversion is that there is no image frequency. Since the mixer difference frequency is effectively zero, and the sum frequency, equal to twice the local-oscillator (LO) frequency, is easily filtered. However, one important disadvantage of direct receivers is that the LO must be very stable, and it is hence costly, especially for millimeter-wave frequencies. In addition, wideband downconverters are not readily available at millimeter-wave frequencies. An alternative method is the use of six-port based direct digital receiver architecture (Fig. 4). More recent results [16,17] with carrier recovery from QPSK signals offer an interesting approach used in six-port-type receivers to reduce LO costs without imposing serious limits on wideband operation.

The six-port-based SDR receiver shown in Fig. 4 also uses a direct conversion scheme, and the baseband signal is digitized at four output terminals of the six-port circuit. The six-port-based digital receiver in SDR targets multi-modulation and multiband wireless communication systems at low cost for mass-market millimeter-wave applications.

The concept of the six-port-based receiver is derived from six-port technology, developed as an amplitude and phase measurement methodology for high-frequency signals [18]. In 1994, a paper proposed application of six-ports for direct receivers [5]. Several six-port receivers have been developed since then for microwave and millimeter-wave communications. The carrier recovery method for six-port receiver has advanced, and LO frequency can be retrieved from the RF input by carrier recovery means [7,19]. Six-port receivers have been proposed for being

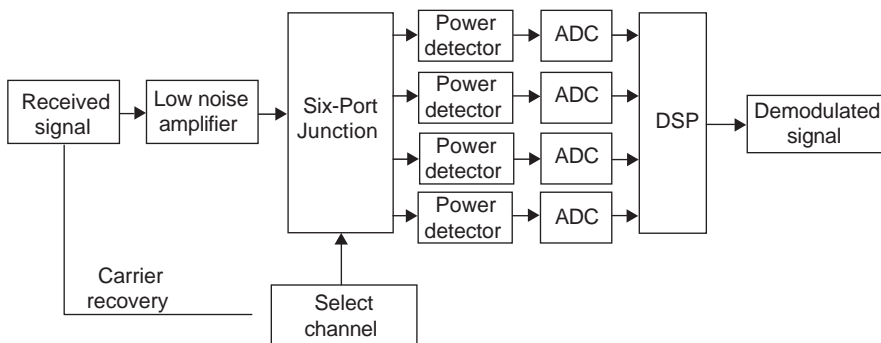

Figure 4. Block diagram of typical direct software six-port receiver.

robust and offering low manufacturing cost and low power consumption. More investigations are needed, however, and present studies indicate that a six-port receiver has a strong potential to solve a number of current communication and marketing problems, including multiuser modulation, seamless radio reception, low cost, and wideband operation.

2. DSP IN SOFTWARE-DEFINED RADIO

Figure 5 is a photograph of a typical DSP board with two A/Ds and D/As (12 bit sampling rate of 65 MHz), an FPGA chip (EP20K1500EBC652-1X) and two digital input/output ports, configuration ports, and an external clock connector. Several DSP boards may be operated in parallel by cabling digital I/O ports.

Today the evolution toward practical software radios is accelerating through a combination of techniques. These include smart antennas, multiband antennas, and wideband RF devices. Nowadays wideband analog-to-digital converters (ADCs) and digital-to-analog converters (DACs) can access gigahertz range of spectra instantaneously. Intermediate frequency (IF), baseband, and bit-stream processing is implemented in increasingly general-purpose programmable processors with application-specific integrated circuits (ASICs), Field-programmable gate arrays (FPGAs), digital signal processors (DSPs), and general-purpose (GP) processor technologies are being introduced in SDR designs. SDR is becoming practical as costs per millions of instructions per second (mips) of DSPs, and general-purpose central processor units (CPUs) have dropped below \$10 per mips. The economics of software radios become increasingly compelling as demands for flexibility increase while numerical processing costs continue to drop by a factor of 2 every few years, but RF parts and subassembly costs tend to remain high, particularly at millimeter-wave frequencies. At the same time, absolute processing capacities continue to climb into the

Figure 5. Photograph of a typical DSP board.

hundreds of millions of floating-point operations per second (mflops) to billions of flops (gflops) per chip. At present time, software radio technology can be cost-effectively implemented for commercial first-generation (1G) analog and second-generation (2G) digital mobile cellular radio air interfaces. Over time, wideband third-generation (3G) air interfaces will also yield to software techniques on wideband RF platforms possibly at millimeter-wave frequencies. The resulting software-defined radio extends the evolution of programmable hardware, increasing flexibility via increased programmability. The ideal software radio represents the point of maximum flexible programmability in this evolution. In addition, ADCs and DACs are available as low-cost chips and single-board open-architecture configurations offer bandwidths of tens of megahertz with the dynamic range required for software radio applications. Multimedia requirements for desktop and wireless personal digital assistants (PDAs) continue to exert downward pressure on parts count and on power consumption of such chipsets. This trend will push the ideal software radio technology from the base station to the mobile terminal. Although the tradeoffs among analog devices, low-power ASICs, DSP cores, and embedded microprocessors in handsets remain fluid, cutting-edge base stations are beginning to employ software radio architectures. New designs for high-end mobile radio nodes such as military vehicular radios are now largely based on some type of software radio approach. Finally, the multiband, multimode, and multiuser flexibility of software radios appears central to the goal of seamless integration of personal communications systems (PCS) and land mobile and satellite mobile services (including truly nomadic computing).

Compared to the traditional hardware radio, the main advantage of software radio is the fact that it can support various modulation schemes with a unique hardware. On the other hand, its main disadvantage is still the present high cost of digital programmable devices. This situation can change with the rapid development in semiconductor processing technology and the development of reconfigurable devices in combination with six-port receiver technology.

2.1. Combination of SDR and Six-Port Technology

One key point of SDR is to possess a digital processing kernel with almost infinite processing ability. Although DSP and semiconductor technology have developed rapidly since the early 1990s, it is still difficult for the operating speed level of current DSP chip to completely support a high-speed multichannel multimodulation SDR at IF level. In the interim, SDR implementations will require a mix of hardware-intensive techniques such as ASICs. Certain software radio systems adopt multichip architecture and parallel algorithms, thereby increasing the design complexity and potential cost.

Instead of digitizing signals at IF, microwave/millimeter-wave signals can be digitized at baseband with six-port technology, and hence reduce the processing requirement for DSP chips. This new solution to SDR design is based on direct demodulation with "six-port technology,"

downconverting RF signal to baseband directly with a six-port module. This work presents more recent results obtained on the six-port receiver suitable for SDR use in multimode microwave/millimeter-wave wireless mass-market communications.

2.2. Broader Implications of the Software Radio

The prospect of a new technology for multiband, multi-mode software radio handsets and infrastructure has social and political implications, particularly for type certification authorities charged with administering the equitable use of the radio spectrum. Among other factors, these authorities certify that radio equipment meets legally imposed constraints. The software radio introduces new levels of complexity in the communication hardware certification process.

In addition, software radios may operate on any RF band that is within the capabilities of the underlying radio platform, and with any mode for which a software load image is available. This raises the possibility of truly novel approaches to spectrum management. One of the more interesting is the possibility that software radios could use a spectrum rental protocol to autonomously share the spectrum. Another is that by incorporating advanced technology such as neural networks [20–22], SDR can develop its own protocols to achieve a radio system called “cognitive radio.” Cognitive radio is an advanced research topic based on the software radio concept.

3. ARCHITECTURE AND OPERATING PRINCIPLE OF SIX-PORT RECEIVER

Six-port technology has been under development since the early 1970s starting with microwave and millimeter-wave measurement applications; in 1994 a six-port receiver was first proposed as a direct digital receivers [5]. In principle, the six-port consists of linear circuits with dividers and combiners interconnected in such a way that four or ‘ N ’ different vectorial additions of reference signal and signal to be measured (receiver signal) are obtained. The use of different phase shifts and attenuation between the components such that the two RF input signals generate different phases at four output ports by vector addition of the input phasors. The signal levels of the four baseband output signals are detected using Schottky diode detectors or another RF quadratic detector including a power detector. By applying suitable baseband signal processing algorithms, the magnitude and phase of the unknown received signal can be determined for given modulation and coding scheme [5,23].

3.1. Six-Port Circuit Reflectometer and Six-Port Receiver

The block diagram of a conventional six-port reflectometer is shown in Fig. 6. RF signal a_1 is normally connected to port 1 as reference signal and RF signal a_2 to port 2 as unknown signal. The other four output ports are connected to RF quadratic detectors or power detectors. The unknown signal of the six-port circuits can be obtained from

Figure 6. Block diagram of six-port reflectometer.

four output power level readings [24–26]:

$$p_3 = |b_3|^2 = |Aa_2 + Bb_2|^2 \quad (1)$$

$$p_4 = |b_4|^2 = |Ca_2 + Db_2|^2 \quad (2)$$

$$p_5 = |b_5|^2 = |Ea_2 + Fb_2|^2 \quad (3)$$

$$p_6 = |b_6|^2 = |Ga_2 + Hb_2|^2 \quad (4)$$

where $A \dots H$ are eight complex constants, to be known by physical calibration procedures, described below

$$|b_2|^2 = \sum_{i=3}^6 \beta_i P_i$$

and β_i are real coefficients, functions of $A \dots H$ complex coefficients.

The measurement of $|b_2|$ in the reflectometer shown in Fig. 6 determines one measurement of interest. The six-port reflectometer is usually designed in such a way that the response of one of the power detectors is proportional to $|b_2|^2$. The fourth port is chosen for normalization. Referring to Eq. (2), the first design objective is for $C = 0$. Hence

$$p_4 = |D|^2 |b_2|^2 \quad (5)$$

In order to explicitly display the measurements of interest, (1), (3), and (4) may be written as follows:

$$p_3 = |A|^2 |b_2|^2 |\Gamma_2 - q_3|^2 \quad (6)$$

$$p_5 = |E|^2 |b_2|^2 |\Gamma_2 - q_5|^2 \quad (7)$$

$$p_6 = |G|^2 |b_2|^2 |\Gamma_2 - q_6|^2 \quad (8)$$

When A , E , and G are known by calibration procedures, then $|b_2|$ and Γ_2 can be determined from Eqs. (6)–(8).

Consider the case of a six-port receiver at a reference plane 2-2'. The “incident wave” a_2 and the “reflected wave” b_2 have frequencies f_{RF} , f_{LO} and have arbitrary relative relationships φ_1 , φ_2 , so that

$$a_2 = |a| e^{j(2\pi f_{RF} t + \varphi_1)} \quad (9)$$

$$b_2 = |b| e^{j(2\pi f_{LO} t + \varphi_2)} \quad (10)$$

If their frequency difference is small, the S parameters of the six-port to be calibrated can be regarded as being constant at each frequency and the equivalent reflection coefficient becomes

$$\Gamma_2 = \frac{b_2}{a_2} = \left| \frac{b}{a} \right| e^{j(2\pi\Delta f t + \Delta\phi)} \quad (11)$$

where $\Delta f = f_{LO} - f_{RF}$ and $\Delta\phi = \phi_2 - \phi_1$

The frequency difference Δf can be readily obtained from the derivative of $\theta(t)$

$$\Delta f = \frac{\theta(t_2) - \theta(t_1)}{t_2 - t_1} \quad (12)$$

where the time interval between two samples $\Delta t = t_2 - t_1$ is properly chosen for best accuracy. It is to be noted that the sign of Δf is direct indication of relative position of f_{RF} and f_{LO} . In this way, we can determine the ratio of amplitude, frequency and phase between LO signal (port 1) and RF signal (port 2) from the power levels at the four output ports. Thus

$$\Gamma_2 = \frac{\sum_{i=3}^6 X_i P_i}{\sum_{i=3}^6 Y_i P_i} \quad (13)$$

where X_i, Y_i are complex constants that can be obtained by calibration procedures. However I,Q data for a given channel can be determined directly from output signals on six-port circuit by use of digital or analog decoder circuit [27].

3.2. Architecture of Six-Port SDR Receiver

The structure of a software six-port receiver was shown in Fig. 3. The six-port junction works as a direct RF downconverter in the proposed receiver. Port 2 connects to RF signal and port 1 connects to LO signal; the other four ports are connected to power detectors. RF signals from port 1 and port 2 are directly downconverted from radiofrequency to baseband frequency from the output levels of the power detectors. The baseband signal levels from power detectors are digitized and sent to DSP. The DSP stage is in charge with suitable algorithms of baseband signal processing such as demodulation and decoding. Six-port receivers were designed at CRP to operate at a center frequency of 24 GHz for SIW, 28, 24, 5.8, and 2.4 GHz for MMIC or MHMIC technology six-port circuits.

3.3. Analysis of Six-Port Circuit

One of the design criteria for an ideal six-port junction as suggested by Engen [26] is as follows. For the ideal situation, a six-port circuit can obtain highest accuracy for all ranges of operation if the six-port circuit q points (complex numbers) correspond to the condition $|q_3| = |q_5| = |q_6|$ and their arguments differ by 120° .

Figure 7. (a) Wilkinson power divider; (b) 90° hybrid coupler.

Suppose that ports 1 and 2 are completely isolated, and then the equivalent q_i point can be expressed as

$$q_i = \frac{S_{i1}}{S_{i2}} \quad (14)$$

In practical circumstances, it is difficult to find such a circuit, especially if extremely broadband operation is required. In general, the more the magnitudes of q_i are equal and the greater the differences between arguments of q_i , the better is the performance of the circuit. According to Stumper [31], the six-port can yield good results even when the ratios of the magnitudes of q_i exceed 4 and the angles between q_i are smaller than 25° . For QPSK hard receivers, the angle separation of q_i points is 90° and their amplitudes are equal.

A typical six-port junction presented below consists of a Wilkinson power divider and a number of 90° hybrid couplers. Figure 7 shows the symbols of these two components.

The scattering parameters of the Wilkinson power divider and 90° coupler are

Wilkinson power divider [S]

$$= \begin{bmatrix} 0 & -\frac{j}{\sqrt{2}} & -\frac{j}{\sqrt{2}} \\ -\frac{j}{\sqrt{2}} & 0 & -\frac{j}{\sqrt{2}} \\ -\frac{j}{\sqrt{2}} & 0 & -\frac{j}{\sqrt{2}} \end{bmatrix} \quad (15)$$

90° hybrid coupler [S]

$$= \begin{bmatrix} 0 & \frac{j}{\sqrt{2}} & \frac{1}{\sqrt{2}} & 0 \\ \frac{j}{\sqrt{2}} & 0 & 0 & \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & 0 & 0 & \frac{j}{\sqrt{2}} \\ 0 & \frac{1}{\sqrt{2}} & \frac{j}{\sqrt{2}} & 0 \end{bmatrix} \quad (16)$$

A block diagram of six-port circuit architecture is shown in Fig. 8. The circuit consists of one power divider and three 90° hybrid couplers.

From (15) and (16), the reflected wave at ports 3–6 can be expressed as follows:

$$\begin{aligned} b_3 &= -\frac{a_1}{2} + \frac{a_2}{2}j \\ b_4 &= -\frac{a_1}{2}j + \frac{a_2}{2}j \\ b_5 &= \frac{a_1}{2}j + \frac{a_2}{2} \\ b_6 &= -\frac{a_1}{2} - \frac{a_2}{2} \end{aligned} \quad (17)$$

Assuming that all six ports are perfectly matched, then $b_1 = b_2 = b_3 = b_4 = b_5 = b_6 = 0$; and

$$[b] = [S] \cdot [a] \quad (18)$$

The scattering parameters for an ideal six-port junction are as follows:

$$\begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \\ b_5 \\ b_6 \end{bmatrix} = \begin{bmatrix} 0 & 0 & \frac{1}{2}e^{j180^\circ} & \frac{1}{2}e^{-j90^\circ} & \frac{1}{2}e^{-j90^\circ} & \frac{1}{2}e^{j180^\circ} \\ 0 & 0 & \frac{1}{2}e^{j90^\circ} & \frac{1}{2}e^{j90^\circ} & \frac{1}{2}e^{j0^\circ} & \frac{1}{2}e^{j180^\circ} \\ \frac{1}{2}e^{j180^\circ} & \frac{1}{2}e^{j90^\circ} & 0 & 0 & 0 & 0 \\ \frac{1}{2}e^{-j90^\circ} & \frac{1}{2}e^{j90^\circ} & 0 & 0 & 0 & 0 \\ \frac{1}{2}e^{-j90^\circ} & \frac{1}{2}e^{j0^\circ} & 0 & 0 & 0 & 0 \\ \frac{1}{2}e^{j180^\circ} & \frac{1}{2}e^{j180^\circ} & 0 & 0 & 0 & 0 \end{bmatrix} \cdot \begin{bmatrix} a_1 \\ a_2 \\ a_3 \\ a_4 \\ a_5 \\ a_6 \end{bmatrix} \quad (19)$$

where a_1 and a_2 represent the incoming signal and the reference LO signal, respectively.

4. SIX-PORT DESIGNS

Based on the analysis of an ideal six-port junction, we now provide various six-port circuit designs. One objective is to design a six-port circuit that is to be used in an SDR receiver operated at a center frequency of 24 GHz with good receiver stability and high sensitivity. This leads to the following design objectives:

- Minimum of insertion loss between the RF input port and power detector ports such as to increase power levels at output ports
- Maximum isolation between RF input port and LO port to reduce leakage to antenna

The q_i points of the six-port circuit should be equal in magnitude and 120° apart in phase. When RF input port and LO ports are completely isolated, the equivalent q_i points of the six-port circuit can be expressed as

$$q_3 = \frac{S_{31}}{S_{32}}, q_4 = \frac{S_{41}}{S_{42}}, q_5 = \frac{S_{51}}{S_{52}}, q_6 = \frac{S_{61}}{S_{62}}$$

Different six-port circuits were designed and fabricated at 24 and 28 GHz. Circuit designs are based on microstrip structure (MHMIC) and substrate-integrated waveguide (SIW) structure [10]. Circuit simulations of these two six-port circuits were made using ADS and HFSS software of Agilent Technologies. In addition, an MMIC six-port circuit was designed at 28 GHz and fabricated using a pseudomorphic high-electron-mobility transistor (PHEMT) process on a GaAs compound semiconductor [17]. Other six-port circuits for six-port receivers were designed at much lower frequencies [7,28].

4.1. Microstrip Six-Port Circuit

Microstrip six-port circuits were designed at 24 and 28 GHz. The 24-GHz circuit was fabricated in MHMIC technology (on a 250- μm ceramic substrate with a relative permittivity $\epsilon_r = 9.9$) with the layout shown in Fig. 9 and photographed in Fig. 10. The circuit at 28 GHz was fabricated in MMIC technology using PHMET process on GaAs and (See Fig. 11). The MHMIC chip measures 9.5×8.4 mm and the MMIC chip, 2×3 mm. Simulated and measured S parameters of the MHMIC six-port circuit are summarized in Table 1, with center frequency at 24 GHz. The reflection coefficients S_{11}, S_{22} are lower than -19.8 dB and the isolation between the RF port and LO port S_{12} is lower than -23.8 dB at center frequency. The transmission coefficients are close to the theoretical predicted value (-6 dB). Similar agreement between measurement and simulated S parameters was found for the MMIC six-port operating from 24 to 30 GHz.

The simulated and measured operating bandwidth results for the microstrip structure six-port MHMIC are shown in Fig. 12. The simulated and measured results agree well over the operating bandwidth. The isolation

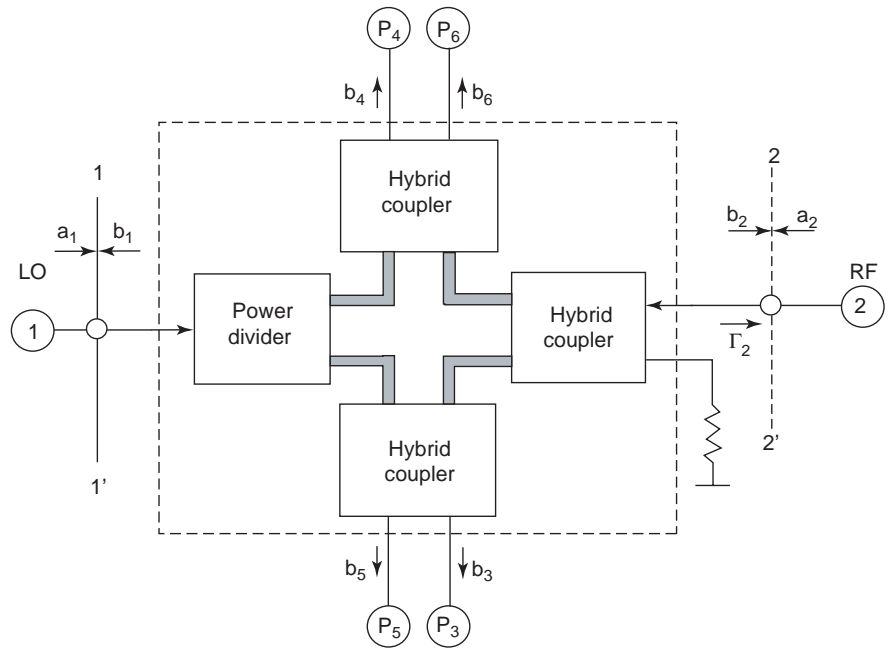

Figure 8. Six-port circuit block diagram.

between RF and LO ports is found to be at least 15 dB, and the transmission coefficients are within ± 0.5 dB of the theoretical predicted value (-6 dB).

4.2. Substrate-Integrated Waveguide (SIW) Structure Six-Port Circuit

Rectangular waveguide components have been widely used in millimeter-wave systems, but their high cost and difficult integration to planar circuits prevent these components from being used in low-cost high-volume applications. The recently proposed substrate-integrated waveguide (SIW) scheme (Fig. 13) provides an interesting alternative. In this case, the rectangular waveguide components are synthesized using arrays of metallic vias and

convenient transitions to planar structures (microstrip, CPW) are designed and integrated on a single substrate. Hence, high-Q rectangular waveguide components and planar circuits can be integrated together on the same planar platform at low cost using standard PCB or compound semiconductor substrates.

SIW is fabricated with a periodic via structure to realize bilateral waveguide edge walls. This periodic structure is much more complex for analysis than the conventional rectangular waveguide. A simulation of the integrated waveguide using a finite-element method that

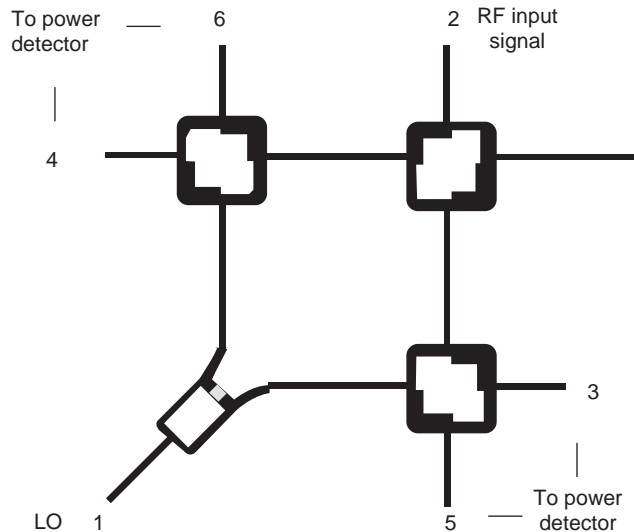

Figure 9. Design layout of the MHMIC six-port circuit.

Figure 10. Photograph of MHMIC six-port circuit.

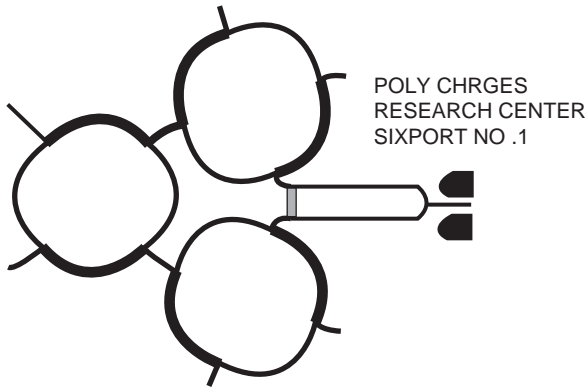

Figure 11. Photograph of MHMIC six-port circuit.

requires abundant resources and its design is not straightforward. To improve the design efficiency, the SIW is transformed to an equivalent rectangular waveguide. It is shown [10] that a TE_{10} -like mode in the SIW has dispersion characteristics almost identical to those of the TE_{10} mode of a dielectric-filled rectangular waveguide of an equivalent width.

For a six-port circuit, it is necessary to match the SIW to a microstrip or CPW transmission line. It is well known that a three-port matched network must be lossy. For a microstrip based six-port circuit, a Wilkinson power divider containing a $100\text{-}\Omega$ resistance is used. For the SIW structure, it is difficult to realize impedance inside a waveguide. Therefore, a Wilkinson power divider structure cannot be used in SIW. In the proposed SIW six-port circuit, the power divider is replaced with a coupler to ensure that its output 14 ports are well matched.

The SIW six-port circuit layout is shown in Fig. 6. The circuit was designed on a 0.508-mm substrate with relative permittivity $\epsilon_r = 2.2$, the via diameter is $d = 0.75\text{ mm}$, and the distance between the bilateral via sidewalls is $a = 6.682\text{ mm}$. The equivalent width a_{eqv} of the waveguide for HFSS simulation is 6.20 mm to operate in desired frequency band. Simulated S parameters of the SIW six-port circuit are summarized in Table 2 at a center frequency of 24 GHz . The reflection coefficients S_{11} and S_{22} are less than -27 dB and the isolation between RF port and LO port S_{12} is less than -37 dB . The transmission coefficients are close to the theoretical predicted value (-6 dB).

The simulated operating bandwidth results for the SIW structure six-port circuit are shown in Fig. 15. The return loss at output ports is less than -20 dB and the isolation between RF and LO ports is -33 dB at center frequency of 24 GHz . Over the operating bandwidth, the isolation

between RF and LO ports is at least -20 dB and the transmission coefficients are very close ($\pm 0.05\text{ dB}$) to the theoretical predicted value (-6 dB).

4.3. Comparison between Microstrip Structures and SIW Circuit Structure for Six-Port Circuit

Compared to microstrip structure, SIW structure can achieve higher Q value, which means smaller energy loss of the whole circuit. Simulation results show that the SIW structure can achieve smaller insertion loss between the RF input port and the power detector ports and more isolation between the RF input port and the LO port. In addition, the SIW structure can work at frequencies above 30 GHz , whereas the high loss of planar microstrip circuit makes this structure unacceptable above 30 GHz . However, the MMIC structure has definite dimensional advantages in the frequency ranges below 10 GHz and between 15 and 35 GHz .

An SIW structure can be effectively converted to an equivalent conventional rectangular waveguide. The SIW can then be modeled by conventional waveguide techniques, and all the existing design methods for the rectangular waveguide can be applied. With an appropriate choice of diameter, the radiation loss can be decreased to a negligible level. These characteristics make the SIW six-port structure a good choice for an SDR working at millimeter-wave frequencies above 40 GHz .

However, the SIW six-port circuit is much larger than the MMIC microstrip six-port circuit operated at 30 GHz . The SIW structure is not suited to low-frequency communications, and at typical microwave frequencies below 10 GHz , microstrip MHMIC or MMIC structure six-port is a better choice.

5. CALIBRATION

It is possible to calculate the ratio of amplitude, frequency, and phase between LO signal (port 1) and RF signal (port 2) from the four output power levels determining the complex constants X_i, Y_i by calibration procedures. We now examine the six-port calibration method and the six-port receiver demodulation results obtained with calibration. Among the many algorithms that have been proposed for the physical calibration of six-port reflectometers (SPRs) [18], Engen's six-port-to-four-port reduction [26,30] seems to be the most attractive. This procedure determines the dependencies between the different power meter readings, yielding five real-valued reduction parameters that permit transformation of the SPR into a virtual four-port. No

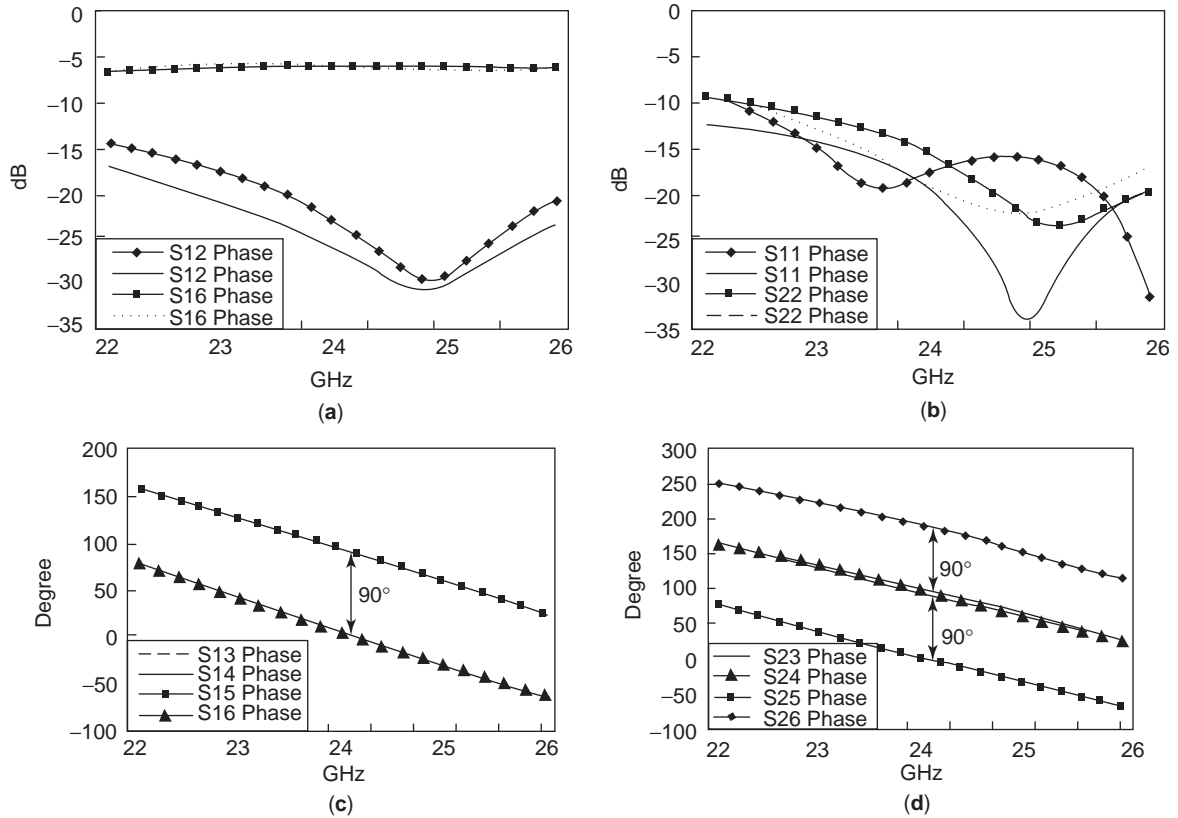

Figure 12. Simulated and measured scattering parameters of the MHMIC six-port circuit.

known standards are required for this reduction. The value measured by the virtual four-port is related to the reflection coefficient of the device under test by an “error box” transformation. The three complex parameters of this transformation may be found by using one of the many existing methods for the calibration of traditional network analyzers.

More recently, some real-time six-port calibration algorithms have been proposed. These calibration algorithms are designed for six-port direct receivers, a brief description of these calibration methods are given here.

5.1. Physical Six-Port Calibration Method

5.1.1. W-Plane Calibration of Six-Port Circuit. Using the same annotation as Stumper [31], the six-port to four-port reduction is given by the equations

$$p_1 = |w|^2 \tag{20}$$

$$Zp_2 = |w - w_1|^2 \tag{21}$$

$$Rp_3 = |w - w_2|^2 \tag{22}$$

where w is the complex reflection coefficient at the input of the imaginary ideal four-port reflectometer and the p_i denote the power levels from p_1 to p_3 , measured with the SPR significantly. However, good initial estimates of the

five parameters are needed for measured at the ports labeled 1–3, normalized with respect to the power value measured at the reference port 4 of the SPR. The five reduction parameters to be determined by the calibration are the values of the real positive variables Z , R , and w_1 , and the real and imaginary parts of the complex variable w_2 .

The variable may be eliminated from (9) to (11), yielding the nonlinear constraint equation

$$\begin{aligned} Ap_1^2 + BZ^2P_2^2 + CR^2P_3^2 + (C - A - B)ZP_1P_2 \\ + (B - C - A)RP_1P_3 + A(A - B - C)ZRP_2P_3 \\ + A(A - B - C)P_1 + B(B - C - A)ZP_2 \\ + C(C - A - B)RP_3 + ABC = 0 \end{aligned} \tag{23}$$

where

$$A = |w_1 - w_2|^2 \tag{24}$$

$$B = |w_2|^2 \tag{25}$$

Equation (9) can be solved by measuring at least 9 (usually 13 in practice) arbitrary different terminations. The solution of (9) $[A, B, C, Z, R]$ allows transformation of six-port to a perfect four-port reflectometer in a notional W

Figure 13. Topology of a substrate-integrated waveguide (SIW).

complex plane. The W -plane reflection coefficient is

$$W = \frac{p_1 - Z^2 p_2 + C}{2\sqrt{C}} + j \frac{[C(A+B-C) + (A-B+C)p_1 - (A-B-C)Z^2 p_2 - 2CR^2 p_3]}{\pm 2\sqrt{C(2AB + 2BC + 2AC - A^2 - B^2 - C^2)}} \quad (26)$$

5.1.2. Error-Box Calibration. A two-port error box is inserted between the notional four-port and the DUT (device under test) such that the virtual reflection reading from the notional perfect reflectometer obtained by W -plane calibration are transferred to the real reflection coefficients Γ . This is done through a bilinear transformation

$$\Gamma = \frac{e - W}{cW - d} \quad (27)$$

where c , d , and e are complex constants related to the S parameters of the error box

$$c = -S_{22}$$

$$d = S_{12}S_{21} - S_{11}S_{22}$$

$$e = S_{11}$$

Figure 14. Design layout of the SIW six-port circuit [29].

W -planet- Γ -plane bilinear transformation is shown in Fig. 16.

After six-port-to-four-port reduction and error box calibration, $|b_2|$ and Γ can be determined. Therefore the phase difference and amplitude ratio of a_1 and a_2 can be obtained.

5.2. Real-Time Calibration Method for Six-Port Receiver [32]

The physical six-port calibration method uses external physical standard terminals to its input port. However, for a six-port receiver, it would be entirely impractical. It is therefore necessary to develop a calibration method free from any external connection. To accomplish this goal, a new six-port calibration methods is achieved by feeding a RF signal other than the reference source into DUT port of the six-port. This signal can be either a unmodulated signal carrier with a frequency adjacent to the six-port local source frequency, or a digital modulated signal with a frequency equal to or close to the local source frequency. The resulting output waveforms of the diode detectors of the six-port are actually beat signals of the two RF signals.

Table 2. Simulated S Parameters of SIW Structure Six-Port ($f = 24$ GHz)

S Parameters	Simulations (dB)	S Parameters	Simulations (dB)

S_{15}	-6.03	—	—

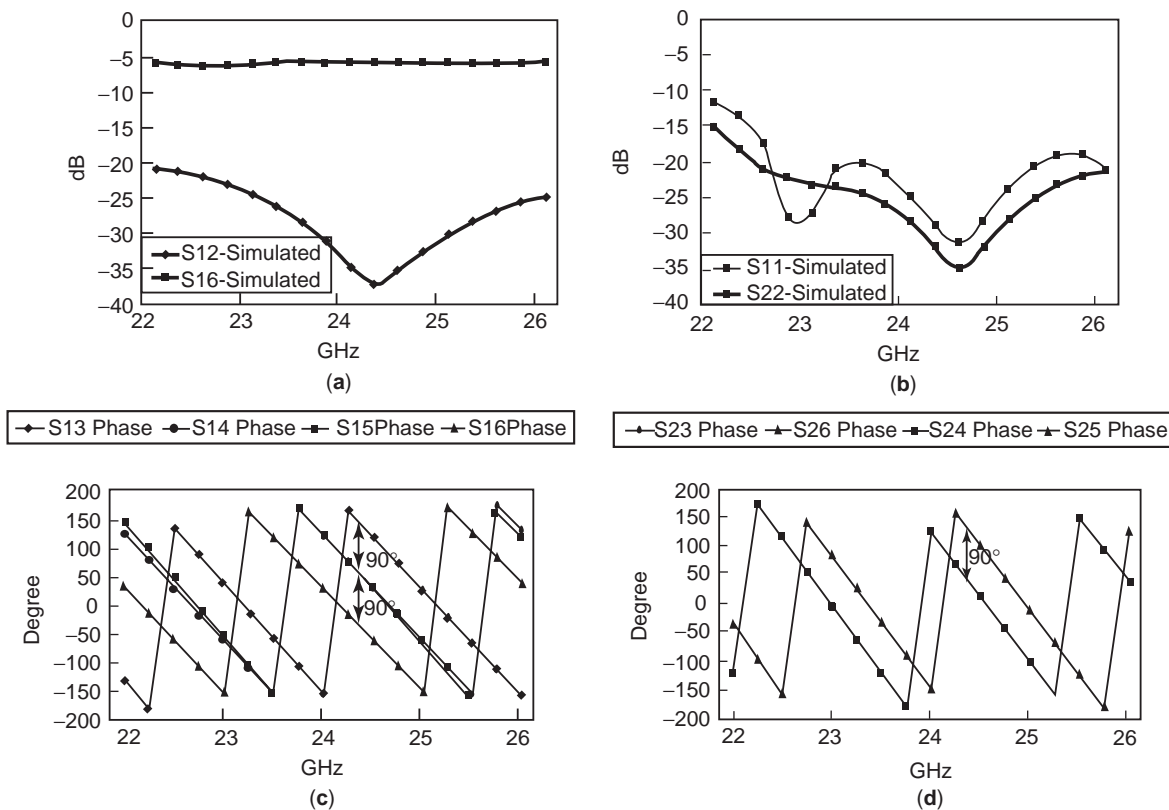

Figure 15. Simulated results of SIW structure six-port circuit.

The voltage readings corresponding to a group of widely distributed terminations are acquired by properly sampling these waveforms.

As we know, the leakage of the received signal to the local-oscillator reference port is small, and may be neglected. In this case, the relationship between the output data of SPR and the three power ratios of the detectors of the six-port become linear, and can be expressed as follows

$$\Gamma_r = A_{r1}p_1 + A_{r2}p_2 + A_{r3}p_3 + C_r \tag{28}$$

$$\Gamma_i = A_{i1}p_1 + A_{i2}p_2 + A_{i3}p_3 + C_i \tag{29}$$

where Γ_r , Γ_i are the calculated output data, whereas A_{rj} , A_{ij} ($j = 1,2,3$) and C_r , C_i are calibration parameters to be determined. Power ratios at the output detectors of the six-port are p_1, p_2, p_3 .

Figure 16. W-plane- Γ -plane bilinear transformation.

It is clear that from the equations above that a total of eight parameters should be determined from the calibration procedure. Therefore, four known sets of I,Q values or signal spread-spectrum (SS) standards should be used to obtain eight linear equations for solution of the preceding eight parameters of calibration A_{rj} , A_{ij} and C_r , C_i . These four known sets of I,Q values are ideally selected as being the four different states in QPSK. However, simulation shows that the calculation diverges when the four known sets of I,Q values have the same amplitude. Hence, at least the amplitude of one signal standard should be different from the remaining three. Therefore, we choose three sets of I,Q values from the four states of a QPSK signal and a zero signal at the input of the receiver as the fourth known I,Q set. The zero signal input can be achieved by applying a large bias to drive the low-noise amplifier (LNA) in the receiver front end far beyond cutoff. An alternative method is to insert an attenuation for example, 3 or 6 dB in the fourth set of QPSK signals.

From the four sets of I,Q values above or signal standards, we have four sets of detector output power ratios of the six-port, namely, Q with $k = 1,2,3,4$ and $j = 1,2,3$. Substituting $Q_{k,j}$ into Eq. (12) and equating the left-hand k, j side of these equations to the standard I,Q values, (1,1), (-1,1), (-1,-1), and (0,0) we have two systems of four linear equations. One of them corresponds to Eq. (13), and the other to Eq. (14). Solving these systems of linear equations, we obtain the parameters $A_{rj}, A_{ij}, j = (1,2,3)$ and C_r, C_i from which the calculations of the receiver output I,Q data

Table 3. Demodulation Data Results for QPSK Signal

Input	Output	Input	Output

are made using the ratios of the output readings of the power detectors in Eq. (12).

6. DEMODULATION ALGORITHM RESULTS

The complex constants related to six-port circuit X_i, Y_i that are obtained from calibration to arrive at required receiver demodulation. Table 3 and 4 show the simulated demodulation results for virtual six-port circuit for QPSK and QAM16 modulations 17 when using suitable algorithms.

The simulated demodulation results show that the receiver has an accuracy of $\pm 5^\circ$ in phase and ± 0.4 dB in amplitude. It is found that actual six-port circuits do indeed comply with above resolution in phase and amplitude.

Within the operating frequency band of the SIW six-port circuit based receiver (22–26 GHz), two modulation schemes (QPSK and QAM-16) are selected to test the performance of algorithms in SDR.

6.1. QPSK demodulation

The input and output waveform and phase of QPSK are shown in Fig. 18. The INPUT is a pseudorandom bit sequence QPSK signal. The OUTPUT signal is obtained at the output port of the receiver. It is seen that the output signals (demodulation signals) are the same as input signals, and this confirms the operating principle of the receiver algorithm. Figure 19 shows the simulated output QPSK signal constellations for various signal-to-noise ratios (SNRs). A white noise is added to the input signal and the output constellations are presented in Figs. 19a–19c for QPSK signal with SNR equal 30, 10, and 4 dB, respectively. Demodulation results are presented in Fig. 19d.

Figure 20 shows the simulated output signal constellations for QPSK with different RF and LO power levels; the power level of RF and LO is changed from -10 to -30 dBm. By defining the demodulation error as follows

$$\text{Error} = \frac{|\text{output_signal} - \text{input_signal}|}{|\text{input_signal}|} \quad (30)$$

Table 4. Demodulation Data Results for QAM-16 Signal

$1.4142 \angle 315^\circ$	$1.4511 \angle 311.64^\circ$	$4.2426 \angle 145^\circ$	$3.9331 \angle 141.67^\circ$

**Figure 17.** Input signal constellations for QPSK (a) and QAM-16 (b) modulation.

it is seen that when the LO power level exceeds the RF power level, the highest error is under 5%, and when the LO power level is the same as the RF power level, the highest error is about 15%. To reduce the error of QPSK demodulation, the LO power level should exceed the RF input power level.

Simulated and theoretical BER versus E_b/N_0 for QPSK modulation is presented in Fig. 21 where E_b is the average energy of a modulated bit and N_0 is the noise power spectral density. For carrier power P_{RF} is (-21 dBm) and local-oscillator power P_{LO} is (-16 dBm) and the bit rate of QPSK signals is 1 Mbps (megabits per second), it is seen that the simulated BER curve matches the theoretical BER curve very well, as the BER is found to be less than 1×10^{-3} for E_b/N_0 higher than 7 dB over the frequency range within the operating band.

6.2. QAM-16 Demodulation Algorithm

Results on input and output waveforms and phase of QAM-16 are shown in Fig. 22. The INPUT is a pseudorandom bit sequence QAM-16 signal. The OUTPUT is the signal obtained at the output port of the receiver. It can be seen the output signals (demodulation signals) are the same as input signals.

Figure 23 shows the simulated output QAM-16 signal constellations for various signal-to-noise ratios (SNRs). A white noise is added to the input signal, and the output constellations are presented in Figs. 23a–23c for a QAM-16 signal with SNR equal 30-, 15-, and 8 dB, respectively. Targeted demodulation results are presented in Fig. 23d.

Figure 24 shows the algorithm simulated output signal constellations for QAM-16 with different RF and LO power levels; the power level of RF and LO is changed from -10

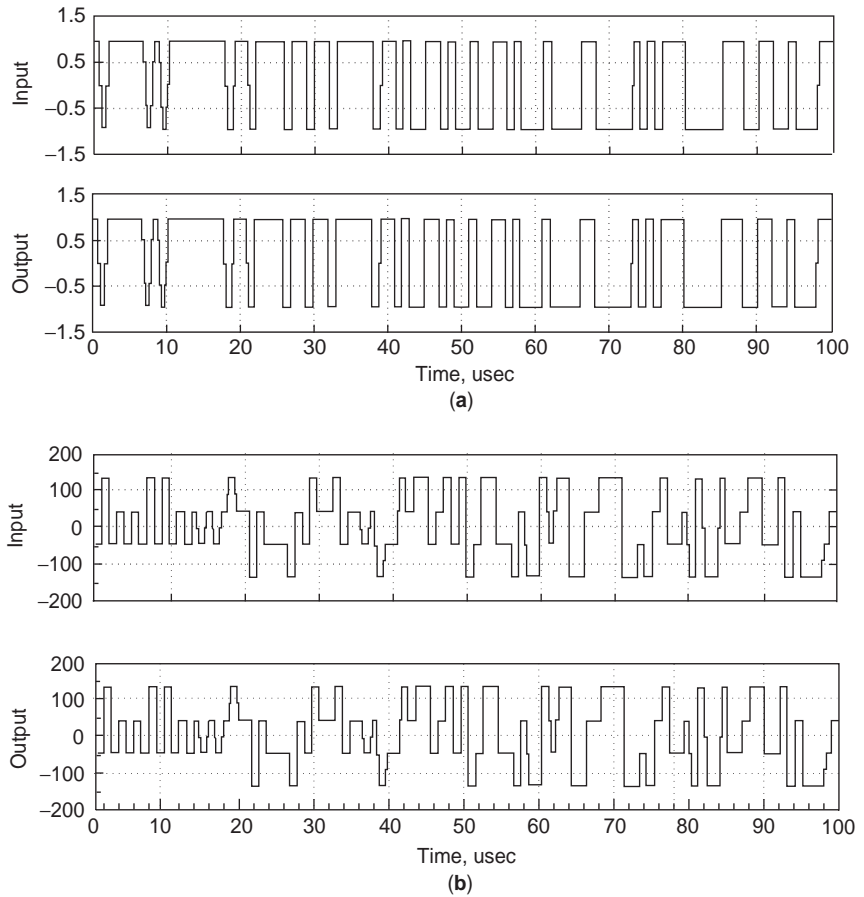

Figure 18. Receiver simulation results of QPSK: input/output waveform (a) and phase (b) as functions of time.

to -30 dBm. We can see that when the LO power level is bigger than RF power level, the highest error is under 5%, and when the LO power level is same as RF power level, the highest error is about 17%. It is seen that the to reduce

the error of QAM-16 demodulation, power level of LO should exceed the power level of RF input.

Simulated and theoretical BER versus E_b/N_0 for QAM-16 algorithm demodulation is presented in Fig. 25. The

Figure 20. Simulated output signal constellations for QPSK with different RF and LO power levels: (a) RF = -20 dBm, LO = -10 dBm; (b) RF = -20 dBm, LO = -20 dBm; (c) RF = -30 dBm; LO = -10 dBm; (d) RF = -30 dBm; LO = -20 dBm.

Figure 21. Simulated and predicted BER for QPSK modulation.

carrier power P_{RF} is -21 dBm and local oscillator power P_{LO} is -16 dBm. The signal bit rate is 1 Mbps. It is seen that the simulated BER curve matches the theoretical BER curve very well; the BER is less than 1×10^{-3} for E_b/N_0 higher than 11 dB (QAM-16) over the frequency range within the operating band.

7. CODING AND CDMA TECHNOLOGY

7.1. Channel Coding

Channel coding [33–35] refers to the class of signal transformations designed to improve communications performance by enabling the transmitted signals to better withstand the effects of various channel impairments, such as noise, interference, and fading. These signal processing techniques can be thought of as a means for accomplishing desirable system tradeoffs (e.g., error performance vs. bandwidth, power vs. bandwidth). The use of very large-scale integrated circuits (VLSI) and high-speed signal processing (DSP) techniques have made it possible to provide as much as 10 dB performance improvement through these methods, at much less cost than by the use of other methods such as high-power transmitters or larger antennas.

According to information theory and the Shannon limit, coding theory has developed rapidly. Many kinds of error control codes such as block code, cyclic code, convolutional code, and turbo code are available. Many early codes were developed for deep-space and satellite communication systems. With the emergence of digital cellular telephony, HDTV, high-density storage, coding technology promises to predominate not only in scientific

(a)

(b)

and military applications but also in numerous commercial applications [36–38].

7.2. Convolutional Encoder [33,34]

A convolutional code is described by three integers, n , k , and K , where the ratio k/n is the coding rate, and the integer K is a parameter known as *constraint length*, representing the number of k -tuple stages in the encoding

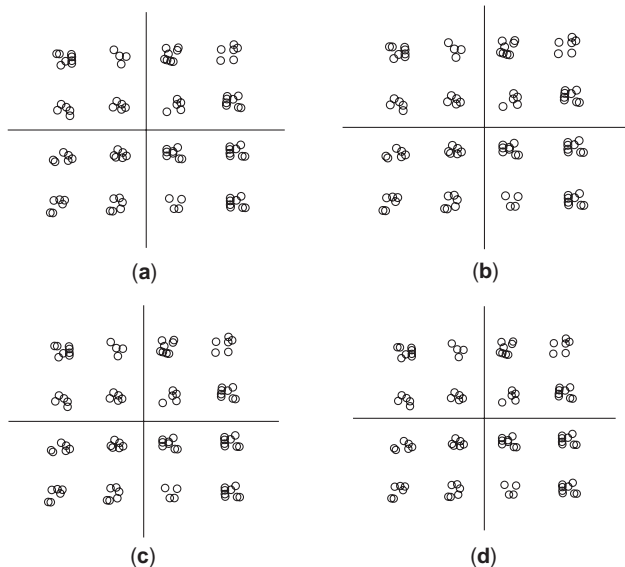

Figure 24. Algorithm-simulated output signal constellations for QAM-16 with different RF and LO power levels: (a) RF = -20 dBm, LO = -10 dBm; (b) RF = -20 dBm, LO = -20 dBm; (c) RF = -30 dBm, LO = -10 dBm; (d) RF = -30 dBm, LO = -20 dBm.

Figure 25. Simulated and predicted BER for QAM-16 modulation.

shift register. An important characteristic of convolutional codes, different from block codes, is that the encoder has memory—the n -tuple emitted by the convolutional encoding procedure is a function not only of an input k -tuple but is also of the previous $K - 1$ input k tuples. In practice, n and k are small integers and K is varied to control the capability and complexity of the code.

Convolutional code can be used in the six-port receiver as in any other receivers because this coding is done in baseband immediately available in proposed receiver as shown in Fig. 26, where convolutional code is used as the channel code. Figure 27 is a convolutional code encoder diagram. The code rate is set to $R = \frac{1}{2}$, and the constraint length $K = 7$, $g[0,0] = 1 + z + z^2 + z^3 + z^6$ with octal number 171, $g[0,1] = 1 + z^2 + z^3 + z^5 + z^6$ with octal number 133.

7.3. Turbo Code Encoder [39]

The component encoders are recursive systematic convolutional (RSC) encoders, specifically, systematic convolutional encoders with feedback. Figure 28 is a schematic diagram of a constituent encoder. The constraint memory length is 2. The generator polynomials are $1 + z + z^2$ and $1 + z^2$.

For systematic codes, the information sequence is part of the codeword, which corresponds to the direct connection from the input to one of outputs. For each input bits, the encoder generates two codeword bits.

The turbo encoder uses two parallel-concatenated RSC (recursive systematic convolutional) encoders with an interleaver before the second RSC encoder shown in Fig. 29. The two recursive convolutional codes are termed the *constituent codes of the turbo code*. The outputs of the constituent encoders are punctured and repeated to achieve

Figure 26. System encoder diagram with six-port receiver.

Figure 27. Convolutional code schematic.

the $(N_{turbo} + 6)/R$ output symbols. A common constituent code (RSC code) is used for turbo codes of rates $\frac{1}{2}$, $\frac{1}{3}$, and $\frac{1}{4}$. Initially, the states of the constituent encoder registers are set to 0. In our system, the overall rate of the encoder is $\frac{1}{2}$.

7.4. CDMA Application In Six-Port Receiver [38]

The initial application of spread-spectrum (SS) techniques was in the development of military guidance and communication systems. The techniques are called *spread spectrum* because the transmission bandwidth employed is much greater than the minimum bandwidth required transmitting the information. With the wide-bandwidth characteristics of six-port receiver, the CDMA technology can be readily applied. A system is defined as a SS system if it fulfills the following requirements:

1. The signal occupies a bandwidth much in excess of the minimum bandwidth necessary to send the information.
2. Spreading is accomplished by means of a spreading signal, often called a *code signal*, which is independent of the data.
3. At the receiver, despreading (recovering the original data) is accomplished by the correlation of the receiver spread signal with a synchronized replica of the spreading signal used to spread the information.

Spread-spectrum multiple-access techniques allow multiple signals occupying the same RF bandwidth to be transmitted simultaneously without interfering with one another. For the CDMA there are two schemes of spread spectrum: (1) frequency-hopped code-division multiple access (FH/CDMA), and (2) direct sequence code-division multiple access (DS/CDMA).

Figure 28. RSC constituent encoder.

Figure 29. Block diagram of general turbo encoder.

7.5. Six-Port Circuits for Multiuser CDMA Technology [38]

The six-port circuits are able to receive any signals, not only QPSK, BPSK, and QAM but also the random complex signals. In the wireless communication system, there are many users talking or sending information at the same time. This means that the received signal at the receiver is a combination of signals from different users with noise and multipath signal characteristics. In order to demodulate the signal from a specific user, the six-port technology in combination with the CDMA approach has the ability to demodulate any random complex signals.

From the power readers of $P_3, P_4, P_5,$ and P_6 , we can use the output value to calculate the complex envelope signal:

$$a_5 = A_{LO} * \exp(j\omega_0 t)$$

$$a_6 = A_{RF} * \text{env}(t) * \exp(j\omega_0 t) \tag{31}$$

$$\text{env}(t) = I(t) + jQ(t)$$

The following is the relationship between the input and output signals of the six-port circuits. The outputs at baseband are digitized for DSP operations:

$$b_1 = -j \frac{a_5}{2} + j \frac{a_6}{2}$$

$$b_2 = \frac{a_5}{2} + j \frac{a_6}{2}$$

$$b_3 = \frac{a_5}{2} + \frac{a_6}{2}$$

$$b_4 = j \frac{a_5}{2} - j \frac{a_6}{2} \tag{32}$$

7.6. Multiuser Six-Port Receiver with CDMA Technology

After the envelope of the RF signal has been obtained, pseudonoise (PN) code is used to decode different user information.

In Fig. 30, at the transmitter end the user, data are first modulated to IF signal and then through the upconverter to RF signal and then multiplied by its own PN code. At the receiving end the RF signal is first multiplied by its own PN code, and then the resultant signal is output to the six-port for demodulation. The PN code can be changed to receive different user’s data information.

In addition, the six-port receiver can be used with another type of transmitter/receiver structure as shown in

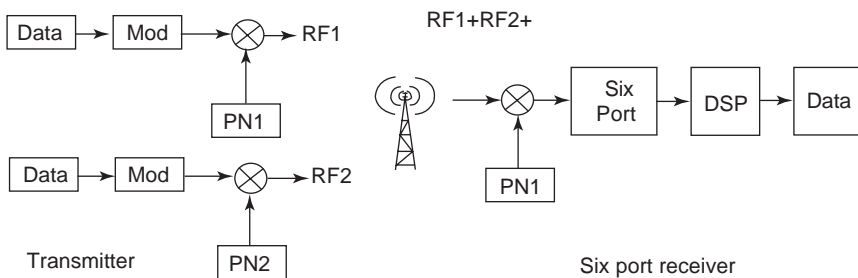

Figure 30. Six-port receiver with CDMA communication technology.

Fig. 31. A PN code is first used on the data, and then the resultant signal is modulated to IF signal frequency and upconverted to the desired RF frequency. At the receiver end, the six-port receiver directly demodulates the RF signal to obtain the baseband data. This desired user data are obtained with the proper PN code.

7.7. Channel Coding Results

At the transmitting end, a convolutional code is used as the channel code. The coding rate is $\frac{1}{2}$, the modulation type is QPSK, and the RF central frequency is 26.5 GHz. At the receiving end, a six-port receiver is used to downconvert the RF signal directly to baseband signal; a judgment circuit is connected to the output of the six-port receiver. After obtaining the channel bits (hard decision), the decoding module is used to obtain the user data. BER measurement equipment is used to calculate the bit error rate versus the bit energy over the noise density. In this system, the channel is assumed to be an AWGN (additive white Gaussian noise) channel [40]. For the turbo convolutional code (TCC), code rate R is $\frac{1}{2}$. The BER curve versus E_b/N_0 is shown in the Fig. 32.

Based on the direct six-port receiver, both convolutional code and turbo code are investigated as the channel codes for the six-port receiver. The improved performance of the six-port receiver is shown in Fig. 32. This new receiver presents a viable alternative for mobile terminals; at a BER of 1×10^{-7} , using the convolutional code, a 3 dB coding gain can be obtained. Using the turbo code the bit error rates are close to the Shannon limit with a coding gain of at least 8 dB.

Based on the direct six-port receiver, both convolutional code and turbo code are investigated as the channel codes for the six-port receiver. The improved performance of the six-port receiver is shown in Fig. 32. This new receiver presents a viable alternative for mobile terminals;

at a BER of 1×10^{-7} , using the convolutional code, a 3 dB coding gain can be obtained. Using the turbo code the bit error rates are close to the Shannon limit with a coding gain of at least 8 dB.

7.8. CDMA Six-Port Receiver Results

At first, the receiver characteristics are examined with respect to bandwidth and validity of six-port receiver simulations. The simulation validity is seen by comparing performance of the actual six-port receiver and ideal six-port receiver. Figure 33 shows an excellent agreement in BER (bit error rate) results between the two types of receivers. The bandwidth of an actual six-port receiver is seen to be at least 3 GHz (Fig. 35).

For the code-division multiple-access (CDMA) application, the six-port receiver can receive any kind of complex envelope signals. In order to obtain the data information of a specific user, the CDMA technology is used in conjunction with six-port receiver and the results are presented. A six-port receiver simulation was performed for one and two users as shown in Fig. 37 with different non-synchronous Walsh codes (0.5 chip delay) in CDMA technology. The results for two users with synchronous Walsh codes show exactly the same performance as for results obtained with one user only.

The curve in Fig. 33 is the BER curve of one user or more users in synchronism with QPSK modulation. This type of receiver can demodulate random complex envelope signals such as BPSK, QPSK, QAM, and 16-QAM.

Using the S parameters of an actual six-port, at 24 GHz, the bit error rate curve is compared with ideal six-port results shown in Fig. 34. From the results it can be seen that the ideal six-port receiver and practical six-port receiver are in very good agreement.

Figure 35 shows BER curves of a SIW six-port receiver at 23 and 26 GHz. The return loss of each ports of the

Figure 31. Six-port receiver with CDMA communication technology.

Figure 32. Simulation and measurement BER versus E_b/N_0 for various codes [40].

six-port is less than -20 dB during this frequency band. From this figure, we can see that six-port receiver is performing well and has a wide operation band if all ports are match-tested with a chip rate of 1 Mbps in a CDMA system.

For an actual circuit at 24 GHz tested under two users' conditions, the input and output waveforms of user 1 are identical as shown in Fig. 36 (the transmitted power of each user is the same). The curve shown presents waveforms of I and Q channels, when each user possesses individual orthogonal Walsh codes.

Figure 37 shows the bit error rate of one user in the presence of a second user for a nonsynchronous case (0.5 chip delay).

8. CONCLUSIONS

The development of SDR technology based on the six-port receiver scheme has been investigated, and some simulations and experimental results obtained particularly at

millimeter-wave frequencies are presented. The six-port based receiver can support multimodulation and multi-band communication and should achieve better performance than existing superheterodyne or direct-conversion receivers when coding, carrier recovery, and a higher level of circuit integration technology are implemented. The six-port receiver scheme is strongly motivated by the fact that the speed and present state-of-the-art reconfigurable devices such as digital signal processors (DSPs) and field-programmable gate arrays (FPGAs) are already satisfactory, and increased performance with price reduction are foreseen. On the other hand, the cost of the microwave components for the six-port receiver can be reduced mainly because of increased circuit integration means and the six-port receiver approach. Therefore, a receiver configuration that shifts the complexity to digital signal processing and alleviates problems associated with RF

Figure 33. Simulation results of BER curve of one user or more in synchronism for CDMA.

Figure 34. Simulation BER comparison between ideal six-port and actual six-port.

Figure 35. Simulation BER curve at 23 and 26 GHz of actual six-port circuit.

components can be viable in terms of cost, functionality, and market penetration.

The proposed six-port SDR receiver scheme is part of the direct-conversion receiver. In addition, it meets important technical and marketing criteria as mentioned in previous paragraphs. A six-port SDR receiver testbench and testbed is under construction at Centre de Recherches Poly-Grames to further evaluate six-port technology in SDR. The following factors favor further development of SDR:

- Amplification of RF signals were expensive in the past and had to be carried out at a low frequency (i.e., IF). Today, low-cost, wideband, high-gain microwave transistors have considerably decreased in cost.
- Wideband microwave amplifier design techniques have matured to maintain uniform gain and noise figure over a wide frequency band. The nonuniform sensitivity of the early direct receiver has been avoided, and such amplifiers, suitable for mass-production means, are now available and can be integrated with six-port circuits.
- “Online” SPR calibration reduces error related to imperfect circuit fabrication, allowing the six-port receiver to be flexible and yet accurate.
- Coding technology can be used to reduce the bit error rate and to allow multiuser modulation schemes (e.g., CDMA).

Figure 36. Input/output simulation waveform of user 1 in presence of second user.

Figure 37. Six-port receiver bit error rate CDMA simulation results for one and two users with nonsynchronous signals (0.5 chip delay).

- The present state in the development of VLSI and ASIC technology makes high-speed digital signal processing practical and cost-effective in six-port receiver technology.

Research work described in this article narrows the gap between six-port technology and emerging SDR. It is shown through a number of computer simulations and measurements that combined SDR and SPR offer a great flexibility in system configuration, reduction in system development cost, and a high potential for software reuse. The characteristics of six-port receiver are simulated and measured using hybrid and monolithic integrated six-port circuits. A new SIW six-port circuit with improved transmission characteristics has been introduced. The results of BER versus E_b/N_0 of the SDR receiver obtained with algorithm for two different modulation schemes have been presented. Simulation and measurement results show that the proposed receiver is flexible and stable, and it has a strong potential for future SDR terminals in various wireless communication systems.

SKIN EFFECT

FRANK OLYSLAGER
DANIËL DE ZUTTER
Ghent University
Ghent, Belgium

1. INTRODUCTION

The term *skin effect* is used to indicate that electromagnetic waves penetrate only a small distance into a conductor. Equivalently, the skin effect is the phenomenon that time-varying current densities are concentrated in a thin layer near the surface or skin of a conductor. The current densities are concentrated at the side of the conductor exposed to the source of these currents. These currents are often referred to by the term *eddy currents*.

For time-harmonic fields the amplitude of these fields decays exponentially with the distance from the surface. The distance over which the amplitude of the fields, and hence of the current density, decreases by a factor e is called the skin depth δ given by

$$\delta = \sqrt{\frac{2}{\omega\mu\sigma}} \quad (1)$$

Thus, the layer in which the fields are concentrated becomes thinner when the frequency $f = \omega/(2\pi)$ increases, the permeability μ increases, or the conductivity σ increases. In the limit of perfect conductors, fields and current density are concentrated in a vanishingly thin layer at the surface of the conductor.

If a current flows in a conductor with finite conductivity, this will cause a voltage drop along the flow of the current. The ratio of the voltage drop to the current is the internal impedance of the conductor. If the current density is concentrated in a thin layer at the surface of the conductor, this internal impedance, expressed per unit square, that is, for a unit length and a unit width of the conductor, is called the surface impedance Z_s . For a cylindrical wire with radius r this amounts to an internal impedance $Z_s/(2\pi r)$ per unit length. The surface impedance Z_s is given by

$$Z_s = \frac{1+j}{\sigma\delta} = \frac{1+j}{\sqrt{2}} \sqrt{\frac{\omega\mu}{\sigma}} \quad (2)$$

If Z_s is decomposed in its real and imaginary parts as $Z_s = R_s + j\omega L_1$, then R_s is the surface resistance and L_1 is the internal inductance per unit square. The surface impedance also expresses the ratio between the tangential electric field and tangential magnetic field at the surface of a conductor.

For a conductor several skin depths thick, the electromagnetic fields will not penetrate through the conductor. For a hollow conductor, such as a coaxial cable, this means that the internal electromagnetic field is decoupled from the external field. This is the electromagnetic shielding property of conductors. Since for copper at 60 Hz the skin depth $\delta = 8.5$ mm, the skin effect not only is important at radiofrequencies but also plays an important role for the design of power transmission lines, electrical machines, and electrification of railways. Because of the concentration of the current density at the surface of the wires, the Ohmic losses per unit length and voltage drops per unit length are substantially higher than what would be expected from a uniform distribution of the current density over the cross section of the wire. This concentration also imposes a limitation on the useful diameter of wires for power transmission.

The dissipated power per unit length P_d by a current I in the skin layer is given by

$$P_d = \frac{1}{2} R_s |I|^2 = \frac{1}{2} \sqrt{\frac{\omega\mu}{2\sigma}} |I|^2 \quad (3)$$

It is thus seen that for a given current this dissipation increases with frequency and permeability and decreases with conductivity.

Strictly speaking, the previous expressions for δ , Z_s , and P_d are valid only in good conductors with planar surfaces. However, if the radii of curvature of the conductor surface are large compared to the skin depth δ , these formulas are still good approximations. Table 1 shows the skin depth δ and surface resistance R_s for a number of conductors. Except for iron, the relative permeability μ/μ_0 , with μ_0 the free-space permeability, is equal to one for all metals.

When the surface of the conductor is rough, the losses inside the conductor will increase because the surface resistance increases. Porosity of the surface also will increase the surface resistance considerably.

To take the skin effect into account in numerical electromagnetic simulations, two approaches are possible. First, one can replace the boundary condition of a vanishing tangential electric field for a perfect conductor by an impedance boundary condition relating the tangential

Table 1. Conductivities, Skin Depths, and Surface Resistances for a Number of Conductors (f in Hz).

	σ	δ	R_s
Gold	41 MS/m	79 mm/ \sqrt{f}	310 n $\Omega\sqrt{f}$
Silver	61.7 MS/m	64.1 mm/ \sqrt{f}	253 n $\Omega\sqrt{f}$
Copper	58 MS/m	66.1 mm/ \sqrt{f}	261 n $\Omega\sqrt{f}$
Aluminium	37.2 MS/m	82.5 mm/ \sqrt{f}	326 n $\Omega\sqrt{f}$
Brass	15.7 MS/m	127 mm/ \sqrt{f}	501 n $\Omega\sqrt{f}$
Iron ($\mu_r = 120$)	10 MS/m	15 mm/ \sqrt{f}	6.88 n $\Omega\sqrt{f}$
Tin	8.69 MS/m	171 mm/ \sqrt{f}	674 n $\Omega\sqrt{f}$
Mercury	1.04 MS/m	494 mm/ \sqrt{f}	1.95 n $\Omega\sqrt{f}$
Zinc	17.4 MS/m	121 mm/ \sqrt{f}	476 n $\Omega\sqrt{f}$
Lead	4.8 MS/m	230 mm/ \sqrt{f}	910 n $\Omega\sqrt{f}$
Platinum	9.66 MS/m	162 mm/ \sqrt{f}	639 n $\Omega\sqrt{f}$
Human tissue (~ 1 GHz)	1.2 S/m	460 m/ \sqrt{f}	1.81 m $\Omega\sqrt{f}$

electric field to the tangential magnetic field through the surface impedance. In most cases this is an approximation, but it can be a very good one. A second approach is to also perform a simulation of the fields inside the conductor. For numerical techniques such as finite-element techniques, finite-difference techniques, or volume integral equation techniques, which discretize the volume of the conductors, a fine discretization is needed in order to accurately model the exponential decay of the fields inside the conductors. For boundary integral equation techniques the second approach, except for an increase in computational complexity, does not entail extra complications.

2. THEORY

2.1. Plane Interfaces

To study the skin effect quantitatively consider the structure of Fig. 1, consisting of a conductor with planar interface that occupies the semiinfinite region $z > 0$ and that is characterised by the material parameters ϵ , μ and σ . The region $z < 0$ is assumed to be free space with parameters ϵ_0 and μ_0 . Outside the conductor and in the absence of sources, the electromagnetic fields in time-harmonic regime $e^{j\omega t}$ satisfy the Maxwell curl equations

$$\nabla \times \mathbf{E} = -j\omega\mu_0\mathbf{H} \quad (4)$$

$$\nabla \times \mathbf{H} = j\omega\epsilon_0\mathbf{E} \quad (5)$$

Inside the conductor the fields satisfy

$$\nabla \times \mathbf{E} = -j\omega\mu\mathbf{H} \quad (6)$$

$$\nabla \times \mathbf{H} = (j\omega\epsilon + \sigma)\mathbf{E} \approx \sigma\mathbf{E} \quad (7)$$

Figure 1. Incident plane electromagnetic TE wave on a plane conductor with conductivity σ and permeability μ . The angle of incidence is θ^i .

In the last equation the displacement current term was neglected compared to the conduction current term, which is allowed for all practical conductors at practical frequencies. For example, in platinum $\omega\varepsilon$ becomes comparable to σ only at 1.5 pHz. Taking the curl of Eqs. (4) and (6), substituting Eqs. (5) and (7), and using the Maxwell divergence equations $\nabla \cdot \mathbf{E} = \nabla \cdot \mathbf{H} = 0$ in both free space and the conductor shows that the electric field in free space satisfies the Helmholtz equation

$$\nabla^2 \mathbf{E} + k_0^2 \mathbf{E} = 0 \quad (8)$$

where $k_0^2 = \omega^2 \varepsilon_0 \mu_0$ and in the conductor the Helmholtz equation

$$\nabla^2 \mathbf{E} - j\omega\mu\sigma \mathbf{E} = 0 \quad (9)$$

Now illuminate the conductor by a plane electromagnetic wave (see Fig. 1). Assume that this plane wave has TE (transverse electric) polarization and that, according to the coordinate system of Fig. 1, the electric field has a component only in the y direction. The incident electric field is given by

$$\mathbf{E}^i = E_0 \mathbf{u}_y e^{-jk_x x} e^{-jk_z z} \quad (10)$$

where \mathbf{u}_y is the unit vector in the y direction. Substituting in Eq. (8) and taking into account an angle of incident θ^i yields $k_x = k_0 \sin \theta^i$ and $k_y = k_0 \cos \theta^i$. From Eq. (4) the incident magnetic field is then found to be

$$\mathbf{H}^i = \frac{k_x \mathbf{u}_z - k_z \mathbf{u}_x}{\omega\mu_0} E_0 e^{-jk_x x} e^{-jk_z z} \quad (11)$$

where \mathbf{u}_x and \mathbf{u}_z are unit vectors in x and z directions, respectively. The incident plane wave will give rise to a reflected plane wave in free space and a transmitted plane wave in the conductor. All these plane waves will have the same phase variation $e^{-jk_x x}$ in the x direction along the interface, and they will all be TE-polarized. This means that the reflected plane wave takes the form

$$\mathbf{E}^r = RE_0 \mathbf{u}_y e^{-jk_x x} e^{jk_z z} \quad (12)$$

$$\mathbf{H}^r = \frac{k_x \mathbf{u}_z + k_z \mathbf{u}_x}{\omega\mu_0} RE_0 e^{-jk_x x} e^{jk_z z} \quad (13)$$

where R is the reflection coefficient, which is still to be determined. The transmitted electric field in the conductor takes the form

$$\mathbf{E}^t = E_0 \mathbf{u}_y e^{-jk_x x} f(z) \quad (14)$$

Substituting in Eq. (9) shows that $f(z)$ satisfies

$$\frac{d^2 f(z)}{dz^2} - (j\omega\mu\sigma + k_x^2) f(z) = 0 \quad (15)$$

Because $k_x = k_0 \sin \theta^i$ is of the same order of magnitude as k_0 , we neglect the term k_x^2 in the previous equation on the

same grounds for neglecting $\omega\varepsilon$ in Eq. (7). Taking into account that $f(z)$ should remain bounded for $z \rightarrow +\infty$ yields that $f(z) = T e^{-(1+j)z/\delta}$ with δ the skin depth as defined in Eq. (1). From Eqs. (14) and (6) the fields in the conductor are thus found to be

$$\mathbf{E}^t = TE_0 \mathbf{u}_y e^{-jk_x x} e^{-(1+j)z/\delta} \quad (16)$$

$$\mathbf{H}^t = \frac{k_x \mathbf{u}_z - (1-j)/\delta \mathbf{u}_x}{\omega\mu} TE_0 e^{-jk_x x} e^{-(1+j)z/\delta} \quad (17)$$

where T is the transmission coefficient. It is seen that the amplitudes of the fields decrease by a factor of e when they propagate over a distance perpendicular to the interface equal to the skin depth δ . The reflection and transmission coefficients follow from imposing the continuity of the tangential fields, that is, of E_y

$$1 + R = T \quad (18)$$

and H_x

$$-\frac{k_z}{\omega\mu_0} + R \frac{k_z}{\omega\mu_0} = -\frac{(1-j)T}{\omega\mu\delta} \quad (19)$$

at the interface $z = 0$. The solution to this set of equations is

$$R = \frac{k_z \mu_r \delta + 1 - j}{k_z \mu_r \delta - 1 + j} \quad (20)$$

and

$$T = \frac{2k_z \mu_r \delta}{k_z \mu_r \delta - 1 + j} \quad (21)$$

At the interface $z = 0$ the relation between the tangential electric field \mathbf{E}_t and the tangential magnetic field \mathbf{H}_t can be expressed as

$$\mathbf{E}_t = Z_s \mathbf{u}_n \times \mathbf{H}_t \quad (22)$$

where Z_s is the surface impedance as defined in Eq. (2) and $\mathbf{u}_n = -\mathbf{u}_z$ for the configuration of Fig. 1. Indeed, from Eq. (16) it follows that $\mathbf{E}_t = TE_0 \mathbf{u}_y e^{-jk_x x}$ and from Eq. (17) that $\mathbf{H}_t = -(1-j)/(\omega\mu\delta) TE_0 \mathbf{u}_x e^{-jk_x x}$ and hence that Z_s is as given by Eq. (2).

The current density \mathbf{J} in the conductor is $\sigma \mathbf{E}$, and from Eq. (16)

$$\mathbf{J} = \sigma TE_0 \mathbf{u}_y e^{-jk_x x} e^{-(1+j)z/\delta} \quad (23)$$

The total current per unit length I flowing in the conductor from the integration of Eq. (23) over all $z > 0$ is given by $I = \mathbf{J}_s \cdot \mathbf{u}_y$ with

$$\mathbf{J}_s = \int_0^{+\infty} \sigma TE_0 \mathbf{u}_y e^{-jk_x x} e^{-(1+j)z/\delta} dz = \frac{\sigma\delta}{1+j} TE_0 \mathbf{u}_y e^{-jk_x x} \quad (24)$$

where the notation \mathbf{J}_s indicates that this can be viewed as an equivalent surface current density. When this current flows across the conductor in the y direction over a unit distance it causes a voltage drop V equal to $\mathbf{E}^t(z=0) \times \mathbf{u}_y = TE_0e^{-jk_x x}$. The ratio V/I can be seen as the internal impedance per unit square of the conductor and is given by the surface impedance Z_s . The real part of the surface impedance is the surface resistance R_s and the imaginary part is the internal reactance ωL_i , which are both equal to $1/(\sigma\delta)$. This means that the surface resistance can be seen as the resistance per unit square when all the current is homogeneously distributed over and concentrated in a layer with thickness δ at the surface of the conductor, that is, as the DC resistance of a planar conductor with thickness δ .

The dissipated power P_d in the skin layer, per unit distance in the x direction due to Ohmic losses is given by

$$P_d = \frac{1}{2} \Re \int_0^{+\infty} \mathbf{J}^* \cdot \mathbf{E}^t dz = \frac{\sigma}{2} \int_0^{+\infty} |\mathbf{E}^t|^2 dz = \frac{\sigma\delta}{4} |E_0|^2 |T|^2 \tag{25}$$

From Eq. (24) it follows that

$$|I| = \frac{\sigma\delta}{\sqrt{2}} |T||E_0| \tag{26}$$

which allows one to recast Eq. (25) as

$$P_d = \frac{|I|^2}{2\sigma\delta} = \frac{1}{2} R_s |I|^2 \tag{27}$$

This shows that P_d can be seen as the power dissipated per unit length in the surface impedance by the surface current I .

The skin depth δ and the surface impedance Z_s are independent of $k_x = k_0 \sin \theta^i$, that is, independent of the angle of incidence of the plane wave. The previous derivations can also be repeated for a TM (transverse magnetic) polarized plane wave leading to the same conclusions. Only the expressions Eqs. (20) and (21) for R and T will change. This means that the previous analysis remains valid for arbitrary plane waves incident on the conductor surface. The amplitudes of the fields inside the conductor will always decrease by a factor e after having traveled a distance δ given by Eq. (1), and the surface impedance Z_s is always given by Eq. (2) independent of the angle of incidence. Since an arbitrary incident field can always be expressed as a superposition of plane waves, these conclusions remain valid for arbitrary illuminations of the conductor. For more on the plane-wave interaction with conductors, we refer the reader to Stratton [1].

2.2. Curved Interfaces

To investigate the effect of curvature on the penetration of electromagnetic fields in a conductor, consider the structure of Fig. 2 consisting of a round wire, with radius r_0 ,

Figure 2. Round wire with radius r_0 , conductivity σ , and permeability μ stretched along the z axis.

conductivity σ , and permeability μ stretched along the z axis (see also Ref. 2). It is assumed that some time-harmonic z -directed current flows inside the wire that depends only on the radial coordinate r . Since $\mathbf{J} = \sigma\mathbf{E}$, it follows from Eq. (9) that the longitudinal current density J_z satisfies the equation

$$\frac{d^2 J_z}{dr^2} + \frac{1}{r} \frac{dJ_z}{dr} - j\omega\mu\sigma J_z = 0 \tag{28}$$

A general solution of this equation is $J_z = AJ_0[(1-j)r/\delta] + BY_0[(1-j)r/\delta]$ where $J_0(x)$ is the Bessel function and $Y_0(x)$ is the Neumann function of order zero and argument x . Since the current density needs to remain finite at the center of the wire, B should be zero. If J_z , at $r=r_0$, is denoted by $J_{z,0}$ then J_z can be expressed as

$$J_z = J_{z,0} \frac{J_0[(1-j)r/\delta]}{J_0[(1-j)r_0/\delta]} \tag{29}$$

In Fig. 3 $|J_z/J_{z,0}|$ is shown for different values of $a = \delta/r_0$ and compared with

$$\left| \frac{J_z}{J_{z,0}} \right| = |e^{-(1+j)(r_0-r)/\delta}| = e^{-(r_0-r)/\delta} \tag{30}$$

for a planar conductor with $r_0 - r$ the distance from the surface [see Eq. (23) with a change of coordinates]. One

Figure 3. Current density distribution in a conducting wire (continuous lines) compared with the current distribution in a plane conductor (dashed lines) for different values of $a = r_0/\delta$ where r_0 is the radius of the wire and δ the skin depth.

notes that for $r_0 > 7\delta$ there is a good agreement between both results. This means that for $r_0 > 7\delta$ the conductor can be regarded to be planar (i.e., the curvature can be neglected) with respect to the skin effect.

The total current I flowing inside the wire is given by

$$\begin{aligned} I &= \oint_S \mathbf{J}_z dS = 2\pi \int_0^{r_0} J_{z,0} \frac{J_0[(1-j)r/\delta]}{J_0[(1-j)r_0/\delta]} dr \\ &= -\sqrt{2}\pi r_0 J_{z,0} (1+j)\delta \frac{J_0'[(1-j)r_0/\delta]}{J_0[(1-j)r_0/\delta]} \end{aligned} \quad (31)$$

The voltage drop V per unit length is given by $E_z = J_z/\sigma$ at $r = r_0$ or

$$V = \frac{J_{z,0}}{\sigma} \quad (32)$$

From Eqs. (31) and (32) it follows that the internal impedance per unit length of the wire is given by

$$\begin{aligned} Z_i &= \frac{V}{I} = -\frac{1-j}{2\sqrt{2}\pi r_0 \sigma \delta} \frac{J_0[(1-j)r_0/\delta]}{J_0'[(1-j)r_0/\delta]} \\ &= \frac{Z_s}{2\pi r_0} \frac{j}{\sqrt{2}} \frac{J_0[(1-j)r_0/\delta]}{J_0'[(1-j)r_0/\delta]} \end{aligned} \quad (33)$$

Comparing Z_i with $Z_s/(2\pi r_0)$ gives an indication of the radius of curvature above which it is possible to use the surface impedance Z_s for a planar conductor to calculate the internal impedance of a curved conductor. For a 10% error on R_s it is easily determined that r_0/δ should be larger than 5.5 and for the same error on ωL_i , r_0/δ should be larger than 2.2. In [3] the results shown in Fig. 3 are compared to spherically curved surfaces.

2.3. Thin Conducting Layer

Instead of a semiinfinite conducting space as shown in Fig. 1, consider a thin conducting layer with thickness d , conductivity σ , and permeability μ . This thin layer between $z=0$ and $z=d$ is embedded in free space. Assume fields inside this layer that only depend on the z coordinate. Taking an x and y dependence into account will not change the conclusions of this section. Assume also, without loss of generality, that the electric field is oriented along the y axis and the magnetic field along the x axis. If the displacement current in the layer is neglected, the total current I flowing in the conductor per unit length in the x direction is given by $I = \mathbf{J}_s \cdot \mathbf{u}_y$ with

$$\begin{aligned} \mathbf{J}_s &= \mathbf{u}_z \times [\mathbf{H}(z=d) - \mathbf{H}(z=0)] \\ &= [H_x(z=d) - H_x(z=0)] \mathbf{u}_y \end{aligned} \quad (34)$$

Maxwell's equations Eqs. (6) and (7) relate the electric and magnetic fields at $z=d$ and $z=0$:

$$\begin{aligned} H_x(z=d) &= -\frac{j}{Z_s \sin[(1-j)d/\delta]} \\ &\times \left\{ \cos\left[\frac{(1-j)d}{\delta}\right] E_y(z=d) - E_y(z=0) \right\} \end{aligned} \quad (35)$$

$$\begin{aligned} H_x(z=d) &= -\frac{j}{Z_s \sin[(1-j)d/\delta]} \\ &\times \left\{ E_y(z=d) - \cos\left[\frac{(1-j)d}{\delta}\right] E_y(z=0) \right\} \end{aligned} \quad (36)$$

From Eq. (34) it now follows that

$$I = -\frac{j[\cos[(1-j)d/\delta] - 1]}{Z_s \sin[(1-j)d/\delta]} [E_y(z=d) + E_y(z=0)] \quad (37)$$

The voltage drop over a unit distance caused by the current I is with good approximation given by $V \approx E_y(z=d/2) \approx \frac{1}{2}[E_y(z=d) + E_y(z=0)]$. This approximation is valid as long as the conductor is thin compared to the wavelength in free space. Hence, the internal impedance per unit square of the thin layer is given by

$$Z_i = \frac{V}{I} = \frac{Z_s \sin[(1-j)d/\delta]}{2j\{1 - \cos[(1-j)d/\delta]\}} = \frac{Z_s}{2j} \tan \frac{(1-j)d}{(2\delta)} \quad (38)$$

This means that under the aforementioned restrictions a thin conducting layer can be replaced with an infinitely thin conducting sheet with impedance Z_i .

In the low-frequency limit, that is, in the limit where the thickness d of the layer is small compared to the skin depth δ , one verifies that

$$Z_i = \frac{1}{\sigma d} \quad (39)$$

In this case the current density is homogeneously distributed over the conductor and the internal impedance becomes equal to the DC resistance of a planar conductor with thickness d .

At high frequencies, that is, when the thickness d of the layer exceeds several skin depths δ , one verifies that

$$Z_i = \frac{Z_s}{2} \quad (40)$$

In this case all the current is concentrated in thin sheets at the top and the bottom of the layer. Each of these current sheets yields an internal impedance Z_s . Since both impedances are in parallel, the total internal impedance is $Z_s/2$.

2.4. Surface Roughness

Because of the increased surface area, the surface resistance increases when the conductor has a rough surface. For limited surface roughness the relative increase of the surface resistance $\Delta R_s/R_s$ is proportional to the RMS

roughness ρ according to the empirical law

$$\frac{\Delta R_s}{R_s} = 0.29 \frac{\rho}{\delta} \quad (41)$$

This law is valid up to $\rho/\delta \approx 1.5$, independent of the type of material or frequency. At $\rho/\delta \approx 3$ the relative increase saturates at $\Delta R_s/R_s \approx 0.6$ [4]. Not only surface roughness but also porosity of the surface will substantially increase the surface resistance. The increase in resistivity will result in an increase of the dissipation according to the first part of Eq. (3).

2.5. Numerical Simulations

In numerical electromagnetic simulation techniques the finite conductivity is most easily taken into account by imposing the impedance boundary condition Eq. (22) instead of $\mathbf{E}_t = 0$ for perfect conductors. The relation Eq. (22) can also be expressed as

$$\mathbf{E}_t = Z_s \mathbf{J}_s \quad (42)$$

where \mathbf{J}_s is the current density concentrated at the surface.

Consider the electric field integral equation for perfect conductors of the form

$$0 = \lim_{r \rightarrow S} \left[\mathbf{E}_t^i(\mathbf{r}) + \int_S \overline{\overline{G}}_{tt}(\mathbf{r}|\mathbf{r}') \cdot \mathbf{J}_s(\mathbf{r}') dS' \right] \quad (43)$$

where $\mathbf{E}^i(\mathbf{r})$ is an incident electric field and $\overline{\overline{G}}_{tt}$ is the electric–electric Green dyadic. This integral equation is a Fredholm equation of the first kind. For a conductor with finite conductivity this integral equation is replaced by

$$Z_s \mathbf{J}_s = \lim_{r \rightarrow S} \left[\mathbf{E}_t^i(\mathbf{r}) + \int_S \overline{\overline{G}}_{tt}(\mathbf{r}|\mathbf{r}') \cdot \mathbf{J}_s(\mathbf{r}') dS' \right] \quad (44)$$

which is a Fredholm integral equation of the second kind.

Inclusion of the surface impedance in the finite-element method goes along the same lines as for integral equation techniques. Consider the functional for a volume V with surface S and internal sources \mathbf{J}

$$F(\mathbf{E}) = \frac{1}{2} \int_V [(\nabla \times \mathbf{E}) \cdot (\nabla \times \mathbf{E}) - k^2 \mathbf{E} \cdot \mathbf{E} + 2j\omega\mu \mathbf{E} \cdot \mathbf{J}] dV + j\omega\mu \int_S \mathbf{E} \cdot (\mathbf{u}_n \times \mathbf{H}) dS \quad (45)$$

where \mathbf{u}_n is the unit normal pointing into V and $k^2 = \omega^2 \epsilon \mu$. The surface impedance is now taken into account by replacing $\mathbf{u}_n \times \mathbf{H}$ in the surface integral term by $Z_s \mathbf{E}$.

The finite-difference time-domain technique is more complicated because of the frequency dependence of Z_s . Equation (22) has to be expressed in the time domain,

which involves a convolution integral

$$\mathbf{e}_t(t) = \mathbf{u}_n \times \int_0^t z_s(t-\tau) \mathbf{h}_t(\tau) d\tau \quad (46)$$

where $z_s(t)$ is the inverse Fourier transform of Z_s . After discretization with respect to time this convolution implies that in principle the magnetic fields of all previous time-steps need to be remembered. However, several techniques [5] have been developed to limit the number of field values that have to be stored. In these techniques the surface impedance is approximated by a series of first-order rational functions in ω .

When analyzing the eigenmodes of resonators, an important quantity is the quality factor of the resonances. If the walls of the resonator consist of good conducting material, the quality factor Q can be estimated very well from a calculation of the eigenmodes in a resonator with perfectly conducting walls followed by a perturbation analysis taking into account the wall losses due to the skin effect. If \mathbf{H}_m are the magnetic fields corresponding to a mode in the resonator, then Q is given by

$$Q = \frac{2}{\delta} \frac{\int_V |\mathbf{H}_m|^2 dV}{\int_S |\mathbf{u}_n \times \mathbf{H}_m|^2 dS} \quad (47)$$

where V is the volume of the resonator and S its surface [6].

For an eigenmode in a waveguide with conducting walls, the skin effect will give rise to an attenuation of the eigenmodes. Just as the quality factor for a resonator, the attenuation constant α_m of an eigenmode can be estimated from the fields \mathbf{E}_m and \mathbf{H}_m of the eigenmode propagating in a waveguide with perfectly conducting walls. If the waveguide is oriented along the z axis, then α_m is given by

$$\alpha_m = \frac{R_s}{2} \frac{\oint_c |\mathbf{u}_n \times \mathbf{H}_m|^2 dc}{\int_S (\mathbf{E}_m \times \mathbf{H}_m^*) \cdot \mathbf{u}_z dS} \quad (48)$$

where S is the crosssection of the waveguide and c is the contour cut out of the crosssection by the perfectly conducting walls. The attenuation of the eigenmode in dB/m is then given by $8.69 \alpha_m$.

In numerical simulations a thin conducting layer can be replaced by an infinitely thin sheet with a sheet condition given by

$$\mathbf{E}_t = Z_i \mathbf{u}_n \times \Delta \mathbf{H}_t \quad (49)$$

where Z_i is as given by Eq. (38) and $\Delta \mathbf{H}_t$ is the jump in the tangential magnetic field over the sheet. The tangential electric field \mathbf{E}_t remains continuous over the sheet.

SKY WAVE PROPAGATION AT LOW FREQUENCIES

J. RALPH JOHLER
Johler Associates

Radiowaves generated by manufactured transmitters near the surface of the earth or radiowaves generated by such natural causes as cloud-to-ground lightning strokes propagate to great distances in a lateral direction between the surface of the earth and the ionized region between approximately 60 km and 100 km above the earth. This region is known as the lower ionosphere or the D and E regions of the ionosphere [1–8]. These radiowaves are called low-frequency (LF) *sky waves* in reference to this propagation phenomenon.

It is common practice to specify 30 kHz to 300 kHz as the LF part of the radio spectrum. This is somewhat arbitrary, and theoretical considerations described herein have been found to be useful far above and below this range of frequencies. In fact, the LF sky wave propagation theory can be used at the lower end of the very low-frequency (VLF) radio spectrum, and at the higher end of the medium-frequency (MF) radio spectrum. Traditionally, the mode theory is used at VLF [9], but the theoretical presentations herein can provide an interesting alternative.

Although LF sky waves have been used since the earliest days of radio science, vigorous study of these waves occurred mainly between 1950 and 1970 (see FURTHER READING). This research was in large measure a consequence of the development of precision pulsed ground-wave radio navigation and positioning systems. Although the ground wave is very stable with time of day, season, and so on, the ionospheric waves vary with time, and if such waves were not somehow sidestepped, the accuracy and precision of the navigation or positioning system would deteriorate. Thus, from an engineering point of view, LF sky waves were a problem in developing navigation systems such as Loran-C or Loran-D. One direct consequence of this research was the development of the *wave hop theory* of LF sky wave propagation, which will be introduced here. A discussion of Loran-C 100 kHz sky waves is given in Ref. 10.

1. EXPERIMENTS TO DETECT LOW-FREQUENCY SKY WAVES

An experimental pulse was radiated from a transmitter located in New York State during the 1953 preliminary tests of the Loran-C radio navigation system [2]. Figure 1(a,b,c) shows oscillograms of the observed pulse at distances west of the transmitter of 0, 1065, and 1381 km (or 0, 662, 858 statute miles), respectively. The electromagnetic (EM) field near the transmitter is vertically polarized and consists of a pulse that rises to a crest in 4 cycles, or 40 μ s. The observation at 1065 km was recorded at 12:55 A.M. EST and therefore includes reflections from the nighttime ionosphere at altitudes as great as 90 km. At 1381 km, the second pulse was recorded at 4:00 A.M. EST, and the shape reflects the changes that occur between day and night. Finally, the daytime pulse is shown at the distance 1381 km. Here, at 9:55 A.M., a daytime sky wave from the D region of the ionosphere dominates the pulse.

It is not difficult to realize that the severe distortion of the pulse is a consequence of multiple reflections from the ionosphere. Thus, many discrete pulses may arrive at the receiver at different delayed points in local times t' . Both the different propagation times and phase distortions resulting from reflection process cause constructive and destructive phase-type interference between the cycles of each pulse.

2. ELEMENTARY THEORETICAL CONSIDERATIONS

A theory to explain these observed phenomena has been constructed by applying Maxwell's equations to a model of the ionosphere and the earth. Before describing this theory, let us use some simple intuition and a simple model for the propagation environment. Consider the relationship between time and frequency:

$$\mathbf{E}(t', d) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp(i\omega t) \mathbf{E}(\omega, d) f_s(\omega) d\omega \quad (1)$$

where $\mathbf{E}(t', d)$ is the propagated field at time t' at a distance d .

Here the transformed field $\mathbf{E}(\omega, d)$ depends on the frequency ω , and $t' = t - d/c$, where $c = 0.299792458$ m/ns, a constant, $\mathbf{E}(\omega, d)$, and $f_s(\omega)$ are transforms of the field and the source, respectively. The observed pulse is $\mathbf{E}(t, d)$, and Re in Fig. 1 denotes the real part [2].

The earliest pulse to arrive at the receiver travels the shortest distance from the transmitter over the geodesic, d . This is the ground-wave pulse with the indexed order $j=0$. Pulses are also reflected from the ionosphere, but these pulses always arrive later in the local time (t')-domain. The earliest sky wave to arrive at the receiver at the greater distances occurs during daylight hours. The arrival of the first hop sky-wave is between 30 μ s and 40 μ s later than the arrival of the earliest precursor of the ground-wave pulse. Thus, the natural world allows only 30 μ s to 40 μ s of pure ground-wave pulse, in daylight hours, for operation of Loran-C. This difficulty was overcome by time-domain data sampling on the leading edge of

(a)

(b)

(c)

Figure 1. (a) Experimental LF pulse radiation close to the transmitter distance, $d \approx 0$, with a characteristic frequency of 100 kHz. (By permission of IEEE, Ref. 2). (b) Pulse observed at distance $d = 1065$ km at 12:55 A.M. EST, illustrating nighttime LF sky wave pulses, with characteristic frequency at 100 kHz. (By permission of IEEE, Ref. 2). the pulse at a point (say less than $30 \mu\text{s}$ to $40 \mu\text{s}$) where pure ground-wave pulse energy can be found.

Figure 2 is a diagrammatic representation of the LF sky waves, valid in both the time and frequency domains of Eq. (1) [2,12]. The concept of a somewhat localized system of reflection coefficients, R and T , at the ground and at the ionosphere respectively is introduced there. For a spherical model of the earth with a concentric ionosphere as depicted in Fig. 2(a,b), a coordinate system is used such that the distance from the center of the earth to the surface of the ground is $r = a$ and at the ionosphere is $r = a + h$, where r is the radial distance from the center of the earth. The *geodesic distance* is $d = a\theta$, where θ is the angle at the earth's center. The lines connecting the source or transmitter (S) with the observer or receiver (O), via the various local reflecting regions both at the ground and at the ionosphere, are called *geometric-optical rays* [13] or *wave hops* [14], where the latter include diffraction around the curve of the earth. The ionosphere lower boundary is located at $r = a + h = g$. For $r\theta$ coordinates, the earth's surface is $r = a$. The earliest part of each sky wave pulse arrives at a time D_j/c , where

$$D_j = 2j[(a + h) \cos \phi_{i,j} - a \cos \tau_j]$$

in which

$\phi_{i,j}$ = angle of incidence on the ionosphere
 τ_j = angle of incidence on the earth

If the ionosphere were perfectly conducting (i.e., sharply bounded and of very high conductivity), the reflection coefficient would be $T = -1$. The composite reflection process with reflections at the ground, R , for any index j

would be

$$C_j = (-1)^j p_0^j R_e^{j-1} \quad (2)$$

where

R_e^{j-1} = $(j - 1)$ th earth reflection coefficient
 p_0^j = ionosphere-ground curvature focusing-defocusing factor.

If the ionosphere is simply imperfectly reflecting with a finite conductivity, an ionospheric reflection coefficient T can be introduced:

$$C_j = (T_{ee})^j p_0^j R_e^{j-1} \quad (3)$$

The subscript *ee* denotes vertical electric (TM, or transverse magnetic) polarization at both the source and the receiver (vertical means in the r direction).

As extensively discussed in the literature (Refs. 15–17, for example), the reflection process at the ionosphere is complicated by the effects of the earth's magnetic field on the reflection process. Thus, notwithstanding the fact that the excitation waves generated at the transmitter are pure vertical polarization (TM) waves, such waves arriving at the receiver, after reflecting from the ionosphere magnetoplasma, contain horizontally polarized (TE) wave components. These components of the reflected waves are shown in Fig. 2(a,b) as dashed lines. These dashed geometric-optical lines always originate at the ionosphere magnetoplasma. The ground, for most practical purposes, is considered to be isotropic.

The wave $j = 1$ is independent of the TE waves if the receiving antenna is a vertical structure (i.e., receives only TM waves). However, the wave $j = 2$ depends on the TE

Figure 2. (a) Diagrammatic representation of LF sky waves, depicting an indexing method for identification of a series of time-domain pulses traveling laterally between the ground and the ionosphere, $j = 1, 2, 3, \dots$. Reflecting regions at the ionosphere are indicated as (j, k) , $j = 1, 2, 3, \dots$, $k = 1, 2, 3, \dots$. (From Ref. 11) (b) Diagrammatic representation of LF sky waves, depicting an indexing method for identification of a series of time-domain pulses traveling laterally between the ground and the ionosphere, $j = 2, 4, \dots$. Reflecting regions at the ionosphere are indicated as (j, k) , $j = 1, 2, 3, \dots$, $k = 1, 2, 3, \dots$. (From Ref. 11).

component, because this component is converted into TM waves at the second reflection point. Thus, in principle, one cannot escape the TE waves that originate in the ionosphere by using vertically polarized transmitting and receiving antennas.

The following reflection coefficients for TM and TE waves are defined as:

T_{ee} is the coefficient for the TM incident, TM reflected wave.

T_{mm} is the coefficient for the TE incident, TE reflected wave.

T_{em} is the TM-incident-TE-reflected conversion coefficient.

T_{me} is the TE-incident-TM-reflected conversion coefficient.

The coupling coefficients for transmission between vertically polarized transmission and reception can now be written as

$$C_1 = T_{ee}$$

$$C_2 = R_e T_{ee}^2 + R_m T_{em} T_{me}$$

$$C_3 = 2R_e R_m T_{ee} T_{em} T_{me} + R_e^2 T_{ee}^3 + R_m^2 T_{mm} T_{em} T_{me} \quad (4)$$

⋮

These equations can be generalized using matrix notation, for vertically polarized transmitters and receivers

$$G_e = \begin{bmatrix} R_e & 0 \\ 0 & -1 \end{bmatrix} \quad (5)$$

$$T = \begin{bmatrix} T_{ee} & T_{em} \\ T_{me} & T_{mm} \end{bmatrix} \quad (6)$$

$$G_m = p_0 \begin{bmatrix} 1 & 0 \\ 0 & -R_m \end{bmatrix}, \quad 1 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad (7)$$

$$(G_m T G_e)^{j-1} G_m T = p_0^j \begin{bmatrix} C_j & x_j \\ y_j & z_j \end{bmatrix} \quad (8)$$

3. THEORY OF PROPAGATION OF LOW-FREQUENCY SKY WAVES

As Eq. (1) is independent of Maxwell's equations, it is necessary only to construct a model for the propagation of the E field in the frequency-domain [2,12]. The propagation model usually employed to describe the LF sky waves in their natural environment is a finitely conducting spherical earth with radius $r = a$. This spherical earth is surrounded by a *magnetoplasma* comprising electrons, ions, and neutral particles with a superposed terrestrial magnetic field and a finite frequency of collision between particles. These particles go from random into orbital motion when excited by the LF electro-magnetic waves. Each particle has a finite collision frequency, which tends to dampen the activity. As the earth's magnetic field changes the particle motion from linear to orbital, and the direction of propagation of the EM wave may vary with respect to the terrestrial magnetic field, the ionospheric reflection process becomes anisotropic.

The detailed structure of the lower ionosphere between approximately 60 km and 100 km above the surface of the earth is well documented in the literature [3,18]. In the daytime, a layer of such plasma placed at 60 km and concentric with the earth usually serves as a simple model. This can be improved by introducing a large number of such concentric shells of plasma as a function of altitude, to take account of the variation of electron and ion density with altitude. Application of Maxwell's equations to this model results in a rigorous full-wave solution, if the ionosphere is assumed to be isotropic [1]. As is indicated in the discussion leading to Eq. (8) and in Refs. 4,15-17, the curved, concentric, isotropic ionosphere reflection coefficient is normally replaced by a suitable planar anisotropic reflection coefficient. This replacement involves the magneto-ionic theory with a full-wave (plane-wave) reflection coefficient. The spherical-wave focusing effect of the curve ionosphere can be retained in this process.

The LF radiowave field for a transmitter and receiver on the surface of the earth separated by a distance d can be represented rigorously by a system of waves traveling in the radial (r) direction

$$E_r = A \sum_{n=0}^{\infty} G(\theta, n) F(r, n) \tag{9}$$

Here

$$A = \frac{I_0 L \mu_0 c}{4\pi k_{-1}^2 a^4}$$

where $I_0 L$ is the current moment of the source, $\mu_0 = 4\pi \times 10^{-7}$ F/m, $c = 0.299792458$ m/ns, and the wave-number for the earth-ionosphere space is $k_{-1} = \omega/c$. We also define

$$k_{-2} = \frac{\omega}{c} \sqrt{\epsilon_{-2} - i \frac{\sigma_{-2}}{\epsilon_0 \omega}}$$

where σ_{-2} is the ground conductivity (s/m), $\omega = 2\pi f$, $\epsilon_0 = 1/c^2 \mu_0$, ϵ_{-2} is the relative dielectric constant of the ground, and f is the frequency (Hz). Furthermore,

$$G(\theta, n) = n(n+1)(2n+1)P_n(\cos \theta)$$

where $P_0(z) = 1, P_1(z) = z$, and

$$P_{n+1}(z) = \frac{2n+1}{n+1} z P_n(z) - \frac{1}{n+1} P_{n-1}(z), \quad n = 1, 2, \dots$$

Finally,

$$F(r, n) = \frac{\zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)}}{\zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)}} \frac{(1+R)(1+p_0 T_{ee})}{1-p_0 R T_{ee}} \tag{10}$$

where

$$p_0 = \frac{-\zeta_{-1a}^{(1)} - \zeta_{-1g}^{(2)}}{\zeta_{-1a}^{(2)} \zeta_{-1g}^{(1)}} \tag{11}$$

$$\zeta_{n+1}^{(1,2)}(z) = \frac{2n+1}{z} \zeta_n^{(1,2)}(z) - \zeta_{n-1}^{(1,2)}(z)$$

$$\zeta_0^{(1,2)}(z) = \pm \exp(\mp iz) \tag{12}$$

$$\zeta_{-1}^{(1,2)}(z) = \exp(\mp iz)$$

The abbreviation $\zeta_{-1a}^{(1,2)}$ means $\zeta_{-1}^{(1,2)}(k_{-1}a)$. The earth's reflection coefficient for the spherical waves is

$$R_e = \frac{\ln' \psi_{-1a} - \frac{k_{-1}}{k_{-2}} \ln' \psi_{-2a}}{-\ln' \zeta_{-1a}^{(2)} + \frac{k_{-1}}{k_{-2}} \ln' \psi_{-2a}}$$

$$\psi_n(z) = \frac{1}{2} [\zeta_n^{(1)}(z) + \zeta_n^{(2)}(z)]$$

where \ln' is the logarithmic derivative defined by

$$\ln' \psi_{-1a} = \left[\frac{\psi_n'(z)}{\psi_n(z)} \right]_{z=k_{-1}a}, \quad \psi_n'(z) = \frac{d}{dz} \psi_n(z)$$

These spherical wave functions are given in Ref. 19.

Equation (10) is derived from this isotropic model by identification of T_{ee} as the reflection coefficient of the lower boundary of this model. If T_{ee} is calculated by the recursion process described in Ref. 1, a rigorous solution of the problem for an arbitrary variation of the electron and ion densities with altitude can be found.

4. GEOMETRIC SERIES REPRESENTATION

Equation (10) can be expanded into a geometric series

$$F(r, n) = (1+R)(1+p_0 T_{ee}) \times \left(1 + \sum_{j=1}^{\infty} (p_0 R T_{ee})^j \right) \zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)} \tag{13}$$

for

$$|p_0 R T_{ee}| < 1 \tag{14}$$

which converges absolutely. The propagated field of Eq. (9) can now be written

$$E_r = E_{r,0} + \sum_{j=1}^{\infty} E_{r,j} \tag{15}$$

where at the surface of the ground the zero-order term is the ground wave

$$E_{r,0} = B \sum_{n=0}^{\infty} G(\theta, n) \zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)} (1+R_e) \tag{16}$$

Here

$$B = \frac{\mu_0 c}{8\pi} \frac{I_0 L}{k_{-1}^2 a^4}$$

and R_e is the ground reflection coefficient

$$1 + R_e = \frac{2i}{\zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)} [-\ln' \zeta_{-1a}^{(2)} + (k_{-1}/k_{-2}) \ln' \zeta_{-1a}^{(2)}]}$$

where the logarithmic derivative is

$$\ln' \zeta_{-1a}^{(1,2)} = \left[\frac{\zeta_{-1a}^{(1,2)'}(z)}{\zeta_{-1a}^{(1,2)}(z)} \right]_{z=k_{-1}}$$

with

$$\zeta_n^{(1,2)'}(z) = \frac{d}{dz} \zeta_n^{(1,2)}$$

The quantity B contains $I_0 L$, the source dipole current moment, and $I_0 L = 1 \text{ A} \cdot \text{m}$ determines the \mathbf{E} -field amplitude.

A particular sky wave can now be written

$$E_{r,j} = B \sum_{n=0}^{\infty} G(\theta, n) \zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)} (1 + R_e)^2 p_0 R_e^{j-1} T_{ee}^j \quad (17)$$

The anisotropic sky waves can now be written using Eqs. (5)–(8)

$$F(r, n) = (1 + R_e) \frac{|1 + G_m T|}{|1 - G_m G_e T|} \zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)} \quad (18)$$

whereon expansion of the determinate ratio in a geometric series yields

$$F(r, n) = \zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)} (1 + R_e) \times \left| \mathbf{I} + (\mathbf{I} + G_e) \sum_{j=1}^{\infty} (G_m G_e T)^{j-1} G_m T \right| \quad (19)$$

with

$$\mathbf{I} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

and so

$$E_{r,j} = \sum_{n=0}^{\infty} G(\theta, n) \zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)} (1 + R_e)^2 p_0^j C_j \quad (20)$$

As the ground wave [17] has been removed as a separate entity, the summation of all the j -terms generalized by Eq. (19) is a full-wave solution for the LF sky waves in the presence of an anisotropic ionosphere. The method for inserting anisotropy is discussed in detail in

Refs. 1,14,10,21. Reference 11 describes a computer program to calculate this equation directly.

The ratio of the two determinants in Eq. (18) can be written

$$\frac{|\mathbf{I} + G_m T|}{|\mathbf{I} - G_m G_e T|} = \left| \left(\mathbf{I} + \sum_{j=1}^{\infty} G_m G_e T \right)^j (\mathbf{I} + G_m T) \right| \quad (21)$$

which is equivalent to the determinant in Eq. (19). This is analogous to the determinant given by Eq. (7) in Ref. 10.

Equation (21) was central to the development of a widely distributed computer program [22,23] based on the use of the asymptotic computation methods for spherical wave functions of complex, noninteger order n . This approach is based on Ref. 14.

The j -series expansion discussed above is called by its author the *wave hop series*. In this approach, Eq. (9) is rewritten in the complex v plane where a suitable contour c is used [24]:

$$E_r = \int_c f(v) (1 + R_e) \frac{|\mathbf{I} + G_m T|}{|\mathbf{I} - G_m G_e T|} dv \quad (22)$$

Here

$$f(v) = -iA \frac{v^3}{\cos v\pi} P_{v-1/2}(-\cos \theta) \zeta_{-1a}^{(1)} \zeta_{-1a}^{(2)} \quad (23)$$

where $P_{v-1/2}(-\cos \theta)$ is the Legendre function of complex order. The function [23] is the complex-order analog to

Figure 3. Coordinate system for each reflecting region of the ionosphere.

that given in Eq. (9), and we have [13].

$$\zeta_{-1a}^{(1,2)} = \zeta_{v-1/2}^{(1,2)}(k_{-1}a), \quad \zeta_{v-1/2}^{(1,2)}(z) = \sqrt{\frac{\pi z}{2}} H_v^{(1,2)}(z)$$

where $H_v^{(1,2)}(z)$ is the well-known Hankel function [24].

The spherical reflection coefficients introduced in Fig. 2 and used in Eqs. (16) and (17) can now be written

$$R_e = \frac{\zeta_{-1a}^{(1)'} - \frac{k_{-1}}{k_{-2}} D_{-2a} \zeta_{-1a}^{(1)}}{-\zeta_{-1a}^{(2)} + \frac{k_{-1}}{k_{-2}} D_{-2a} \zeta_{-1a}^{(2)}} \quad (24)$$

where

$$D_{-2a} = \frac{\zeta_{-2a}^{(m)'}}{\zeta_{-2a}^{(m)}} \approx (-1)^m \sqrt{\left(\frac{v}{k_{-2}a}\right)^2 - 1}$$

provided $n = v - \frac{1}{2}$. This is called the Debye approximation; it is used extensively in the literature, for example, Refs. 9,12,14,20,24, and 25. The isotropic reflection from the ionosphere lower boundary located at altitude h above the

earth, or $r = g = a + h$, is

$$T = T_{ee}^s = \frac{-\zeta_{1g}^{(2)}}{\zeta_{1g}^{(2)}} T_{ee} \quad (25)$$

$$T_{ee}^s = \frac{\zeta_{1g}^{(2)} - \frac{k_{-1}}{k_3} D_{3g} \zeta_{1g}^{(2)}}{-\zeta_{1g}^{(1)} + \frac{k_{-1}}{k_3} D_{3g} \zeta_{1g}^{(1)}} \quad (26)$$

where K_3 is an isotropic wavenumber representing a simple model ionosphere reflector. The angle of incidence on the ionosphere and the earth shown in Fig. 2(a-d) can now be identified

$$\phi_{ij} = \sin^{-1} \frac{v}{k_{-1}g}, \quad \tau_j = \sin^{-1} \frac{v}{k_{-1}a} \quad (27)$$

Using the expansion given in Eq. (21) for an anisotropic ionosphere and integrating each term of the series along a suitable contour in the complex v plane again gives the ground-wave analog of Eq. (16) and a series of terms, each of which is a particular sky wave analog of Eq. (17).

The reduction of Eq. (22) is detailed in Refs. 14 and 20.

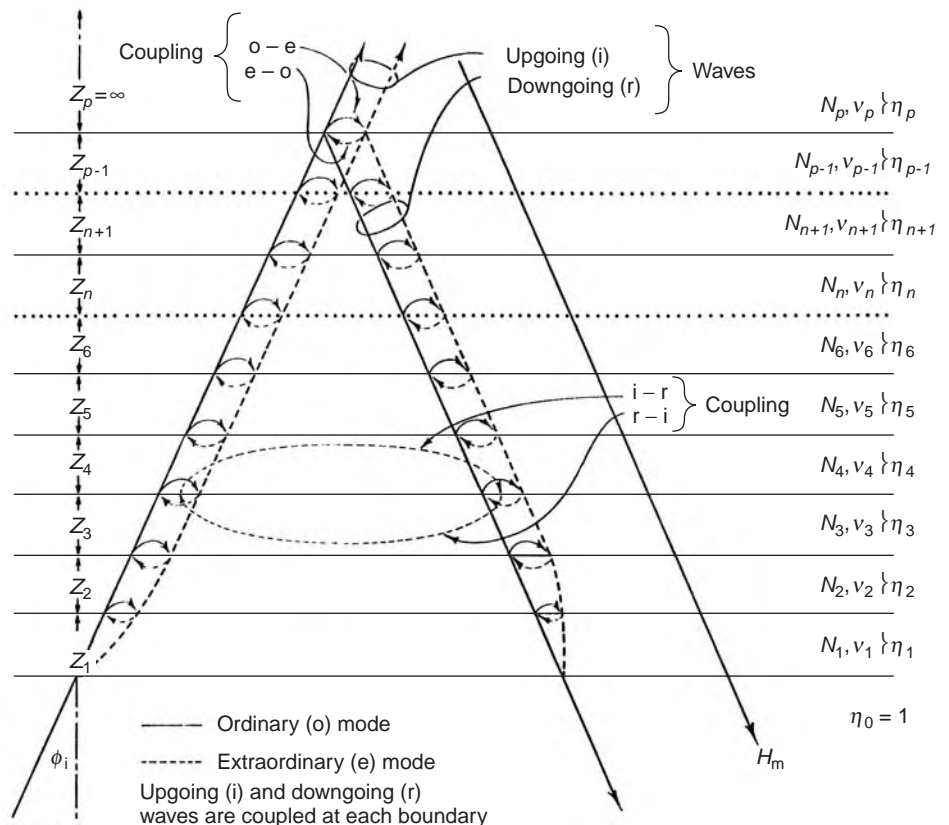

Figure 4. Magnetoplasma model showing detailed structure of the system of waves. The model is flexible, and the number of layers can be increased and the thickness decreased until convergence is obtained on electron-ion density profiles of the lower ionosphere. (After Ref. 2, by permission of IEEE).

The wave hop series now becomes

$$E_r = \int_c f(v)(1 + R_e) dv + \sum_{j=1}^{\infty} \int_c f(v)(1 + R_e)^2 p_0^j (a_j T_{ee} + c_j T_{me}) dv \quad (28)$$

$$\begin{bmatrix} a_j & b_j \\ c_j & d_j \end{bmatrix} = G_m^1 G_e T \begin{bmatrix} a_{j-1} & b_{j-1} \\ c_{j-1} & d_{j-1} \end{bmatrix} \quad (29)$$

where

$$G_m^1 = \frac{G_m}{p_0}$$

$$a_1 = 1 \quad c_1 = 0$$

$$a_j = R_e(T_{ee} a_{j-1} + T_{me} c_{j-1}) \quad \text{for } j \geq 2$$

$$c_j = R_m(T_{em} a_{j-1} + T_{mm} c_{j-1}) \quad \text{for } j \geq 2$$

Notwithstanding the fact that only TM waves have been excited and only TM waves are received at the receiver, a TE-type ground reflection coefficient is required at the ground as a result of the effects of the earth's magnetic

Table 1. Coefficients of Quartic Equation for an Electron Plasma

$$\begin{aligned} a_L &= \sin \phi_i \cos \phi_a, \quad a_T = \sin \phi_i \sin \phi_a \\ a_0 &= S_2^2 \left(1 - \frac{s}{s^2 - h^2} \right) + S_2 \left(\frac{1}{s} + \frac{s-2}{s^2 - h^2} + \frac{a_1^2 h_T^2}{s(s^2 - h^2)} \right) + \frac{s-1}{s(s^2 - h^2)} \\ a_1 &= 2 \frac{h_L h_T a_L}{s(s^2 - h^2)} S_2 \\ a_2 &= \left[2 \left(1 - \frac{s}{s^2 - h^2} \right) + \frac{h_L^2}{s(s^2 - h^2)} \right] S_2 + \frac{h_T^2 a_T^2}{s(s^2 - h^2)} + \frac{s-2}{s(s^2 - h^2)} \\ a_3 &= 2 \frac{h_L h_T a_L}{s(s^2 - h^2)} - a_L \sec^2 \phi_i \\ a_4 &= 1 - \frac{s^2 - h_L^2}{s(s^2 - h^2)} \\ s &= \frac{\omega^2}{\omega_N^2} \left(1 - i \frac{v}{\omega} \right), \quad S_2 = \sin^2 \phi_i - 1 \\ h &= \frac{\omega_H \omega}{\omega_N^2}, \quad h_L = h \sin I, \quad h_T = h \cos I \\ \omega_N^2 &= \frac{N e^2}{\epsilon_0 m} \\ \omega_H &= \frac{\mu_0 e H_m}{m} = \text{gyrofrequency} \end{aligned}$$

N and m are the electron number density and mass. H_m is the earth's magnetic intensity; I is the magnetic declination.

field on the ionosphere. Thus because of anisotropy, the TE ground reflection coefficient is required, as found explicitly in Refs. 20 and 23

$$R_m = \frac{\zeta_{-1a}^{(1)'} - \frac{k-2}{k-1} D_{-2a} \zeta_{-1a}^{(1)}}{\zeta_{-1a}^{(2)'} + \frac{k-2}{k-1} D_{-2a} \zeta_{-1a}^{(2)}} \frac{\zeta_{-1a}^{(2)}}{\zeta_{-1a}^{(1)}} \quad (30)$$

5. THEORY OF REFLECTION FROM THE IONOSPHERE

There remains to be explained a reflection process that leads to the four ionosphere reflection coefficients

$$T_{ee}, T_{mm}, T_{em}, T_{me}$$

The details leading to the mathematical theory of this reflection process are given in Refs. 4,15–17. Consider one of the reflecting regions at the ionosphere depicted in Fig. 2(a,b). The reflection process at one such region will now be given in detail.

The particle statistics of the electron-ion-neutral gas with superposed electrodynamic and magnetostatic fields was first treated in radio science between 1927 and 1931 [5–8] (see also Ref. 26, pp. 59–99).

The use of the full magneto-ionic theory to model LF sky wave propagation is given in Ref. 14. A local coordinate system is set up at a particular reflecting region depicted in Fig. 2. This Cartesian xyz coordinate system is shown in Fig. 3. The terrestrial magnetic field vector is contained in the yz plane. The EM wave propagates in the z' direction, and the wavefronts are contained in the $x'y'$ plane. The directions relative to the magnetic field vector are as follows:

ϕ_i is the angle of incidence.

ϕ_a is the magnetic azimuth.

I is the magnetic dip angle.

$\phi_{i,j}$ is now abbreviated to ϕ_i .

Figure 4 depicts a flexible model for the lower ionosphere. The plasma electron density is divided into layers. The thickness of each layer is decreased and the number of layers is increased until a stable reflection coefficient set is obtained for a particular electron number density, collision frequency, and so on. Figure 4 depicts ordinary and extraordinary propagation components coupled at each boundary. Each plasma slab, $n = 1, 2, 3, \dots, p$, becomes smaller as the number of slabs, p , is increased. The complex index of refraction for each layer in the model is obtained from a simultaneous solution of Maxwell's equations and the equation of motion in the velocity \mathbf{V} :

$$\begin{aligned} \nabla \times \mathbf{E} + \mu_0 \frac{\partial \mathbf{H}}{\partial t} &= 0 \\ \nabla \times \mathbf{H} - \mathbf{J} - \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} &= 0 \end{aligned} \quad (31)$$

$$m \frac{d\mathbf{V}}{dt} + m v \mathbf{V} + \mu_0 e \mathbf{V} \times \mathbf{H} + e \mathbf{E} = 0 \quad (32)$$

where $\mu_0 = 4\pi \times 10^{-7}$ H/m, ν is the collision frequency, m is the electronic mass, and e is the electronic charge. Reference 4 extends these equations to include ions, and Ref. 17 provides an extension for collision rate proportional to energy [27–29]. The lower boundary of the model electron plasma (Fig. 3), below which ($z < 0$) the ionization is nil ($N = 0$), is taken as the xy plane. The region above the xy plane ($z > 0$) is characterized by an electron number density N , which, along with the collision frequency, varies with altitude z . A plane-wave incident on the ionosphere is assumed to be

$$\mathbf{E}_i = |\mathbf{E}_i| \exp \left[i \left(\omega t - \frac{\omega}{c} \eta D \right) \right] \tag{33}$$

Below the ionosphere, $\eta = \eta_0 = 1$. Here

$$D = x \sin \phi_i \sin \phi_a + y \sin \phi_i \cos \phi_a + z \cos \phi_i$$

A wave transmitted into the ionosphere is assumed to have the form

$$\mathbf{E}_t = |\mathbf{E}_t| \exp \left[i \left(\omega t - \frac{\omega}{c} \eta D \right) \right] \tag{34}$$

Elimination of the vectors \mathbf{V} and \mathbf{H} results in a quartic equation

$$\eta D = x \sin \phi_i \sin \phi_a + y \sin \phi_i \cos \phi_a + z \xi \tag{35}$$

$$a_4 \xi^4 + a_3 \xi^3 + a_2 \xi^2 + a_1 \xi + a_0 = 0$$

The detailed explicit expressions for the coefficients of this quartic are given in Table 1 for an electron

magnetoplasma. The coefficients for an electron-ion magnetoplasma are given in Ref. 4. The quartic equation is readily solved numerically with various computer programs that exist in the literature, such as Refs. 11 and 22. The complex index of refraction of a particular layer in the model now can be found

$$\eta^2 = \zeta^2 + \sin^2 \phi_i \quad (36)$$

The significance of the four roots of the quartic equation is depicted in Fig. 4. There are two upgoing waves, called the ordinary and the extraordinary upgoing wave. There are two downgoing waves, the ordinary and the extraordinary downgoing wave. These four waves are coupled at each boundary in the model and hence are modified by the change in electron density on each side of the boundary.

The boundary of each stratum, or plasma slab, is introduced through the continuity of the tangential \mathbf{E} and \mathbf{H} field components in Maxwell's equations. This is accomplished by equating the fields immediately above and

$c_{23} = -c_{13} \exp\left(-i \frac{ga}{c} z_1 \zeta_{1o}^{(1)}\right)$	$d_{23} = -d_{13} \exp\left(-i \frac{ga}{c} z_1 \zeta_{1o}^{(1)}\right)$
$c_{24} = -c_{14} \exp\left(-i \frac{ga}{c} z_1 \zeta_{1e}^{(1)}\right)$	$d_{24} = -d_{14} \exp\left(-i \frac{ga}{c} z_1 \zeta_{1e}^{(1)}\right)$
$c_{25} = -c_{15} \exp\left(-i \frac{ga}{c} z_1 \zeta_{1ro}^{(1)}\right)$	$d_{25} = -d_{15} \exp\left(-i \frac{ga}{c} z_1 \zeta_{1ro}^{(1)}\right)$
$c_{26} = -c_{16} \exp\left(-i \frac{ga}{c} z_1 \zeta_{1re}^{(1)}\right)$	$d_{26} = -d_{16} \exp\left(-i \frac{ga}{c} z_1 \zeta_{1re}^{(1)}\right)$
$c_{27} = -(a_L P_{2o}^{(2)} - \zeta_{2o}^{(2)})$	$d_{27} = -(\zeta_{2o}^{(2)} Q_{2o}^{(2)} - a_T P_{2o}^{(2)})$
$c_{28} = -(a_L P_{2e}^{(2)} - \zeta_{2e}^{(2)})$	$d_{28} = -(\zeta_{2e}^{(2)} Q_{2e}^{(2)} - a_T P_{2e}^{(2)})$
$c_{29} = -(a_L P_{2ro}^{(2)} - \zeta_{2ro}^{(2)})$	$d_{29} = -(\zeta_{2ro}^{(2)} Q_{2ro}^{(2)} - a_T P_{2ro}^{(2)})$
$c_{210} = -(a_L P_{2re}^{(2)} - \zeta_{2re}^{(2)})$	$d_{210} = -(\zeta_{2re}^{(2)} Q_{2re}^{(2)} - a_T P_{2re}^{(2)})$
$c_{37} = -c_{27} \exp\left(-i \frac{ga}{c} z_2 \zeta_{2o}^{(2)}\right)$	$d_{37} = -d_{27} \exp\left(-i \frac{ga}{c} z_2 \zeta_{2o}^{(2)}\right)$
\vdots	\vdots
$c_{p(p+9)} = -(a_L P_{1e}^{(p)} - \zeta_{1e}^{(p)})$	$d_{p(p+9)} = -(\zeta_{1e}^{(p)} Q_{1e}^{(p)} - a_T P_{1e}^{(p)})$

immediately below each boundary, which results in the matrix equation in Table 2.

Using Fig. 3, the following transmission and reflection coefficients can be recovered by a numerical solution of the matrix equation in Table 2:

$$T_{ee} = \frac{E_{y'r}}{E_{y'i}}, \quad T_{em} = \frac{E_{x'r}}{E_{y'i}}$$

$$T_{me} = \frac{E_{y'r}}{E_{x'i}}, \quad T_{mm} = \frac{E_{x'r}}{E_{x'i}}$$

$$U(n)_{eio} = \frac{E_{yio}^{(n)}}{E_{y'i}}, \quad U(n)_{mio} = \frac{E_{yio}^{(n)}}{E_{x'i}}$$

$$U(n)_{eie} = \frac{E_{yie}^{(n)}}{E_{y'i}}, \quad U(n)_{mie} = \frac{E_{yie}^{(n)}}{E_{x'r}}$$

Table 5. Elements of Matrix Equation

$$\begin{aligned}
 a_{oe} &= \cos \phi_i \sin \phi_a & a_{om} &= \cos \phi_a \\
 b_{oe} &= \cos \phi_i \sin \phi_a & b_{om} &= -\sin \phi_a \\
 c_{oe} &= -\cos \phi_a & c_{om} &= \cos \phi_i \sin \phi_a \\
 d_{oe} &= \sin \phi_a & d_{om} &= \cos \phi_i \cos \phi_a \\
 A_1 &= -\left(a_L \zeta + \frac{h_T h_L}{s(s^2 - h^2)}\right) \left(1 - a_L^2 - \zeta^2 - \frac{s}{s^2 - h^2}\right) \\
 B_1 &= \left(a_L a_T - i \frac{h_L}{s^2 - h^2}\right) \left(a_T \zeta - i \frac{h_T}{s^2 - h^2}\right) \\
 C_1 &= -\left(1 - a_s^2 - \frac{s^2 - h_L^2}{s(s^2 - h^2)}\right) \left(a_L a_T - i \frac{h_L}{s^2 - h^2}\right) \\
 D_1 &= \left(a_T \zeta + i \frac{h_T}{s^2 - h^2}\right) \left(a_L \zeta + \frac{h_L h_T}{s(s^2 - h^2)}\right) \\
 E_1 &= \left(1 - a_s^2 - \frac{s^2 - h_L^2}{s(s^2 - h^2)}\right) \left(1 - a_L^2 - \zeta^2 - \frac{s}{s^2 - h^2}\right) \\
 F_1 &= -\left(a_T \zeta + i \frac{h_T}{s^2 - h^2}\right) \left(a_T \zeta - i \frac{h_T}{s^2 - h^2}\right) \\
 P &= \frac{A_1 + B_1}{E_1 + F_1} & Q &= \frac{C_1 + D_1}{E_1 + F_1}
 \end{aligned}$$

Here $\zeta = \zeta^{(n)}$, $P = P^{(n)}$, $Q = Q^{(n)}$ for a particular slab (Fig. 4), and $a_s = \sin \phi_i$; io, ie, ro, re refer to the four roots of Eq. (35).

Figure 5. Amplitude of the total E field as a function of distance along the surface of the earth, together with the individual wave hops, $j=0$ (the ground wave), 1, 2, 3, ..., illustrating propagation in the presence of an ionosphere with infinite conductivity. (From Ref. 11 by permission IEEE [2].)

using the ratios $Q = E_x/E_y$, and $P = E_z/E_y$, where (Fig. 2) $n = 1, 2, 3, \dots, p-1$. The elements of the matrix equation in Table 2 are defined in Tables 3, 4, and 5 for an electron magnetoplasma.

6. SKY WAVE DIFFRACTION

The angle of incidence of the sky wave on the earth [Eq. (26)] is in general complex:

$$\tau_j = \frac{v}{k_{-1} a}$$

This is implied in the full-wave solutions given by Eqs. (16), (17), and (26). LF sky wave diffraction theory has been treated in Refs. 25, 30, and 31. However, it can now be demonstrated that the full-wave solution discussed herein implies sky wave diffraction into the earth's shadow region. The hypothetical ionosphere reflection was set equal to that of a perfect reflector [Eq. (2)], and Eqs. (16)

Figure 6. Amplitude of the total E field as a function of distance along the surface of the earth, together with the individual wave hops, $j=0$ (the ground wave), 1, 2, 3, ..., illustrating propagation in the presence of a sharply bounded semiinfinite plasma slab placed at the height $h=65$ km for a signal at 26.1 kHz and an assumed ratio of electron number density to collision frequency equal to 9.375 [1]. (From Ref. 1, by permission of AGU.)

and (17) were used to generate the wave hop series shown in Fig. 5. Each wave hop in Fig. 5— $j=0$ (the ground wave) and $j=1, 2, 3, \dots$ —will ultimately go beyond the geometric-optical horizon, and the attenuation finally takes on a slope as a function of distance like the ground wave. The conductivity of the ground is assumed to be 0.005 S/m with a dielectric constant of 15 relative to space. The frequency is 26 kHz, and the ionosphere height $h=65$ km.

A more sophisticated model of the ionosphere is shown in Fig. 6. Here a single sharply bounded electron plasma slab is placed at 65 km and extends uniformly out to infinity with a constant ratio of electron density to collision frequency of 9.375 [1]. The frequency is again 26 kHz. The influence of a finitely conducting ionosphere is here introduced into the model. Again, each sky wave at great distance attenuates with a slope parallel to that of the ground wave on this linear distance–decibel (logarithmic) amplitude scale. A rather interesting set of standing waves as a function of distance appears at shorter distances on the higher order wave hops. The total field, which sums the wave hops together with the ground wave, does not give any evidence of the existence of these waves.

It is concluded from Fig. 6 that the inclusion of a finitely conducting ionosphere is an important improvement in the modeling technique. At this juncture, one could still go further with the full-wave solution and use concentric spherical shells that follow known electron-density–collision-frequency profiles such as given in Ref. 1. However, this would not take into account the effects of the earth's magnetic field on the propagation. By following the procedures dictated by Eq. (20) or by using the asymptotic methods used with Eq. (28), the effects of a more realistic model can be generated as shown in Fig. 7.

Figure 7. Sample wave hop calculation using the full magneto-ionic theory for the model given in Table 2, for a propagation path over sea water with magnetic parameters and ionosphere electron density profiles given in Ref. 11.

The electron density profile for the ionosphere is given in Ref. 11.

It is interesting to note that the standing waves on the individual wave hops are more highly damped as a function of distance. This is quite reasonable, because the ionosphere lower boundary is more diffuse (gradual) in this model. It therefore seems quite justified to use this more sophisticated model.

SKY WAVE PROPAGATION AT MEDIUM AND HIGH FREQUENCIES

KENNETH DAVIES
National Oceanic and
Atmospheric Administration

1. SPECTRUM CONSIDERATIONS

Medium frequencies and high frequencies are usually defined as the frequency bands from 300 kHz to 3000 kHz and from 3 MHz to 30 MHz, respectively. However, as far as ionospheric propagation is concerned, there are no sharp divisions. The medium-frequency band is dominated by the amplitude modulated (AM) broadcasting band between about 500 kHz and 1700 kHz, which is designed primarily for ground-wave usage. On the other hand, high-frequency systems are designed for long-distance sky wave propagation and for some 50 years (from about 1925 to about 1975) provided the primary vehicle for global communications. High frequencies are still used extensively for communications because of the following advantages: (1) low cost of terminal equipment, (2) low power requirements, and (3) adequate bandwidths. By contrast, medium frequencies suffer heavy ionospheric absorption during daytime and, therefore, there is relatively little cochannel interference; whereas by night, when the absorption is small, interference between closely spaced channels is common. High-frequency sky waves suffer from several disadvantages brought about by (1) the temporal and geographical variability of the ionosphere, (2) the large number of possible propagation paths and the consequent time dispersion of the resulting signal, (3) large and rapid amplitude and phase fluctuations, (4) high interference because of spectrum congestion, and (5) frequency distortion of wideband signals. An important disadvantage is the occurrence of several types of ionospheric disruptions caused by solar disturbances. These disruptions can be hemispheric, such as those on the dayside caused by bursts of solar X rays (sudden ionospheric disturbances) or confined mostly to high latitudes (e.g., polar cap disturbances and ionospheric storms that originate in the auroral zones and spread to populated middle latitudes). Ionospheric storms are major concerns for high-frequency (HF) users. They occur mostly at high sunspot numbers when the higher critical frequencies help to mitigate their adverse effects.

In this article, we shall discuss the following topics:

1. Basic physical properties of sky wave propagation (namely, refraction, reflection, penetration, and absorption)
2. relationships between vertical propagation and oblique propagation
3. ionospheric models
4. characteristics of medium frequencies
5. characteristics of high frequencies

SKY WAVE PROPAGATION AT MEDIUM AND HIGH FREQUENCIES

KENNETH DAVIES
National Oceanic and
Atmospheric Administration

1. SPECTRUM CONSIDERATIONS

Medium frequencies and high frequencies are usually defined as the frequency bands from 300 kHz to 3000 kHz and from 3 MHz to 30 MHz, respectively. However, as far as ionospheric propagation is concerned, there are no sharp divisions. The medium-frequency band is dominated by the amplitude modulated (AM) broadcasting band between about 500 kHz and 1700 kHz, which is designed primarily for ground-wave usage. On the other hand, high-frequency systems are designed for long-distance sky wave propagation and for some 50 years (from about 1925 to about 1975) provided the primary vehicle for global communications. High frequencies are still used extensively for communications because of the following advantages: (1) low cost of terminal equipment, (2) low power requirements, and (3) adequate bandwidths. By contrast, medium frequencies suffer heavy ionospheric absorption during daytime and, therefore, there is relatively little cochannel interference; whereas by night, when the absorption is small, interference between closely spaced channels is common. High-frequency sky waves suffer from several disadvantages brought about by (1) the temporal and geographical variability of the ionosphere, (2) the large number of possible propagation paths and the consequent time dispersion of the resulting signal, (3) large and rapid amplitude and phase fluctuations, (4) high interference because of spectrum congestion, and (5) frequency distortion of wideband signals. An important disadvantage is the occurrence of several types of ionospheric disruptions caused by solar disturbances. These disruptions can be hemispheric, such as those on the dayside caused by bursts of solar X rays (sudden ionospheric disturbances) or confined mostly to high latitudes (e.g., polar cap disturbances and ionospheric storms that originate in the auroral zones and spread to populated middle latitudes). Ionospheric storms are major concerns for high-frequency (HF) users. They occur mostly at high sunspot numbers when the higher critical frequencies help to mitigate their adverse effects.

In this article, we shall discuss the following topics:

1. Basic physical properties of sky wave propagation (namely, refraction, reflection, penetration, and absorption)
2. relationships between vertical propagation and oblique propagation
3. ionospheric models
4. characteristics of medium frequencies
5. characteristics of high frequencies

- 6. prediction programs for ionospheric sky wave performance
- 7. real-time channel evaluation

There is extensive literature in the field of ionospheric radio propagation, and the interested reader is referred to books by Davies [1], Goodman [2], Hunsucker [3], and McNamara [4] and the bibliographies therein. Groundwaves are particularly important on medium frequencies (see RADIOWAVE PROPAGATION CONCEPTS).

2. PROPAGATION CHARACTERISTICS

2.1. The Ionosphere

Sky waves result from radio refraction and reflection from the ionosphere. The ionosphere is usually defined as that part of the upper atmosphere where sufficient ionization exists to affect the propagation of radiowaves. The ionosphere lies between about 50 km and about 2000 km. The peak electron density usually occurs in the F region (above 140 km) (Fig. 1). The F region often contains two layers: the lower F1 layer and the upper F2 layer. Below the F region is the E region (90 km to 140 km), which contains the normal E layer and sporadic E. The D region (50 km to 90 km) contains the D layer and the C, or cosmic ray, layer. Above the F peak is the topside, and above about 2000 km is the protonosphere. The boundaries between these regions are not well defined. The alphabetic nomenclature was introduced by Appleton (see Ref. 1, Sec. 1.1), who used the letter E for electric and F for field. These letters left room for the discovery of other layers. Ionospheric electron densities vary by orders of magnitude depending on altitude, time of day, season, sunspot number, solar distur-

Figure 1. Ionospheric structure on a summer day and night in middle latitudes, and the main bands of solar and cosmic-ray ionizing radiations.

bances, and geographical location. It is this variability that renders sky waves so difficult to manage.

2.2. Refraction, Reflection, and Penetration

In an ionized plasma, with electron density $N \text{ el} \cdot \text{m}^{-2}$, in the absence of collisions and an external magnetic field, the radio refractive index μ of a wave of frequency f Hz, is given by

$$\mu^2 = 1 - (f_N/f)^2 = 1 - 80.5N/f^2 \tag{1}$$

where f_N is the plasma frequency in Hz. Ionospheric electron densities are such that typical E layer and F layer plasma frequencies lie in the range from 0.5 MHz to 30 MHz. Thus, for medium and high frequencies, the refractive index of the ionosphere is less than unity and application of Snell's law shows that, on entry into the ionosphere, a wave is refracted away from the vertical. When the electron density is sufficient, the direction of propagation becomes horizontal and reflection occurs. The main sky wave propagation mechanisms are illustrated in Fig. 2: absorption, reflection, scatter, and penetration. When the maximum electron density is insufficient, the wave penetrates; this is essential for ground-to-satellite communication. As ionospheric scatter propagation is considered elsewhere, it will not be discussed in detail in this article.

2.3. Absorption

The neutral atmosphere affects the propagation of radiowaves because of electron-neutral collisions that convert

Figure 2. The four main mechanisms in MF and HF sky wave propagation: absorption, reflection, scatter, and penetration.

the ordered momentum of the wave into heat and electromagnetic noise. To a first approximation, the loss L , in decibels per kilometer, is

$$L = 0.00117N\nu/\mu f^2 \quad (2)$$

where ν is the number of collisions made by one electron per second. From Eq. (2), we see that with $\mu \approx 1$, the non-deviative absorption is inversely proportional to the frequency squared so that, in general, signals are stronger on high frequencies than on medium frequencies. The product $N\nu$ maximizes in the D region. The loss L can be large where $\mu \approx 0$; this deviative absorption occurs near reflection, or where there is pronounced refraction of the wave.

2.4. Effects of the Earth's Magnetic Field

The earth's magnetic field affects sky waves by splitting the incident wave into ordinary and extraordinary waves that are oppositely polarized and by affecting the global structure of the ionosphere (see ELECTROMAGNETIC WAVES IN THE IONOSPHERE). The ordinary (o) wave is polarized such that, with the thumb pointing in the direction of the earth's magnetic field, the electric field rotates in a left-handed sense, whereas the extraordinary (x) wave rotates in a right-handed sense. For example, an incident, vertically polarized wave on exit from the ionosphere will be elliptically polarized, which depends on the relative amplitudes and polarizations of the emerging o and x waves. The relative amplitudes of the o and x waves are determined by the extent to which the incident power is divided between the two component waves and the relative absorptions of the two waves thereafter. The relative absorptions are

$$L(o, x) = A/(f \pm f_H)^2 \quad (3)$$

where the $+$ sign refers to the ordinary wave and the $-$ sign to the extraordinary wave, and A is essentially the same for both waves. The electron gyrofrequency f_H is the natural frequency of rotation of an electron (right-handed) about the magnetic field. In the ionosphere, f_H varies from about 0.8 MHz at the magnetic equator to about 1.6 MHz near the magnetic poles. Current models of the geomagnetic field are available on the Internet (e.g., see Ref. 5). Equation (3) shows that the absorption of the ordinary wave is less than that of the extraordinary wave, so that an antenna should be designed to excite as much of the ordinary wave as possible (see Ref. 1, Sec. 7.6).

The global effects of the geomagnetic field are two-fold. Near the magnetic equator there is an F2-layer anomaly in which the peak electron densities maximize in the late afternoon at magnetic latitudes near $\pm 15^\circ$. Magnetic latitude Φ is defined in terms of the dip angle I by which the earth's magnetic field dips below the horizontal.

$$\tan \Phi = 0.5 \tan I \quad (4)$$

Another way in which the earth's field affects the ionosphere is via the precipitation of magnetospheric charged particles into the polar caps and the auroral zones (65° to

70° magnetic latitude), where energy is deposited that produces ionospheric storms. In the auroral zones, D-region electron densities are enhanced producing auroral absorption. Energetic solar protons enter the atmosphere over the polar caps (latitudes $> 70^\circ$) and produce intense polar cap absorption (PCA) that can black out HF signals for several days.

3. VERTICAL AND OBLIQUE PROPAGATION

3.1. Equivalence of Vertical and Oblique Reflection

Equation (1) shows that, with a radiowave incident at an angle ϕ with the vertical on a plane ionosphere, reflection occurs when

$$f_N = f \cos \phi \quad (5)$$

With vertical propagation, $\phi = 0^\circ$, so $f = f_N$ and, therefore, for a given maximum electron density (i.e., maximum f_N) a maximum, or critical, frequency is reflected. With oblique propagation, the maximum frequency depends jointly on the critical frequency and on the incident angle, which is determined by the ground range and the layer height. The subject of vertical-to-oblique conversion has been discussed extensively by numerous authors (e.g., Ref. 1, Chapter 6; Ref. 2, Chapter 4; Ref. 4, Chapter 4). With a flat earth and flat ionosphere, the relationship between a frequency f_o incident obliquely at an angle ϕ and a frequency f_v reflected vertically from the same true height is

$$f_o = f_v \sec \phi = f_v [1 + (D/2h')^2]^{1/2} \quad (6)$$

where D is the ground range and h' is the virtual height of reflection. The variation of virtual height with frequency is called an ionogram, and the relationship between $\sec \phi$ and h' , when presented graphically, is called a transmission curve. The intersection of a transmission curve with the ionogram trace gives the virtual heights of reflection of the obliquely traveling signal. When the transmission curve is tangent to the ionogram, we have the maximum reflected frequency. On frequencies below the maximum frequency, there are two intersections of the transmission curve and the ionogram trace (for a single layer) showing that, for a given ground range, there is a low-angle ray and a high-angle ray. Modifications to the plane ionosphere geometry are required for ground ranges over about 200 km and for the extraordinary ray that determines the maximum frequency, but the principles are essentially the same (the reader is referred to the aforementioned texts and references therein).

3.2. Parabolic Layer Theory

Transmission curves were used extensively for the determination of maximum usable frequencies (MUF) for a number of years (approximately 1940 to 1980). With the advent of inexpensive and fast computers, an alternative method has come to the fore. Essentially, the method consists of using ionogram data to approximate the electron-density profile by an analytic function such as a parabola,

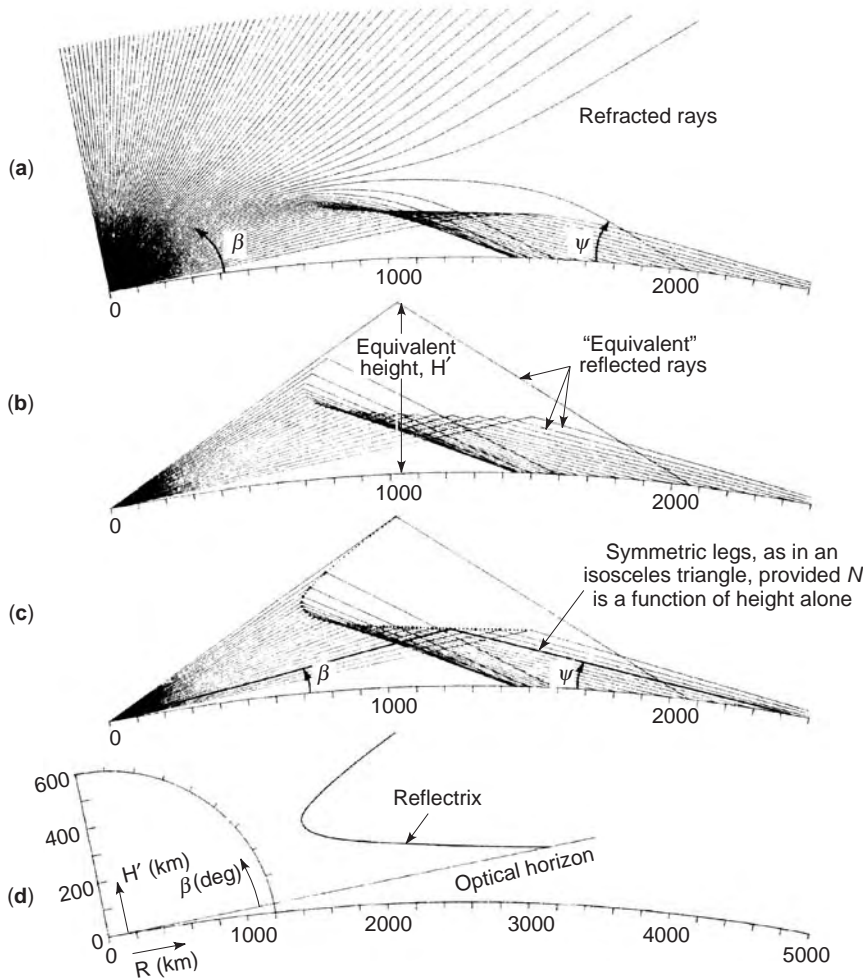

Figure 3. (a) Real rays in a concentric earth and Chapman ionosphere, $f = 8$ MHz, $f_c = 4$ MHz, $h_{\max} = 300$ km, semi-thickness = 200 km. (b) Equivalent or virtual paths reflected at the apexes of the fictitious triangular paths. (c) The reflectrix as the locus of the virtual reflection heights. (d) The reflectrix as a function of virtual height, range, and elevation angle. (Adapted from Croft [9] by permission of the American Geophysical Union.)

or a quasiparabola, and calculating the maximum frequency. A parabolic profile is defined by its critical frequency f_c , the semithickness y_m , and the height of the peak h_m . More complicated ionospheres can be approximated by two (or more) parabolas or by two parabolas joined by linear segments. The International Reference Ionosphere [6] also uses a segmented profile. The ground range in each segment is calculated analytically.

3.3. Ray Tracing

With realistic profiles obtained by ionogram inversion, which have horizontal and vertical structures and cannot be represented by simple analytical formulas, there is recourse to ray tracing. This involves starting with a ray from a specified transmitting site and with specified angles of elevation and azimuth, and plotting the flow of energy step by step until it returns to earth or escapes into space. This is a complicated procedure and is feasible only with adequate computers. A comprehensive three-dimensional ray tracing program has been constructed by Jones and Stephenson [7] and is available on the Internet [8]. In Fig. 3a, we see what happens to the ray paths (on a given frequency) as the angle of elevation slowly increases. For

low angles, the ground range is long. As the elevation increases, the ground range decreases until the skip is reached, after which the range increases rapidly. Eventually penetration occurs. Figure 3b shows the equivalent triangular paths for different angles of elevation. The apexes of the equivalent triangles lie on a smooth curve, called a reflectrix, as shown in Fig. 3c. The ray with its apex at the “nose” of the reflectrix is the skip ray and its frequency is the MUF. Rays reflected at lower virtual heights are low-angle rays, and rays reflected on the upper side of the reflectrix are high-angle rays. For a given reflectrix, the relationship between virtual height and angle of elevation (β) is given by Fig. 3d [9].

3.4. Maximum Frequencies

When the ground range, D , is plotted against the angle ϕ we find that, for $f > f_c$, there is a minimum range, D_s , called the skip distance, within which no power is received via the normal reflection process. However, signal power in the skip zone may result from ground waves, ground scatter, and scatter from ionospheric irregularities. At the edge of the skip zone, the signal frequency corresponds to the maximum usable frequency for the skip distance,

MUF(D_s). The MUF for a distance D is related to the critical frequency by

$$\text{MUF}(D) = f_c M(D) \quad (7)$$

where $M(D)$ is called the MUF factor corresponding to the distance D . The $M(3000)F_2$ is used extensively both as a reference and as a measure of the height of the F2 layer.

4. IONOSPHERIC MODELS

Ionospheric models are of two types: (1) empirical models based on data and (2) physical models based on production, loss, and movement of plasma by winds and/or electric fields. For long-term sky wave predictions, it is customary to use monthly median models of the main ionospheric characteristics, such as critical frequencies (f_oE_{hmE} , fE_{sh_mF2} , f_oF1 , f_oF2) and layer heights (h_mE , h_mF2) or equivalent M factors. The diurnal, seasonal, and sunspot number dependencies of the regular E and F1 layers are well behaved and are represented by analytical expressions (e.g., see Ref. 1, Chapter 5). However, the most important (F2) layer varies irregularly, and its characteristics are expressed in the form of numerical maps of median values. The day-to-day variability is expressed in terms of upper-decile and lower-decile values. D-region absorption, although highly variable in space and time, is represented by an analytical expression (see Ref. 1, Eq. 12.12). Electron-density profiles can be represented numerically or, for ray tracing, more conveniently by integrable segments. Several such approximations are discussed in Davies (Ref. 1, Sec. 5.3.2, 5.3.4, and 5.3.5). Of particular interest is the International Reference Ionosphere (IRI), which produces electron-density profiles, ion- and electron-temperature profiles, layer heights, and so on and is available from World Data Centers on the Internet [5,8]. Some models, such as PRISM [10], can be updated using current ionospheric data, such as total electron contents (see Ref. 1, Chapter 8) and/or critical frequencies.

5. PROPAGATION ON MEDIUM FREQUENCIES

5.1. Importance of Medium Frequencies

The medium-frequency (MF) band is dominated by the AM broadcast band (≈ 500 kHz to 1700 kHz), which during daytime depends on ground-wave propagation. This frequency band has a major economic, social, and political impact on everyday life and is intensively used. Knowledge of sky wave properties in the MF band is restricted because of (1) the congested spectrum, (2) high ionospheric absorption, (3) the role of the earth's magnetic field, (4) difficulty in separating deviative ($\mu \approx 0$) from nondeviative ($\mu \approx 1$) effects, (5) effects of collisions, and (6) the medium not always slowly varying on the lower frequency end, so that ray theory may be inapplicable. For efficient use of the MF band it is essential for several users to operate on the same, or adjacent, channels with minimum interference. Thus determination of the signal strength in distant

regions is important in channel sharing [11]. Atmospheric radio noise on the MF band has been modeled by Herman and DeAngelis [12]. It is difficult to collect sky wave data during the daytime because the signals are weak and/or over short distances the ground wave may mask the sky wave. For estimating sky wave field strengths, the Radio Communications Sector of the International Telecommunications Union (ITU) has recommended the Wang [11] method for North America and the CCIR (Consultative Committee on International Radio) [13] Recommendation 435-8 elsewhere. These two methods are in reasonable agreement throughout Europe.

5.2. Temporal Variations

5.2.1. Diurnal Variations. As the MF band is dominated by the broadcast band, relatively little is known about the sky wave signal structure. Yet this band has the heaviest usage. During daylight, high D-region absorption suppresses sky wave signals to an extent sufficient for interference-free broadcasting in most areas. However, in areas remote from an MF transmitter, weak sky waves may suffice to produce unwanted interference. Shortly after sunset, when the electron content of the D region essentially disappears, sky wave strengths increase and AM stations can be received at distances of several thousand kilometers. During daytime, MF waves are reflected from the E layer, but during nighttime, sky waves may be received from both E and F layers, especially on the upper end of the MF band.

5.2.2. Seasonal Variations. Measurements in Europe (see Ref. 14, Report 431-4) show equinoctial maxima of signal strength and minima in summer and winter, the summer minimum being the more pronounced. The overall seasonal variation may be as much as 15 dB at the lower end of the MF band, decreasing to about 3 dB at the upper end of the band. Over the western hemisphere there is little seasonal variation, and over the United States there is a slight minimum in summer. The sensitivity to length of day and to magnetic disturbance of broadcast signals received in Canada is illustrated in Fig. 4. This figure shows the frequency-integrated power in the AM broadcast band (550 kHz to 1600 kHz) received in Arviat, Northwest Territories during a six-month interval, September 1994 through April 1995. Local time is on the vertical axis, with local midnight (0600 UT) near midscale. The figure shows the normal diurnal pattern of MF sky wave reception in that signals are strong at night (middle of the figure) and weak during the day (top and bottom of the figure). The span of reception extends from near sunset (≈ 00 UT) to near sunrise (≈ 12 UT), corresponding to the seasonal variations of the terminator. The reception is longest near midwinter. In summer, reception is short lived. There is an asymmetry between the dawn and dusk terminators: The dawn terminator produces a sharper transition between nighttime conditions and daytime conditions than is the case near dusk. This phenomenon results from the prompt production of the D layer at sunrise versus the relatively slow decay of the D layer after sunset.

Figure 4. Integrated power in the frequency range 550 kHz to 1600 kHz received in Arviat, Northwest Territories, Canada from September 1994 through April 1995. Local meridian (270°E) time is on the vertical axis. The reception is best near the winter solstice. (Courtesy of J. La-Belle.)

The lower panel in Fig. 4 shows the daily magnetic index from September 1994 to April 1995 and illustrates the dependence on geomagnetic activity of the high-latitude reception of distant AM broadcast band transmissions. Several-day intervals with high magnetic disturbance correlate one-to-one with intervals when the integrated power in the AM broadcast band at night is nearly the same as it is during the day. The latter intervals appear as light vertical bands in the top panel of Fig. 4. On shorter timescales, prompt absorption of distant AM transmissions is a sensitive indicator of auroral disturbance [15]. Another indication of the seasonal variation is the average daily number of hours of MF reception at Fairbanks, Alaska of signals from five stations in the United States and Canada: Hunsucker and DeLana [16] found these hours to be 13.3 h in winter and spring, 4.0 in summer, and 11.0 in autumn. Daytime field strengths, though weak, are higher in winter than in summer. The winter-to-summer ratio is typically 10 dB to 20 dB. For planning purposes, “annual median” field strengths are used (Ref. 11, Sec. 4.1). Measurements indicate that the annual median value at noon is some 42.5 dB lower than at 6 hours after sunset, which is the reference time used by Europeans.

5.2.3. Sunspot Dependence. In Europe, Ebert [17] found that the 11-month smoothed midnight signal,

$F(11)$, and the corresponding smoothed sunspot number, $R(11)$, are related by

$$F(11) \approx 60 - 0.02R(11) \text{ dB} \quad (8)$$

The sensitivity to sunspot number depends on the hour of observation. In Europe, the reference hour is normally 6 h after sunset, whereas in North America it is customary to use sunset + 2 h, at which the difference between field strengths at sunspot maximum and sunspot minimum during 1944 through 1947 was 14 dB compared with only 8 dB at sunset + 6 h.

5.3. Dependence on Wave Frequency

Some measurements indicate that the signal strength increases with wave frequency, whereas others suggest a decrease of signal strength with increase of frequency. Both these conclusions have some basis because, at night, an appreciable fraction of the ionospheric absorption may occur near the reflection level (i.e., deviative absorption, which may increase with increasing frequency; see Ref. 1, Sec. 11.5.3, which gives several formulas for the frequency dependence of MF field strengths). For many practical purposes, it is sufficient to take the field strength on 1000 kHz as representative of the entire band.

5.4. Dependence on the Geomagnetic Field

The CCIR [13] basic loss factor is

$$K = 3.2 + 0.19f^{0.4} \tan^2(\Phi + 3) \quad (9)$$

where the frequency, f , is in kHz and Φ is the magnetic latitude at the center of the path for $\Phi \leq 60^\circ$ and $\Phi = 60^\circ$ for magnetic latitudes greater than 60° . Thus reception is poor near the auroral zones. This is illustrated in Fig. 4, which shows gaps in the reception of signals on days with high magnetic indexes. This is the result of increased auroral absorption on the path because of increased D-region electron content and equatorial motion of the auroral zone. MF signals are sensitive to auroral absorption and, above a certain threshold of disturbance, are blacked out.

For east–west and west–east propagation in low magnetic latitudes (e.g., in Africa), polarization coupling loss is important. This develops because the electric field, from a vertical antenna, is perpendicular to the (horizontal) magnetic field and excites only an extraordinary wave, which suffers high D-region absorption [see Eq. (3), with $f \approx f_H$].

5.5. Predicting Field Strengths

Methods for predicting MF sky wave field strengths are given in CCIR [see Ref. 13, pp. 311–390; PoKempner [18], and Davies [1], Sec. 11.7]. The CCIR method takes into account antenna gain, propagation loss, polarization coupling, and, where appropriate, sea gain.

5.6. Fading on MF

Nearly all sky waves fluctuate, or fade, with time as a result of interference between component echoes, absorption changes, polarization changes, and so on. To determine a station's sky wave service area and its interference potential, it is important to know the percentage of time that a given field strength is exceeded. For example, fields exceeded for 1% and 10% of the time are about 13 dB and 8 dB, respectively, higher than the median. In high geomagnetic latitudes, the corresponding differences are 15 dB and 10 dB [19].

6. PROPAGATION ON HIGH FREQUENCIES

6.1. The Available Spectrum

The HF sky wave spectrum is bounded on the upper end by the MUF, which is essentially determined by the maximum electron density in the reflecting layer, and on the lower end by the lowest usable frequency (LUF), which is determined by D-region absorption and/or by E-layer cut-off. As a result of day-to-day fluctuations ($\approx 15\%$ about the monthly median) of the F2 critical frequencies, operation on the MUF would provide reception for 50% of the time at a particular hour. To ensure communications 90% of the time, it is customary to operate at, or below, the optimum working frequency (or FOT from the French initials), which is defined empirically as 0.85 of the monthly median MUF. As the MUF can be defined in several ways, the CCIR (Ref. 14, Recommendation 373-5) has adopted the

following: (1) Basic MUF is the highest frequency by which a radiowave can propagate between given terminals, on a specified occasion, by ionospheric refraction alone; and (2) operational MUF, or simply MUF, is the highest frequency that would permit acceptable operation of a radio service between given radio terminals at a given time under specified working conditions (such as antennas, transmitter power, class of emission, information rate, and required signal-to-noise ratio).

The operational MUF refers to propagation in the actual ionosphere and includes effects of scattering, partial reflection, and so on, whereas the basic MUF essentially depends only on ionospheric refraction. Hence, in general, the operational MUF is equal to or greater than the basic MUF.

6.2. Path Structure

The layered structure of the ionosphere can produce complicated oblique echoes. A composite echo may consist of the following: high- and low-angle rays from the E (including E_s), F1, and F2 layers (See CHARACTERISTICS OF THE IONOSPHERE for a discussion of ionospheric structure and variability); one-hop, two-hop, and so on echoes; and scatter from the ground and from ionospheric irregularities. Figure 5 shows a sample oblique ionogram taken, during magnetically quiet conditions, over a geographically east–west path. The traces are sharp and the maximum, or junction (J), frequency of the one-hop F₂ trace is well defined. The high-angle, or Pedersen, trace can be seen for the one-hop trace. Splitting of the high (H)-angle, two-hop trace into ordinary and extraordinary traces can be seen. The time spread sets a limit to the rate of transmission of information because overlapping echoes can result in errors. Roughly speaking, the maximum rate of transmission (in binary units per second) is equal to the reciprocal of the time spread, which is a function of signal frequency, path length, geographical location, season, sunspot number, and so on. Ionospheric structures, both vertical and horizontal, produce echoes with various angles of elevation and azimuth. The interested reader should consult Ref. 4, Chapters 12–15, for a detailed discussion of direction finding.

6.3. Fading on HF

When the ionosphere changes with time and/or space with moving terminal(s), the relative phases of the component echoes change and the resultant signal fluctuates or fades. Fading may result from interference between (1) echoes reflected from different parts of the ionosphere; (2) ordinary and extraordinary waves, called polarization fading; (3) reflection or penetration, called MUF fading or skip fading; (4) absorption fading; and (5) focusing. The fading rate depends largely on the type of fading and may range from 100/s (flutter fading) to once per day (MUF fading). The speed of interference fading is related to the width of the fading power spectrum. The autocorrelation falls to 0.37 after a time, t , called the fading time, given by

$$t = \lambda/4\pi v \quad (10)$$

Figure 5. Oblique ionogram for the 2370 km, geographic approximately west–east path from Boulder, Colorado, to Sterling, Virginia, September 1, 1954, 2112 (90° West Meridian Time). Here the junction frequency (FJF) or basic MUF is the same as the maximum observed frequency (FMOF). LOF is the lowest observed frequency.

where λ is the signal wavelength and v is a measure of the velocity of the reflecting sources.

For practical purposes, it is customary to make fading allowances to ensure that the field strength is exceeded a certain percentage (e.g., 90%) of the time. Circuit planning requires comparison of the strengths of the wanted signal relative to (1) natural and synthetic noise, and (2) cochannel and adjacent channel interference (called electromagnetic compatibility). Hence, in addition to monthly medians, fading allowances are necessary that depend on short-term (<1 h) and long-term (day-to-day) fading of the wanted signal and the background interference. Some proposed fading allowances are discussed in ITU [20], Recommendations 339 and 411.

In high magnetic latitudes, rapid ionospheric motions ($\approx 1 \text{ km} \cdot \text{s}^{-1}$) result in Doppler frequency shifts and, hence, frequency spreading on great-circle paths of 0.1 Hz to 0.5 Hz. On nongreat-circle paths, spreading of 5 Hz to 10 Hz is typical. Some typical time-delay spreads are 100 ms to 200 ms. Sky wave fading models are available (e.g., see [21]). Further, in high latitudes, vertical antennas, which generate vertical electric fields, are preferred to horizontal antennas because they excite ordinary waves, which suffer less absorption than extraordinary waves.

6.4. HF Propagation Programs

As the ionosphere varies in space and time (local time, season, sunspot numbers, etc.), so does the usable frequency spectrum and, also, the characteristics of the received signals (e.g., signal strength, fading). Hence, knowledge of the variability of the ionosphere has been invaluable in the design and operation of point-to-point and broadcasting HF systems. For continuous operation of a given point-to-point circuit, a set of frequencies is required to avoid MUF failure (e.g., at night) and excessive ionospheric absorption by day. For long-term planning, the f_oF2 is the most important single parameter in controlling the MUF, and it is highly variable. In spite of the increase in the number of solar disturbances, HF sky wave propagation is better near sunspot maximum than near sunspot minimum because of the broader available frequency band.

When the f_oF2 and the layer height [or $M(3000)F2$] are known, from vertical soundings, the basic MUF can be calculated by graphical methods or by parabolic theory. The behaviors of the E and F1 layers are regular and are expressed by analytic formulas (see Ref. 1, Sec. 5.2) and are such that the smaller $F1M$ factor essentially compensates for the higher f_oF1 so that the products, the MUFs, for both layers are nearly equal. During daytime, the E layer is usually the controlling layer for distances up to about 2000 km and the F1 layer for distances between 2000 km and 3000 km. Over distances of 4000 km and longer, the F2 is normally the controlling layer. Single-hop propagation is limited to paths shorter than about 4000 km. Empirically, it has been found that as the distance increases beyond the “limit,” sky wave propagation is maintained by such mechanisms as ionospheric and ground scatter, high-angle rays that have longer one-hop limits, and ionospheric tilts that produce “super-modes” such as those that occur on transequatorial circuits. Propagation fails only when the ionosphere fails to support propagation at one of two “control points” on the great-circle path at 2000 km from each end (see Ref. 1, Sec. 12.2). The path MUF is the lower of the two MUFs for 4000 km with the ionospheric parameters at the control points. In the cases of the E, Es, and F1 layers for paths longer 2000 km, control points 1000 km from each end are used and the MUFs for a range of 2000 km are calculated (the lower of the two MUFs is taken as the circuit MUF). Global numerical maps of f_oF2 are available at reference high- and low-sunspot numbers (or equivalent indexes), and the values for other sunspot numbers are obtained by interpolation or extrapolation. There is a saturation of f_oF2 at sunspot numbers ≥ 150 so that for sunspot numbers greater than 150, the value is set at 150. The monthly median f_oF2 correlates better with the 12-month smoothed sunspot number than with the individual monthly number. For prediction purposes, the zero distance MUF ($=f_oF2 + 0.5f_H$) together with the MUF at a reference distance (e.g., 3000 km or 4000 km) and, for paths with other lengths, the MUFs are found by interpolation. The $M(3000)$ is related to the virtual height, in km, by

$$M(3000) = (67.6542 - 0.014938h') / \sqrt{h'} \quad (11)$$

The optimum working frequency (FOT) is 0.85 (monthly median MUF), and it ensures sky wave propagation 90% of the days of the month at a particular hour (usually local or universal time). Operating on the monthly median MUF results in sky wave reliability of 50%. The highest probable frequency, or HPF, is exceeded 10% of the time. The higher the signal frequency the greater is the signal strength, but this has to be balanced against the spectrum congestion caused by many operators using similar circuits. An advantage of using a frequency close to the MUF is that the time dispersion is a minimum.

In planning a circuit, it is necessary to determine (1) the maximum MUF for the various layers and, hence, the FOT; (2) the radiation angle for the appropriate layer; (3) the power delivered to a receiver (using spatial spreading, ionospheric absorption, fading and polarization losses, antenna gains); and (4) the noise and interference (see RADIO NOISE).

Before about 1970, individual circuit evaluations were necessary using laborious methods, and graphical techniques were customary for the determination of sky wave propagation parameters such as those discussed previously. Today, these laborious methods are replaced by convenient user-friendly computer programs, many written for personal computers, that only require basic circuit information, such as time of day, month, sunspot number (or equivalent), and path terminals (or area coverage for broadcasting). The computer programs normally include

numerical maps, or formulas, for calculating the necessary ionospheric characteristics and noise and interference; the more comprehensive models include reference antennas for calculation of received signal-to-noise ratios. The sophistication of these PC programs ranges from basic frequency outputs to broad coverage. A list of some commercially available programs is given in Goodman (Ref. 2, Table 5.16; see also Ref. 22, Resolution ITU-R25). An example of a prediction program is the Ionospheric Communications Enhanced Profile Analysis and Circuit (ICEPAC), which includes, in addition to a global ionospheric model, models of the subauroral trough, auroral zones, and polar caps. This software is available (free) on the Internet [23]. A sample output from ICEPAC is shown in Fig. 6, which includes contours of signal strength around a broadcasting transmitter that has an isotropic antenna.

Besides the basic sky wave characteristics, such as MUF, FOT, and LUF, the more comprehensive of these computer programs give signal-to-noise ratio for a given circuit performance (see RADIO NOISE) and the following characteristics that depend on the ionosphere (see Ref. 2, Sec. 5.11, and references therein). Mode availability, Q ($0 < Q < 1$), is the fraction of time that a path is available (see Ref. 1, Sec. 12.6.2). To a first approximation, the standard deviation of f_oF_2 about the monthly average is about 15%. On the median MUF, $Q = 0.5$; on the FOT, $Q = 0.9$; and on the HPF, $Q = 0.1$.

Figure 6. Contours of signal strength on the ground around a transmitter at Tangier at 1800 UT in June with sunspot number of 100. Transmitter power is 100 kW; signal strength is decibels above $1 \mu\text{V}$ per meter with an isotropic antenna obtained from the ICEPAC program. (Courtesy of G. Hand.)

Circuit reliability, ρ , ($0 < \rho < 1$) is the fraction of days that successful communication may be expected at a given hour of a month on a specified operating frequency

$$\rho = QP \quad (12)$$

where P is the probability that the mean received signal-to-noise ratio exceeds a specified level. The reliability, ρ , depends on P increasing with increasing frequency, whereas Q decreases with increasing frequency.

Grade of service defines the quality of communication desired (for example, the percentage of error-free messages in teletype transmitted or the percentage of satisfied customers of a given service). Service probability is the fraction of time that a specified grade of service (e.g., signal to noise) or better is achieved.

Above-the-MUF loss, L_m , accounts for the fact that signals may be received on frequencies above the basic MUF (e.g., resulting from ionosphere scatter, E_s , etc.). The CCIR [14], Report 252-2, recommends

$$L_m = 130\{(f/MUF) - 1\}^2 \quad (13)$$

To account for a wide variety of ionospheric effects, such as E_s , spread F, off-great-circle propagation, focusing, day-to-day variability, and aurora, ITU [20] Report 252 contains information on additional system loss resulting from these extra effects.

Compatibility is defined as the percentage of time during which a specified criterion of service quality is achieved at a receiver in the presence of interference, relative to the value that would be obtained if only noise were present.

6.5. Digital System Considerations

Digital systems are particularly affected by ionospheric dispersion, which produces fading (e.g., by multipath, polarization, etc.). The performance of a digital system is characterized by its bit error rate, which is the probability that a transmitted binary digit is wrongly detected by the receiver. On HF, intervals with high error densities alternate with intervals of low error densities. Error bursts occur when the signal-to-noise ratio temporarily falls below a critical level (e.g., selective fading). Curves are available in the ITU [20] Report 197, that gives the duration and probability of fades as a function of the signal level for specific circuits. In the absence of fading, the signal-to-noise ratio (SNR) is the controlling factor for digital transmission speed. The theoretical error-free channel capacity, C , is

$$C = B \log_2(1 + \text{SNR}) \text{bits} \cdot \text{s}^{-1} \quad (14)$$

where B is the channel bandwidth (Hz). As a result of all the effects described above, these ionospheric channels usually operate far below the theoretical capacity (Eq. (14)).

6.6. Real-time Channel Evaluation

Although the prediction systems discussed previously are valuable for circuit planning and frequency allocation, they have limited value for operational purposes, primarily because of the high hour-to-hour and day-to-day variability of the F2 layer. To meet operational requirements, several real-time circuit evaluation (RTCE) systems have been developed (see Ref. 14, Report 889-1). The first such system involved oblique sweep-frequency sounding over the operational circuit and, from the oblique ionogram, selection of a suitable frequency with low time dispersion, adequate signal, and minimum noise and interference. The channel selection is normally limited by the channel allocation. A critical feature of this technique is the interval between soundings. When the interval is long, changing ionospheric conditions can catch the operator unaware. On the other hand, too frequent soundings generate excessive interference to other services. An alternative, and less bothersome, approach is channel sounding on the allocated channels only. This technique has the following advantages: simpler equipment, lower installation costs, and less interference. When the optimum channel is identified, a message is dispatched to the sender, who can commence transmission. This method assumes reciprocity (that is, the sender-to-receiver conditions are the same as the receiver-to-sender conditions). This is usually a good assumption. Adaptive systems are essential for RTCE in order to respond to rapidly changing sky wave conditions. An adaptive system needs (1) a fast frequency response, (2) antenna agility, and (3) the ability to adjust rates of information.

Use of RTCE allows adaptive frequency management by which usage of the HF spectrum can be maximized. Such an approach is preferable to increasing the transmitter power and/or transmitting simultaneously on all allocated frequencies, both of which may be self-defeating. The term *channel estimation* is used to describe the process of monitoring channel characteristics with the aim of describing the states of a set of channels. Real-time adaptive systems are of particular value when one of the terminals is mobile (e.g., ship, airplane, vehicle) and the other is fixed, so that the fixed terminal can avail itself of high power and directive antennas. One advantage of RTCE over prediction is to maximize above-the-median MUF propagation, in which interference is usually lower than on the FOT.

7. CONCLUSIONS

The medium-frequency and high-frequency bands have great commercial, social, and scientific value and are used extensively for broadcasting and for point-to-point communications. The pronounced (orders of magnitude) variability of the ionosphere makes sky wave communications problematic, both as a means of communicating and as a source of interference. Using HF systems, frequency agility is essential for continuous operation and, therefore, a set of suitable assigned frequency channels. Even with such a frequency allocation, by the appropriate national authority, sky wave propagation is liable to disruption by

several solar disturbances and synthetic disturbances (e.g., nuclear explosions and ionospheric modification). For many purposes, satellite communications, on giga-Hertz frequencies, have replaced HF for global communications. However, sky waves will continue to be used well into the foreseeable future.

SLOT ANTENNAS

HISAMATSU NAKANO
Hosei University
Koganei, Tokyo, Japan

1. INTRODUCTION

The advantages of a slot antenna (a slot cut in a conducting sheet) are that it is simple and robust. The slot can radiate either a linearly polarized wave or a circularly polarized wave. Numerous slot antennas have been proposed for radiocommunication systems [1–3]. This article focuses on representative slot antennas, including straight, bow-tie, loop, curl, and spiral slot antennas, and reveals their radiation characteristics.

First, a thin straight slot [4] is discussed in Section 2, assuming a sinusoidal electric field over the slot. The radiation pattern and the radiation conductance are formulated under the condition that a conducting sheet, in which the thin slot is cut, is of infinite extent. Subsequently, a relationship between the impedances of a slot

Figure 1. Thin straight slot cut in a conducting sheet of infinite extent.

antenna and a corresponding plate antenna, both having the same shape, is discussed in Section 3. This relationship, called “Babinet’s principle [4,5],” is then applied to the aforementioned thin slot antenna and its radiation conductance is again discussed.

The conducting sheet used for the derivation of Babinet’s principle is of *infinite* extent. However, in practice, the conducting sheet is of *finite* extent and Babinet’s principle cannot be applied to a slot cut in a finite sheet. To overcome the limitation regarding the size of the conducting sheet, an analysis method called the *finite-difference time-domain method* (FDTD) [6–8] is presented in Section 4. Evaluation of antenna characteristics (including the input impedance, radiation pattern, and gain) based on the FDTD is briefly described. Note that the FDTD can be used for both a slot in a finite sheet and in an infinite sheet.

Sections 5–10 present the analysis results for the representative slot antennas (including the straight, bowtie, loop, curl, and spiral slot antennas), obtained by using the FDTD.

The antenna characteristics of a straight half-wavelength slot as a function of the source location are analyzed in Section 5 (note that the slots in Sections 2 and 3 are fed from their centerpoints). It is found that the straight

half-wavelength slot shows a purely resistive input impedance, when it is fed from an off-center feedpoint. The gain as a function of the source location is also revealed.

Effects of the finiteness of a conducting sheet on the radiation characteristics of a half-wavelength slot are revealed in Section 6, where an x -directed slot is cut in a sheet with an x -directed side length of S_{GPx} and a y -directed side length of S_{GPy} [9,10]. Variations in the input impedance, radiation pattern, and gain are evaluated as a function of S_{GPx} , holding S_{GPy} constant. Similarly, variations in the input impedance, radiation pattern, and gain are evaluated as a function of S_{GPy} , holding S_{GPx} constant.

A variation on the shape of the straight slot (width w) is the bowtie slot, whose width increases along the slot axis. The increase in the width is specified by the bowtie angle ϕ_{bow} . The size of this angle affects the antenna characteristics [11,12]. Fixing the length of the bowtie to be a half-wavelength, the effects of the bowtie angle on the antenna characteristics are revealed in Section 7 [13]. The frequency responses of the half-power beamwidth and the gain are also presented and discussed.

A loop slot presented in Section 8 has a closed-arm structure, as opposed to the straight and bowtie slots. The antenna characteristics of the loop slot as a function of the loop circumference are evaluated under the condition that the conducting sheet, in which the loop slot is cut, is of infinite extent [14]. In addition, a comparison between loop slots with finite and infinite conducting sheets is made to clarify the differences in the radiation patterns and the gains.

The straight slot in Sections 5 and 6, the bowtie slot in Section 7, and the loop slot in Section 8 radiate a *linearly* polarized wave. The antennas discussed in Sections 9 and 10 radiate a *circularly* polarized wave.

A curl slot antenna, discussed in Section 9, has a triplate transmission-line structure [15–17], where the curl slot is cut in the upper plate of the triplate transmission line. The middle plate of the triplate transmission line forms the feed probe for the slot. The radiation from the curl is unidirectional by virtue of the lower plate, which acts as a reflector. After investigating the curl slot, dual-curl slots are arrayed to realize a high gain of more than 30 dBi [18].

A spiral slot with two arms [19] is discussed in Section 10. Finite arm lengths are considered for practicality. The frequency responses of the radiation pattern, gain, and input impedance for this finite arm-length case are evaluated and the wideband characteristics within a frequency range of 3–7 GHz are discussed [20].

Finally, some comments on slot antennas are added, referring to recent research work [21–25].

2. THIN STRAIGHT SLOT

A straight slot antenna is a simple radiation element, similar to the straight wire antenna. This section discusses how to calculate the radiation field and the radiation conductance of the straight slot antenna. For the calculation, the slot is assumed to have a very small width relative to the wavelength; that is, the slot is assumed to be thin.

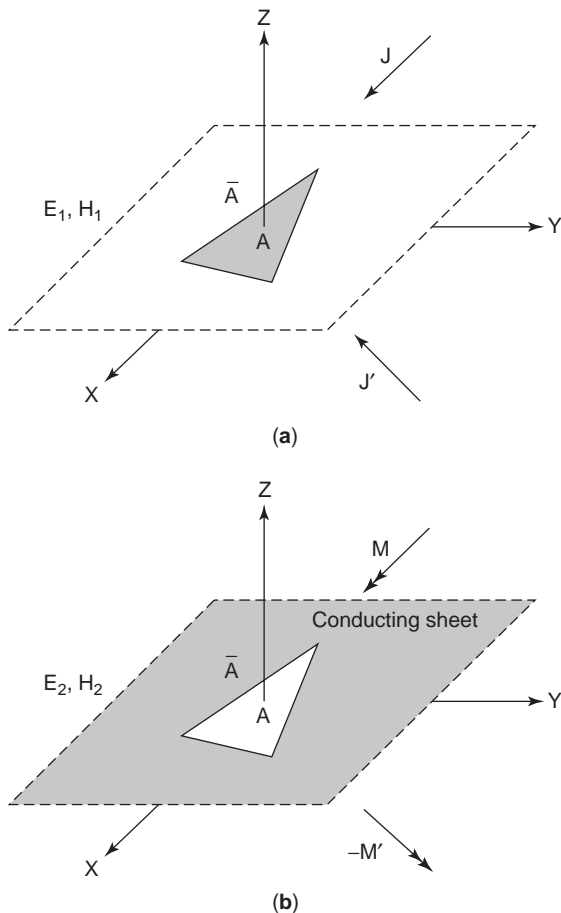

Figure 2. Complementary structures: (a) conducting plate of area A ; (b) slot of area A in a conducting sheet of infinite extent.

2.1. Radiation Field

Figure 1 shows a thin straight slot cut in a conducting sheet of infinite extent, where the length and width of the slot are denoted as $2L$ and w , respectively. The slot is excited with a voltage source at its center. We assume that the electric field over the slot is

$$E_y = E_m \sin[k_0(L - |x'|)],$$

$$-L \leq x' \leq L \text{ and } -\frac{w}{2} \leq y' \leq \frac{w}{2} \quad (1)$$

where k_0 is the wavenumber ($= 2\pi/\lambda$, where λ is the wavelength in free space).

The radiation field $\mathbf{E}(r, \theta, \phi) = E_\theta(r, \theta, \phi)\hat{\theta} + E_\phi(r, \theta, \phi)\hat{\phi}$ in the $+z$ side of the sheet is calculated using the equivalence principle [26] as

$$E_\theta(r, \theta, \phi) = -\frac{jk_0}{4\pi} \frac{e^{-jk_0r}}{r} \int_{-(w/2)}^{w/2} \int_{-L}^L M_\phi e^{jk_0\hat{r}\cdot\mathbf{r}'} dx' dy' \quad (2)$$

$$E_\phi(r, \theta, \phi) = \frac{jk_0}{4\pi} \frac{e^{-jk_0r}}{r} \int_{-(w/2)}^{w/2} \int_{-L}^L M_\theta e^{jk_0\hat{r}\cdot\mathbf{r}'} dx' dy' \quad (3)$$

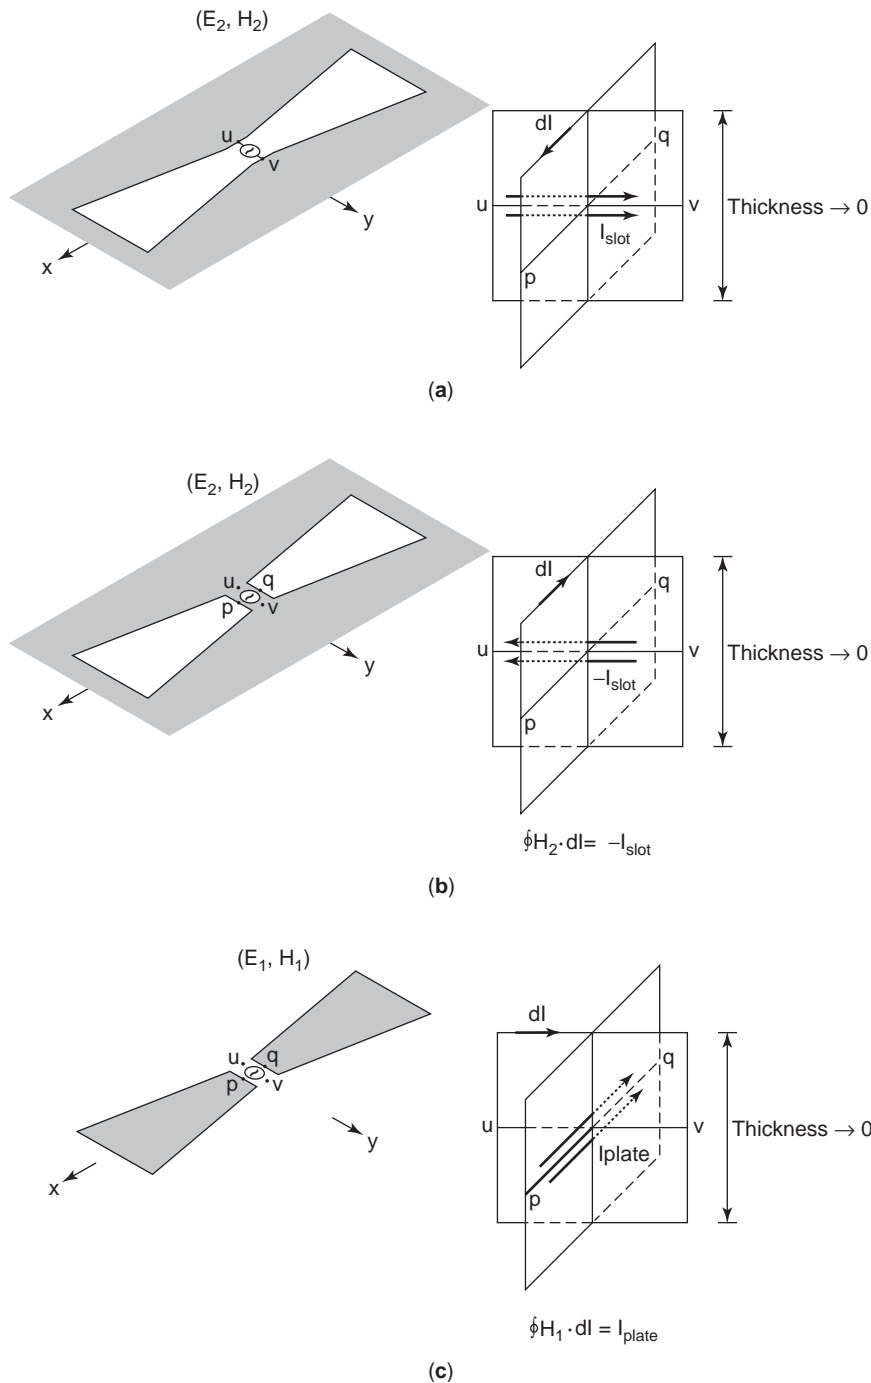

Figure 3. Babinet's principle: (a) slot excited by a voltage source (original problem); (b) slot excited by magnetic current source (equivalent to Fig. 3a); (c) conducting plate excited by a voltage source (complementary to Fig. 3b).

Figure 4. Finite-difference time-domain method: (a) analysis space, which is subdivided into numerous cells; (b) assignment of electric field \mathbf{E} and magnetic field \mathbf{H} on a cell; (c) radiation field calculation using equivalence theorem.

where r , θ , and ϕ are spherical coordinates and \hat{r} , $\hat{\theta}$, and $\hat{\phi}$ are the corresponding unit vectors; M_θ and M_ϕ are the components of the magnetic current density \mathbf{M} (equivalent source density) over the slot

$$M_\phi = -2E_y \sin \phi \quad (4)$$

$$M_\theta = 2E_y \cos \theta \cos \phi \quad (5)$$

Note that $\mathbf{r}' [= \mathbf{r}'(x', y')]$ in Eqs. (2) and (3) is the position vector from the coordinate origin to a point within the slot, and hence

$$\hat{r} \cdot \mathbf{r}' = x' \sin \theta \cos \phi + y' \sin \theta \sin \phi \quad (6)$$

When the slot length $2L$ is a half-wavelength and $k_0 y' \rightarrow 0$, Eqs. (2) and (3) become

$$E_\theta = \frac{j}{\pi} \frac{e^{-jk_0 r}}{r} V_0 \sin \phi \frac{\cos \left[\frac{\pi}{2} \sin \theta \cos \phi \right]}{1 - \sin^2 \theta \cos^2 \phi} \quad (7)$$

$$E_\phi = \frac{j}{\pi} \frac{e^{-jk_0 r}}{r} V_0 \cos \theta \cos \phi \frac{\cos \left[\frac{\pi}{2} \sin \theta \cos \phi \right]}{1 - \sin^2 \theta \cos^2 \phi} \quad (8)$$

where $V_0 = \omega E_m$, which is the voltage across the center terminals u and v . Note that Eqs. (7) and (8) in the x - z

plane ($\phi = 0$) are

$$E_\theta = 0 \quad (9)$$

$$E_\phi = \frac{j}{\pi} \frac{e^{-jk_0 r}}{r} V_0 \frac{\cos\left[\frac{\pi}{2} \sin \theta\right]}{\cos \theta} \quad (10)$$

and Eqs. (7) and (8) in the y - z plane ($\phi = \pi/2$) are

$$E_\theta = \frac{j}{\pi} \frac{e^{-jk_0 r}}{r} V_0 \quad (11)$$

$$E_\phi = 0 \quad (12)$$

As will be shown later, the radiation fields in the two principal planes, as given above, are in good agreement with those obtained using the finite-difference time-domain method.

2.2. Radiation Conductance

Using Eqs. (7) and (8), we calculate the total power P radiated in the $+z$ space from a thin half-wavelength slot (shown in Fig. 1). Integrating the Poynting power over the surface of a hemisphere of radius r leads to

$$\begin{aligned} P &= \int_{\theta=0}^{\pi/2} \int_{\phi=0}^{2\pi} \frac{1}{2Z_0} (|E_\theta|^2 + |E_\phi|^2) r^2 \sin \theta d\theta d\phi \\ &= \frac{1}{2Z_0} \frac{1}{\pi^2} \frac{1}{r^2} V_0^2 \int_{\theta=0}^{\pi/2} \int_{\phi=0}^{2\pi} (\sin^2 \phi + \cos^2 \theta \cos^2 \phi) \\ &\quad \times \frac{\cos^2\left(\frac{\pi}{2} \sin \theta \cos \phi\right)}{(1 - \sin^2 \theta \cos^2 \phi)^2} r^2 \sin \theta d\theta d\phi \end{aligned} \quad (13)$$

where Z_0 is the intrinsic impedance of free space: $Z_0 = 120\pi \Omega$.

Equation (13) becomes (see Appendix)

$$\begin{aligned} P &= \frac{V_0^2}{4\pi Z_0} [\ln 2\pi\gamma - \text{Ci}(2\pi)] \\ &= 73 \frac{V_0^2}{Z_0^2} \end{aligned} \quad (14)$$

where $\ln \gamma = 0.5772$ (Euler's constant) and $\text{Ci}(x)$ is the cosine integral:

$$\text{Ci}(x) = - \int_x^\infty \frac{\cos x}{x} dx \quad (15a)$$

$$\int_0^x \frac{1 - \cos x}{x} dx = \ln x\gamma - \text{Ci}(x) \quad (15b)$$

The total power P can alternatively be written, using the radiation conductance G_r , as

$$P = \frac{1}{2} G_r V_0^2 \quad (16)$$

From Eqs. (14) and (16), G_r is given as

$$\begin{aligned} G_r &= \frac{2(73)}{Z_0^2} \\ &= 1.03 \times 10^{-3} \text{ mhos} \end{aligned} \quad (17)$$

Note that the radiation conductance in Eq. (17) applies for a slot radiating only in the $+z$ space. The radiation conductance will be discussed again in Section 3.2.

3. IMPEDANCE RELATIONSHIP BETWEEN COMPLEMENTARY STRUCTURES

The conductance determined in the previous section can be evaluated directly from Babinet's principle [4,5,29]. Before applying Babinet's principle to a slot antenna, let us understand what Babinet's principle is.

3.1. Babinet's Principle

For derivation of Babinet's principle, we consider an arbitrarily shaped conducting plate of area A in the x - y plane, shown in Fig. 2a. Let the shape of the conducting plate be exactly the same as the aperture (slot) cut in a conducting sheet of infinite extent, as shown in Fig. 2b, where the conducting sheet of area \bar{A} is located in the x - y plane. The two structures, where $A + \bar{A}$ covers the entire x - y sheet, are said to be "complementary" to each other.

\mathbf{J} and \mathbf{J}' in Fig. 2a are electric currents, which are located symmetrically with respect to the x - y plane. The electric and magnetic fields for this case are specified by \mathbf{E}_1 and \mathbf{H}_1 , respectively. Similarly, the electric and magnetic fields for the case shown in Fig. 2b are specified by \mathbf{E}_2 and \mathbf{H}_2 , where antisymmetric magnetic currents \mathbf{M} and $-\mathbf{M}'$ exist [5,29].

Maxwell's curl equations for Figs. 2a and 2b are written as

$$\nabla \times \mathbf{E}_1 + j\omega\mu\mathbf{H}_1 = 0 \quad (18)$$

$$\nabla \times \mathbf{H}_1 - (j\omega\epsilon + \sigma)\mathbf{E}_1 = \mathbf{J} \quad (z > 0) \quad (19a)$$

$$\nabla \times \mathbf{H}_1 - (j\omega\epsilon + \sigma)\mathbf{E}_1 = \mathbf{J}' \quad (z < 0) \quad (19b)$$

$$\nabla \times \mathbf{E}_2 + j\omega\mu\mathbf{H}_2 = -\mathbf{M} \quad (z > 0) \quad (20a)$$

$$\nabla \times \mathbf{E}_2 + j\omega\mu\mathbf{H}_2 = \mathbf{M}' \quad (z < 0) \quad (20b)$$

$$\nabla \times \mathbf{H}_2 - (j\omega\epsilon + \sigma)\mathbf{E}_2 = 0 \quad (21)$$

If the magnetic currents are chosen to be $(\mathbf{M}, \mathbf{M}') = (Z_\sigma \mathbf{J}, Z_\sigma \mathbf{J}')$, then Eqs. (20a), (20b), and (21) are transformed,

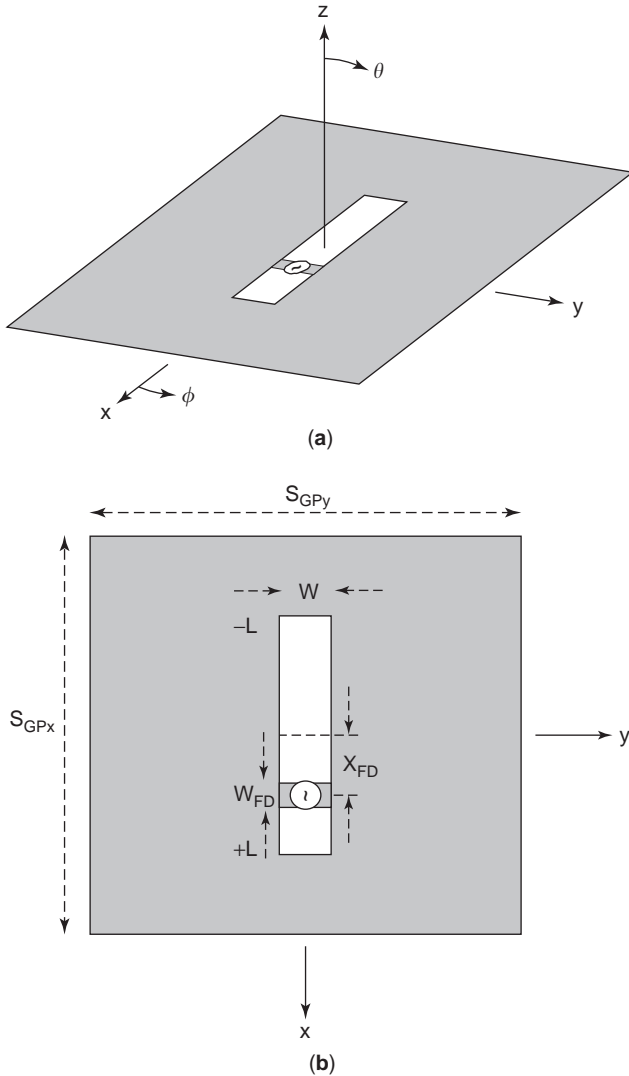

Figure 5. Half-wavelength straight slot excited by an off-center voltage source: (a) perspective view; (b) top view.

respectively, to

$$\nabla \times \left(-\frac{1}{Z_\sigma} \mathbf{E}_2 \right) - (j\omega\epsilon + \sigma)(Z_\sigma \mathbf{H}_2) = \mathbf{J} \quad (z > 0) \quad (22a)$$

$$\nabla \times \left(\frac{1}{Z_\sigma} \mathbf{E}_2 \right) - (j\omega\epsilon + \sigma)(-Z_\sigma \mathbf{H}_2) = \mathbf{J}' \quad (z < 0) \quad (22b)$$

$$\nabla \times (Z_\sigma \mathbf{H}_2) + j\omega\mu \left(-\frac{\mathbf{E}_2}{Z_\sigma} \right) = 0 \quad (23)$$

where Z_σ is

$$Z_\sigma = \left(\frac{j\omega\mu}{j\omega\epsilon + \sigma} \right)^{1/2} \quad (24)$$

These electric and magnetic fields $(\mathbf{E}_1, \mathbf{H}_1)$ and $(\mathbf{E}_2, \mathbf{H}_2)$ must satisfy the boundary conditions on the areas A

Figure 6. Input impedance Z_{in} of a half-wavelength straight slot as a function of the source location x_{FD} .

and \bar{A} [5,29]

$$\mathbf{E}_1 \times \hat{n} = \mathbf{H}_1 \cdot \hat{n} = 0 \quad \text{on } A \quad (25a)$$

$$\mathbf{E}_1 \cdot \hat{n} = \mathbf{H}_1 \times \hat{n} = 0 \quad \text{on } \bar{A} \quad (25b)$$

$$\mathbf{E}_2 \times \hat{n} = \mathbf{H}_2 \cdot \hat{n} = 0 \quad \text{on } \bar{A} \quad (26a)$$

$$\mathbf{E}_2 \cdot \hat{n} = \mathbf{H}_2 \times \hat{n} = 0 \quad \text{on } A \quad (26b)$$

where \hat{n} is the unit vector normal to the x - y plane. Equations (25b) and (26b) are derived from the symmetric electric currents and antisymmetric magnetic currents, respectively.

Comparing Eqs. (18), (19a), and (19b) to Eqs. (23), (22a), and (22b), respectively, and taking into account the boundary conditions Eqs. (25) and (26), we have

$$\mathbf{H}_1 = \mp \frac{1}{Z_\sigma} \mathbf{E}_2 \quad (z \geq 0) \quad (27a)$$

$$\mathbf{E}_1 = \pm Z_\sigma \mathbf{H}_2 \quad (z \geq 0) \quad (27b)$$

This means that, once the electric and magnetic fields are obtained for either case of Fig. 2a or Fig. 2b, the fields for the remaining case can be calculated using Eq. (27). Such a principle is referred to as *Babinet's principle*.

Similarly, if we choose the magnetic currents as $(\mathbf{M}, \mathbf{M}') = (\mathbf{J}, \mathbf{J}')$, as Kotani did [5,29], the field equations for Babinet's principle can be written as

$$\mathbf{H}_1 = \mp \mathbf{E}_2 \quad (z \geq 0) \quad (28a)$$

$$\mathbf{E}_1 = \pm Z_\sigma^2 \mathbf{H}_2 \quad (z \geq 0) \quad (28b)$$

3.2. Application of Babinet's Principle to a Slot Antenna

The purpose of this section is to obtain the radiation conductance of the slot antenna shown in Fig. 3a, using Babinet's principle. For this, the voltage and the current across terminals u and v are denoted as V_{slot} and I_{slot} ,

Figure 7. Radiation pattern of a half-wavelength straight slot excited by an off-center source.

$$f = 3 \text{ GHz}, 2L = 0.5\lambda_3, w = 0.03\lambda_3, w_{FD} = 0.02\lambda_3, x_{FD} = 0.15\lambda_3, S_{GPx} = S_{GPy} = \infty$$

respectively. In addition, the electric and magnetic fields for this case are specified by \mathbf{E}_2 and \mathbf{H}_2 , respectively.

We replace the voltage source in Fig. 3a with a magnetic current source, as shown in Fig. 3b. The magnetic current source surrounds a conducting plate section connecting points p and q . In other words, the directions of the magnetic current in the front and back of this section are opposite to each other [5]. It follows that Fig. 3b corresponds to Fig. 2b. Note that the electric and magnetic fields in Fig. 3b are specified by the initial \mathbf{E}_2 and \mathbf{H}_2 , respectively, so that Fig. 3b is equivalent to Fig. 3a.

Figure 3c shows the complementary structure of Fig. 3b. The voltage and the current across terminals p and q are denoted by V_{plate} and I_{plate} , respectively. The electric and magnetic fields for this case are specified by \mathbf{E}_1 and \mathbf{H}_1 , respectively. Note that Fig. 3c corresponds to Fig. 2a.

To solve the original problem shown in Fig. 3a, we apply Babinet's principle to Figs. 3b and 3c with Eq. (27)

$$\begin{aligned} V_{\text{slot}} &= - \int_u^v \mathbf{E}_2 \cdot d\mathbf{l} = \int_u^v (Z_\sigma \mathbf{H}_1) \cdot d\mathbf{l} \\ &= \frac{1}{2} \oint (Z_\sigma \mathbf{H}_1) \cdot d\mathbf{l} = \frac{Z_\sigma}{2} I_{\text{plate}} \end{aligned} \quad (29)$$

$$\begin{aligned} V_{\text{plate}} &= - \int_p^q \mathbf{E}_1 \cdot d\mathbf{l} = - \int_p^q (Z_\sigma \mathbf{H}_2) \cdot d\mathbf{l} \\ &= - \frac{1}{2} \oint (Z_\sigma \mathbf{H}_2) \cdot d\mathbf{l} = \frac{Z_\sigma}{2} I_{\text{slot}} \end{aligned} \quad (30)$$

where $d\mathbf{l}$ is a line element vector. The input impedance of the slot antenna Z_{slot} and that of the plate antenna Z_{plate} are given as

$$Z_{\text{slot}} = \frac{V_{\text{slot}}}{I_{\text{slot}}} \quad (31)$$

$$Z_{\text{plate}} = \frac{V_{\text{plate}}}{I_{\text{plate}}} \quad (32)$$

Therefore, from Eqs. (29) and (30), we have

$$Z_{\text{slot}} \cdot Z_{\text{plate}} = \frac{Z_\sigma^2}{4} \quad (33)$$

Note that this relationship can also be derived using Eq. (28) [5,29].

When $Z_{\text{plate}} = 73 \Omega$ and $Z_\sigma = 120\pi \Omega \equiv Z_0$ (for $\sigma = 0$), Eq. (33) becomes

$$Z_{\text{slot}} = \frac{Z_0^2}{4(73)} \quad (34)$$

Hence, the radiation conductance G_{slot} is written as

$$G_{\text{slot}} = \frac{4(73)}{Z_0^2} \quad (35)$$

It is emphasized that Eq. (35) is derived under the condition that the slot radiates in both the $+z$ and $-z$ spaces. When the slot radiates only in the $+z$ space, as discussed

Figure 8. Gain of a half-wavelength straight slot as a function of the source location x_{FD} .

Figure 9. Radiation pattern of a center-fed half-wavelength straight slot as a function of the side length in the x direction, S_{GPX} .

in Section 2, the radiation conductance is given as one-half of G_{slot} :

$$\frac{1}{2}G_{slot} = \frac{2(73)}{Z_0^2} \quad (36)$$

This equals Eq. (17).

4. NUMERICAL TECHNIQUES

The discussion in Section 2 starts with the assumption that the electric field distribution over a straight slot can be represented by Eq. (1). The value of the slot width w for Eq. (1) is not explicitly mentioned. The width is described only as “thin.” The radiation conductance given by Eq. (17) is the value for the limited case where the slot width w approaches zero.

As will be described later, the radiation pattern depends on the size of the conducting sheet in which the slot is cut. Equations (7) and (8) are derived under the condition that the conducting sheet is of infinite extent. However, in practice, the conducting sheet is of finite extent.

One powerful tool for analyzing the slot antenna, taking into account the slot width w and finite sheet size, is the finite-difference time-domain method (FDTD) [6–8].

The FDTD is a numerical solver for the electric field \mathbf{E} and the magnetic field \mathbf{H} . On the basis of the fields obtained using the FDTD, we can evaluate the antenna characteristics.

4.1. FDTD

As shown in Fig. 4a, we form an analysis space of $X \times Y \times Z$ such that it encloses the antenna to be considered. This

Figure 10. Gain of a center-fed half-wavelength straight slot as a function of the side length in the x direction, S_{GPX} .

Figure 11. Input impedance of a center-fed half-wavelength straight slot as a function of the side length in the x direction, S_{GPx} .

analysis space consists of numerous cells, each having a volume of $\Delta x \times \Delta y \times \Delta z$. To apply Maxwell's equations to the analysis space, the field components on a cell are assigned, as shown in Fig. 4b, where the Cartesian coordinates are expressed as $(x, y, z) = (i\Delta x, j\Delta y, k\Delta z)$ with i, j , and k being integers.

To terminate the outer surface of the analysis space, we express the tangential electric field components E_y and E_z

at the boundary $x = \xi_x$ as $E_y(t + \Delta t, \xi_x)$ and $E_z(t + \Delta t, \xi_x)$, respectively, and denote them as $E(t + \Delta t, \xi)$ for simplicity, where t and Δt denote the time coordinate and timestep, respectively. Similarly, the tangential electric field components at $y = \xi_y$ and $z = \xi_z$ are expressed as $E(t + \Delta t, \xi)$. Liao shows that this $E(t + \Delta t, \xi)$ is updated using $E(t, \xi)$, $E(t, \xi - \Delta \xi)$, $E(t, \xi - 2\Delta \xi)$, $E(t - \Delta t, \xi)$, $E(t - \Delta t, \xi - \Delta \xi)$, $E(t - \Delta t, \xi - 2\Delta \xi)$, $E(t - \Delta t, \xi - 3\Delta \xi)$, and $E(t - \Delta t, \xi - 4\Delta \xi)$ [8]. In this article, we use Liao's result as the absorbing boundary condition.

The time coordinate t is expressed as $n\Delta t$, where n is an integer. For simplicity, a function $g(x, y, z, t) = g(i\Delta x, j\Delta y, k\Delta z, n\Delta t)$ is denoted as $g^n(i, j, k)$ in the FTDDM. Then, derivatives with respect to x and t are approximated with central finite differences as follows:

$$\frac{\partial g^n(i, j, k)}{\partial x} \approx \frac{g^n\left(i + \frac{1}{2}, j, k\right) - g^n\left(i - \frac{1}{2}, j, k\right)}{\Delta x} \quad (37)$$

$$\frac{\partial \mathbf{E}}{\partial t} \Big|_{t=[n-(1/2)]\Delta t} \approx \frac{\mathbf{E}^n - \mathbf{E}^{n-1}}{\Delta t} \quad (38)$$

$$\frac{\partial \mathbf{H}}{\partial t} \Big|_{t=n\Delta t} \approx \frac{\mathbf{H}^{n+(1/2)} - \mathbf{H}^{n-(1/2)}}{\Delta t} \quad (39)$$

Figure 12. Radiation pattern of a center-fed half-wavelength straight slot as a function of the side length in the y direction, S_{GPy} .

Figure 13. Gain of a center-fed half-wavelength straight slot as a function of the side length in the y direction, S_{GPy} .

Using Eqs. (38) and (39), Maxwell's curl equations

$$\nabla \times \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} \quad (40)$$

$$\nabla \times \mathbf{H} = \sigma \mathbf{E} + \varepsilon \frac{\partial \mathbf{E}}{\partial t} \quad (41)$$

are transformed to

$$\mathbf{E}^n = \frac{2\varepsilon - \sigma\Delta t}{2\varepsilon + \sigma\Delta t} \mathbf{E}^{n-1} + \frac{2\Delta t}{2\varepsilon + \sigma\Delta t} \nabla \times \mathbf{H}^{n-(1/2)} \quad (42)$$

$$\mathbf{H}^{n+(1/2)} = \mathbf{H}^{n-(1/2)} - \frac{\Delta t}{\mu} \nabla \times \mathbf{E}^n \quad (43)$$

where ε , μ , and σ are the permittivity, permeability, and conductivity, respectively. Note that the time at which $\sigma \mathbf{E}$ in Eq. (41) is evaluated is $t = [n - (1/2)]\Delta t$, corresponding to the time at which $\partial \mathbf{E}/\partial t$ is evaluated. This $\sigma \mathbf{E}$ is expressed as $\sigma \mathbf{E}^{n-(1/2)}$ and approximated by the average of $\sigma \mathbf{E}^n$ and $\sigma \mathbf{E}^{n-1}$ to obtain Eq. (42).

Figure 14. Input impedance of a center-fed half-wavelength straight slot as a function of the side length in the y direction, S_{GPy} .

Using Eq. (37), the finite-difference form for the x component of Eq. (42) is written as

$$\begin{aligned} E_x^n \left(i + \frac{1}{2}, j, k \right) &= e_{x/0} \left(i + \frac{1}{2}, j, k \right) E_x^{n-1} \left(i + \frac{1}{2}, j, k \right) \\ &+ e_{x/y} \left(i + \frac{1}{2}, j, k \right) \left[H_z^{n-(1/2)} \left(i + \frac{1}{2}, j + \frac{1}{2}, k \right) \right. \\ &\quad \left. - H_z^{n-(1/2)} \left(i + \frac{1}{2}, j - \frac{1}{2}, k \right) \right] \\ &- e_{x/z} \left(i + \frac{1}{2}, j, k \right) \left[H_y^{n-(1/2)} \left(i + \frac{1}{2}, j, k + \frac{1}{2} \right) \right. \\ &\quad \left. - H_y^{n-(1/2)} \left(i + \frac{1}{2}, j, k - \frac{1}{2} \right) \right] \end{aligned} \quad (44)$$

where

$$\begin{aligned} e_{x/0} \left(i + \frac{1}{2}, j, k \right) &= \frac{2\varepsilon \left(i + \frac{1}{2}, j, k \right) - \sigma \left(i + \frac{1}{2}, j, k \right) \Delta t}{2\varepsilon \left(i + \frac{1}{2}, j, k \right) + \sigma \left(i + \frac{1}{2}, j, k \right) \Delta t} \end{aligned} \quad (45)$$

$$\begin{aligned} e_{x/y} \left(i + \frac{1}{2}, j, k \right) &= \frac{2\Delta t}{2\varepsilon \left(i + \frac{1}{2}, j, k \right) + \sigma \left(i + \frac{1}{2}, j, k \right) \Delta t} \frac{1}{\Delta y} \end{aligned} \quad (46)$$

$$\begin{aligned} e_{x/z} \left(i + \frac{1}{2}, j, k \right) &= \frac{2\Delta t}{2\varepsilon \left(i + \frac{1}{2}, j, k \right) + \sigma \left(i + \frac{1}{2}, j, k \right) \Delta t} \frac{1}{\Delta z} \end{aligned} \quad (47)$$

The two other components of the electric field \mathbf{E}^n and three components of the magnetic field $\mathbf{H}^{n+(1/2)}$ are similarly formulated.

After determining \mathbf{E} and \mathbf{H} , the current along the antenna conductor I is obtained by integrating the magnetic field \mathbf{H} around the antenna conductor (Ampere's law). The input impedance $Z_{in} = R_{in} + jX_{in}$ is given as $V_{in}(\omega)/I_{in}(\omega)$, where $V_{in}(\omega)$ and $I_{in}(\omega)$ are the input voltage and current in the frequency domain, respectively. These $V_{in}(\omega)$ and $I_{in}(\omega)$ are obtained by Fourier-transforming the time-domain voltage and current, $V_{in}(t)$ and $I_{in}(t)$, respectively.

The radiation field \mathbf{E}_{rad} is calculated using the equivalence theorem [26]. The θ and ϕ components of the

Figure 15. Bowtie slot antenna: (a) perspective view; (b) top view.

radiation field (in the frequency domain) are given as

$$E_{\theta}(\omega) = -\frac{jk_0}{4\pi} \frac{e^{-jk_0 r}}{r} [Z_0 \mathbf{N}(\omega) \cdot \hat{\theta} + \mathbf{L}(\omega) \cdot \hat{\phi}] \quad (48)$$

$$E_{\phi}(\omega) = -\frac{jk_0}{4\pi} \frac{e^{-jk_0 r}}{r} [Z_0 \mathbf{N}(\omega) \cdot \hat{\phi} - \mathbf{L}(\omega) \cdot \hat{\theta}] \quad (49)$$

where

$$\mathbf{N}(\omega) = \int_{\text{closed surface}} \mathbf{J}_s(\omega, \mathbf{r}') e^{jk_0 \hat{\mathbf{r}} \cdot \mathbf{r}'} dS' \quad (50)$$

$$\mathbf{L}(\omega) = \int_{\text{closed surface}} \mathbf{M}_s(\omega, \mathbf{r}') e^{jk_0 \hat{\mathbf{r}} \cdot \mathbf{r}'} dS' \quad (51)$$

Z_0 is the intrinsic impedance ($120\pi \Omega$) and k_0 is the wave-number. Note that the $\mathbf{J}_s(\omega, \mathbf{r}')$, and $\mathbf{M}_s(\omega, \mathbf{r}')$ are, respectively, the Fourier transforms of the time-domain currents $\mathbf{J}_s(t, \mathbf{r}') = \hat{\mathbf{n}} \times \mathbf{H}(t, \mathbf{r}')$ and $\mathbf{M}_s(t, \mathbf{r}') = \mathbf{E}(t, \mathbf{r}') \times \hat{\mathbf{n}}$, where \mathbf{r}' is the position vector from the coordinate origin to the point at which $\mathbf{E}(t, \mathbf{r}')$ and $\mathbf{H}(t, \mathbf{r}')$ are evaluated on the closed surface and $\hat{\mathbf{n}}$ is the outward unit vector normal to the closed surface (see Fig. 4c).

For the axial ratio (AR) calculation, the radiation field ($\mathbf{E}_{\text{rad}} = E_{\theta} \hat{\theta} + E_{\phi} \hat{\phi}$) is decomposed into two circularly polarized (CP) wave components

$$\begin{aligned} \mathbf{E}_{\text{rad}}(r, \theta, \phi) = & E_R(r, \theta, \phi)(\hat{\theta} - j\hat{\phi}) \\ & + E_L(r, \theta, \phi)(\hat{\theta} + j\hat{\phi}) \end{aligned} \quad (52)$$

where the first term represents a right-hand CP wave component and the second represents a left-hand CP wave component. Using these two components, the axial ratio is given as $\text{AR} = (|E_R| + |E_L|) / |E_R - E_L|$.

The antenna gain at a far-field point (r, θ, ϕ) is defined as $G = (|E_{\theta}|^2 + |E_{\phi}|^2) r^2 / 30P_{\text{in}}$, where P_{in} is the power input to the antenna. Since a relationship of $|E_{\theta}|^2 + |E_{\phi}|^2 = 2(|E_R|^2 + |E_L|^2)$ is obtained from Eq. (52), the gain is written as $G = (|E_R|^2 + |E_L|^2) r^2 / 30P_{\text{in}}$. Therefore, the gains for a right-hand circularly polarized wave and left-hand circularly polarized wave are calculated as $G_R = |E_R(r, \theta, \phi)|^2 r^2 / 30P_{\text{in}}$ and $G_L = |E_L(r, \theta, \phi)|^2 r^2 / 30P_{\text{in}}$, respectively.

For $|E_R| > |E_L|$, G_R increases and G_L decreases as the axial ratio AR decreases, in accordance with $G_R = G / [1 + \{(AR - 1)/(AR + 1)\}^2]$ and $G_L = G / [1 + \{(AR + 1)/(AR - 1)\}^2]$. Note that $G_R = G$ and $G_L = 0$ when $\text{AR} = 1$ (i.e., the polarization is perfectly circular with a right-hand sense).

5. ANTENNA CHARACTERISTICS OF A HALF-WAVELENGTH STRAIGHT SLOT AS A FUNCTION OF SOURCE LOCATION x_{FD}

We continue our analysis of a half-wavelength straight slot cut in a conducting sheet of infinite extent using the FDTD. As shown in Fig. 5, the slot is excited with a voltage source at $x = x_{\text{FD}}$. No assumption about the electric field over the slot is made for the analysis, unlike the analysis in Section 2. In addition, the analysis is performed with an explicit slot width w [9].

Figure 6 shows the input impedance Z_{in} as a function of the source location x_{FD} , where the slot width is chosen to be $w = 0.03\lambda_3$ (λ_3 : the wavelength in free space at 3 GHz). It is found that the input impedance has a purely resistive value at $x_{\text{FD, res}}$ off the centerpoint ($x_{\text{FD}} = 0$).

The source location x_{FD} does not affect the radiation pattern. Figure 7 shows a representative radiation pattern at $x_{\text{FD}} = x_{\text{FD, res}}$. The radiation is *linearly polarized*. The half-power beamwidth (HPBW) is approximately 76° in the x - z plane [which is nearly equal to the HPBW for an infinitesimally thin slot (78° for $w \rightarrow 0$)]. Note that the radiation pattern is symmetric with respect to the x - y plane.

Figure 8 shows the gain in the z direction as a function of x_{FD} . The fact that the HPBW remains almost unchanged with x_{FD} leads to nearly constant gain. The gain is approximately 2.2 dBi at $x_{\text{FD}} = 0$. This value is very close to the gain of a center-fed cylindrical dipole antenna (2.16 dBi) [27].

6. EFFECTS OF FINITENESS OF CONDUCTING SHEET ON RADIATION CHARACTERISTICS OF A CENTER-FED HALF-WAVELENGTH STRAIGHT SLOT

The discussion above is based on the condition that the half-wavelength straight slot is cut in a conducting sheet

$$f = 3 \text{ GHz}, 2L = 0.5\lambda_3, w = 0.03\lambda_3, w_{FD} = 0.02\lambda_3, s_{GPx} = s_{GPx} = 1\lambda_3$$

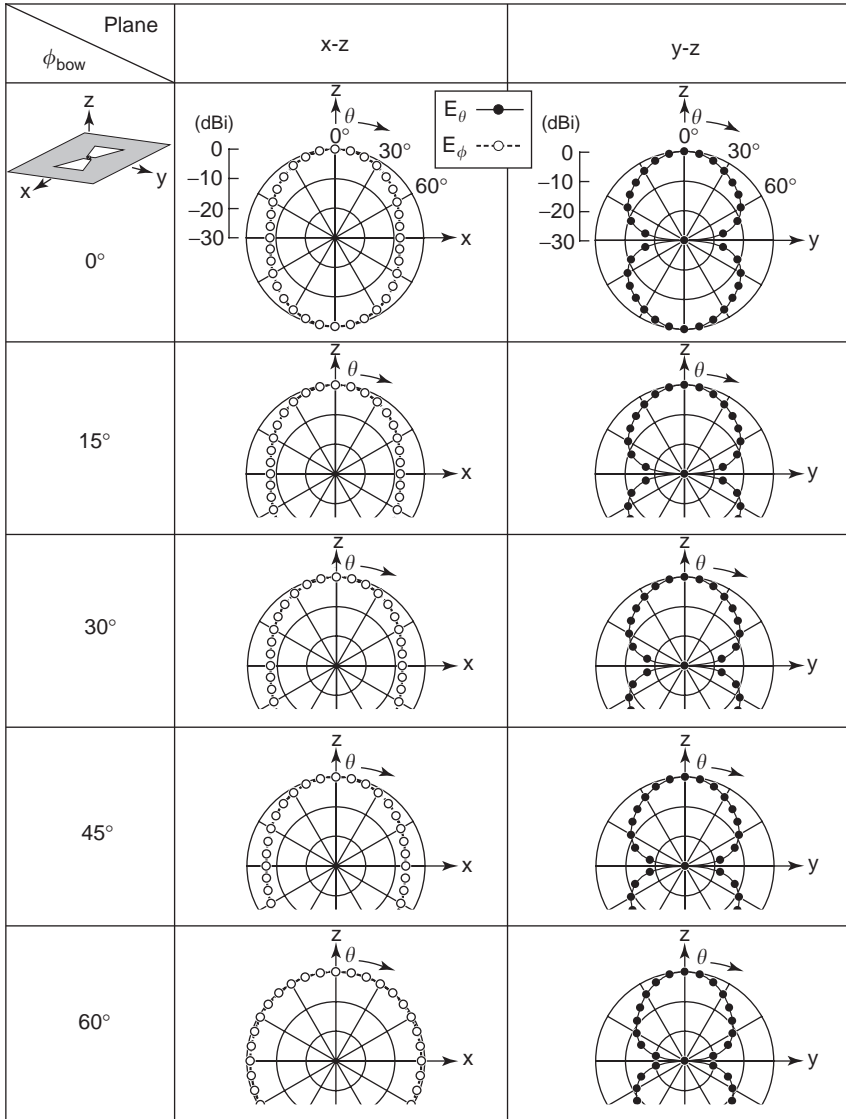

Figure 16. Radiation pattern of a bowtie slot as a function of the bowtie angle ϕ_{bow} .

of infinite extent ($s_{GPx} = \infty$ and $s_{GPy} = \infty$). In this section, the conducting sheet is chosen to be of finite extent [9,10]. Note that the slot width is fixed to be $w = 0.03\lambda_3$ (the same value used in Section 5) and the voltage source is located at $x = 0$ throughout this section.

6.1. Effects of Side Length in x Direction, s_{GPx}

Figure 9 shows the radiation pattern as a function of the side length in the x direction s_{GPx} , where the side length in the y direction s_{GPy} is fixed to be $1\lambda_3$ (λ_3 : the wavelength in free space at 3 GHz). The radiation pattern is symmetric with respect to the x - y plane, and hence the radiation pattern in the $-z$ region is not fully shown except for $s_{GPx} = 0.5\lambda_3$. It is clear that the radiation pattern in the x - z plane is affected by the finiteness of the conducting sheet. This leads to a gain higher than that for an infinite conducting sheet (2.2 dBi), as shown in Fig. 10.

Figure 11 shows the input impedance as a function of the side length s_{GPx} . The variation in the input impedance is relatively small for s_{GPx} greater than two wavelengths. As seen later, this behavior contrasts with that of the impedance as a function of the side length in the y direction, s_{GPy} .

6.2. Effects of Side Length in y Direction, s_{GPy}

Noticeable effects of the finiteness of the conducting sheet on the antenna characteristics are found when the side length in the y direction, s_{GPy} , is varied. Figure 12 shows the radiation pattern as a function of the length s_{GPy} , where the side length in the x direction is fixed to be $s_{GPx} = 1\lambda_3$. Note that the radiation patterns are symmetric with respect to the x - y plane.

As the side length s_{GPy} increases, the radiation pattern in the y - z plane undulates. This undulation results from

Figure 17. Gain of a bowtie slot as a function of the bowtie angle ϕ_{bow} .

radiation fields from the following three sources [10]: (1) the y -directed electric field source over the slot, (2) the y -directed electric field source distributed along the x -directed edge at $y = \frac{1}{2}s_{\text{GP}y}$, and (3) the y -directed electric field source distributed along the x -directed edge at $y = -\frac{1}{2}s_{\text{GP}y}$. The maximum and minimum values of the undulation occur at

$$\theta = \sin^{-1} \frac{n\lambda}{s_{\text{GP}y}} \quad (53)$$

where n is an integer. If $\cos \delta$ (where δ is the phase difference of the edge sources 2 and 3 with respect to source 1) is positive, then maxima are obtained with even values of n and minima with odd values of n .

The effects of the variation in the radiation pattern clearly appear in the gain. Figure 13 shows the z -direction gain as a function of the side length $s_{\text{GP}y}$. The gain drops at $s_{\text{GP}y} = 1.5\lambda_3$ and $3.5\lambda_3$ are due to the decrease in the radiation field intensity in the z direction (see the radiation patterns at $s_{\text{GP}y} = 1.5\lambda_3$ and $3.5\lambda_3$ in Fig. 12).

The input impedance is also clearly varied with the side length in the y direction, $s_{\text{GP}y}$. Figure 14 shows the input impedance as a function of $s_{\text{GP}y}$. It is observed that the input impedance varies periodically with $s_{\text{GP}y}$.

Figure 18. Input impedance of a bowtie slot as a function of the bowtie angle ϕ_{bow} .

Figure 19. Input impedance of a bowtie slot as a function of frequency.

7. BOWTIE SLOT ANTENNA

A bowtie slot antenna is created by linearly increasing the width of a straight slot antenna, shown in Fig. 1, from its center to both ends (see Fig. 15). The following parameters specify the bowtie: the inner width w , radial length r_{bow} , and bowtie angle ϕ_{bow} .

A bowtie cut in a conducting sheet of finite extent ($s_{\text{GP}x} \times s_{\text{GP}y} = 1\lambda_3 \times 1\lambda_3$, where λ_3 is the wavelength in free space at 3 GHz) is investigated in this section, where the bowtie length and the inner width are fixed to be $2L = 0.5\lambda_3$ and $w = 0.03\lambda_3$, respectively [13]. The excitation of this half-wavelength bowtie is performed with a voltage source located at $x = 0$.

Here we describe the effects of the bowtie angle ϕ_{bow} on the antenna characteristics. Figures 16 and 17 show, respectively, the radiation pattern and gain as a function of ϕ_{bow} . The effects of the bowtie angle on the radiation pattern are more noticeable in the x - z plane than in the y - z plane. As the bowtie angle increases, the half-power beamwidth in the x - z plane gradually increases, leading to the gradual decrease in the gain. The gain is approximately 5.2 dBi at $\phi_{\text{bow}} = 45^\circ$ and 2.6 dBi at $\phi_{\text{bow}} = 60^\circ$.

Note that the gain at $\phi_{\text{bow}} = 0^\circ$ in Fig. 17, which is the gain of a half-wavelength straight slot in a $1\lambda_3 \times 1\lambda_3$ conducting sheet, is approximately 5.5 dBi. This value is

Figure 20. Half-power beamwidths of a bowtie slot as a function of frequency.

Figure 21. Gain of a bowtie slot as a function of frequency.

3.3 dBi higher than the gain of a half-wavelength straight slot cut in an *infinite* conducting sheet (approximately 2.2 dBi, as described in Section 5).

Figure 18 shows the input impedance as a function of the bowtie angle ϕ_{bow} . The impedance seamlessly changes

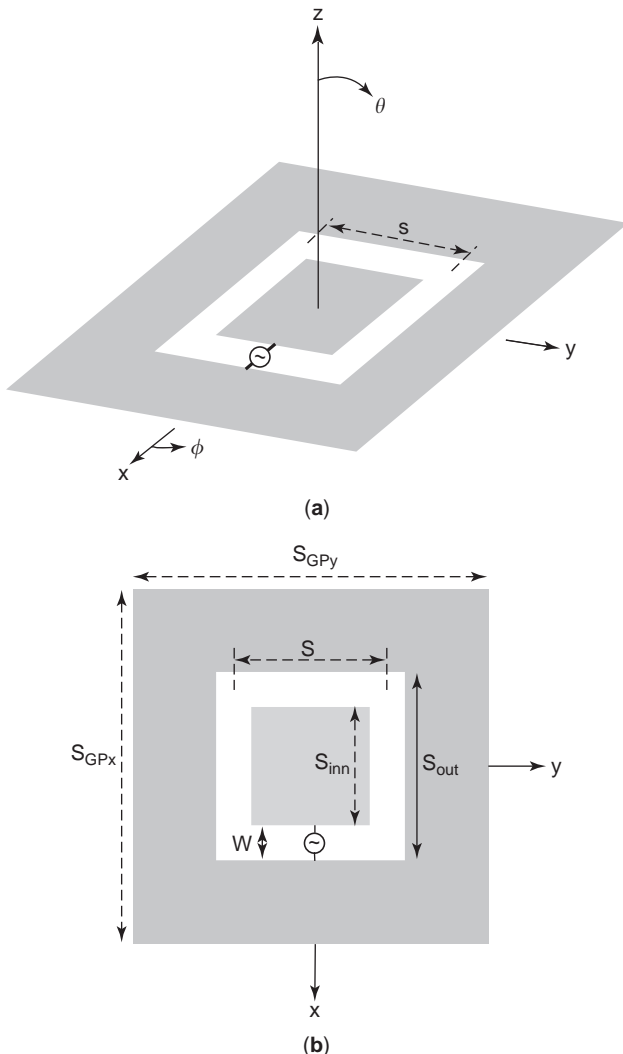

Figure 22. Loop slot antenna: (a) perspective view; (b) top view.

Figure 23. Input impedance of a loop slot as a function of the circumference.

with the bowtie angle. From this fact it is expected that the input impedance will vary smoothly when the frequency is changed. Figure 19 confirms this expectation, where the bowtie angle is chosen to be $\phi_{\text{bow}} = 45^\circ$.

We further investigate the frequency response of the bowtie with $\phi_{\text{bow}} = 45^\circ$. Figures 20 and 21 show, respectively, the half-power beamwidth and gain as a function of frequency. It is found that an average value of the half-power beamwidths in the two principal planes (x - z and y - z planes) is relatively constant below 3.5 GHz, corresponding to a relatively constant gain at frequencies below 3.5 GHz. The lower gain at 4 GHz corresponds to the wider half-power beamwidths.

8. LOOP SLOT ANTENNA

The slots analyzed in the previous sections have distinct ends, while the slot in this section forms a loop (see Fig. 22). The loop is specified by the outer side length s_{out} and inner side length s_{inn} . The slot width is given as $w = \frac{1}{2}(s_{\text{out}} - s_{\text{inn}})$ and an average value of the outer and inner lengths of the loop (simply called “loop circumference”) is given as $4s$, where $s = \frac{1}{2}(s_{\text{out}} + s_{\text{inn}})$. The loop slot is excited with a voltage source on the x axis.

First, we analyze the loop slot under the condition that the loop is cut in a conducting sheet of infinite size ($S_{\text{GPx}} = \infty$ and $S_{\text{GPy}} = \infty$) [14]. Figures 23 and 24 show, respectively, the input impedance and the radiation pattern as a function of the loop circumference $4s$, where the frequency and the slot width are fixed to be $f = 3 \text{ GHz}$ and $w = 3 \text{ mm} = 0.03\lambda_3$, respectively. It is found that the input impedance becomes purely resistive at two loop circumferences below $1\frac{3}{4}$ wavelengths. It is also found that, as the loop circumference $4s$ is increased, the radiation pattern in the x - z plane becomes increasingly asymmetric with respect to the z axis. Note that the radiation pattern in the y - z plane is always symmetric with respect to the z axis.

The cross-polarization component in the y - z plane (E_θ) is due to the radiation from the two x -directed slots, which are part of the loop slot (one is located on the $+y$ side of the x - y plane, and the other is located on the $-y$ side of the x - y plane). The electric field distributed along the

$$f = 3 \text{ GHz}, w = 0.03\lambda_3, s_{GPx} = s_{GPy} = \infty$$

Figure 24. Radiation pattern of a loop slot as a function of the circumference.

x -directed slot on the $+y$ side has the same amplitude as that along the x -directed slot on the $-y$ side. However, the phase difference between these electric fields is 180° . Therefore, the resulting radiation field E_θ in the z direction is always zero. The radiation pattern of the E_θ depends on the distance between these two slots.

The asymmetric pattern in the x - z plane and the increase in the intensity of the E_θ component in the y - z plane affect the gain in the z direction, $G(\theta = 0^\circ)$. Figure 25 shows the gain as a function of the loop circumference $4s$. A gain of approximately 4 dB_i, observed at $4s = 1\frac{1}{2}\lambda_3$, is decreased to 1.1 dB_i at $4s = 1\frac{3}{4}\lambda_3$.

Figure 25. Gain of a loop slot as a function of the circumference.

The discussion above is based on the condition that the conducting sheet, in which the loop slot is cut, is of infinite extent. It is worth comparing the radiation characteristics of a loop slot in an infinite sheet with those of a loop slot in a finite sheet [14]. For comparison, we choose the loop circumference to be $4s = 1\lambda_3$.

Figures 26a and 26b show the radiation patterns of the loop slot in an infinite sheet and a finite sheet, respectively, where the finite sheet is square with side lengths $s_{GPx} = s_{GPy} = 1\lambda_3$. It is found that, in the x - z plane, an almost omnidirectional radiation pattern is obtained for the infinite sheet, while a figure-eight-shaped radiation pattern is obtained for the finite sheet. The difference in the radiation patterns appears as a difference in the gains; the gain for the infinite sheet is 3.0 dB_i and the gain for the finite sheet is 5.4 dB_i. Note that the input impedance for the finite sheet ($s_{GPx} = s_{GPy} = 1\lambda_3$) is found to be almost equal to that for the infinite sheet.

9. CURL SLOT ANTENNA

The radiation from the straight, bowtie, and loop slot antennas in the previous sections is linearly polarized. The radiation from the curl slot antenna to be discussed in this section is circularly polarized. Note that the curl is a simplified spiral structure with an extremely small number of turns.

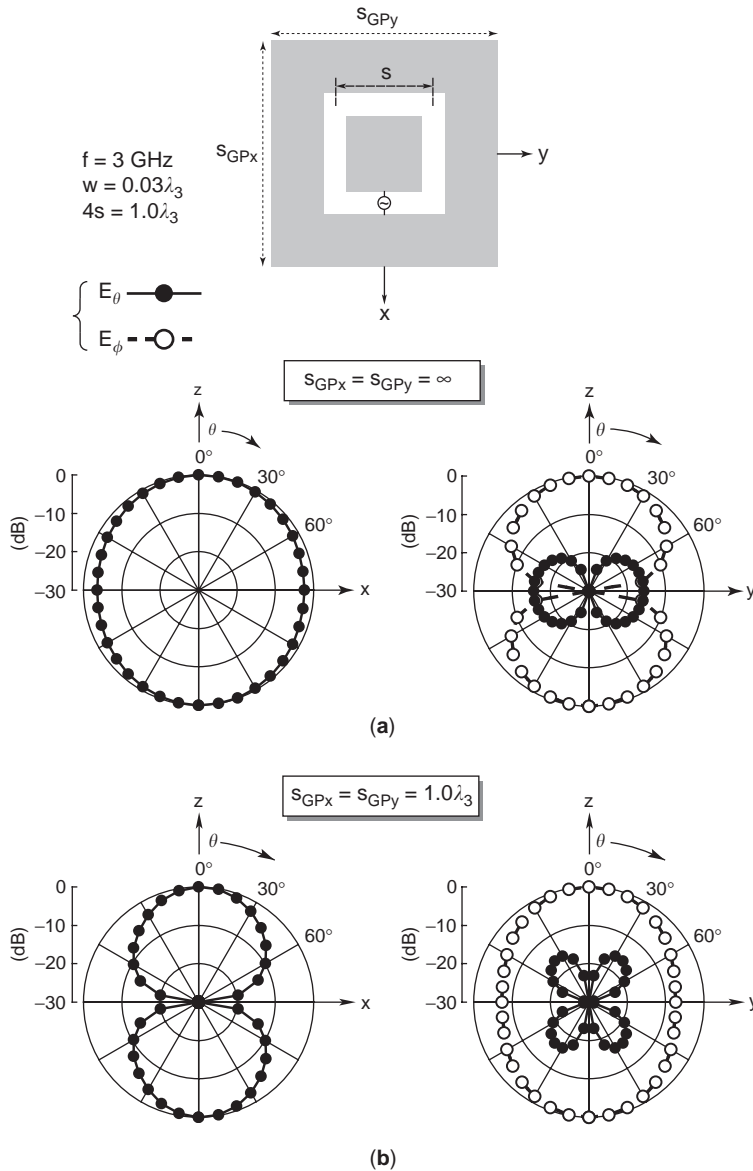

Figure 26. Radiation patterns: (a) loop slot cut in an infinite conducting sheet; (b) loop slot cut in a finite conducting sheet.

9.1. A Circularly Polarized Wave from a Curl Slot Antenna

Figure 27 shows a curl slot cut in the upper conducting plate of a triplate transmission line. The curl slot is defined by an Archimedean spiral function of $r = a_{sp}\phi_s$, where r is the radial distance from the center of the curl to the centerline of the slot arm, a_{sp} is the spiral constant, and ϕ_s is the winding angle (starting at ϕ_{st} and ending at ϕ_{end}). The width of the curl slot is denoted by w .

A feed stripline of width w_{strip} , which is made from the middle plate of the triplate, is sandwiched by dielectric sheets of low relative permittivity ϵ_r . The feed stripline is not in contact with the curl slot. The electromagnetic energy flowing along the stripline is coupled to the curl slot at point P_c . This kind of coupling is called *proximity coupling*. Note that the length of the stripline from point P_c to the open end P_e is chosen to be one-quarter wavelength at the design frequency.

The curl slot is designed to radiate a circularly polarized wave at 11.85 GHz. For this, we optimize the end angle of the curl ϕ_{end} by observing the axial ratio [17]. Figure 28 shows the axial ratio AR as a function of ϕ_{end} . It is found that the radiation is circularly polarized near $\phi_{end} = 8.16\pi \text{ rad} \equiv \phi_{end, opt}$. In the following discussion, we fix the end angle to be $\phi_{end, opt}$.

The radiation from the curl slot is unidirectional by virtue of the lower conducting plate of the triplate transmission line (which acts as a reflector). Figure 29 shows unidirectional radiation patterns, where the radiation field is decomposed into two components: a right-hand circularly polarized wave component E_R and a left-hand circularly polarized wave component E_L . The E_R component results from a dominant magnetic current flowing from the inner slot end toward the outer slot end. Note that the E_L component results from a minor reverse magnetic current flowing from the outer slot end toward the

Figure 27. Curl slot antenna: (a) perspective view; (b) top view; (c) side view.

inner slot end. The E_L component is undesirable because it deteriorates the axial ratio.

Figure 30 shows the axial ratio as a function of frequency. The frequency bandwidth for a 3-dB axial ratio criterion is calculated to be 6.2%. Within this axial ratio bandwidth the directivity in the z direction is relatively constant with a maximum value of approximately 6.4 dB.

Figure 28. Axial ratio of a curl slot as a function of the end angle.

Figure 29. Radiation pattern of a curl slot.

Figure 30. Axial ratio of a curl slot as a function of frequency.

Note that impedance matching between the triplate transmission line and the curl can be performed by inserting a matching network (e.g., quarter-wavelength transformer) into the feed stripline.

Figure 31. Dual-curl slot array.

9.2. Dual-Curl Slot Array

We are able to realize a high-gain antenna radiating a circularly polarized wave by arraying radiation elements. Figure 31 shows an example of such arrays, where the array element (array unit) is a pair of curl slots, whose outer slot arm ends are connected to the ends of a short straight slot. This array element is called a *dual-curl slot* (DCS) or *dual-spiral slot*. The DCS has the advantage that it is simultaneously coupled to a single feedline.

Figure 33. Spiral slot antenna: (a) perspective view; (b) top view.

Figure 32. Radiation pattern of a dual-curl slot array: (a) radiation pattern in the x - z plane; (b) radiation pattern in the y - z plane.

The design procedure for the DCS array and the optimized configuration parameters of the DCS are presented in Ref. 18. Figure 32 shows an example of the measured radiation patterns of a DCS array antenna, where 254 DCS elements are used. These elements are excited with the same amplitude and phase. This array antenna shows a gain of more than 31 dB within a frequency range of 11.7–12 GHz (direct-broadcasting satellite frequency band).

10. SPIRAL SLOT ANTENNA

It is known that a spiral *wire* antenna of *infinitely* long arms has wideband characteristics with respect to the radiation pattern, input impedance, and gain [28]. In this section, we use a slot arm, instead of the wire, as shown in Fig. 33. Note that the arm length is finite, as opposed to that of the wire spiral, and the conducting sheet is assumed to be of infinite extent ($s_{GPx} = \infty$ and $s_{GPy} = \infty$) [20].

The antenna is composed of two arms, each having N straight slots of width w . The first slot length along its center line is s_1 , and the n th slot length is $s_n = 2(n - 1)s_1$, $n = 2, 3, \dots, N$. The spiral slot is excited at point o (the coordinate origin) with a voltage source.

$$w = 2.0 \text{ mm}, s_1 = 2.0 \text{ mm}, N = 10, S_{GPx} = S_{GPy} = \infty$$

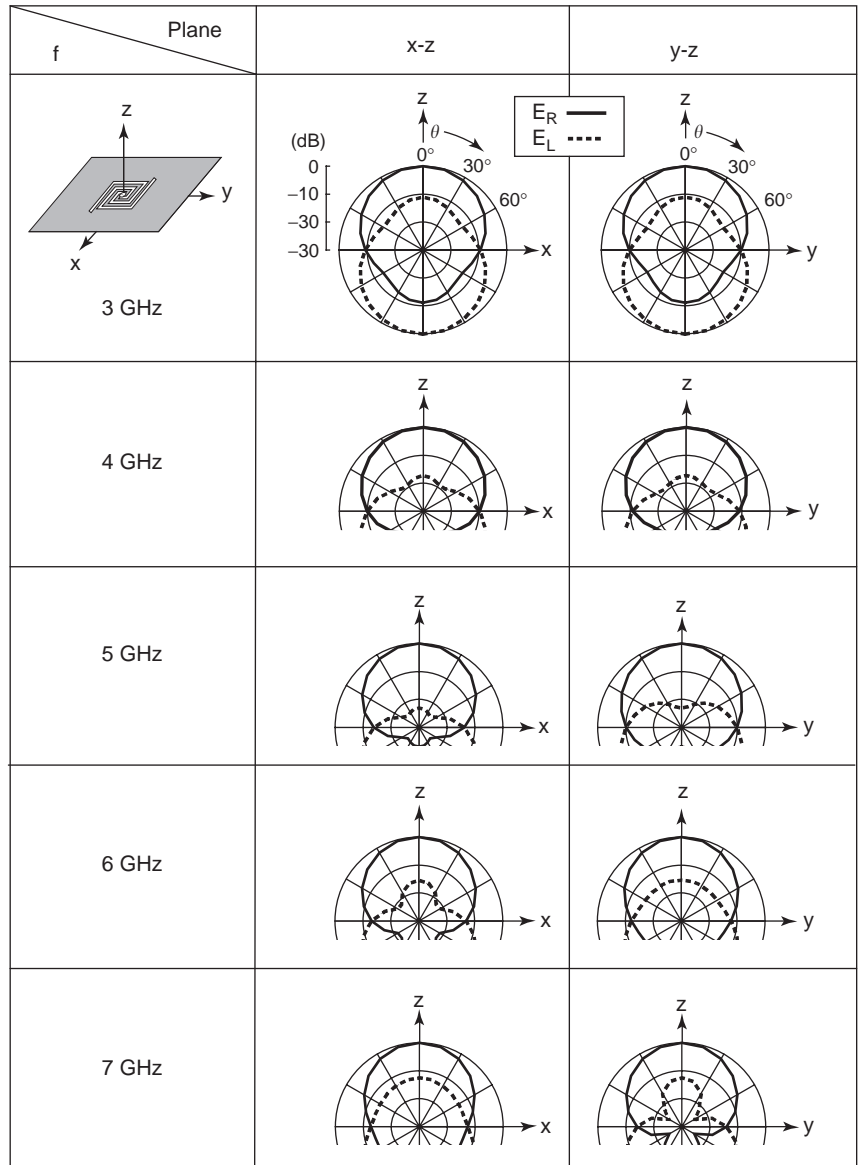

Figure 34. Radiation pattern of a spiral slot antenna as a function of frequency.

The periphery of the spiral, defined as $C_{\text{spiral}} = 4s_N$, must be more than one wavelength to support first-mode radiation [28], which yields a circularly polarized wave. The spiral to be considered here has a periphery of $C_{\text{spiral}} = 1.4\lambda_3$ at 3 GHz, satisfying the requirement for first-mode radiation.

Figure 34 shows the radiation pattern as a function of frequency. The radiation pattern is symmetric with respect to the x - y plane and only half of the radiation pattern is illustrated except at 3 GHz. It is found that the bidirectional radiation is circularly polarized around the z axis.

As seen from Fig. 34, as the frequency increases, the half-power beamwidth gradually decreases. This gradual decrease in the half-power beamwidth leads to a mild variation in the gain, as shown in Fig. 35. The gain

variation within the 3–7 GHz frequency band is only approximately 1.6 dBi.

In addition to the gain, the input impedance also has a wideband characteristic. Figure 36 shows the input impedance as a function of frequency. It is revealed that the input impedance in this analysis range is almost purely resistive with a relatively constant value.

11. ADDITIONAL INFORMATION

Applications of straight slots for array antennas are found in the literature [2,3,21,22]. The straight slots in Ref. 2 and in Chap. 12 of Ref. 3 are cut in a rectangular waveguide, and those in Refs. 21 and 22 are cut in the upper plate of a radial waveguide. Note that the radiation from

Figure 35. Gain of a spiral slot antenna as a function of frequency.

Figure 36. Input impedance of a spiral slot antenna as a function of frequency.

the arrays in Refs. 2 and 3 is linearly polarized and that from the arrays in Refs. 21 and 22 are circularly polarized.

The bowtie in Section 7 is composed of two identical triangular slots. A recent study reveals that a bowtie antenna composed of two different-size triangular slots has a dual-frequency operation mode. The design process for realizing resonances at 2.45 and 5.2 GHz is presented in Ref. 23.

The loop slot in Section 8 radiates a linearly polarized wave. It is possible to obtain a circularly polarized wave by making use of a loop slot structure. Figure 37 shows such a loop slot structure, where the loop slot, cut in the upper conducting plate of a triplate transmission line, has two perturbation sections of length d_p and width w_p [24]. These perturbation sections are designed to generate a traveling-wave magnetic current along the slot [25]. Figure 38 demonstrates that the radiation from the slot is circularly polarized with the help of the perturbation sections. Note that, since the lower plate of the triplate acts as a reflector, the radiation becomes unidirectional, as was the case for the curl slot antenna discussed in Section 9.

Finally, a numerical experiment based on a relationship between a thin-slot element and a thin-wire element is worth mentioning. A slot of width w and length s , cut in

a conducting sheet of *infinite* extent, is equivalent to a wire of radius $w/4$ and length s , isolated in free space. The radiation characteristics of the equivalent wire can be analyzed using the method of moments (MoM) [30]. Note that the radiation fields E_ϕ and E_θ obtained using MoM correspond to E_θ and E_ϕ , respectively, for the FDTD. In this article, some slots, each cut in an infinite conducting sheet, are analyzed using both the FDTD and MoM. The FDTD results (see Figs. 6–8, 23–26a, 34–36) are in good agreement with the MoM results (not presented). This agreement confirms the validity of the FDTD results.

Acknowledgments

I appreciate the kind assistance of V. Shkawrytko in the preparation of this manuscript. Also, I would like to thank the following people for their assistance in verifying the results of the analyses: K. Motoyama for Sections 5 and 6 (straight slot antennas), N. Ohki for Section 7 (bowtie slot antennas), M. Seto for Section 8 (loop slot antennas), S. Shimada for Section 9 (curl slot antennas), T. Goto for Section 10 (spiral slot antennas), and T. Nakajima for Section 11 (circularly polarized loop slots).

Figure 38. Radiation pattern of a loop slot antenna radiating a circularly polarized wave.

12. APPENDIX

Equation (13) is written as

$$P = \frac{1}{2Z_0} \frac{1}{\pi^2} \frac{1}{r^2} V_0^2 \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \frac{\cos^2\left(\frac{\pi}{2} \sin \theta \cos \phi\right)}{(1 - \sin^2 \theta \cos^2 \phi)} \times r^2 \sin \theta d\theta d\phi \quad (A.1)$$

Using angles ξ and ζ , which are defined in Fig. 39, Eq. (A.1) is transformed into

$$P = \frac{1}{2Z_0} \frac{1}{\pi^2} \frac{1}{r^2} V_0^2 \int_{\zeta=-(\pi/2)}^{\pi/2} \int_{\xi=0}^{\pi} \frac{\cos^2\left(\frac{\pi}{2} \cos \xi\right)}{1 - \cos^2 \zeta} \times r^2 \sin \xi d\xi d\zeta \quad (A.2)$$

Note that the small surface area ($r^2 \sin \theta d\theta d\phi$) in Eq. (A.1) is replaced with ($r^2 \sin \xi d\xi d\zeta$) in Eq. (A.2). We define I_{integral} as

$$I_{\text{integral}} \equiv \int_0^{\pi} \frac{\cos^2\left(\frac{\pi}{2} \cos \xi\right)}{\sin \xi} d\xi \quad (A.3)$$

Figure 39. Definition of angles ξ and ζ .

Then, Eq. (A.2) is written as

$$P = \frac{1}{2Z_0} \frac{1}{\pi} V_0^2 I_{\text{integral}} \quad (A.4)$$

Replacing $\cos \xi$ in Eq. (A.3) with $1 - v$, we transform Eq. (A.3) into

$$I_{\text{integral}} = \frac{1}{2} \int_0^2 \frac{1 - \cos \pi v}{v} dv \quad (A.5)$$

This can be written as

$$I_{\text{integral}} = \frac{1}{2} \int_0^{2\pi} \frac{1 - \cos x}{x} dx \quad (A.6)$$

where πv in Eq. (A.5) is replaced with x .

Using the cosine integral Ci [see Eqs. (15a) and (15b)], we obtain

$$I_{\text{integral}} = \frac{1}{2} [\ln 2\pi\gamma - \text{Ci}(2\pi)] \quad (A.7)$$

Substituting Eq. (A.7) into Eq. (A.2), P is expressed as

$$P = \frac{V_0^2}{Z_0} \frac{1}{4\pi} [\ln 2\pi\gamma - \text{Ci}(2\pi)] = 73 \frac{V_0^2}{Z_0^2} \quad (A.8)$$

SLOTLINE COMPONENTS

LU FAN
KAI CHANG
Texas A&M University
College Station, Texas

Slotline components, just as the term implies, are the microwave circuit components consisting of slotlines and combinations of slotlines and other transmission lines such as microstrip and coplanar waveguides (CPWs).

Slotline is a nontransverse electromagnetic (non-TEM) uniplanar transmission structure using a single slot etched on a dielectric-supported layer of metal without a backside ground plane [1]. The slotline configuration is useful in circuits requiring high-impedance lines, series stubs, short-circuited ends, and easy series and shunt connections of passive and active solid-state devices without via holes. With its advantages of small size, light weight, and low cost, the slotline has emerged as an alternative transmission line for applications in microwave integrated circuits (MICs) and monolithic microwave integrated circuits (MMICs). These circuits include filters, couplers, ferrite devices, and other components as well as complete circuits.

The slotline can also be combined with the microstrip and CPW for many circuit applications. These types of hybrid combinations allow flexibility in the design of MIC and MMIC components. For example, a wide range of line impedance, compact circuit structure, easier device mounting, and better integration are achievable in printed form. These features have led to many novel circuits such as hybrid couplers, magic Ts, oscillators, mixers, receivers, and antennas. In spite of these numerous advantages and uses, the description of the slotline components is generally hidden in many papers and books. Because of limited space, this article is intended to present merely the typical slotline components. By outlining their basic operation principle, an overview of the general function of the important circuit components is given. The basic characteristics of slotlines, such as wavelength, characteristic impedance, quality factor, and its discontinuities, can be found in *SLOTLINES*.

This article first discusses the fundamental slotline elements such as various T junctions, resonators, and transitions. After these general topics, several kinds of passive slotline integrated circuits are presented through a discussion of filters, hybrid couplers, and nonreciprocal devices. Finally, the applications of slotline to solid-state integrated circuits, that is, mixers, oscillators, modulators, and frequency doublers, are described. These applications are supported by real circuit demonstrations and actual circuit performances. The implementation of solid-state devices for the tuning and switching of resonances is also discussed.

KAI CHANG
Texas A&M University
College Station, Texas

Slotline components, just as the term implies, are the microwave circuit components consisting of slotlines and combinations of slotlines and other transmission lines such as microstrip and coplanar waveguides (CPWs).

Slotline is a nontransverse electromagnetic (non-TEM) uniplanar transmission structure using a single slot etched on a dielectric-supported layer of metal without a backside ground plane [1]. The slotline configuration is useful in circuits requiring high-impedance lines, series stubs, short-circuited ends, and easy series and shunt connections of passive and active solid-state devices without via holes. With its advantages of small size, light weight, and low cost, the slotline has emerged as an alternative transmission line for applications in microwave integrated circuits (MICs) and monolithic microwave integrated circuits (MMICs). These circuits include filters, couplers, ferrite devices, and other components as well as complete circuits.

The slotline can also be combined with the microstrip and CPW for many circuit applications. These types of hybrid combinations allow flexibility in the design of MIC and MMIC components. For example, a wide range of line impedance, compact circuit structure, easier device mounting, and better integration are achievable in printed form. These features have led to many novel circuits such as hybrid couplers, magic Ts, oscillators, mixers, receivers, and antennas. In spite of these numerous advantages and uses, the description of the slotline components is generally hidden in many papers and books. Because of limited space, this article is intended to present merely the typical slotline components. By outlining their basic operation principle, an overview of the general function of the important circuit components is given. The basic characteristics of slotlines, such as wavelength, characteristic impedance, quality factor, and its discontinuities, can be found in *SLOTLINES*.

This article first discusses the fundamental slotline elements such as various T junctions, resonators, and transitions. After these general topics, several kinds of passive slotline integrated circuits are presented through a discussion of filters, hybrid couplers, and nonreciprocal devices. Finally, the applications of slotline to solid-state integrated circuits, that is, mixers, oscillators, modulators, and frequency doublers, are described. These applications are supported by real circuit demonstrations and actual circuit performances. The implementation of solid-state devices for the tuning and switching of resonances is also discussed.

1. BASIC SLOTLINE CONFIGURATIONS

1.1. Slotline T Junctions

Slotline T junctions appear very frequently in slotline-microstrip circuits (double-sided MICs) and slotline-CPW circuits (uniplanar MICs). Figure 1 shows the physical

Figure 1. Various slotline T junctions: (a) coax-slot T; (b) microstrip-slotline T; (c) CPW-slotline T; (d) slotline-microstrip series T; (e) slotline T; and (f) CPW (even mode)-slotline series T. Solid lines show slotlines and CPW lines on the substrate. Dotted lines show microstrip lines on the back side of the substrate.

configurations of various slotline T junctions. In accordance with the input and output transmission lines, the T junctions can be classified into parallel and series types. The parallel T junctions (Figs. 1a–1c) require the unbalanced line (coaxial line, microstrip, or CPW) as an input transmission line, while the series T junctions (Figs. 1d–1f) require the balanced line (slotline). It is necessary to note that the CPW (without bonding wire) in Fig. 1f is the coupled slotline that operates in coupled-slotline mode (also called the CPW even mode). Figure 2 shows equivalent transmission-line circuits and schematic expression of the circuit behavior for the parallel and series T junctions of Fig. 1. The arrows in the figure indicate the electric field distribution in the circuits. For the parallel tee as shown in Fig. 2a when an incident wave fed to port 1 propagates through the input line, at the T junction it will divide into two components that both arrive in phase at ports 2 and 3. For series tee as shown in Fig. 2b when an incident wave fed to port 1 propagates through the input line, at the T junction it will divide into two components that arrive at ports 2 and 3 with a 180° phase difference.

Both series and parallel T junctions can be combined to realize hybrid circuits and balanced circuits. In addition, it is worth mentioning that the T junctions in Figs. 1c, 1e, and 1f can be fabricated using only one side of the substrate. This is a great advantage in developing uniplanar MICs as discussed in later sections.

1.2. Slotline Transitions

To test slotline circuits, a transition between slotline and the measuring transmission lines is necessary. A coaxial (coax) slotline transition is first used for this purpose. To increase the application of slotlines, transitions from slotline to other transmission lines are also useful. Such transitions are slotline to microstrip and slotline to CPW. These three types of transitions discussed in this section are based on the slotline T junctions of Fig. 1. Interested readers may refer to Refs. 1–5.

Figure 2. Equivalent transmission-line models of the slotline T junctions of Fig. 1: (a) shunt model of the slotline T junctions for Figs. 1a–1c; (b) series model of the slotline T junctions for Figs. 1d–1f.

1.2.1. Coax-Slotline Transitions. Figure 3 shows a commonly used coax slotline transition reported by S. B. Cohn [2] in 1969. It consists of a miniature semirigid coaxial line placed at the end of an open slotline. Both the inner and outer conductors of the coaxial line are electrically connected (with solder or epoxy) to the conductive plating on the two sides of the slot. As mentioned above, this transition is based on the coax slotline T junction of Fig. 1a. This T junction works like a power divider with an open termination at one of its output ports. The transition was constructed with a slot width of 0.79 mm on a 1.57-mm-thick Trans-Tech D-16 substrate ($\epsilon_r = 16.3$). The slotline impedance corresponding to these dimensions is about 75Ω. The voltage standing-wave ratio (VSWR) looking into the 50-Ω coaxial line was less than 1.2 over a 500 MHz bandwidth at 3 GHz.

Figure 3. A coax slotline transition that is a wideband transition between slotline and miniature cross section coaxial line. (From Ref. 2 with permission, ©1969 IEEE.)

1.2.2. Microstrip–Slotline Transitions. Microstrip–slotline transitions are transformers between unbalanced and balanced lines. The majority of transitions are based on the well-known concept of the Marchand balun. Since 1969 when the first microstrip–slotline transition was reported, various microstrip–slotline transitions have been developed for double-sided MICs that use a combination of microstrip and slotlines on both sides of the substrate. Various microstrip–slotline transitions are shown in Fig. 4. In Figs. 4a–4e, the transitions consist of uniform and nonuniform impedance stubs as well as soldered and virtually shorted (short-circuited) microstrip stubs. They are based on the microstrip–slotline T junctions of Figs. 1b and 1d with a different termination at one of the T junction output ports. Modeling and experimental investigation on these transitions was carried out by Schuppert [3]. The back-to-back connection of two transitions shown in Fig. 4e has a bandwidth of approximately one decade. The bandwidth of a single transition will obviously be larger than that of two transitions. It was also found that the transition with a microstrip short (circuit) shown in Fig. 4b has a larger bandwidth than the transition with a microstrip open stub. However, its implementation needs a via hole grounding that may sometimes be difficult. The transition shown in Fig. 4f is not based on the type of Marchand baluns, but on a six-port junction. Although this transition has good performance over a broadband from 2 to 9 GHz, it occupies more substrate space.

1.2.3. CPW–Slotline Transitions. Coplanar waveguide and slotline are the fundamental transmission lines and are useful in uniplanar MICs and MMICs. CPW–slotline transitions are realized on one substrate side without metallization on the backside. This feature can significantly reduce the substrate processing complexity and consequently the cost. To fully utilize the advantages of uniplanar structures, the transition between CPW and slotline is necessary. Extensive study and modeling

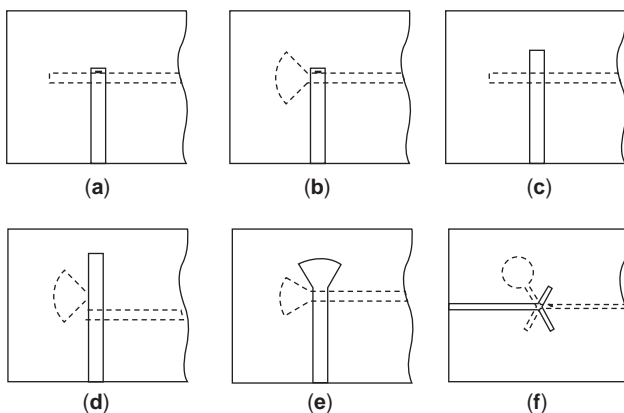

Figure 4. Circuit configurations of microstrip–slotline transitions with different terminations: (a, c) transitions with uniform impedance stubs; (b–e) transitions with nonuniform impedance stubs; (f) double Y-junction microstrip–slotline transition. Solid lines show microstrip lines on the substrate. Dotted lines show slotlines on the backside of the substrate.

Figure 5. Circuit configurations of CPW–slotline transitions with different terminations: (a) a CPW short with a uniform slotline short stub; (b) a CPW short with a nonuniform slotline short stub; (c) a uniform CPW open stub with a uniform slotline short stub; (d) a uniform CPW open stub with a nonuniform slotline short stub; (e) a nonuniform CPW open stub with a nonuniform slotline short stub; (f) a uniplanar double Y-junction CPW–slotline transition.

have been carried out to investigate various transition configurations. CPW–slotline transitions that are equivalent to the microstrip–slotline transitions of Fig. 4 are shown in Fig. 5. They have been evaluated both experimentally [4] and theoretically [5]. The transition in Fig. 5a is based on the CPW–slotline T junction of Fig. 1c. One of the output ports of the T junction is terminated in a quarter-wavelength slotline short stub that provides tuning capability. To improve the bandwidth, the short stub has been replaced by a radial slotline stub in Fig. 5b. Figures 5c–5e show the transition where a quarter-wavelength CPW open stub or a CPW radial stub is used instead of CPW shorts of the transitions in Figs. 5a and 5b. Overall, the transition with nonuniform radial stubs has larger bandwidth than that with uniform stubs. Experimental investigations of these transitions show that the transition in Fig. 5b gives the best performance with a 5.2–1 bandwidth and insertion loss of less than 1 dB. Other transitions of Figs. 5a and 5c–5e have a bandwidth ranging from 1.6:1 to 4.1:1. Similar to the microstrip–slotline transition in Fig. 4f, the transition shown in Fig. 5f uses a double-Y junction between CPW and slotline. This transition has better performance than do other uniplanar transitions except for its need for more substrate room. The measured results of this transition show less than a 1.6 VSWR and 0.7 dB insertion loss for a bandwidth ratio of 6:1.

1.3. Slotline Resonators

Slotline resonators are basic elements served as wavelength measurements, filters, and other MIC components. The slotline resonator is a uniplanar structure etched on one substrate side without back metallization. As shown in Fig. 6a, a half-wavelength rectangular slot is a typical resonator used exclusively for the various filters. If necessary, the rectangular resonator slot can be made by

Figure 6. Slotline resonators: (a) rectangle; (b) rectangle with capacitive loading; (c) bent rectangle; (d) ring.

capacitive loading over a portion of its length to reduce its resonator frequency as in Fig. 6b or by bending it as in Fig. 6c to conserve length with relatively little effect on the resonant frequency.

The slotline ring resonator as shown in Fig. 6d is widely used in many circuit applications [6]. Coupling between the feedlines and slotline ring can be the following three types: microstrip coupling, CPW coupling, and slotline coupling. Figure 7 shows these three possible coupling schemes. The microstrip coupling is a capacitive coupling. The length of input and output microstrip coupling stubs can be adjusted to optimize the loaded Q

Figure 7. Circuit configuration of slotline ring resonator with different coupling schemes: microstrip-fed, CPW-fed, and slotline-fed slotline rings. (From Ref. 9 with permission, © 1993 IEEE.)

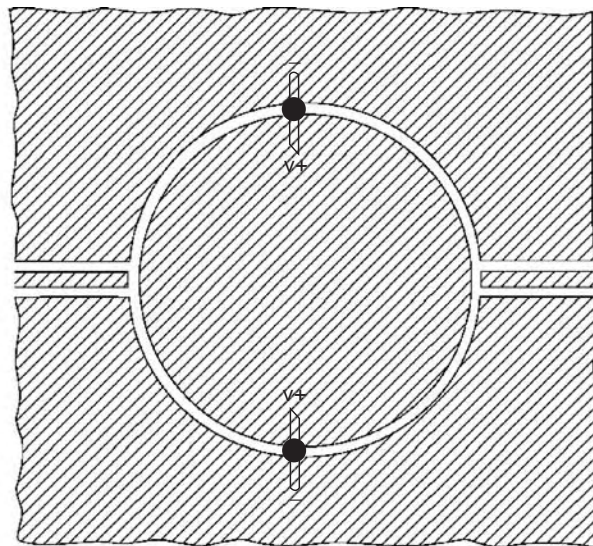

Figure 8. Varactor-tunable slotline ring resonator with CPW feeds. Two 50- Ω CPW lines feed an 85- Ω slotline ring through a 0.05 mm series gap. The ring has a mean radius of 11.26 mm and uses a 0.5-mm slotline on a 0.63-mm-thick RT-Duroid 6010 substrate ($\epsilon_r = 10.5$). (From Ref. 7 with permission, © 1993 IEEE.)

values. However, less coupling may effect the coupling efficiency and cause higher insertion loss. The tradeoff between the loaded Q and coupling loss depends on the application. CPW coupling is also a capacitive coupling and is formed by a small coupling gap between the CPW feed lines and the slotline ring. The loaded Q value and insertion loss are dependent on the gap size. The smaller gap size will cause a lower loaded Q and smaller insertion loss. Unlike microstrip and CPW couplings, the slotline ring coupled to slotline feed is an inductively coupled ring resonator. The metal gap between the slotline ring and slotline feed is for the coupling of magnetic field energy. Therefore, the maximum electric field points of this resonator are opposite those of the capacitively coupled slotline ring resonators.

The last two types of slotline ring resonators are truly coplanar and also allow easy series and shunt device mounting. Varactor diodes can be incorporated into the ring resonators to make the resonant frequencies electronically tunable. For example, Fig. 8 shows varactor-tunable slotline ring resonator [7]. The varactors located at 90° and 270° along the ring tune the even modes of the resonator and allow a second mode electronic tuning bandwidth of more than 22% from 3.13 to 4.07 GHz. The frequency responses of the circuit agree very well with those calculated using a distributed transmission line model.

2. PASSIVE SLOTLINE COMPONENTS

Based on the discussion of the fundamental slotline elements in the previous section, this section describes passive slotline components such as filters, magic Ts, and various hybrid couplers in detail.

2.1. Slotline Filters

The slotline on high dielectric substrate provides a microwave medium for fabricating bandpass and bandstop filters that have been used in MICs. In 1970, Mariani and Agrios [8] reported two types of bandpass filters using the end-coupled and quarter-wave-coupled resonant slots as shown in Fig. 9. For example, a three-resonator end-coupled bandpass filter was designed and constructed on a D-16 substrate ($\epsilon_r = 16.3, h = 1.6$ mm). Important dimensions are shown in Fig. 9b. The distance X was adjusted experimentally for matching external loading of the end resonators. The measured response as shown in Fig. 9c was in reasonable agreement with the design goals. The filter had a 3 dB bandwidth of 145 MHz centered at 2998 MHz. The insertion loss, including the losses of the coax slotline transition, was 4.5 dB, which corresponds to Q_u of about 150.

Slotline bandstop filters are easily implemented by using the combination of slotline and microstrip as shown in Fig. 10a. The slot resonators are etched on the ground

Figure 9. Slotline bandpass filters: (a) configuration of quarter-wavelength-coupled slot resonator filter; (b) circuit configuration of end-coupled slot resonator filter; (c) bandpass response of (b). (From Ref. 8 with permission, © 1970 IEEE.)

plane of the microstrip line, which acts as the terminating line. Such a two-resonator bandstop filter was built on a 1.6-mm-thick D-16 substrate using the same configuration as that in Fig. 10a. The slots had an impedance of 85Ω , were approximately $\lambda_g/2$ long, and had a separation of $3\lambda_m/4$ (λ_m is the wavelength of the microstrip line). Figure 10b shows a rejection response of about 15% at the 20 dB level for the filter.

Another application of slotline–microstrip combination in filters is the microstrip-fed slotline dual-mode bandpass filter [9]. By using microstrip tuning stubs on the backside of the slotline ring at 45° and 135° , the dual resonant mode can be excited. Figure 11a shows the physical configuration of the slotline dual-mode bandpass filter. The microstrip feedlines located at 0° and 270° are used to extract both sine and cosine resonant modes that are orthogonal to each other in the ring structure. Figure 11b shows the measured insertion and return loss as for the slotline dual-mode bandpass filter with mode number $n = 3$. The dual-mode filter has a 12% bandwidth at the center frequency of 3.5 GHz, a stopband attenuation of more than 30 dB, and a sharp gain slope transition. Compared with the microstrip dual-mode filter, the slotline dual-mode filter has a better

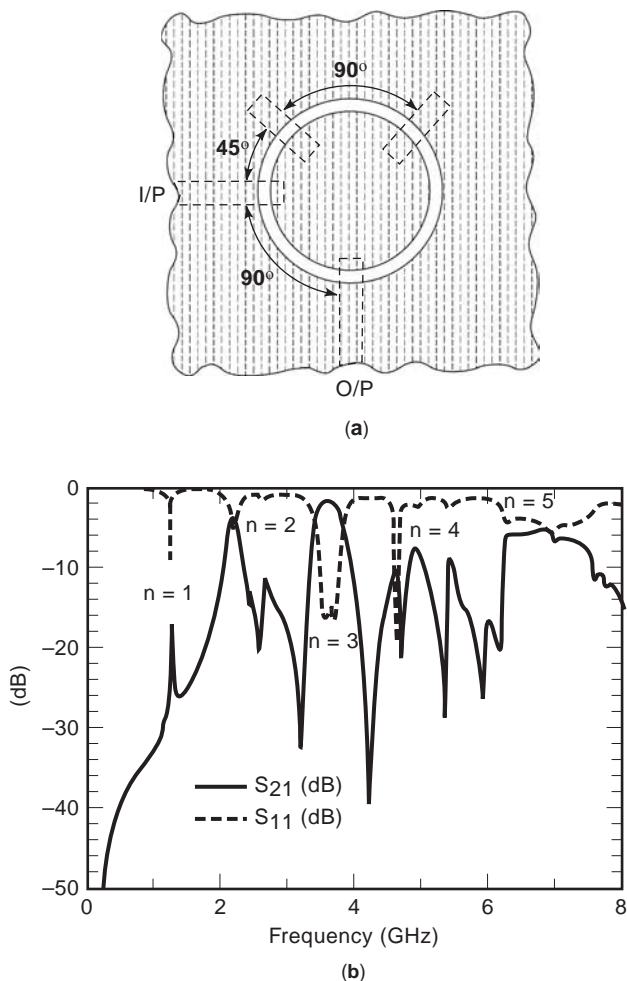

Figure 11. Slotline ring dual-mode bandpass filter: (a) physical circuit etched on a RT-Duroid 6010 substrate ($\epsilon_r = 10.5$, $h = 0.63$ mm); (b) measured frequency responses of insertion loss and return loss. (From Ref. 9 with permission, © 1993 IEEE.)

in-band and out-of-band performance. Also, the slotline ring dual-mode filter has the advantages of flexible tuning and ease of adding series and shunt devices.

2.2. Ferrite Devices

Slotline application to ferrite devices was reported in 1969 when the slotline was first introduced as an alternative transmission line for microwave integrated circuits [10]. Based on the existence of an elliptically polarized magnetic field, slotline was used for the design of planar ferrite phase shifters, circulators, and isolators. The design procedure for the slotline ferrite devices is the same as that for the microstrip line. However, the experimental results reported so far indicate that the performance of the slotline ferrite devices is not superior to those using a microstrip line.

2.3. Slotline Branchline Couplers, Hybrid Couplers, and Magic Ts

Hybrids and couplers form an indispensable component group in modern MIC and MMIC technology. With the inventions of new planar transmission lines like CPW,

slotline, coplanar stripline (CPS), coupled microstrip–slotlines, and their derivatives, many types of hybrids and couplers have been developed over the past several decades. This growth is due to the rapidly expanding applications in wireless communications, radar, sensors, electronic warfare, and space technology.

This section describes different types of slotline branchline couplers, hybrid couplers, and magic Ts and their applications.

2.3.1. Parallel-Coupled Slotline Directional Coupler. The first attempt in fabricating a parallel-coupled slotline coupler was successful by Mariani and Agrios in 1970 [8]. The coupler used a D-16 dielectric substrate ($\epsilon_r = 16.3$, $h = 1.6$ mm) with aluminum tape metallization. The actual circuit dimensions are shown in Fig. 12 along with the measured results. Unlike the backward coupling (electric coupling) in the case of parallel microstrip-coupled line couplers, the coupling of the coupled slotline coupler is magnetic coupling in the forward direction as in the case of the waveguide narrow-wall coupler. As shown in Fig. 12b, the coupler had a 4 dB coupling (3 dB is ideal coupling) over a wideband of about 600 MHz. The insertion loss was nearly 1 dB, which includes the coax-slotline transitions. The isolation bandwidth of 18 dB was 400 MHz centered at 2.8 GHz (about 14% bandwidth). According to their experiments, the reporters indicated that

Figure 12. Parallel-coupled slotline coupler: (a) physical configuration (all dimensions in millimeters); (b) measured frequency responses of insertion loss and return loss. (From Ref. 8 with permission, © 1970 IEEE.)

(1) the performance of the slotline coupler could be improved by optimizing the various important physical dimensions such as the separation, coupling length, and slot width; and (2) a 3 dB coupling implementation in using parallel-coupled slotline is quite practical and a wider bandwidth of 40% is possible.

2.3.2. Uniplanar Branchline Couplers. It is well known that microstrip branchline couplers are basic components in applications such as power dividers, balanced mixers, frequency discriminators, and phase shifters. The concept and analysis of the branchline couplers can be found in many microwave textbooks. This section presents two uniplanar branchline couplers using slotline and CPW structures [4]. The design technique for the slotline branchline coupler uses series branchlines. The design technique for the slotline–CPW hybrid branchline coupler uses shunt branchlines.

Figure 13a shows the physical configuration of the slotline two-branchline coupler [11]. For the case of 3 dB coupling, when a signal is applied to port 1 the outputs appear at ports 2 and 3 and are equal in amplitude and differ in phase by 90°. Port 4 is the isolation port. Figure 13b shows the equivalent transmission-line model of the slotline branchline coupler. The through arms and branch arms are connected in series. The corresponding line characteristic impedances of the slotline through and branch arms, in terms of the termination impedance Z_0 , can be expressed as

pressed as

$$Z_{S1} = \sqrt{2}Z_0; \quad Z_{S2} = Z_0 \quad (1)$$

where Z_{S1} is the characteristic impedance of the slotline through arms and Z_{S2} is the characteristic impedance of the slotline branch arms.

The measured performance is summarized below. The amplitude imbalance of 1 dB is within a bandwidth of less than 20% at the 3 GHz center frequency. The measured isolation between ports 1 and 4 is greater than 30 dB at the center frequency of 3 GHz. A computer program based on the equivalent transmission-line model of Fig. 13b was developed and was used to analyze the circuit. The calculated results agree very well with the measured results.

Another type of uniplanar branch coupler is a slotline–CPW hybrid branchline coupler consisting of a rectangular slotline ring coupled with two parallel slotline feeds. The uniplanar hybrid branchline coupler is dual to the slotline branchline coupler in Fig. 13a. Figure 14a shows the physical configuration of the branchline coupler [13]. The two CPW through arms are fed by input and output slotlines and connected by two slotline shunt branch arms. The equivalent transmission-line model of the coupler is shown in Fig. 14b. Adding bonding wires at the circuit's discontinuities is important to prevent the coupled slotline mode from propagating on the CPW arms. The corresponding line characteristic impedances of slotline and CPW branch arms for 3 dB coupling, in terms of the termination impedance Z_0 , can be expressed as

$$Z_{CPW} = \frac{Z_0}{\sqrt{2}}; \quad Z_S = Z_0 \quad (2)$$

where Z_{CPW} is the impedance of the CPW arms and Z_S is the impedance of the slotline shunt branch arms. According to the Eq. (2), a truly uniplanar hybrid branchline coupler was built on a 1.27-mm-thick RT/Duroid ($\epsilon_r = 10.8$) substrate. To test the hybrid branchline coupler, the wideband slotline–CPW transitions shown in Fig. 4b was connected at ports 1–4. The measurements were performed on an HP-8510 network analyzer using standard subminiature (SMA) connectors. The performance includes two coax CPW transitions and two CPW–slotline transitions. Figure 14c shows the measured frequency responses of the hybrid branchline coupler. Over a 40% bandwidth centered at 3 GHz, the power dividing balance and phase difference between ports 2 and 3 are ± 1 dB and $83^\circ \pm 3^\circ$, respectively. The isolation between ports 1 and 4 is greater than 20 dB, and the return loss is more than 19 dB over the same bandwidth. This slotline–CPW hybrid branchline coupler exhibits superior broadband performance over conventional microstrip branchline couplers.

2.3.3. De Ronde's Couplers. In 1970 de Ronde proposed a new coupler that has been named after him. The de Ronde coupler is particularly suitable for tight coupling such as in 3-dB hybrids in MIC technology. The coupler configuration consists of a microstrip–slotline coupling

Figure 13. Slotline branchline coupler: (a) physical configuration; (b) equivalent transmission-line model. Two branch arms are connected to the through arms in series. (From Ref. 12.)

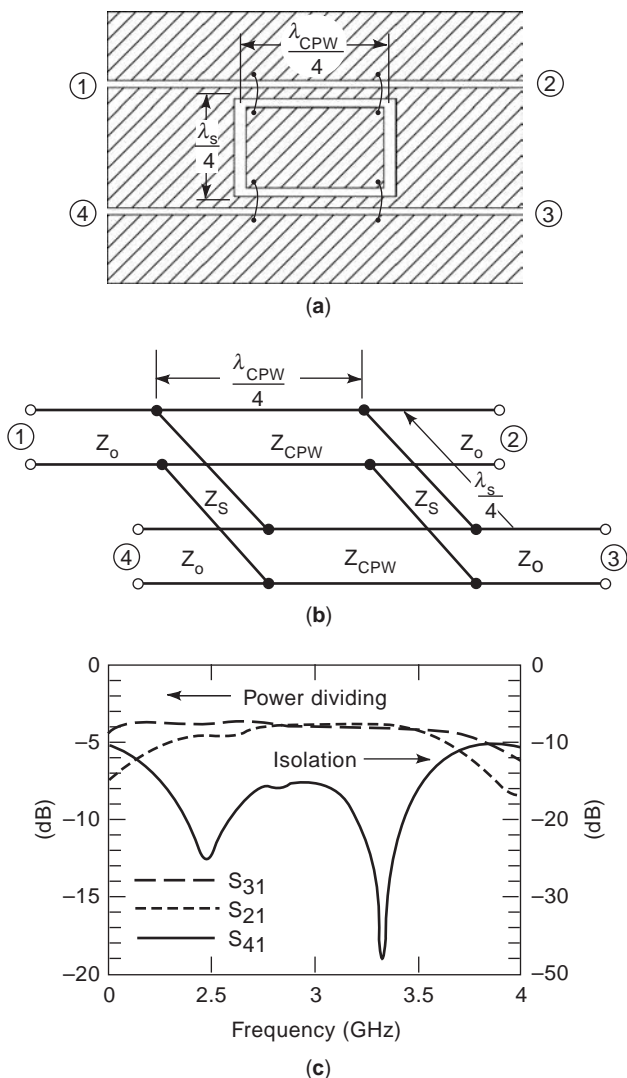

Figure 14. Uniplanar slotline-CPW hybrid branchline coupler: (a) physical configuration; (b) equivalent transmission-line model; (c) measured frequency responses of power dividing and isolation. (From Ref. 4 with permission, © 1993 IEEE.)

section (with a strip on top of the substrate and a slot in the ground plane) connected by four microstrip output lines as shown in Fig. 15a. An analysis of the coupler has been made by Schiek [12] with the aid of the equivalent transmission-line model of the hybrid branchline coupler. From this design theory, an empirical de Ronde's 3-dB coupler was built at X band with a measured performance as shown in Fig. 15b, which is close to the expected behavior. A complete analysis of de Ronde's coupler has been carried out by Hoffman and Siegl [13] using the method of the even-odd mode of four-port network with double symmetry. The scattering parameters of the couplers were derived and the compensated couplers were also demonstrated. In 1995, Ho et al. [14] presented a uniplanar de Ronde CPW-slotline directional coupler. The new coupler uses parallel and series CPW-slotline connections. Both the CPW and slotline are on the same side of substrate. A truly uniplanar de Ronde's CPW-slotline direc-

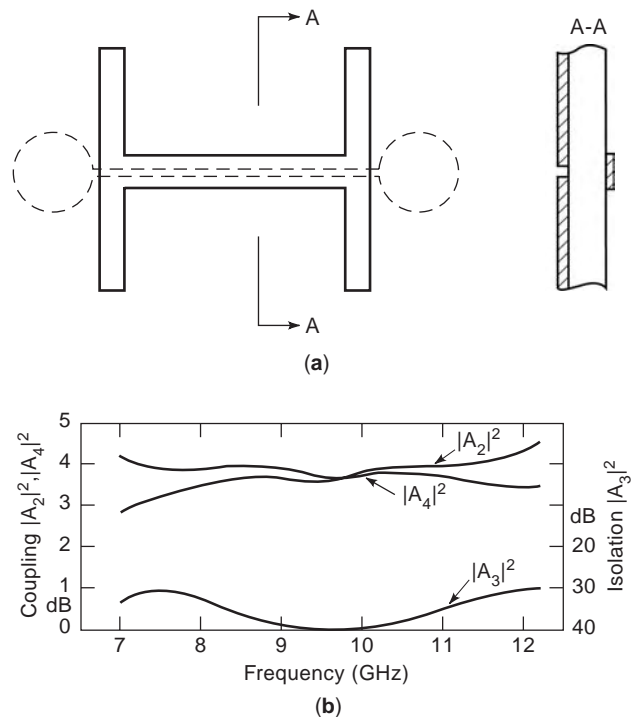

Figure 15. Microstrip-slotline de Ronde coupler: (a) physical configurations (left—top view; right—side view); (b) measured performance for the coupler's couplings and isolation. (From Ref. 14 with permission, © 1974 IEEE.)

tional coupler with 5 dB coupling was demonstrated for use from 2.4 to 3.4 GHz.

Figure 16a shows the physical configuration of the uniplanar de Ronde CPW-slotline directional couplers [16]. The couplers consist of sections of CPW and slotline that are in close proximity and are continuously coupled. The slotline coupling section with a compensation length L_S is terminated with a slotline radial stub on both ends, as shown in Fig. 16a. The purpose of adding an extended slotline section L_S is to compensate for the difference of phase velocity between the even- and odd-mode coupling. The output four ports are formed by two CPW-slotline T junctions. Figure 16b shows the equivalent transmission-line model of the coupler.

To test the coupler, a wideband CPW-slotline transition was used to connect to ports 1-4. The measurements were made using standard SMA connectors and an HP-8510 network analyzer. Experimental results showed that the uniplanar de Ronde coupler achieved a greater than 30% bandwidth from 2.4 to 3.4 GHz, a power coupling of 5.5 dB (including insertion loss), a >14 dB return loss, greater than 17 dB isolation, and $90^\circ \pm 4^\circ$ phase difference between ports 2 and 3. The poor return loss is due to the mechanical tolerances, misalignments, and connectors.

2.3.4. 180° Reverse-Phase Hybrid Ring Couplers. The microstrip ratrace hybrid ring has been widely used in microwave power dividers and combiners. Figure 17a shows the physical configuration of the hybrid ring coupler consisting of three $\lambda_m/4$ sections, $3\lambda_m/4$ delay section, and four

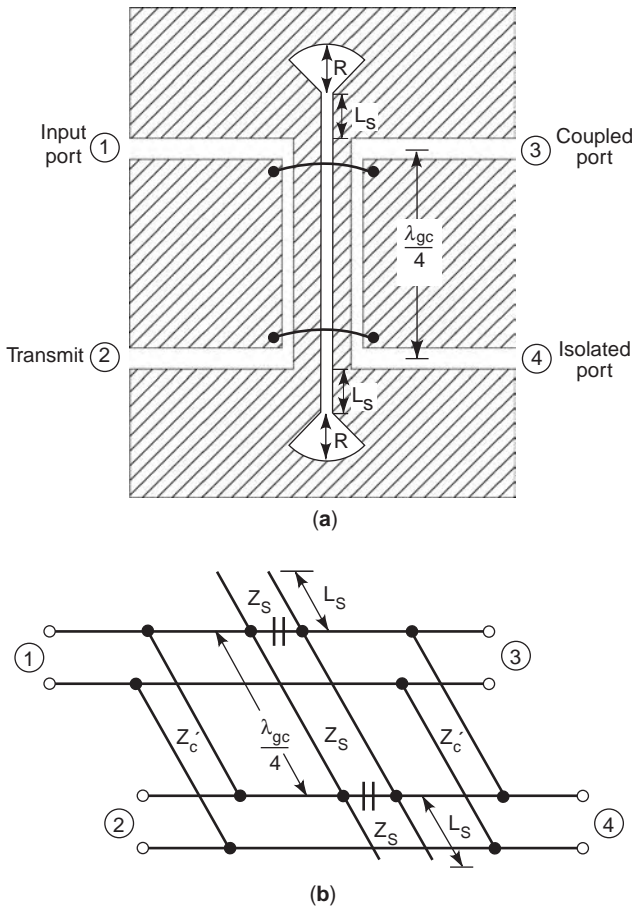

Figure 16. Uniplanar de Ronde CPW-slotline directional coupler: (a) physical configuration; (b) equivalent transmission-line model. (From Ref. 16 with permission, © 1995 IEEE.)

microstrip T junctions. Typically this coupler has a bandwidth of 20–25%. To extend the bandwidth, a modified version of this coupler was proposed by Chua in 1971 [15]. This modified reverse-phase hybrid ring coupler used a $\lambda_s/4$ section of a pair of microstrip-slotline transitions to replace the $3\lambda_m/4$ section of the conventional $3\lambda_m/2$ microstrip ratrace hybrid ring coupler as shown in Fig. 17b. The microstrip-slotline transitions provide a remaining 180° phase delay. Since the phase change of the microstrip-slotline transition is frequency-independent, the resulting reverse-phase hybrid ring coupler has a bandwidth of greater than an octave. Although the modified version gives good performance with a wide bandwidth, the double-sided implementation of a curved $3\lambda_m/4$ microstrip line with an inserted $\lambda_s/4$ slotline is not easy for the photolithography process. Also, ground pins are needed for the microstrip shorts.

More recently, uniplanar transmission lines have emerged as alternatives to microstrip in planar microwave integrated circuits. A narrowband uniplanar hybrid coupler was proposed by Hirota et al. in 1987 [16]. The circuit is based on a slotline ring with three in-phase CPW feeds via an airbridge. More recently, a broadband uniplanar hybrid ring coupler [5] operating over an octave bandwidth was developed using a one-wavelength cross-

Figure 17. Circuit configurations of microstrip hybrid ring couplers: (a) ratrace hybrid ring coupler using microstrip lines only; (b) reverse-phase hybrid ring coupler using a $\lambda_s/4$ slotline section instead of the $3\lambda_m/4$ microstrip line in (a).

over slotline ring and a one-wavelength crossover CPW ring structure. However, these devices consist of $\lambda/4$ sections that occupy large areas in MIC applications and the bandwidth is limited by the electrical linelength. To overcome these problems for monolithic integration, a uniplanar reverse-phase hybrid ring coupler [17] was proposed using a slotline-CPW ring with a 180° reverse-phase slotline-CPW back-to-back balun and four CPW feeds as shown in Fig. 18a. The circuit consists of four CPW-slotline T junctions and one 180° reverse-phase slotline-CPW back-to-back balun that is formed using a pair of slotline-CPW transitions. Figure 18b shows the equivalent transmission-line model. The twisted transmission line represents the 180° reverse-phase CPW-slotline balun. The characteristic impedance of slotline Z_S and CPW Z_C in terms of CPW feedline impedance Z_{co} and θ are given by

$$Z_S = Z_C = Z_{co} \sqrt{2(1 - \cot^2 \theta)} \quad (3)$$

In this design, $\theta = 72^\circ$ (i.e., $\lambda_{gs}/5$) was chosen, resulting in the characteristic impedances Z_S and $Z_C = 66.9\Omega$. The hybrid ring coupler was fabricated on a 1.524-mm-thick RT/Duroid 6010 ($\epsilon_r = 10.5$) substrate. Experimental measurements presented in Fig. 18c show that the hybrid ring coupler has a 1.3-octave bandwidth centered at 4 GHz, a maximum power dividing imbalance of 0.4 dB, and a 2.5° maximum phase imbalance. Compared to microstrip reverse-phase hybrid ring coupler, the reduced-size slotline-CPW hybrid ring coupler has the advantages of uniplanar structure, small size, and broadband operation.

2.3.5. Magic Ts. Magic Ts (also known as “magic tees”) are widely used as 0° and 180° power dividers or combiners in microwave circuits such as balanced mixers, balanced amplifiers, and frequency discriminators. The matched waveguide double-T is a well-known and commonly used waveguide magic T. In 1964, Kraker [18] first proposed a planar magic T that uses an asymmetric coupled transmission-line directional coupler and Schiffman’s phase shift network [19]. In 1980, Aikawa and Ogawa [20] proposed a double-sided magic T that is constructed with

Figure 18. Uniplanar reduced-size reverse-phase hybrid ring coupler: (a) circuit configuration; (b) equivalent transmission-line model; (c) measured frequency responses of coupling, return loss, and isolation. (From Ref. 17 with permission, © 1995 IEEE.)

microstrip–slotline T junctions and coupled slotlines. The two balanced arms of the double-sided magic T are on the same side and do not need a crossover connection. The double-sided magic T has a bandwidth from 2 to 10 GHz.

More recently, uniplanar magic Ts have been preferred for planar microwave integrated circuits because they allow easy series and shunt connections of passive and active solid-state devices without via holes. In 1987, Hirota et al. [16] proposed a uniplanar magic T that uses three CPW–slotline T junctions and a slotline T junction. The in-phase CPW excitation is via an airbridge, and the slotline T junction is used as a phase inverter. The uniplanar magic T has a narrow bandwidth. We next present a double-sided slotline magic T [21], then a uniplanar slotline magic T will be discussed [22]. These two magic Ts are based on a 180° phase reversal of the slotline T junction as shown in Fig. 1e. Finally, a reduced-size uniplanar magic T will be discussed [17] with its equivalent circuit. Since the out-of-phase CPW–slotline T junction is basically frequency-in-

Figure 19. Double-sided slotline magic T with microstrip feeds: (a) physical configuration; (b) equivalent circuit. (From K. Chang, *Microwave Ring Circuits and Antennas*, 180 degree double-sided slotline ring magic-Ts, New York: Wiley & Sons, p 203, © 1996. Reprinted by permission of John Wiley & Sons, Inc.)

Figure 20. Uniplanar slotline magic T using a 180° reversed-phase slotline T junction: (a) physical configuration; (b) equivalent transmission-line model. (From K. Chang, *Microwave Ring Circuits and Antennas*, 180 degree double-sided slotline ring magic-Ts, New York: Wiley & Sons, pp. 207–208, © 1996. Reprinted by permission of John Wiley & Sons, Inc.)

dependent, the resulting magic T has a broad bandwidth with good performance.

2.3.5.1. 180° Double-Sided Slotline Magic T. Figure 19a shows the circuit configuration of the double-sided slotline magic T [21]. The circuit simply consists of a slotline T junction connected to a slotline–microstrip transition and a slotline ring with three microstrip feeds. The slotline T junction is a well-known 180° reverse-phase T junction and is used as a phase inverter in the slotline magic T. In Fig. 19a, ports *E* and *H* correspond to the *E* and *H* arms of the conventional waveguide magic T, respectively. Ports 1 and 2 are the power-dividing balanced arms. The equivalent transmission-line model of the slotline magic T is shown in Fig. 19b. The twisted transmission line represents the phase reversal of the slotline T junction. The

Figure 21. Reduced-size uniplanar hybrid magic T using a $4\lambda_g/5$ circumference CPW-slotline ring that is 20% smaller than comparable designs: (a) circuit configuration; (b) equivalent transmission-line model. The magic T has a bandwidth of 1.6 octaves centered at 4 GHz with a 0.4 dB power dividing imbalance and a 2.5° phase imbalance. (From Ref. 17 with permission, © 1995 IEEE.)

characteristic impedance of the slotline Z_S in terms of the input–output characteristic impedance Z_{S0} is given by $Z_S = \sqrt{2}Z_{S0}$. The radius of the slotline ring is determined by $2\pi r = \lambda_{gs}$, where λ_{gs} is the guide wavelength of the slotline ring. The test circuit was built on a RT/Duroid 6010.8 substrate ($\epsilon_r = 10.8$, $h = 1.27$ mm). Measured results show that the slotline magic T has an excellent isolation of greater than 35 dB and a good power-dividing balance of 0.2 dB over an 80% bandwidth. The calculated results from the equivalent model agreed very well with the measured data.

2.3.5.2. 180° Uniplanar Slotline Magic T. Figure 20 shows the physical configuration of the uniplanar slotline magic T and its equivalent circuit [16]. Similar to the double-sided slotline magic T, the *E* arm of the uniplanar

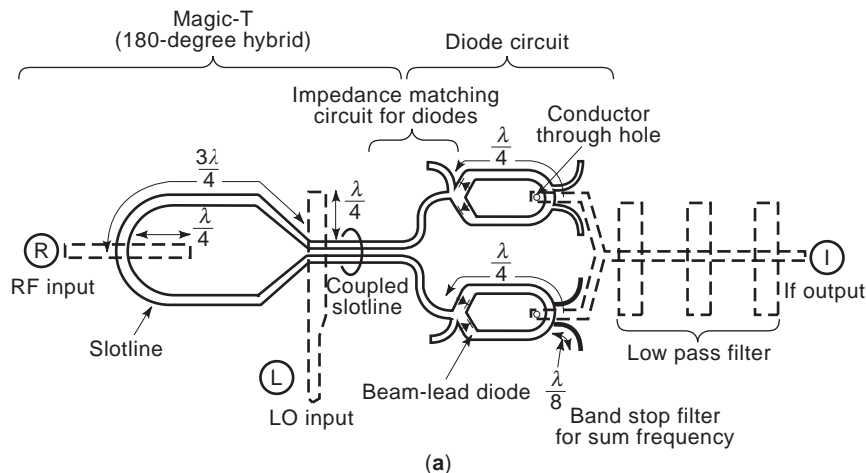

Figure 22. (a) Physical configuration of double-balanced mixer. Solid lines show slotlines and coupled slotlines on the substrate. Dotted lines show microstrip lines on the backside of the substrate. (b) Conversion loss of the mixer. (From Ref. 23 with permission, © 1980 IEEE.)

magic T is fed through a slotline connected to a broadband slotline-CPW transition. The slotline T junction is used as a phase inverter to achieve the 180° phase reversal. The H arm and output balanced arms are all fed by CPW lines. This uniplanar slotline magic T also has good performance over a bandwidth of one octave from 2 to 4 GHz with ±0.25 dB power-dividing balance and ±1° phase balance.

2.3.5.3. Reduced-Size Uniplanar Magic T. Figure 21a shows the circuit configuration of the magic T consisting of one out-of-phase and three in-phase CPW-slotline T junctions [17]. The out-of-phase T junction serves as a phase inverter. In Fig. 21a, ports E and H correspond to the E and H arms of the conventional waveguide magic T, respectively. Ports 1 and 2 are the balanced arms. Figure 21b shows the equivalent transmission-line model of the magic T. The twisted transmission line represents the phase reversal of the CPW-slotline T junction.

3. SOLID-STATE INTEGRATED CIRCUITS (ACTIVE COMPONENTS) USING SLOTLINES

This section presents various microwave integrated circuits such as mixers, oscillators, modulators, and frequency doublers constructed by using slotlines or the combination

of the slotlines and other transmission lines with solid-state devices. A few quasioptical circuits integrated with slotline antennas are also briefly described.

3.1. Mixers

There are three basic types of mixer circuits: single-ended, single-balanced, and double-balanced, which are commonly used in microwave applications. Some examples of planar mixer circuits with slotline follow.

3.1.1. Double-Balanced Mixer. In 1980, Ogawa et al. [23] described a MIC double-balanced mixer. The mixer consists of a magic T for combining the radiofrequency (RF) and local-oscillation (LO) signals, and a balun transition circuit for separating the RF(LO) and intermediate-frequency (IF) signals as shown in Fig. 22a. These circuits are constructed by using combinations of microstrip lines, slotlines, and coupled slotlines, together with four beam-lead Schottky barrier diodes. In Fig. 22a through the magic T, the RF and LO signals are supplied to two pairs of diodes in phase and 180° out of phase, respectively. The IF signal is derived from port I composed of a microstrip low-pass filter, which is used to suppress undesired signals. The diode circuit in Fig. 22a consists of two impedance-matching slotline sections, four λ/4 slotlines, two pairs of

(a)

(b)

Figure 23. Double-double-balanced mixer: (a) photograph of the circuit, chip size $4.57 \times 6.1 \times 0.4 \text{ mm}^3$; (b) detail of dual diode ring connection to the circuit. (From Ref. 24 with permission, © 1991 IEEE.)

beam-lead diodes, six $\lambda/8$ slotline shorted stubs, and two cylindrical conductors used for connecting slotlines and microstrip lines through holes in the substrate. These $\lambda/4$ slotlines are used to utilize effectively the RF and LO pow-

Figure 24. Quasi-optical slotline ring mixer. Four diodes are separated by 90° along the ring, and the basic operation of the mixer is in a balanced polarization-duplexed mode. (From Ref. 25 with permission, © 1983 IEEE.)

ers fed to the diodes. The six $\lambda/8$ slotline shorted stubs serving as bandstop filters are connected to the slotlines in order to suppress the sum frequency.

The double-balanced mixer was fabricated on a 0.3-mm-thick alumina substrate with a dielectric constant of 9.6. Figure 22b shows the measured conversion loss for several LO frequencies. The minimum conversion loss of the mixer is 4.7 dB at a signal frequency of 9.6 GHz, and isolation between the three ports is greater than 20 dB from 18 to 21 GHz. This type of double-balanced mixer can be easily fabricated using ordinary MIC techniques and can be applied to other balanced devices like balanced modulators and upconverters.

3.1.2. Uniplanar Double-Double-Balanced MMIC Mixer.

An arrangement for a double-double-balanced mixer (DDBM) using slotlines, coplanar waveguides (CPW), and coplanar strips (CPSs) is shown in Fig. 23 [24]. The DDBM is composed of a 180° hybrid, an IF balun, and eight GaAs Schottky diodes. The circuit uses a balanced LO input and an unbalanced RF input. The LO signal is applied to the difference port, and the RF signal is fed to the sum port. The 180° hybrid couples the RF signal in phase and LO signal opposite phase to the diodes. Matching between the hybrid and diodes is accomplished by a slotline section and a CPS section in cascade. The IF output is through the IF balun consisting of a CPW-slotline transition followed by a slotline-CPS transition.

The MMIC mixer was fabricated on a 0.4-mm-thick GaAs substrate without the use of via holes. The resulting DDBM operated over a RF bandwidth of 6 GHz, a LO bandwidth of 8–18 GHz, and IF bandwidth of 2–7 GHz with conversion loss ranging from 6.2 to 9.8 dB. Isolations

between the three ports were all greater than 20 dB. The mixer was analyzed using the harmonic-balance method, and the measured and simulated results were in reasonable agreement.

3.1.3. Quasioptical Slotline Ring Mixer. The slotline ring discussed in the previous section was also used as an antenna to build a quasioptical mixer [25]. Figure 24 shows the circuit arrangement. The RF signal arrives as a horizontally polarized plane wave incident perpendicular to the antenna. The LO signal is vertically polarized, and can arrive from either side of the structure. V_{LO} and V_{RF} are the electric field vectors on the antenna plane. By resolving each vector into two perpendicular components, it is easy to see that the mixer diode D_1 receives $(V_{LO} - V_{RF})/\sqrt{2}$, while D_2 receives $(V_{LO} + V_{RF})/\sqrt{2}$. In effect, each diode has its own independent mixer circuit with the intermediate-frequency (IF) outputs added in parallel. The IF signal appears as a voltage between the central metal disk and the surrounding ground plane and is removed through an RF choke. A double-balanced mixer

with improved isolation can be made by adding two additional diodes D_3 and D_4 , as indicated.

The antenna mixer has good LO-to-RF isolation because of the symmetry provided by the balanced configuration. A conversion loss of 6.5 dB was measured for this quasioptical mixer operating at X band.

3.2. Oscillators

Oscillators are one-port circuits generating sinusoidal signals, and are widely applied in microwave transmission and measurement systems. Early oscillator circuits were made using waveguide or coaxial-line technology. Modern designs are often made in planar technology such as microstrip, CPW, slotline, and their combination technologies as well as MIC and MMIC technologies. Examples of oscillator circuits using slotlines follow.

3.2.1. MMIC Varactor-Tuned Oscillator Using a Slotline Resonator. Varactor-tuned oscillators provide more constant output power, wider tuning range, and faster

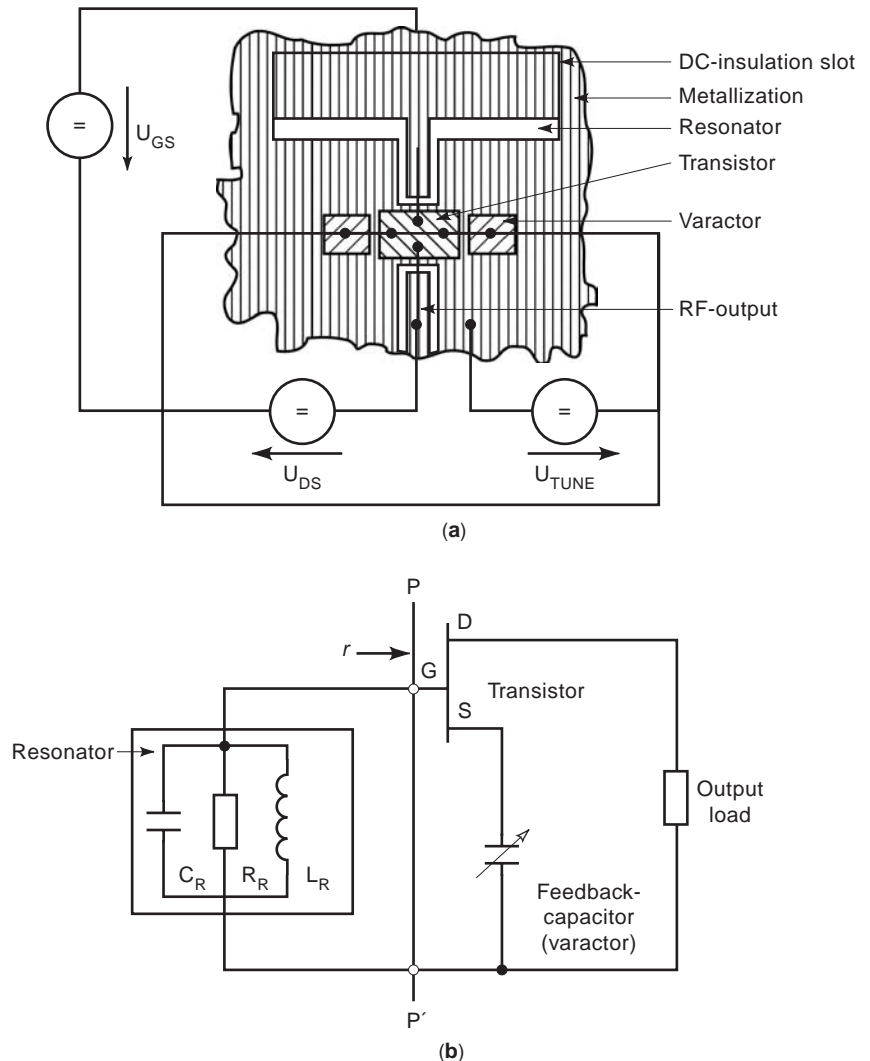

Figure 25. MMIC varactor-tuned oscillator using slotline resonator: (a) physical configuration; (b) equivalent circuit for calculation of RF behavior. (From Ref. 26, reprinted with permission from *Microwave Journal*, Sept. 1990, p. 223.)

response than those of bias tuning oscillators. Figure 25a shows an MMIC varactor-tuned oscillator using a slotline resonator proposed by Roth et al. [26] in 1990. The oscillator was driven by a GaAs field-effect transistor (FET) connected in common source with a capacitive serial feedback. Coupling was realized by a GaAs varactor integrated on the same substrate with the FET. A slotline resonator was built as a linear resonator with coplanar waveguide (CPW) coupling to the FET gate. Bonding wires were used to connect the circuit elements while the output CPW connection was made with a microwave probe. The equivalent circuit of the oscillator as shown in Fig. 25b was used for circuit simulation and predicting circuit performance. The capacitive serial feedback of the FET provides a reflection coefficient r greater than unity in the plane $p-p'$. The resonant frequency was determined by the resonant circuit and the feedback varactor. A test circuit was fabricated and measured. A tuning range of nearly one octave was achieved with 10 mW output power. The experimental results had good agreement with the calculated electrical properties.

Another varactor-tuned oscillator driven by a Gunn diode was built on CPW and slotline [27] as shown in Fig. 26a. The circuit consists of a Gunn diode, a varactor diode, a CPW resonator, a slotline lowpass filter for RF choke and diode biases, and a slotline-microstrip transition for coupling power to output. This VCO provides 16.3 ± 0.35 dB output power throughout a 350 MHz tuning range centered at 10.37 GHz. Figure 26b shows the power output as a function of frequency and varactor bias. The output power is fairly constant over the tuning range.

3.2.2. Active Slot Antennas Driven by Oscillators. Slot resonators have been used as radiators for antenna applications. A ring-stabilized Gunn oscillator coupled with a

Packaged Gunn (MA49106) and varactor (MA46602F) diodes from M/A COM were used for the circuit integration. The circuit was fabricated on a 0.635-mm-thick RT/Duroid 6010 substrate ($\epsilon_r = 10.5$). (From Ref. 27 with permission, © 1991 IEEE.)

Figure 27. Gunn oscillator driving slot antenna: (a) circuit configuration; (b) H -plane pattern of the antenna. The antenna circuit was fabricated on RT/Duroid 5880 dielectric substrate of $\epsilon_r = 2.20$ and thickness $h = 1.57$ mm with Gunn diodes of model number MA49135 from M/A COM. (From Ref. 28 with permission, © 1995 IEEE.)

Figure 28. Circuit configuration of an FET active slotline ring antenna. The circuit was etched on RT/Duroid 5870 board with the following dimensions: relative dielectric constant $\epsilon_r = 2.20$; substrate thickness $h = 1.57$ mm; inner radius of the slotline ring $d_1 = 9.54$ mm; outer radius of the slotline ring $d_0 = 11.54$ mm. The active device used in the circuit is an Avantek ATF-26836 FET. (From Ref. 29 with permission from *Electronics Letters*.)

slot radiator to form an active antenna was reported in 1995 [28]. The circuit configuration is shown in Fig. 27a. A circular microstrip ring is used as the resonant element of the oscillator. A slot on the ground plane of the substrate coupled with the microstrip ring served as the radiating element. A Gunn diode is mounted between the ring and the ground plane of the substrate at either side of the ring. A metal mirror block is introduced a quarter-wavelength behind the ring to avoid any backscattering. The operating frequency of the active antenna was designed to be close to the first resonant frequency of the circular microstrip ring. A radiated power of 16 dBm at 5.5 GHz was obtained with the bias level of 12.6 V. The H -plane radiation patterns are shown in Fig. 27b.

An FET oscillator integrated with a slotline ring antenna was also developed [29]. Figure 28 shows the physical configuration. A simple transmission-line method was used to predict the resonant frequency. The FET oscillator-driven slotline antenna radiated 21.6 mW at 7.7 GHz with 18% DC-to-RF efficiency.

3.3. Modulators

A number of digital modulators have been developed for digital communication systems. Digital modulators are classified into three types: the amplitude shift keying (ASK) modulator, the phase shift keying (PSK) modula-

tor, and the frequency shift keying (FSK) modulator. The basic information about modulation can be found elsewhere in this encyclopedia (see the article MODULATION ANALYSIS FORMULA). Here we introduce some examples of modulator circuits using slotlines.

3.3.1. ASK Modulator Using Double-Sided MIC. There are three types of ASK modulators: reflection, transmission, and balanced. Reflection-type modulators need circulators to separate input and output power or hybrid couplers to maintain perfect matching, while transmission-type modulators use isolators instead of circulators. Balanced-type modulators require balanced/unbalanced hybrid transitions for transformation from unbalanced modes to balanced modes, or vice versa. Generally, non-reciprocal components or the matching resistance are necessary to implement ASK modulators.

In 1989, an ASK modulator that does not require circulators and matching resistances was proposed [30]. The circuit using double-sided (slotlines and microstrips) MIC is shown in Fig. 29. It consists of two $\lambda/4$ slotlines, a slotline-microstrip transition, and two beam-lead p-i-n diodes. The measurements for the ASK modulator were performed in the frequency range from 25.0 to 29.5 GHz. A 2.8 dB insertion loss, a 12 dB return loss, and an ON/OFF ratio of greater than 40 dB were obtained. This balanced ASK modulator had a size more compact than that of other types of ASK modulators because no circulators and hybrid couplers were needed, and it had a fairly high ON/OFF ratio because of the balanced circuit configuration.

3.3.2. Integrated Balanced Biphase Shift Keying (BPSK) and Quadriphase Shift Keying (QPSK) Modulators. PSK modulators have two types of reflection and transmission (balanced). The basic principle of the reflection-type PSK modulators is similar to that of the ASK modulators. Transmission-type PSK modulators use the difference in pathlengths for carriers. By selecting a quarter-wavelength for the carrier pathline, a 0° - 180° (BPSK) modulator can be produced. If a one-eighth wavelength of the carrier line is selected, a 0° - 90° (QPSK) modulator can be obtained.

3.3.2.1. Balanced BPSK Modulators. Balanced BPSK modulators are commonly used as digital modulators.

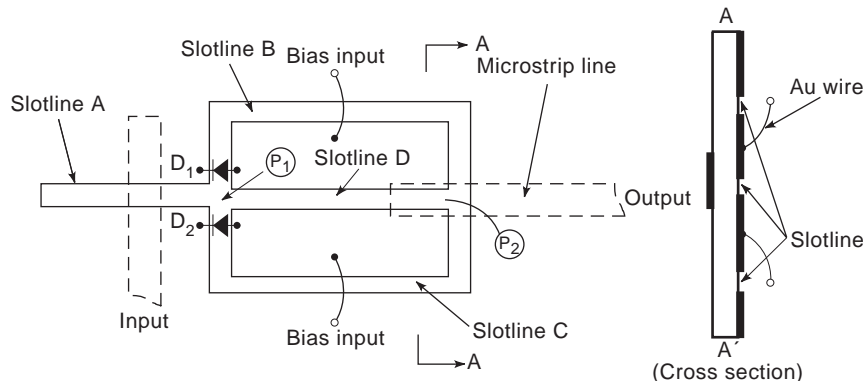

Figure 29. Circuit configuration of the balanced ASK modulator. Solid lines represent slotlines on the substrate. Dotted lines show microstrips on the backside of the substrate. (From Ref. 30 with permission, © 1987 IEEE.)

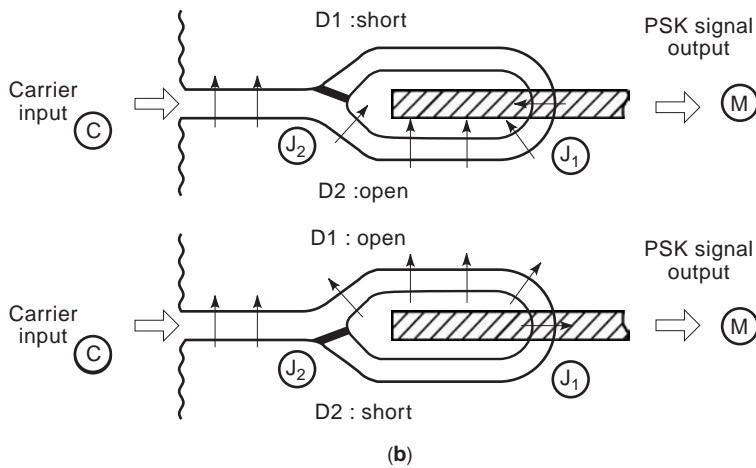

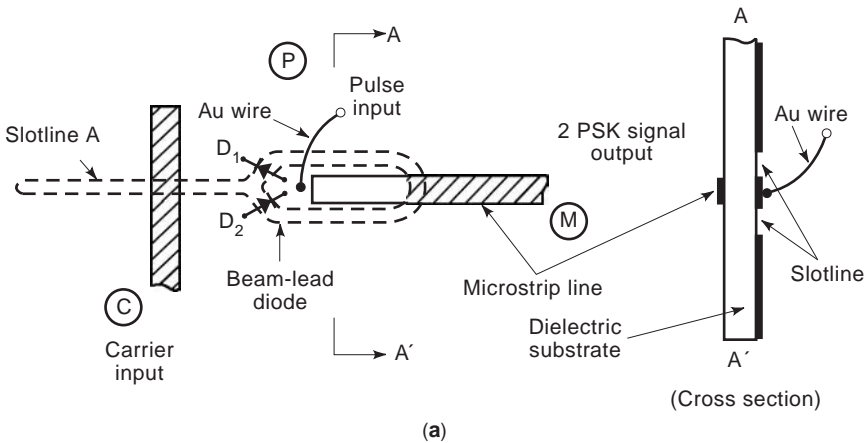

Figure 30. (a) Circuit configuration; (b) operating principle of balanced biphase shift keying (BPSK) modulator. (From Ref. 31 with permission, © 1982 IEEE.)

Figure 30a shows the circuit configuration of a single-balanced BPSK modulator proposed [31] for use in Ka band. The circuit consists of two $\lambda/4$ slotlines, two switching diodes, two slotline–microstrip transitions, and a gold wire used to supply modulating pulses to the diodes. The BPSK modulator operates as shown in Fig. 30b. The arrows represent the electric field of the carrier propagating along the slotlines. When the carrier is supplied to port C, the bias states of the diodes determine which path the carrier takes as the data alternately switch the diodes ON and OFF. The carrier takes path 1 or path 2, producing a biphase output signal because the direction of the electric field at the junction J_1 is 180° out of phase, as shown in Fig. 30b. The modulated carrier is then fed to the microstrip port M through the slotline–microstrip transition. The performance of the BPSK modulator has 2.2 dB insertion loss at a carrier frequency of 27 GHz and a greater than 25 dB isolation over a 1 GHz bandwidth. The phase error and amplitude deviation were less than 1° and 0.5 dB, respectively.

3.3.2.2. Balanced QPSK Modulators. A balanced QPSK modulator is important for digital wireless or satellite communication systems because it allows effective use of frequencies and has also been applied to microwave and millimeter-wave transceivers. A QPSK modulator using

double-sided MIC techniques was reported in 1984 [32] for directly modulating a 60 GHz carrier frequency. Figure 31 shows a block diagram and circuit layout of the QPSK modulator. The circuit consists of a Wilkinson power divider with 90° phase shift in one arm, two biphase switches (BPSK modulators) using coupled slotline–microstrip structure, and a microstrip–waveguide transition at the output.

The circuit operates as follows. The unmodulated RF carrier enters the circuit on microstrip and goes to the in-phase power divider. The carrier is divided into two signals with equal amplitude and in phase. One arm of the power divider drives biphase switch 1 directly. A 90° phase shifter is introduced at the input of biphase switch 2 by increasing the microstrip pathlength between the power divider and biphase switch 2. The biphase switches introduce an additional 0° or 180° phase shift to each signal as the data inputs switch the Schottky diodes. The two biphase-modulated signals are then summed in an in-phase power combiner producing a quadriphase-modulated signal. The QPSK modulator has the following design features and advantages:

1. High isolation between the carrier input port and the modulated carrier output port is obtained because of the balanced configuration.

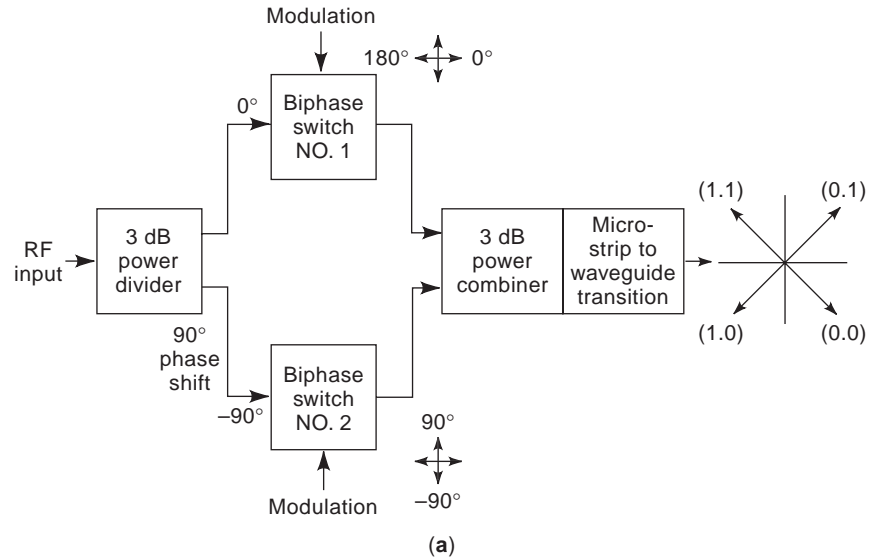

Figure 31. (a) Block diagram; (b) circuit layout of a quadriphase shift keying (QPSK) modulator chip (shown are both sides of the chip). (From Ref. 32 with permission, © 1984 IEEE.)

2. A DC return path is not required because a slotline is used.
3. The 90° phase shift is introduced by an additional pathlength instead of using a 90° hybrid (this simplifies the design since a low-loss, well-balanced 90° hybrid is difficult to realize at 60 GHz).
4. The 180° phase shift is introduced by the built-in field distribution of the slotting.
5. A simple configuration using only a wire bonding is sufficient for a baseband input circuit.
6. Small size is achieved by using a sapphire substrate.

The QPSK modulator chip was integrated with a Gunn voltage-controlled oscillator (VCO), a subharmonic mixer, and a microstrip–waveguide transition to form the RF exciter/modulator module. The modulator demonstrated excellent performance at 60 GHz with an output phase error of less than 3° and maximum amplitude error of 0.5 dB.

3.4. Frequency Multiplier

Microwave and millimeter-wave signals can be generated by frequency multiplication of lower-frequency signals produced by a quartz-controlled generator. Frequency multipliers are usually used to realize this conversion. Figure 32 shows a block diagram of frequency multiplier. A signal of angular frequency ω_0 is fed to a nonlinear device (varactor diodes or transistors), which generates harmonics at angular frequencies $n\omega_0$. The output signal at the desired frequency is then selected by a bandpass filter.

Figure 32. Block diagram of frequency multiplier.

Figure 33. Configuration of an X/K-band quasioptical frequency multiplier. The circuit is built on a thin quartz substrate and mounted on a stycast-filled ($\epsilon_r = 3.9$) parabola. (From Ref. 33 with permission, © 1997 IEEE.)

Two examples of quasioptical frequency multipliers using slot antennas follow.

3.4.1. Quasioptical Frequency Multipliers Using Slot Antennas. Using a uniplanar structure of slotline and CPW, a parabola-feed frequency multiplier for millimeter- and submillimeter-wave signal renovation has been recently reported [33]. The multiplier uses a quadbridge diode configuration to provide effective isolation between input and output signals. Two pairs of double-slot antennas with orthogonal polarizations directly couple input and output signals to the diodes without the need for hybrid couplers in conventional balanced circuits. Figure 33 shows the circuit configuration of the frequency multiplier implemented on a parabola feed with two pairs of slot antennas. The two input antennas receive a vertically polarized signal in phase while sending the signal to the diodes with opposite phase. The output signal generated by the diodes will be transmitted in phase through the two

Figure 34. Configuration of frequency multiplier using microstrip-fed slot array. (From Ref. 34 with permission, © 1987 IEEE.)

horizontally polarized antennas. The input and output signals are then coupled to free space by placing the multiplier circuit on an electrically thick substrate lens (a dielectric-filled parabola in this case). This configuration maintains the same conversion efficiency as single-diode multipliers but quadruples the power-handing capability. Measurement results of an X/K-band multiplier show frequency conversion loss of 6.8 dB at the 20.3 GHz output frequency.

Another quasioptical frequency multiplier using double-sided MIC (coupled slot microstrip) techniques was proposed [34] in 1987. The configuration shown in Fig. 34 uses a meander microstrip line to feed an array of diode-loaded slot antennas that are positioned in correct phase to maximize the radiation performance of the multiplier. A 26 dBm, 5.4 GHz input multiplied to 10.8 GHz, was achieved for the circuit. With a planar structure, controllable power coupling, and flexibility in array geometry, the quasioptical frequency multiplier is suited for MIC and MMIC applications.

The propagation and radiation of high-frequency signals are getting more important as the technology progresses. For example, the clock rate for digital circuitry is over hundreds of megahertz. The booming wireless applications have pushed the low-cost and high-volume products to the gigahertz range. Engineers need to understand the behavior of high-frequency signals to have a proper and efficient layout when they design a new circuit. This article introduces one type of high-frequency transmission line called the slotline. The configuration, terminology, analysis, and applications are discussed in subsequent sections.

A slotline is an uniplanar wave-guiding structure proposed by Cohn in 1968 [1]. Figure 1(a) shows the basic configuration of a slotline. It consists of a narrow slit between two metal planes that are on one side of the substrate. It is different from a microstrip line that has a strip and a ground plane on the opposite sides of a substrate. The substrate property (μ, ϵ) and thickness h , the slot width w , and the metal thickness t are parameters determining slotline characteristics. The electromagnetic fields of a slotline concentrate around the slot region and propagate along the longitudinal direction as depicted in Fig. 1(b). The main electric field lines are on the transverse plane, and there are more lines in the substrate region because it has a higher dielectric constant. The propagation mode is nontransverse electromagnetic (non-TEM). Unlike the non-TEM metal waveguide, the slotline has no cutoff frequency because it has two separated metals. We will use the spectral domain approach to analyze the slotline. The propagation constant and the characteristic impedance are obtained from this rigorous analysis.

Microwave circuits are frequently packaged in a metal shield. That is, the bottom of the substrate in Fig. 1(a) is attached to a metal plane. Figure 2 shows a conductor-backed slotline (CBSL). The additional bottom ground plane provides better mechanical strength and heat-sinking ability. However, the presence of the conductor backing can cause a serious problem, which is power leakage in the transverse direction. This power loss results in undesirable package and crosstalk effects. The leakage phenomenon is easy to understand. Besides the slotline mode, the conductor-backed slotline also supports a parallel-plate mode in a region away from the open slit. A slotline mode is a non-TEM wave and has its fields spread in both the substrate and air regions. A parallel-plate mode is a TEM wave and has all its energy confined in the substrate between two metal planes. Therefore, the effective dielectric constant of a parallel-plate mode is always higher than that of a slotline mode. Under these circumstances, the parallel-plate mode behaves as the dominant mode,

The propagation and radiation of high-frequency signals are getting more important as the technology progresses. For example, the clock rate for digital circuitry is over hundreds of megahertz. The booming wireless applications have pushed the low-cost and high-volume products to the gigahertz range. Engineers need to understand the behavior of high-frequency signals to have a proper and efficient layout when they design a new circuit. This article introduces one type of high-frequency transmission line called the slotline. The configuration, terminology, analysis, and applications are discussed in subsequent sections.

A slotline is an uniplanar wave-guiding structure proposed by Cohn in 1968 [1]. Figure 1(a) shows the basic configuration of a slotline. It consists of a narrow slit between two metal planes that are on one side of the substrate. It is different from a microstrip line that has a strip and a ground plane on the opposite sides of a substrate. The substrate property (μ, ϵ) and thickness h , the slot width w , and the metal thickness t are parameters determining slotline characteristics. The electromagnetic fields of a slotline concentrate around the slot region and propagate along the longitudinal direction as depicted in Fig. 1(b). The main electric field lines are on the transverse plane, and there are more lines in the substrate region because it has a higher dielectric constant. The propagation mode is nontransverse electromagnetic (non-TEM). Unlike the non-TEM metal waveguide, the slotline has no cutoff frequency because it has two separated metals. We will use the spectral domain approach to analyze the slotline. The propagation constant and the characteristic impedance are obtained from this rigorous analysis.

Microwave circuits are frequently packaged in a metal shield. That is, the bottom of the substrate in Fig. 1(a) is attached to a metal plane. Figure 2 shows a conductor-backed slotline (CBSL). The additional bottom ground plane provides better mechanical strength and heat-sinking ability. However, the presence of the conductor backing can cause a serious problem, which is power leakage in the transverse direction. This power loss results in undesirable package and crosstalk effects. The leakage phenomenon is easy to understand. Besides the slotline mode, the conductor-backed slotline also supports a parallel-plate mode in a region away from the open slit. A slotline mode is a non-TEM wave and has its fields spread in both the substrate and air regions. A parallel-plate mode is a TEM wave and has all its energy confined in the substrate between two metal planes. Therefore, the effective dielectric constant of a parallel-plate mode is always higher than that of a slotline mode. Under these circumstances, the parallel-plate mode behaves as the dominant mode,

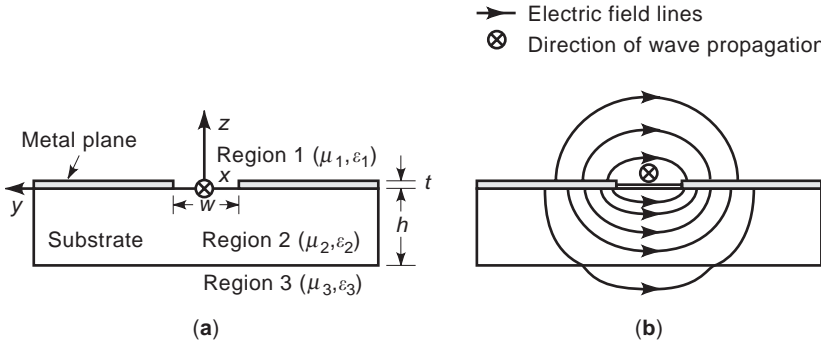

Figure 1. Slotline configuration: (a) cross-sectional view, (b) electric field distribution and wave direction.

and the slotline mode is the first higher order mode on the dispersion curves. Therefore, the energy in the slotline mode tends to leak to the parallel-plate mode. This leaky energy propagates at an angle with the longitudinal direction and is frequency-dependent. A rigorous analysis to predict the leaky performance and some methods to reduce the energy loss are discussed in Section 1.

Slotlines can be built using the same fabrication process for the microstrip line and the coplanar waveguide (CPW). All these transmission lines have planar geometries and are very useful in integrated circuit designs. The easy integration of these structures on a substrate provides an additional design choice. It becomes important to understand completely the transition between different transmission lines. Slotline discontinuities, coaxial-to-slotline, microstrip-to-slotline, and CPW-to-slotline transitions are investigated in this article. Compared with a microstrip line and a CPW, the slotline has high dispersive characteristics and a divergent field distribution. Therefore, the slotline is not commonly used as a long transmission line but rather as a short high-impedance line or a radiating geometry. As another application, the slotline has an elliptically polarized magnetic field that makes it suitable for use with a ferromagnetic material to build a nonreciprocal device [2].

1. THEORETICAL ANALYSIS

Several methods can be used to analyze a uniform slotline. They range from a closed form expression, a quasistatic approach, to full-wave frequency- and time-domain approaches [3–9]. The closed form and quasistatic approach are time efficient but have limited accuracy. The rigorous full-wave methods, on the other hand, provide accurate data with a lengthy formulation and programming

Figure 2. Conductor-backed slotline that has a good mechanical strength and heat-sinking capability.

process. As a result of the progress in computer technology, a well-written simulation code can give complete characteristics of a transmission line within few minutes on a personal computer. We will concentrate on one of the most versatile numerical methods called spectral domain analysis, and also known as the spectral domain approach (SDA) [10]. This technique is very efficient in analyzing multilayered planar structures. Moreover, the same formulation can be extended to analyze circuit discontinuities. Readers who are interested in closed form expressions can refer to Ref. 11.

1.1. Spectral Domain Analysis

1.1.1. Formulation of the Dyadic Green's Function.

Figure 1(a) shows a single-layered slotline with its coordinate system. The metal and substrate extend into infinity in the transverse, $\pm y$, direction. The wave propagates along the $+x$ direction. The conductor thickness t and loss from metal and dielectric are neglected in the following derivation. We can easily extend the procedures to a multilayered and lossy slotline. The formulation is based on the concept of Hertz potentials [10,12]. If we define TE-to- z and TM-to- z Hertz potentials as ϕ_i^e and ϕ_i^h , the field components can be expressed as

$$E_{xi}(x, y, z) = \frac{\partial^2 \phi_i^e(x, y, z)}{\partial x \partial z} - j\omega\mu_i \frac{\partial \phi_i^h(x, y, z)}{\partial y} \quad (1a)$$

$$E_{yi}(x, y, z) = \frac{\partial^2 \phi_i^e(x, y, z)}{\partial y \partial z} + j\omega\mu_i \frac{\partial \phi_i^h(x, y, z)}{\partial x} \quad (1b)$$

$$E_{zi}(x, y, z) = \left(\frac{\partial^2}{\partial Z^2} + k_i^2 \right) \phi_i^e(x, y, z) \quad (1c)$$

$$H_{xi}(x, y, z) = j\omega\epsilon_i \frac{\partial \phi_i^e(x, y, z)}{\partial y} + \frac{\partial^2 \phi_i^h(x, y, z)}{\partial x \partial z} \quad (1d)$$

$$H_{yi}(x, y, z) = -j\omega\epsilon_i \frac{\partial \phi_i^e(x, y, z)}{\partial x} + \frac{\partial^2 \phi_i^h(x, y, z)}{\partial y \partial z} \quad (1e)$$

$$H_{zi}(x, y, z) = \left(\frac{\partial^2}{\partial Z^2} + k_i^2 \right) \phi_i^h(x, y, z) \quad (1f)$$

$$k_i = \omega\sqrt{\mu_i\epsilon_i} \quad (1g)$$

where a harmonic time dependence of $e^{j\omega t}$, $\omega = 2\pi f$, is assumed and $i = 1, 2$, and 3 refer to regions 1, 2, and 3, respectively. ε_i and μ_i are the electric permittivity and magnetic permeability of each region. Hertz potentials satisfy the Helmholtz wave equation

$$(\nabla^2 + k_i^2)\phi_i^{e,h} = 0 \tag{2}$$

Equations (1a)–(1f) and (2) are second-order partial differential equations. However, they can be simplified into ordinary differential equations by (1) assuming the x -dependence as $e^{-j\alpha x}$ and (2) defining the spatial Fourier transform in the y direction as

$$\tilde{\phi}_i^{e,h}(\beta, z) = \sum_{-\infty}^{\infty} \phi_i^{e,h}(y, z) e^{j\beta y} dy \tag{3}$$

With these definitions, the transformed fields of Eqs. (1a)–(1f) and (2) are

$$\tilde{\mathbf{E}}_{xi}(\beta, z) = -j\alpha \frac{d\tilde{\phi}_i^e}{dz} - \omega\mu_i\beta\tilde{\phi}_i^h \tag{4a}$$

$$\tilde{\mathbf{E}}_{yi}(\beta, z) = -j\beta \frac{d\tilde{\phi}_i^e}{dz} + \omega\mu_i\alpha\tilde{\phi}_i^h \tag{4b}$$

$$\tilde{\mathbf{E}}_{zi}(\beta, z) = \left(\frac{d^2}{dz^2} + k_i^2\right)\tilde{\phi}_i^e \tag{4c}$$

$$\tilde{\mathbf{H}}_{xi}(\beta, z) = \omega\varepsilon_i\beta\tilde{\phi}_i^e - j\alpha \frac{d\tilde{\phi}_i^h}{dz} \tag{4d}$$

$$\tilde{\mathbf{H}}_{yi}(\beta, z) = -\omega\varepsilon_i\alpha\tilde{\phi}_i^e - j\beta \frac{d\tilde{\phi}_i^h}{dz} \tag{4e}$$

$$\tilde{\mathbf{H}}_{zi}(\beta, z) = \left(\frac{d^2}{dz^2} + k_i^2\right)\tilde{\phi}_i^h \tag{4f}$$

$$\left(\frac{d^2}{dz^2} - \gamma_i^2\right)\tilde{\phi}_i^{e,h}(\beta, z) = 0 \tag{4g}$$

where $\gamma_i^2 = \alpha^2 + \beta^2 - k_i^2$. Equation (4g) is an ordinary second-order wave equation. The general solutions of this wave equation at each region in Fig. 1(a) are

$$\tilde{\phi}_1^e = A_1 e^{-\gamma_1 z} \tag{5a}$$

$$\tilde{\phi}_1^h = A_2 e^{-\gamma_1 z} \tag{5b}$$

$$\tilde{\phi}_2^e = B_1 \sinh[\gamma_2(h+z)] + B_2 \cosh[\gamma_2(h+z)] \tag{5c}$$

$$\tilde{\phi}_2^h = B_3 \sinh[\gamma_2(h+z)] + B_4 \cosh[\gamma_2(h+z)] \tag{5d}$$

$$\tilde{\phi}_3^e = C_1 e^{-\gamma_3(h+z)} \tag{5e}$$

$$\tilde{\phi}_3^h = C_2 e^{-\gamma_3(h+z)} \tag{5f}$$

where $A_1, A_2, B_1, B_2, B_3, B_4, C_1$, and C_2 are unknown coefficients. All solutions are functions of the spatial variable z only. We use the hyperbolic functions to represent the standing wave nature of fields at the stratified region 2. The decaying feature of energy in air regions above and

below the substrate is in the form of an exponential function. Substituting Eqs. (5a)–(5f) in Eqs. (4a)–(4f), we have the general field solutions. There are a total eight unknowns in Eqs. (5a)–(5f). We need eight independent equations to get the dyadic Green's function. The next step is to match the transformed boundary conditions: At $z = -h$,

$$\tilde{\mathbf{E}}_{x2} = \tilde{\mathbf{E}}_{x3} \tag{6a}$$

$$\tilde{\mathbf{E}}_{y2} = \tilde{\mathbf{E}}_{y3} \tag{6b}$$

$$\tilde{\mathbf{H}}_{x2} = \tilde{\mathbf{H}}_{x3} \tag{6c}$$

$$\tilde{\mathbf{H}}_{y2} = \tilde{\mathbf{H}}_{y3} \tag{6d}$$

At $z = 0$,

$$\tilde{\mathbf{E}}_{x1} = \tilde{\mathbf{E}}_{x2} = \tilde{\mathbf{e}}_x \tag{7a}$$

$$\tilde{\mathbf{E}}_{y1} = \tilde{\mathbf{E}}_{y2} = \tilde{\mathbf{e}}_y \tag{7b}$$

$$\tilde{\mathbf{J}}_x = \tilde{\mathbf{H}}_{y2} - \tilde{\mathbf{H}}_{y1} \tag{7c}$$

$$\tilde{\mathbf{J}}_y = \tilde{\mathbf{H}}_{x1} - \tilde{\mathbf{H}}_{x2} \tag{7d}$$

By eliminating eight unknown coefficients using boundary conditions in Eqs. (6a)–(6d) and (7a)–(7d), we have a set of dyadic Green's function

$$\begin{bmatrix} \tilde{\mathbf{J}}_x \\ \tilde{\mathbf{J}}_y \end{bmatrix} = \begin{bmatrix} \tilde{\mathbf{G}}_{xx} & \tilde{\mathbf{G}}_{xy} \\ \tilde{\mathbf{G}}_{yx} & \tilde{\mathbf{G}}_{yy} \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{e}}_x \\ \tilde{\mathbf{e}}_y \end{bmatrix} \tag{8}$$

where $(\tilde{\mathbf{e}}_x, \tilde{\mathbf{e}}_y)$ and $(\tilde{\mathbf{J}}_x, \tilde{\mathbf{J}}_y)$ are electric fields and currents at the slot and the conductor of the $z = 0$ plane, respectively. In the formulation, all unknown coefficients in Eqs. (5a)–(5f) are only functions of two variables $(\tilde{\mathbf{e}}_x, \tilde{\mathbf{e}}_y)$. The field characteristic of a slotline is solved if we can find proper functions to describe the slot fields accurately. This task is done using the method of moment (MoM). One such technique, called the Galerkin's method, is discussed in Section 1.1.2.

1.1.2. Galerkin's Method. To solve the propagation constant α and field distributions, we can use Galerkin's method. The Galerkin method uses the same weighting function as the basis function. Suppose that the aperture electric field is expressed as

$$\tilde{\mathbf{e}}_x(\beta) = \sum_{m=1}^M a_m \tilde{\mathbf{f}}_{xm}(\beta) \tag{9a}$$

$$\tilde{\mathbf{e}}_y(\beta) = \sum_{n=1}^M b_n \tilde{\mathbf{f}}_{yn}(\beta) \tag{9b}$$

where $\tilde{\mathbf{f}}_{xm}$ and $\tilde{\mathbf{f}}_{yn}$ are complete basis functions with unknown coefficients a_m and b_n . As the electric fields and currents are nonzero in complementary regions at the interface $z = 0$, we can multiply both sides of Eq. (8) by the complex conjugate of aperture electric fields. Then, integrating the product at $z = 0$, we obtain a set of eigenvalue

equations

$$\begin{bmatrix} \tilde{Z}_{xx} & \tilde{Z}_{xy} \\ \tilde{Z}_{yx} & \tilde{Z}_{yy} \end{bmatrix} = 0 \quad (10)$$

By setting the determinant of Eq. (10) equal to zero, all modes supported by the slotline are solved from the root-searching results of α . The unknown coefficients in Eqs. (9a) and (9b) are also obtained during this process. Substituting the solved Eqs. (9a) and (9b) into Eqs. (4a)–(4g) and (5a)–(5f), the electric and magnetic fields can be calculated.

1.1.3. Characteristic Impedance. There is no unique definition of characteristic impedance for a non-TEM transmission line. Power-and-current, power-and-voltage, and voltage-and-current are three commonly used definitions in calculating the characteristic impedance. The characteristic impedance of a slotline is usually defined in terms of the power-and-voltage relation

$$Z_0 = \frac{V^2}{2P_{avg}} \quad (11)$$

where V is the voltage across the slot. This potential difference is calculated by integrating the electric field

$$V = \int_{slot} E_y(y) dy \quad (12)$$

The time-averaged power P_{avg} propagated along the slotline is

$$P_{avg} = \frac{1}{4\pi} \text{Re} \iint [\tilde{E}_y(\beta, z)\tilde{H}_z^*(\beta, z) - \tilde{E}_z(\beta, z)\tilde{H}_y^*(\beta, z)] dz d\beta \quad (13)$$

where * means the complex conjugate.

1.1.4. Dispersion Behaviors of a Slotline. A computer code based on Eqs. (10) and (11) is written for analyzing a slotline. Figure 3 shows the propagation constant and impedance of a slotline as a function of substrate thickness. As the substrate thickness increases, the effective dielectric constant of a slotline increases because there is more energy in the substrate. Also, the slotline is a slow wave structure because the normalized propagation constant is always greater than one. Besides the characteristics of the dominant mode, a full-wave analysis also provides the information of higher order, evanescent, and leaky modes [8,11].

As the fields of a slotline are concentrated around the narrow slot, any parameter changes at this area affect the slotline characteristic. Kitazawa analyzed the effect of finite metal thickness on the slotline performance with the modified SDA [13]. He added a narrow, thin air region of the height of the metal thickness into the formulation as shown in Fig. 4. Then two sets of basis functions were set at the top and bottom edges of the narrow slot region.

Figure 3. Normalized propagation constant and characteristic impedance of slotline ($\epsilon_r = 4.5$). The slotline characteristics are determined by its constituent parameters.

Figure 5 depicts the normalized propagation constant and impedance of a slotline with different metal thicknesses. As the slot is modeled as an air-filled region, there is increasing energy in the air when the metal thickness increases. Therefore, the propagation constant decreases with increasing metal thickness. Obviously the metal thickness influences the slotline. It is important to incorporate the metal thickness into consideration in designing slot-type transmission lines (e.g., the slotline and the coplanar waveguide).

1.1.5. Choice of Basis Functions [10,12]. The accuracy and efficiency of the final solution depend on the accuracy with which the basis functions represent the true electric field. The entire domain basis functions (e.g., the sinusoidal functions or Chebyshev polynomials) are preferred in the analysis of a uniform transmission line. Only two or three terms can yield a very accurate result. On the other hand, the subdomain basis functions (e.g., rectangular and triangular functions) are commonly used in the analysis of circuit discontinuities. Table 1 compares the results of using the entire and subdomain basis functions in analyzing a uniform slotline.

1.1.6. Leaky Phenomenon and Control on Conductor-Backed Slotline. Recently, some work has been done to investigate and reduce the leaky phenomena in various planar structures [14–19]. This power leakage in terms of

Figure 4. Basis functions used to simulate a slotline with a finite conductor thickness t in SDA.

Figure 5. Normalized propagation constant and characteristic impedance of slotline with different conductor thickness ($\epsilon_r = 10.5, w/h = 0.5$). The conductor thickness has an obvious influence on slotline performance.

other guided waves is an interesting behavior and can be analyzed easily with a little modification on the conventional SDA. The integration path of a conventional SDA is along the real axis of the spectral variable β . In order to include the contribution of leaky waves, special attention should be paid to the integration path [20]. For a leaky transmission line, the model field is no longer bounded, and the propagation constant becomes complex instead of real. Therefore, a deformed integration path or residue calculation is commonly used to handle the leaky waves as depicted in Fig. 6. The deformed integration path is numerically easily implemented. However, it suffers from the numerical divergence when the integration path is close to leaky-wave poles. In this case, the residue calculation is preferred for an accurate and general formulation.

1.1.7. Leaky Phenomenon. The conductor-backed slotline shown in Fig. 2 has the inherent problem of power leakage in the transverse direction. This is so because the slotline mode of a CBSL has a lower effective dielectric constant than that of a parallel-plate mode. Figure 7 depicts the dispersion curves for both modes. Clearly, the phase constant of the slotline mode is always less than that of a parallel-plate mode. With the complex root-searching method, the attenuation constant (the imaginary part of α) exists over all frequencies. It says that the

Table 1. Analysis of a Uniform Slotline^a

^aThe entire domain function is more suitable in analyzing a uniform slotline.

Figure 6. Integration paths in the spectral domain analysis to calculate the leaky wave-guiding structures.

guided slotline mode loses energy when it propagates. The leakage phenomenon is also frequency-dependent. Shigesawa et al. conducted a comprehensive analysis and measurement of this issue [14].

1.1.8. Leakage Control. The leakage problem shadows the CBSL. It is important to eliminate or reduce the power leakage that causes unwanted coupling and energy loss. Figure 8 depicts some proposed configurations to control the power leakage [15–17]. The basic idea is to make the effective dielectric constant of the slotline mode higher than that of a parallel-plate mode with the additional dielectric compensation [Fig. 8(a,b)]. Or, we can physically confine the fields within the slot region using metal vias in the substrate [Fig. 8(c)]. Figure 8(a) can be easily analyzed using the SDA. Figure 9 demonstrates the leakage control of a CBSL with a proper material combination. It must be pointed out that the leaky phenomenon is caused by the so-called LSM mode in Fig. 8(a) because there are two substrates between metal plates. The attenuation becomes zero when the propagation constant of a slotline

Figure 7. Normalized propagation constant of CBSL and parallel-plate mode. $\epsilon_r = 9.5, h = 1 \text{ mm}, w = 0.25 \text{ mm}$. There is a nonzero attenuation constant because the phase constant of a slotline is always less than that of a parallel-plate mode.

Figure 8. Configurations to reduce or eliminate the leakage on a CBSL: (a) with an additional substrate layer, (b) with a superstrate for dielectric compensation, (c) with periodic vias in the substrate.

is higher than the LSM mode. There is a transition region between then leaky and nonleaky regions. Some researchers have studied this microscopic picture of mode transitions [21,22].

1.2. Slotline Discontinuities

The short end and the open end are two single-ended slotline discontinuities. These two discontinuities are frequently used as parts of slotline components. Their characteristics are, therefore, important for understanding the component behavior.

1.2.1. Short End. The short end is realized by connecting one end of the slotline shown in Fig. 1 with metalization. This discontinuity has been analyzed both theoretically and experimentally [23–25]. Figure 10 plots the comparison for the normalized end reactance. The short-end slotline exhibits inductive loading because the reactance is positive. It means that the stored energy is mainly in the form of magnetic energy. Besides the reactive energy, there is a radiation and surface wave loss

caused by this discontinuity. The loss makes the reflection coefficient less than one, which can be modeled as a resistor in the equivalent circuit. Figure 11 shows the normalized resistance of a shorted slotline using a full-wave analysis technique [25]. Figures 10 and 11 say that the inductive loading and the radiation loss gets stronger as the frequency increases.

1.2.2. Open End. Unlike the microstrip line, an open-ended slotline is difficult to realize and is sometimes impractical in circuit applications. Figure 12 depicts some variations of an open-ended slotline. There is a very strong radiation loss for the configurations in Fig. 12(a,b). Although it is not a good candidate in circuit applications, Fig. 12(b) is commonly used in the end-fired antenna design. Figures 12(c,d) have confined energy and are experimentally studied by Chramiec [26]. If the operating frequency is higher than the resonant frequency of the disk resonator, Fig. 12(c,d) behaves like an open circuit.

1.3. Transitions

Transitions between the slotline and other wave-guiding structures extend the design and test capabilities of a

Figure 9. Normalized propagation constant of a nonleaky CBSL with an additional substrate layer. $\epsilon_{r1} = 9.5$, $\epsilon_{r2} = 2.33$, $h_1 = 1$ mm, $w = 0.25$ mm, frequency = 20 GHz. The attenuation constant becomes zero when the phase constant of a slotline is higher than that of a LSM.

Figure 10. Normalized end reactance of a shorted slotline, $\epsilon_r = 12$. The shorted slotline is inductively loaded. Dots are measured data; solid and dashed lines are calculated results. (Reprinted with permission from Ref. 25, © 1988 IEEE.)

slotline. For example, a coaxial-to-slotline transition is needed to test the slotline in a standard microwave measurement system. There are several different ways to combine two transmission lines. The one with a natural field match at the junction region gives maximum energy transfer. That is, for a good transition, the orientations of electric and magnetic fields should match each other. In the following sections, we will discuss several practical transitions.

1.3.1. Coaxial-to-Slotline Transition. Most microwave measurement systems use the coaxial cable as the input/output transmission line. It needs a good coaxial-to-slotline transition to test the slotline performance. Figure 13 depicts the coaxial-to-slotline transition. These two structures cross each other with a right angle to have the proper field match. The center conductor of the coaxial

Figure 13. Coaxial-to-slotline transition. (Reprinted with permission from Ref. 27, © 1974 IEEE.)

line is connected to one of the slotline metal planes, and the outer conductor is connected to the other one. With the open end at one side of the slotline, the energy propagates along the uniform section. This configuration is also useful in exciting a slotline antenna, which is a double short-ended slotline. Knorr analyzed and measured this transition with a 50 Ω microstrip line and a 75 Ω slotline [27]. It has a good voltage standing-wave ratio (VSWR) for frequencies less than 4 GHz. The performance of the transition gets worse at higher frequencies

The open end of the slotline shown in Fig. 13 may cause unwanted radiation loss. Although it has low return loss, it does not mean that there is a maximum energy transfer in the form of a guided wave. To reduce this radiation loss, a movable short-end configuration is proposed [11]. As a result of the resonant wavelength, this type of transition has an optimal VSWR over a narrow frequency range.

1.3.2. Microstrip-to-Slotline Transition. Microstrip circuits are most widely used in microwave integrated circuits. The microstrip-to-slotline transition expands applications for both the microstrip line and the slotline. Also, the fabrication is very easy and accurate by etching the metallization on both sides of the substrate. It makes the double-sided circuit design feasible. A branch-line coupler based on this transition has been demonstrated [28]. Figure 14 shows the transition with both lines crossing at a right angle and extending about a quarter wavelength beyond each other. Chambers et al. used an approximate transmission line method to analyze this transition [29]. More rigorous full-wave methods were also reported [25,30,31]. All simulations agree well with the experiment done by Knorr at the lower frequency, but there is a large discrepancy at the high-frequency end. The deviation may be caused by fabrication tolerance. Besides, the substrate used in the experiment [27] is Custom Hik 707-20

Figure 14. Microstrip-to-slotline transition.

Figure 15. CPW-to-slotline transitions: (a) two slotline outputs, (b) single slotline output. (Reprinted with permission from Refs. 36 and 39, © 1987 and 1993 IEEE.)

($\epsilon_r = 20$), which is usually very lossy at higher frequencies. This loss parameter was not included in the previously mentioned simulations.

Figure 14 is a narrow-band transition. The bandwidth limitation is a result of the frequency dependence of the quarter wavelength sections. Several papers have tried to improve the bandwidth with different approaches [32–35]. It is found that the bandwidth is related to the stub reactance and impedance. The lowest VSWR occurs when the reactances cancel each other for the quarter wavelength sections. Moreover, there is a maximum bandwidth when the characteristic impedance of the microstrip stub is 2.618 times the characteristic impedance of the slotline stub [35].

1.3.3. Coplanar Waveguide-to-Slotline Transition. Unlike the microstrip-to-slotline transition, the coplanar waveguide (CPW)-to-slotline transition can be built on the same side of metallization. This configuration is preferred in the monolithic microwave integrated circuits (MMICs), where all metals are on one side of the substrate only. Much effort has been made to study this transition [36–39]. Figure 15 shows some of the representative configurations. Figure 15(a) is a CPW-to-slotline T-junction that behaves like a power divider. Two output ports on the slotline are available in Fig. 15(a). If a single output is necessary, the other port can be shorted at a quarter wavelength from the junction. The bonding wire is used to suppress the unwanted mode on the CPW. To increase the bandwidth, a radial stub is used as shown in Fig. 15(b), even though it requires a large circuit space. It is found that Fig. 15(b) has the best performance in terms of bandwidth and return loss [39]. The 1 dB insertion loss bandwidth for this transition is more than 5.2:1. Unlike coaxial and microstrip-to-slotline transitions discussed previously, one design advantage of this transition is that the I/O lines can have an angle from 0° to 90° . The optimal transition can be obtained with a modification of circuit dimensions.

1. GUIDED WAVES AND WAVEGUIDES

Electromagnetic wave propagation, which is fundamentally governed by Maxwell's field equations, is usually

characterized by its propagation constant. The propagation constant is used to derive its phase and group velocity and attenuation relative to frequency or wavelength. The phase velocity of a freely propagating wave is reduced or increased compared with the speed of light if such a propagation takes place in material other than air or vacuum. Guided-wave phenomena [1–4] are electrically or magnetically bounded waves propagating in air- or material-filled tubes or strips, or called wave-guides or sometimes transmission lines, and are the physical foundation for designing and manufacturing radiofrequency (RF), microwave, and optical components and systems. A waveguide can also be defined as a structure that causes a wave to propagate in a chosen direction because of some measure of confinement in the plane transverse to the direction of propagation. The topological view of a waveguide is graphically sketched in Fig. 1(a), which may involve materials of different properties and multiple conductors with or without a specifically shaped dielectric or conducting enclosure. Dielectric guides, hollow-pipe waveguides, and planar guides are the most important building blocks in practical use to date.

Generally, the guided-wave properties of a waveguide depend on physical aspects, such as boundary conditions, materials, and frequency. Conventional uniform waveguides (rectangular metallic waveguides without physical variations in the longitudinal direction, for example) exhibit phase velocities of wave propagation greater than the velocity of light, or in other words, guided wavelengths are longer than the free-space wavelength: these structures are usually called fast-wave structures. Fast-wave structures, in most cases have cutoff frequencies below which wave propagation is halted.

The slow wave is a particular type of wave propagation, usually of the guided-wave type, and it is described mostly in the frequency-domain. Slow-wave structures [5–7] are wave-guides or transmission lines in which the wave travels with a phase velocity equal to or less than a certain predesignated velocity of wave propagation. In other words, the slow wave should be interpreted relative to its fast-wave counterpart compared with a velocity of reference, such as the speed of light in a hollow metallic waveguide. However, it may be disputable how to choose the velocity of reference that is directly connected with the slow-wave structure. Of course, one may always choose the speed of light as the reference velocity (classic consideration) to distinguish slow-wave propagation from other guided waves. This was the common practice in very early studies of slow-wave structures probably because the early slow-wave development was closely related to the rectangular and circular waveguiding structures. Since the emergence of planar integrated dielectric-layered geometry, such a classic definition of slow-wave structure was somewhat altered by the relative dielectric and magnetic properties of the materials of the structure. It is now widely accepted that a slow-wave structure can support wave propagation that has a phase velocity less than the attainable value because of the inherent properties of the waveguiding material, such as permittivity and permeability.

Figure 1. Graphic illustration of a generalized waveguide problem and its guided waves, (a) Physical view of an arbitrary waveguiding structure and (b) concise description of any potential guided-wave propagation along its axial direction, which are classified in terms of three types of waves: slow wave, dielectric guided wave, and fast wave. The waveguide consists of a composite medium with three blocks of different relative permittivities, ϵ_r , and permeabilities, μ_r , with the subscript r denoting 1, 2, and 3. The outer enclosure may be in the form of a dielectric or metallic boundary. The classification of guided waves is made by measuring the free-space counterpart v_0 relative to its guided-wave phase velocity v_p , or equivalently the freespace wavelength λ_0 versus the guided-wave wavelength λ_g . The abscissa in (b) refers to any susceptible physical and electrical parameter connected with wave propagation.

Figure 1(b) depicts schematically a concise classification of guided-wave structures by comparing the normalized guided wavelength with its free-space counterpart. We consider the basic waveguiding geometry of Fig. 1(a) as the reference in which the maximum permittivity and permeability of a relevant subregion sets up the border between material-related guided-wave and slow-wave propagation. In most cases, only linear isotropic dielectric materials are used in waveguides. In this description, the slow- and fast-wave-guiding properties are simply characterized by a popular technical term called the effective permittivity, which may involve the effect of permeability if the relative permeability is not equal to one, even though the concept of a separate effective permeability is valid.

2. FUNDAMENTALS OF SLOW-WAVE STRUCTURES

Generally, a slow wave cannot be obtained without artificial guided-wave structures. Special mechanisms in a guided-wave structure need to be designed to generate slow-wave propagation. The basic and absolute condition of a guided-wave structure that supports slow-wave propagation is that this structure should provide separate storage of electric and magnetic energy in space either in the axial or transverse directions. Obviously, any susceptible slow-wave generation depends on the geometry and/or the core materials of a guided-wave structure subject to some particular criteria of construction, that lead to a critical separation of energy in space. The effective spatial separation of electric (capacitive effect) and magnetic (inductive effect) energy constitutes the fundamental principle for designing a slow-wave structure.

There are two fundamental classes of slow-wave structures, several typical examples of which are shown in Figs. 2 and 3. One is the periodic structure (Fig. 2) in the axial or longitudinal direction, and the other consists of uniform structures that have special geometry designed in the transverse direction (Fig. 3). Periodic structures can be formed with two configurations: (1) structures with continuous but periodically varying material properties and (2) structures with periodically loaded sections or periodic boundary conditions. The most common type is the latter. Uniform slow-wave structures usually consist of multilayered or composite materials that have a specially arranged thickness ratio and dielectric/magnetic property. The best known example today in this category is probably the metal-insulator-semiconductor (MIS) transmission line described by the examples of Fig. 3. In this case, planar transmission lines are deposited onto a very thin insulator that is formed, depleted, or grown by using a semiconductor

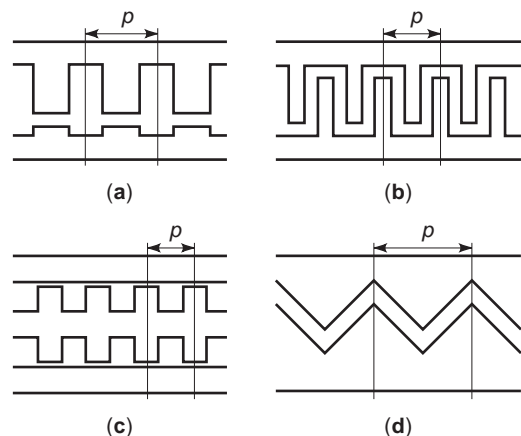

Figure 2. Bidimensional view of generalized periodic slow-wave structures that may depict conventional metallic waveguides and planar transmission lines with a class of typical periodically nonuniform physical layout or patterns (slots or strips) along the propagative axis. p refers to the length of a periodic cell or block. (a) A corrugated waveguide or comb-like line. (b) Either an interdigital line (strip case) or a meander line (slot case). (c) Either a stub-loaded planar line or waveguide. (d) A zigzag nonuniform coupled transmission line.

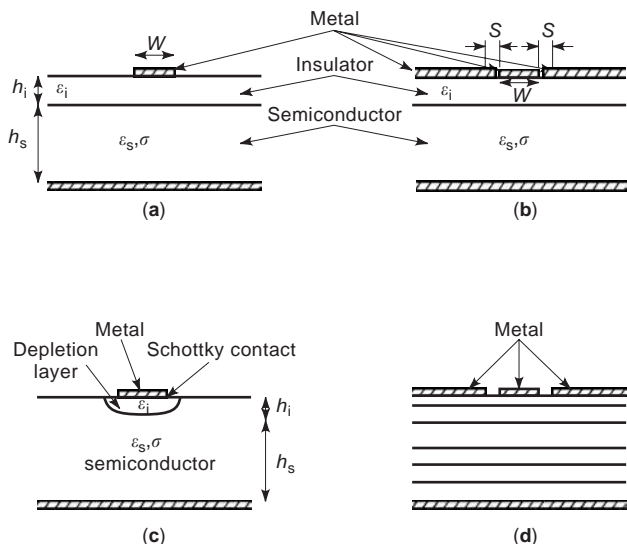

Figure 3. Cross-sectional view of various metal-insulator-semiconductor (MIS) planar slow-wave transmission lines with low-loss or ideally lossless insulator and doped lossy semiconductor. (a) An MIS microstrip structure. (b) An MIS coplanar waveguide (CPW). (c) A Schottky-contact slow-wave microstrip line with a depletion layer that can be regarded as a special case of the MIS structures. (d) A general multilayered planar structure that may involve quantum-well layers. This structure is subject to slow-wave propagation. Mathematical symbols used in the figure are as follows: w and s stand for the widths of the center conductor and slot, respectively. Subscripts i and s refer to the insulating and semiconductor layers, respectively. ϵ is the dielectric permittivity, σ is the conductivity of the doped semiconductor, and h is the thickness of layer.

microfabrication process on an appropriately doped semiconductor substrate. Interestingly, slow-wave generation in periodic structures is achieved by separating electric and magnetic energy in the longitudinal space, whereas the uniform structures, such as MIS lines, use storage of electric and magnetic energy separated in the transverse direction.

Based on the building block, periodic structures usually require a three-dimensional (3-D) description, whereas uniform slow-wave structures are simply two-dimensional (2-D) problems. The slow-wave characteristics of the two classes of structures differ in some aspects, but they also share some common features. Slow-wave propagation is related to particular electromagnetic modes of the structure, and its fundamental characteristic parameters are the slow-wave factor and propagation loss even though they may be represented differently in some cases. As for other conventional waveguides or transmission lines, characteristic impedance is useful for design purposes, but it may be difficult to define for some structures. To accurately describe the guided-wave properties of slow-wave structures, Maxwell's field equations are required to calculate the electrical parameters and to plot the distribution of the field quantities over the structures. The calculation is usually done numerically except for some classic periodic waveguides. These are typical boundary value problems. Normally, the guided-wave properties of a

slow-wave structure are dispersive or frequency-dependent, and they can also be greatly modified by changing structure parameters, which are of paramount importance for design purposes.

Now, let us consider some physical aspects of slow-wave structures via two classic examples of periodic structure (see Fig. 4), helix and cavity-chain waveguide, and two popular examples of MIS structures (see Fig. 3), the coplanar waveguide (CPW) and the Schottky-contact microstrip line. Of course, slow-wave generation along MIS structures differs, but its physical principle remains similar to that of periodic structures.

A practical helical slow-wave structure typically consists of a metal wire or tape wound in the form of a helix, supported by a longitudinal dielectric rod/bar. The entire structure may also be enclosed in a dielectric/metallic envelope, depending on its intended use. Figure 4(a) shows a typical geometry for a single-tape or single-wire helix that was studied by J. R. Pierce [8] and S. Sensiper [9]. The field is guided at the velocity of light along the helical path if no dielectric rod is involved, so that the velocity along the axial or z -direction is considerably less than the velocity of light. Obviously, the tighter the helix is wound, the smaller the pitch p , and the more slowly the wave appears to travel in the axial direction. If an electron beam introduced into the above structures travels along the axis with the same axial velocity as the wave, cumulative field interactions take place, and we have a form of traveling-wave tube. Interestingly, the induced inductance over one helical period prevails over the capacitance, leading to the separation of electric and magnetic energy in the axial direction.

Figure 4. Two examples of classic periodic waveguides. (a) A simple helix slow-wave structure made of tape or wire. p is the pitch, θ the pitch angle, and a the radius. (b) A periodically disk-loaded (cavity-chain) circular waveguide. p is the periodic spacing of the disks. In both cases, z is the propagation direction of the slow waves.

Figure 4(b) presents an example of metallic waveguides loaded periodically by a series of obstacles, fins in this instance, which slow the wave, as they would slow a stream of water running through the pipe. The smaller the center holes, the greater the reduction in field velocity through the pipe. This structure belongs to the class of cavity-chain, slow-wave structures, each of which consists of a chain of coupled resonant cavities. These cavities are very frequency-selective. Electrons, of course, can be introduced to flow along the axis with a velocity that allows them either to absorb power from or to deliver power to the circuit wave. This mechanism can be used to realize forward-wave traveling-wave amplifiers or backward-wave oscillators, “Carcinatron.” Similarly, it can be observed from guided-mode concepts that the spatial separation of electric and magnetic fields satisfy the critical condition of slow-wave guidance.

The basic slow-wave MIS structures consist of planar transmission lines usually in the form of a few or a hundred micrometer-size microstrip, CPW, or other planar patterns, which are fabricated on a doped thin or thick semiconductor substrate, such as N^+ silicon (Si) or GaAs. In an MIS CPW, as shown in Fig. 3(b), the metals are separated from the doped semiconductor by a low-loss or ideally lossless insulating layer, such as silicon dioxide (SiO_2) or silicon nitride (Si_3N_4), that is usually extremely thin and ranges from the submicrometer range to two micrometers. The presence of back metallization usually has a negligible influence on slow-wave propagation, whereas in the Schottky-contact microstrip described in Fig. 3(c), a low-loss depletion region is formed by applying a negative bias voltage over the microstrip with respect to the ground plane. Such a depletion region is equivalent to the insulator of an MIS structure but inhomogeneous in profile over the cross section. Therefore, the Schottky-contact line can be regarded as a special MIS structure. The existence of slow-wave propagation along these MIS structures can be explained in the following manner. The low-impedance doped semiconductor, which is a nonmagnetic material, is virtually invisible to the magnetic field. Therefore, the magnetic field freely penetrates into the semiconductor layer, and it is nearly identical to that of an undoped CPW structure. However, the electric field is highly confined in the insulating layer between the semiconductor and the center strip of the CPW. This field distribution corresponds to separate storage of electric and magnetic energy in space, which is the well-known condition for a slow-wave mode to propagate. Obviously, transmission loss is inevitable and is often the main design problem because MIS structures always contain a doped semiconductor layer. Heuristically, applying different bias voltages on these MIS structures should modify the physical profile of the insulating layer or depletion region, thereby changing the slow-wave propagation. This feature is exploited in designing electronically tunable MIS devices.

3. A BRIEF HISTORY OF SLOW-WAVE DEVELOPMENT

Based on their classification, the development of the electro-magnetic slow-wave structures passed two historical

landmarks: the periodic structure and the metal-insulator-semiconductor (MIS) structure. Of course, the MIS structure is not unique for generating slow-wave propagation on the basis of a uniform line made of special material. Slow-wave effects are also observed in waveguides that involve ferromagnetic, plasma, or other complex media, such as chiral materials, if the mechanism and conditions of generating slow-wave propagation in those structures exist. In other words, the spatial separation of electric and magnetic energy takes place.

The very early development of slow-wave structures can be traced back to World War II, when there was an explosion of activity in the microwave electronics field. In 1939, a high-frequency tube, known as the klystron, was developed by W. W. Hansen and the Varian brothers, following the invention of the high-power magnetron by A. W. Hull in 1921. At that time, slow-wave structures were built by cascading resonant cavities, which usually provided tremendous power gains over relatively short waveguiding length, but the frequency bandwidth was very limited. These cavity-connected and ladder-type slow-wave structures are still widely used today for highly frequency-selective devices, such as narrowband filters, multiplexers, and field polarization control devices.

In the early 1940s, R. Kompfner [10], reflecting on the relative inefficiency and narrow bandwidth offered by the klystron, reasoned that if an electron beam were to interact continuously with a wave on a helix, it would interact more efficiently. This is the velocity-matching principle for the electron beam and electromagnetic wave, which are supposed to travel at equal speeds in the ideal case, such that maximum field interaction or energy exchange occurs between the two waves. Furthermore, the helix would not be strongly resonant at any frequency, and therefore it would have a broad bandwidth. Kompfner's first traveling-wave tube (TWT) was successfully developed in 1943, which marked the beginning of slow-wave structures. In fact, a similar concept was proposed but not explicitly described in the patent filed by Percival in 1935 [11] for distributed circuits. Subsequently, the TWT was refined by Bell laboratory workers during and after World War II. Among them, J. R. Pierce is perhaps most prominent. He worked on the TWT theory and built high-performance tubes [8]. Since then, a large class of broad-band and high-performance traveling-wave electronic devices has been proposed and developed on the basis of various slow-wave structures [9,12]. These include distributed TWT amplifiers, oscillators, and linear particle accelerators [13–16]. In addition, the slow-wave phenomena were also observed and studied for other classes of structures including plasma- and ferrite-filled waveguides [17]. In those early times, periodic structures were sometimes called delay structures instead of slow-wave structures.

Since the mid 1950s, there has been tremendous research and development into planar transmission lines and high-frequency integrated circuits printed on low-loss dielectric substrates or semiconductor wafers. These transmission lines may be in the form of microstrip lines, coplanar waveguides (CPW), slot lines, and other derivatives. The concept of hybrid microwave integrated circuits (HMICs) and monolithic MICs (MMICs) was eventually

proposed in the early 1960s. Such microwave integrated circuits (MICs) may be designed on lossy semiconductor substrates. Slow-wave propagation along these layered structures was predicted in 1967 [18], and immediately an extensive and detailed study on MIS (Si-SiO₂) slow-wave microstrip lines was published in [19]. Subsequently, a Schottky contact microstrip line [20,21] was used as a variable slow-wave structure with an external voltage control.

Periodic structures using planar fabrication techniques had basically received no attention until the emerging design requirement of the broad-band or high-directivity microstrip line coupler in the early 1970s. A coupled parallel-line system had been used to design couplers whose electrical performance is usually limited by the mismatch in the phase velocity of the even and odd modes. An effective solution to this problem was introduced by Podell [22] by wiggling the edges of coupled lines. It is used to deliberately control the ratio of capacitance and inductance, leading to the equalization of even and odd mode velocities. This marked the beginning of planar periodic structures that effectively generate slow-wave propagation [23].

Since the early 1970s, research on both MIS and planar periodic slow-wave structures have continued, and a selected set of publications issued before 1987 was presented for MIS-related topics [7]. Other published works related to MIS-based and planar periodic slow-wave structures can easily be found in the *IEEE MTT Transactions*, letters and conference publications (*Microwave Theory and Techniques*), *IEE Proceedings* (Part-H), and *Electronics Letters*. Recent advances include (1) the use of hybrid MIS and periodic structures (cross-tie overlay) for low-loss, slow-wave enhancement; (2) the observation of slow-wave effects because of lossy conductor strips at low frequency; (3) the proposal of inhomogeneous doping techniques for improving MIS transmission loss; and (4) the development of slow-wave structures using new materials, such as chiral media, photonic bandgap structures, and quantum-barrier traveling-wave devices. Some of these new developments are discussed in a subsequent section. Readers are encouraged to consult those periodicals and publications for more detailed information on this subject.

4. BASIC THEORY OF SLOW-WAVE STRUCTURE

It is known that periodic and MIS structures yield slow-wave propagation, depending on whether the fundamental condition of spatial separation of electric and magnetic energy is sustained. This is to say that slow-wave propagation does not necessarily occur along these structures under certain circumstances. This critical requirement for slow-wave propagation depends, in turn, on the physical layout of the structure and the working range of frequency. The question is, how shall we describe them electromagnetically at a given frequency and also on which theoretical platform should we rely to predict slow-wave propagation? Furthermore, characteristic parameters must be identified to formulate such guided-wave proper-

ties clearly because they are very important for understanding and designing slow-wave structures and circuits.

To begin with, let us consider Figs. 2–4, which show a class of planar and nonplanar periodic and MIS structures. We realize, first of all, that the electric \vec{E} and magnetic \vec{H} fields along these structures should always satisfy Maxwell's equations, which are usually formulated in the frequency-domain (angular frequency $\omega = 2\pi f$ and f frequency) for slow-wave guiding structures. Maxwell's field equations are easily found elsewhere [1–4,6]. To study guided-wave properties, slow-wave structures are usually assumed to be infinitely long. This stipulation is not just a practical one imposed to simplify matters, as indeed it does, but it turns out that fields and guided-wave characteristics are rather useful and accurate for practical design of a finitely but sufficiently long structure. In addition, results obtained for an infinitely long structure may approach results for its finitely long counterpart quite accurately if both ends are terminated or matched, so as to satisfy the boundary conditions. In this case, the slow-wave structures can be characterized simply by the classic transmission-line theory in a unified lumped-circuit way, that is, the complex propagation constant $\gamma = \alpha + j\beta$ and characteristic impedance Z_0 derived from a generic ladder network are described by its constituent circuit elements *RGLC* that stand for distributed resistance, conductance, inductance, and capacitance per unit of length for a uniform line or per period for periodic structures. Guided-wave properties, such as γ and Z_0 , can be rigorously modeled by applying Maxwell's equations with appropriate boundary conditions. This may call for numerical approaches if simple analytical or closed-form techniques fail to extract the characteristic parameters. This is true in particular for planar periodic and MIS slow-wave structures.

A unified transmission line model is introduced for both periodic and MIS structures because they can be considered special classes of transmission lines. In addition, it can be shown that transmission line theory (circuit aspect) is consistent with Maxwell's equations (field aspect) for such guided-wave structures. This model mathematically confirms the origin and existence of slow-wave propagation once an effective spatial separation of electric and magnetic energy takes place. In addition, it should reveal some guided-wave properties of the slow-wave structure. Based on the difference in geometry compared with the uniform MIS slow-wave line, the periodic structure may be subject to some unique mathematical theorems and treatments, which are described following, together with other pertinent definitions frequently used with slow-wave structures.

4.1. Periodicity or Floquet's Theorem

The periodicity theorem helps us to formulate the guided-wave properties of a linear, periodic, slow-wave system, that is, to determine modes of electric and magnetic fields subject to periodic boundary conditions. This theorem is sometimes called Floquet's theorem, a generalized mathematical theorem for differential equations with periodic coefficients. A *mode* denotes a particular solution to

Maxwell's equations or to the wave equations at a certain frequency. A slow-wave could be composed of a number of modes in a hybrid form called hybrid mode, depending on the nature of the structure. The electric and magnetic fields over the cross section should be identical for the infinitely long helix and periodic waveguide, but with a phase shift given by the factor $e^{-j\beta p}$ from any point z to the point $z + p$, where β and p are the fundamental propagation constant and the periodic length, respectively. Without loss of generality, let us consider only electric fields in a Cartesian coordinate system for the periodic cavity-chain waveguide. Floquet's theorem in Cartesian coordinates states that

$$\begin{aligned}\vec{E}(x, y, z + p) &= \vec{E}(x, y, z) \cdot e^{-j\beta p} \\ &= \vec{E}(x, y, z) \cdot e^{-j\beta_n p} \\ \beta_n &= \beta + \frac{2n\pi}{p}\end{aligned}\quad (1)$$

in which $n = 0, \pm 1, \pm 2, \pm 3, \dots$ and so forth, which stand for the index terms of space harmonics. This equation suggests that the electromagnetic solution to a periodic cell with space-harmonic expansion constitutes the completeness of a field solution for the entire periodic structure. Equation (1) implies that "local" waves contained to some extent in the periodic cells that interact with "guided" waves eventually yield a space separation of electric and magnetic energy. The exponent says that the n th mode has a propagation constant β_n on the basis of a Fourier (space harmonic) expansion and that the periodic phase shift of the structure is always dictated by the term or βp or φ .

The determination of β at a given frequency ω is the central problem in a periodic slow-wave structure. The solution is sometimes called the ω - β diagram, or dispersion curve. Note that the concept of a space harmonic differs from that of a mode in that a space harmonic is the inseparable component of a wave containing the explicit exponent factor and it may be a component of a mode. A single space harmonic rarely satisfies all of the boundary conditions, and it may or may not satisfy Maxwell's equations. Nevertheless, under some circumstances, the space harmonic expansion may correspond directly to the modes. Sometimes in the literature, this expansion of fields over a periodic cell is called spatial harmonics, or sometimes Hartree harmonics, to represent the guided-wave properties of the complete structure.

Of the infinite number of spatial harmonics, half are forward waves, whereas the other half are backward waves. This interesting and useful feature of periodic slow-wave structures is discussed following.

5. ($\omega - \beta$) DISPERSION DIAGRAM AND SLOW-WAVE PARAMETERS

Our general understanding of the behavior of slow-wave structures depends greatly on ω - β dispersion curves, sometimes called the Brillouin diagram. This is a plot of

ω against β . In some cases, the phase shift φ ($\varphi = \beta p$) may also be used (ω - φ curves) for periodic structures. This classic graphic representation is popular for periodic structures but not for uniform MIS structures, which use other alternatives, such as a slow-wave factor. Figure 5 depicts a typical ω - β dispersion curve for a slow-wave periodic structure. The phase and group velocities are calculated from

$$\begin{aligned}v_p &= \frac{\omega}{\beta} \\ v_g &= \frac{\partial \omega}{\partial \beta}\end{aligned}\quad (2)$$

The phase velocity v_p of a mode is the velocity with which an observer must travel to keep in step with this mode, and it stands for the phase transmission characteristic of each frequency relative to the frequency of reference. Usually, v_p differs from mode to mode on the basis of Floquet's theorem. The group velocity v_g yields the energy transmission (or power flow) velocity at a finite frequency. The concept of dispersion is used to measure the degree of field variation over the cross section or periodic cell of a structure as the frequency changes. If v_g remains constant over a range of frequency, signal information carried by these frequencies travel with the same velocity in the structure. In other words, a structure may be dispersionless if its ω - β curves are simply straight lines or the two characteristic parameters are linearly related to each other. Interestingly, in a periodic structure, the group velocity is the same for all the modes because $\partial \omega / \partial \beta_n = \partial \omega / \partial \beta$ is always satisfied according to Eq. (1). Thus the group velocity is a parameter for an entire wave. If β is positive in Fig. 5, v_g is positive at point A, meaning that the signal power flows in the $+z$ -direction (forward wave), whereas v_g negative at point B means that the signal power flows in the $-z$ -direction (backward wave). At point C, the wave is cutoff or

Figure 5. Characteristic dispersion curve, or ω - β diagram, for a slow-wave structure (typically for periodic structures). ω is angular frequency, β propagation constant (usually β is for the fundamental mode of a periodic slow-wave structure). Points A and B represent forward and backward propagating waves in the case of a positive β , respectively, and point C is the cutoff frequency at which energy flow is halted.

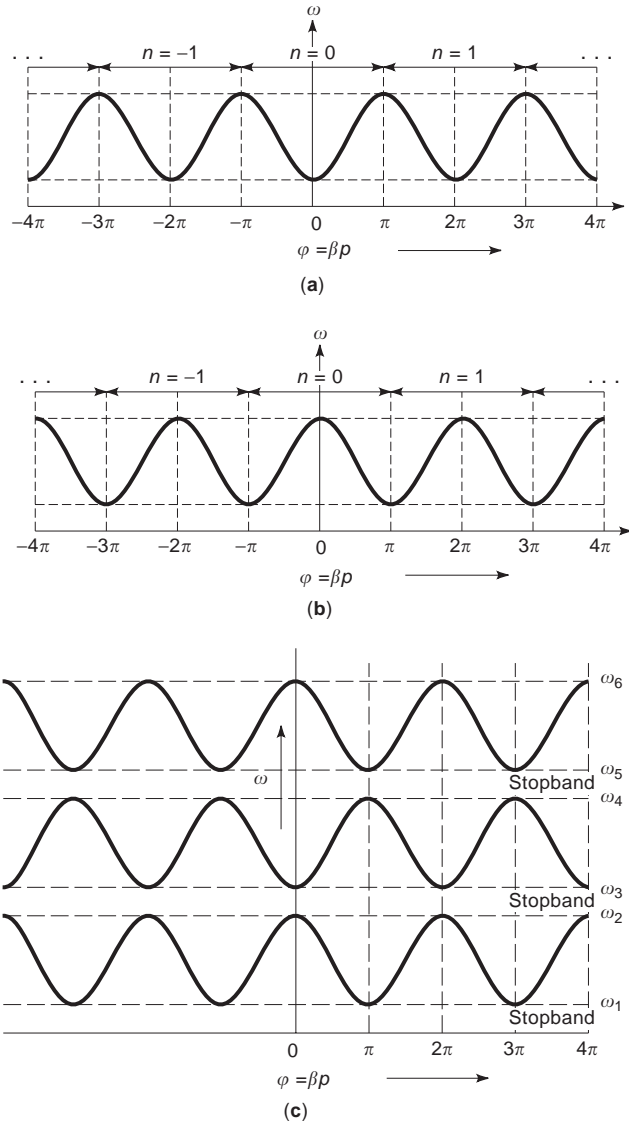

Figure 6. A general form of ω - φ dispersion curve, or Brillouin diagram, for a typical periodic waveguide structure. (a) Forward wave ω - φ relationship and curve slopes for space harmonics with the energy flowing in the $+z$ -direction ($\beta_n = \beta + 2n\pi/p$) for the solid lines; and with the energy flowing in the $-z$ -direction ($\beta_n = -\beta + 2n\pi/p$) for the dotted line. (b) Backward wave ω - φ relationship and curve slopes for space harmonics with energy flowing in the $+z$ -direction ($\beta_n = -\beta + 2n\pi/p$) for the solid lines, and with energy flowing in the $-z$ -direction ($\beta_n = \beta + 2n\pi/p$) for the dotted line. (c) Composite ω - φ diagram showing alternated passbands and stopbands. The first three characteristic passbands feature forward and backward spatial harmonics. The bandwidths of the three stopbands are not necessarily the same.

in a state of local resonance where v_g becomes zero. The forward and backward waves are the fundamental physical attributes of periodic waveguides. Obviously, the forward and backward waves are not related only to positive β .

Figure 6 gives a set of ω - φ dispersion curves for a typical periodic waveguide structure. The fundamental forward and backward slow waves are described in Fig. 6(a)

and Fig. 6(b), respectively, via the sign of β and slope of ω - φ dispersion curves relative to the space harmonics. There are two possible scenarios for realizing forward waves as shown in Fig. 6(a): (1) the dispersion curves have positive slopes ($v_g > 0$, and the energy propagates in the $+z$ -direction) because $\beta_n = \beta + 2n\pi/p$; or (2) the dispersion curves have negative slopes ($v_g < 0$, and the energy propagates in the $-z$ -direction) because $\beta_n = -\beta + 2n\pi/p$. Obviously, forward wave propagations take place if and only if $\partial\omega/\partial\beta_n = \partial\omega/\partial\beta$ and ω/β have the same sign at a given frequency. Similarly, there are also two corresponding scenarios for achieving backward waves, as shown in Fig. 6(b): (1) the dispersion curves have positive slopes ($v_g > 0$, and the energy propagates in the $+z$ -direction) because $\beta_n = -\beta + 2n\pi/p$; or (2) the dispersion curves have negative slopes ($v_g < 0$, and the energy propagates in the $-z$ -direction) because $\beta_n = \beta + 2n\pi/p$. In this case, the backward wave propagations take place if and only if $\partial\omega/\partial\beta_n = \partial\omega/\partial\beta$ and ω/β have opposite signs at a given frequency. It is helpful to remember that the propagative direction of the fundamental mode guidance differs from that of the energy flow. Based on the difference of dispersion curve behavior between the two classes of waves ($\beta = 0$, for example), the slow-wave structure design for forward wave propagations may differ from those of backward waves. The forward wave structures have been used to design amplifiers, such as TWT, usually on the basis of the fundamental mode ($n = 0$). The space harmonics ($n \neq 0$) are often involved in spurious field interactions. The backward wave structures have been popular in designing voltage-controlled oscillators. Space harmonics ($n \neq 0$) could sometimes be used to obtain lower control voltages.

Figure 6(c) shows a composite diagram or general form of $(\omega - \varphi)$ dispersion curve, which involves the frequency response of spatial harmonics for three characteristic curves. A transverse electric and magnetic (TEM) mode periodic line may be considered when $\omega_1 = 0$. Otherwise, this is for a non-TEM mode structure. The frequency ranges between the extremes of an $\omega - \varphi$ curve are called passbands, that is $\omega_1 - \omega_2, \omega_3 - \omega_4$, and $\omega_5 - \omega_6$ because β_0 is real and the fields carry real power through the structure. A frequency range between two passbands is a stopband, that is $0 - \omega_1, \omega_2 - \omega_3$, and $\omega_4 - \omega_5$ within which no real power can flow because the fields decay exponentially away from the reference source. This important feature is of considerable significance in designing filters and other components based on periodic structures.

Passband and stopband characteristics are unique for periodic structures. In the MIS structures, the wave propagation depends, first of all, on the fundamental characteristics of a planar line. A microstrip line is different from a slotline [7,24], for example. The slow-wave characteristics of an MIS structure are characterized by a complex propagation constant and a complex characteristic impedance. In turn, the complex propagation constant can be expressed by the slow-wave factor η and loss α in dB/mm. The slow-wave factor is simply defined as

$$\eta = \frac{v_0}{v_p} = \frac{\lambda_0}{\lambda_g} = \frac{\beta}{\beta_0} = \sqrt{\epsilon_{\text{eff}}} \quad (3)$$

where λ_0 and λ_g denote the free-space and guided wavelengths, respectively. β_0 and ϵ_{eff} are the free-space propagation constant (or wavenumber) and the effective dielectric constant, respectively. Obviously, the slow-wave factor, which is identical to the effective index commonly used in optics, can also be applied to the characterization of periodic structures. The central problem in MIS research work is to obtain the highest slow-wave factor possible at higher frequencies, and the lowest line loss is desired. Potential dielectric, ohmic, and radiative losses contribute to the whole loss. Generally speaking, each loss effect is strongly frequency-dependent. In addition, the physical layout may be designed with some expected impedance value. Sometimes, the MIS slow-wave propagation is measured by a quality factor or figure-of-merit as Q as follows:

$$Q = \frac{\eta}{\alpha} \tag{4}$$

There is no consistency in the literature for the definition of Q , which is also defined elsewhere as $(\alpha \cdot \lambda_g)^{-1}$ [25] or $\beta/2(\alpha)$ [26].

5.1. Unified Transmission Line Model

For the periodic and MIS structures shown in Figs. 2–4, the slow-wave propagation of a mode can be represented simply by an equivalent transmission line model with the characteristic lumped elements whether per unit length or per periodic cell, denoted by *RGLC*. Conventionally, R and G (resistance and conductance per unit length) are caused by the longitudinal current flow on the lossy conductor and transverse current dissipation in the dielectric

region, respectively. L and C (inductance and capacitance per unit length) are produced by the longitudinal current flow and transverse electric field effect, respectively. As multiple modes possibly exist in a waveguide, for instance, the periodic waveguides, multiple lossy network topologies are required to characterize different guided-wave properties of these modes, such as lowpass, highpass, and bandpass prototypes. Nevertheless, any network topology can be theoretically transformed from the fundamental lowpass prototype, shown in Fig. 7. Therefore, a unified transmission line model can be set up to interrelate line voltages and currents at an interval of a unit or a period, which is very informative in analyzing slow-wave properties.

In the frequency-domain, the transmission line equations (or telegraph equations) can be expressed by

$$\frac{dV(z)}{dz} = -(R + j\omega L)I(z) \tag{5a}$$

and

$$\frac{dI(z)}{dz} = -(G + j\omega C)V(z) \tag{5b}$$

Uncoupling these two equations leads to wave equations for the voltage and current on the line

$$\frac{d^2V(z)}{dz^2} = \gamma^2 V(z) \tag{6a}$$

Figure 7. Unified network prototypes or equivalent transmission line model of the slow-wave structures, characterizing frequency responses or guided-wave properties through a set of lumped elements. (a) Arbitrary T or π network representation for any type of slow-wave transmission line. Z and Y stand for complex impedance and admittance, respectively. (b) A general cascaded *RGLC* lumped-element transmission line model for the periodic and MIS slow-wave structures with the concept of distributed voltages and currents.

and

$$\frac{d^2 I(z)}{dz^2} = \gamma^2 I(z) \quad (6b)$$

where $\gamma = \alpha + j\beta = \sqrt{(R + j\omega L)(G + j\omega C)}$ is the complex propagation constant and the complex characteristic impedance of the line can be calculated from $Z_0 = Z_{0r} + Z_{0i} = \sqrt{(R + j\omega L)/(G + j\omega C)}$.

The propagation constant may be expanded in a Taylor series to show the asymptotic behavior of the loss and the phase velocity. For high frequency and low loss, such that $R \ll \omega L$ and $G \ll \omega C$, the first-order approximation is easily made to obtain the following formulas:

$$\alpha \approx \frac{1}{2} \left(R \sqrt{\frac{C}{L}} + G \sqrt{\frac{L}{C}} \right) \quad (7a)$$

and

$$\beta \approx \omega \sqrt{LC} \quad (7b)$$

Similarly, the complex characteristic impedance can be approximated for low-loss lines such that the real and imaginary parts are given by

$$Z_{0r} \approx \sqrt{\frac{L}{C}} \quad (8a)$$

and

$$Z_{0i} \approx -\frac{1}{2\omega} \sqrt{\frac{L}{C}} \left(\frac{R}{L} - \frac{G}{C} \right) \quad (8b)$$

Of course, the phase velocity of a slow-wave structure can be directly derived from Eq. (7b) via

$$v_p \approx \frac{1}{\sqrt{LC}} \quad (9)$$

This simple equation reveals the fundamental requirements for a guided-wave structure to allow slow-wave propagation: either a large inductance or a large capacitance per unit of length or per period, or both, along the signal path by spatially separating electric and magnetic energy. In a periodic structure, a large reactance (inductance and/or capacitance) is induced by the periodic cell, whereas the MIS structure produces only an excess capacitance and its inductance remains basically unchanged with reference to its normal line counterpart. Based on other equations, the loss may be critical in using an MIS structure as opposed to a periodic structure because the lossy semiconductor layer is always required in constructing an MIS structure, and both conductance and resistance could be significant at high frequencies. The transmission attenuation of a periodic structure is essentially caused by the conductive (ohmic) loss and potential radiation loss (discontinuity effect). The change in v_p should affect the other line parameters. Consider a helix

slow-wave structure that generates a large inductance. Its characteristic impedance may be high, whereas the MIS structure yields a low impedance because of its large capacitance. In fact, the lumped elements can be obtained by approximate and quasistatic models for the slow-wave structures.

6. APPROXIMATE AND QUASISTATIC MODELS

As some slow-wave structures like helical and planar periodic lines are complex, it is rather difficult or even impossible to solve these problems analytically. In the earlier days, high-speed computing resources and modeling capacity were quite limited, and it was not practical to generate tedious field solutions for design purposes. Approximate and quasistatic models that are common in engineering practice were widely used to obtain, within an acceptable margin of error, guided-wave properties and design databases for a large class of slow-wave structures including helical and lumped-element models of planar transmission lines. The approximate models are usually developed on the basis of a much simplified geometry that neglects some physical effects and parameters, whereas the quasistatic models are generated simply by considering the limiting case of $f = 0$. The approximate models can be applied to any slow-wave structures, but the quasistatic models are applicable only to those supporting TEM modes or static field solutions. Generally, all of these models are amenable to simple analytical procedures or sometimes closed-form solutions. Advantages of the quasistatic models are that they allow one to gain insight easily into the slow-wave properties of a structure through its extracted lumped elements.

As the models and analysis techniques of waveguide slow-wave structures are easily found in the literature and technical books [1,2,6,8,13–15,17], our attention in this article is focused on slow-wave models and characteristics of planar structures, which are also recent subjects of interest in research and development. Selected quasistatic and lumped-element models are briefly presented to showcase earlier development of modeling and design tools.

6.1. Sheath-Helix Model

Probably the best known approximate model of periodic structures is the sheath-helix model introduced by P. R. Pierce and then refined by Sensiper. Subsequently, it was extensively used for a large class of helices. This model is not presented in this article because it is well documented [6,8,9,14]. Other recently published textbooks contain detailed information [2,3]. The sheath-helix has dispersion, or $(\omega - \beta)$ curves, that approximate the reality of a helical structure remarkably well. In this model, the actual helix of a finite thickness, whether made of wire or tape, is replaced by a fictitious cylindrical tube model, which has such features as (1) an infinitesimal thickness; (2) a radius equal to the mean radius of the actual helix of finite thickness; and (3) anisotropic conductivity, such that the sheath conductivities are infinite and zero in directions parallel and perpendicular to the helical winding direction,

respectively. The sheath-helix model would be closer to the actual situation if the helix is more tightly wound.

6.2. Model for Planar Periodic Structure

As a typical and simplified example of planar periodic structures, Fig. 8 shows a linear and isotropic microstrip line consisting of its double-layered geometrical layout with an infinitely thin periodic strip conductor. Its lumped-element equivalence is built on the basis of quasistatic or quasi TEM mode propagation or low-frequency operation such that the length p of a periodic cell is much smaller than the wavelength. The structure is considered lossless for most quasistatic models even though the ohmic dissipation in a conductor may be significant at higher frequency. Obviously, the wide line section W_1 generates a capacitive effect, whereas the narrow line section is responsible for an inductive effect. In this way, the separation of electric and magnetic energy is achieved in longitudinal space, potentially leading to slow-wave propagation. The lumped capacitance C and inductance L per cell section can be effectively calculated, and the voltage and current are considered stationary over the periodic section. The phase velocity and characteristic impedance

can be readily obtained if L and C are calculated. Therefore, the slow-wave problem is simply reduced to calculations of L and C per periodic cell. The approach, as described in Ref. 23, can be applied to other quasistatic periodic structures.

6.2.1. Capacitance Calculation. Electrostatic field problems are usually handled via the 3-D Poisson equation, which operates on scalar potential functions. With reference to the symmetrical structure of Fig. 8, which is divided into two cross-sectional regions I and II, the periodic cell section is bounded by magnetic walls over which there are no normal electric fields. This is a consequence of the quasistatic condition. The 2-D electric charge density distributed over the periodic conductor surface is denoted by $\rho_e(x, z)$. The electrostatic potentials are expanded in a Fourier series considering boundary conditions. Such expansions are usually in the form of infinite series summations of trigonometric functions, which satisfy the bidimensional boundary conditions over the periodic cells [23]. The infinite summation is subject to a convergence-allowable truncation in numerical calculations. This procedure involves some unknown coefficients. The total energy W_e stored in a periodic section is simply given by $0.5 \int_0^p \int_0^a \epsilon |\vec{E}|^2 dv$, in which the electric fields are derived from the scalar potential functions. To eliminate the unknown coefficients, a set of boundary conditions at $y = h_2$ are used. In this case, the coefficients are formulated by $\rho_e(x, z)$. Therefore, the energy is explicitly expressed by

$$W_e = \frac{2}{ap} \sum_{m=1}^{\infty} \sum_{n=0}^{\infty} G_e(m, n) \cdot \left[\int_0^p \int_0^a \rho_e(x, z) \sin \frac{m\pi x}{a} \cos \frac{n\pi z}{p} dx dz \right]^2 \quad (10a)$$

$$G_e(m, n) = \frac{1}{\delta(n)k_{mn}} (\epsilon_1 \coth k_{mn} h_1 + \epsilon_2 \coth k_{mn} h_2)^{-1} \quad (10b)$$

$$\delta(n) = \begin{cases} 1 & (n \neq 0) \\ 2 & (n = 0) \end{cases} \quad (10c)$$

In Eq. (10b), the term G_e denotes Green's function for this electrostatic field problem. Now, capacitance per periodic section is given by $C = Q/V = Q^2/(2W_e)$, where $Q = \int_0^p \int_0^a \rho_e(x, z) dx dz$. Q is the total electric charge on the conductor, and it is calculated from the charge density function $\rho_e(x, z)$.

6.2.2. Inductance Calculation. As a result of the structural symmetry, the inductance L can be calculated by applying a procedure similar to that for calculating the capacitance. Otherwise, the L calculations are not so simple, and it may require vectorial magnetic potentials that are related to the current density distributed over the conductor. Nevertheless, the magnetic fields in this case have only normal components at the interface $y = h_2$ outside the conductor strip. This is a complementary problem

Figure 8. (a) Cross-sectional view (b) longitudinal view and network equivalence of a generalized periodic microstrip slow-wave line sandwiched by two different linear and isotropic dielectric substrates. This periodic line is simply represented by a lumped-element LC model in the absence of both losses and conductor thickness. Geometrical dimensions and substrate parameters sketched in the figure are similar to the previous illustrations. The lumped elements are extracted by an approximate quasistatic model.

of duality. The scalar magnetostatic potentials proportional to the magnetic fields ($H = -\psi_m$) are used to satisfy the Poisson equation, and they can be expanded with a set of unknown coefficients. At the boundary between the two layers, the normal component of the magnetic flux density is continuous.

In contrast with the electrostatic case, the magnetic flux density is a hypothetical term, and of course, its normal component cannot exist on the conductor surface ($\rho_m = 0$ on the conductor). Similarly, the unknown expanded coefficients can be effectively eliminated, and the total magnetostatic energy is easily obtained by equations in magnetic identity similar to Eq. (10), except that ϵ is replaced by μ^{-1} . The inductance L is given by $L = \Phi/I = \Phi^2/(2W_m)$ with $\Phi = \int_0^p \int_0^a \rho_m(x,z) dx dz$. Φ is the total magnetic flux interlinking the strip conductor. As the magnetic flux across one side of the conductor is equal in magnitude and opposite in sign to that over the other side, it can be calculated from the one-side flux density function $\rho_m(x, z)$.

6.2.3. Charge Density Calculation. To complete our calculations of capacitance and inductance, we need to know the electric and magnetic charge density functions. Usually, various techniques connected to the method of moments, such as the Rayleigh–Ritz variational procedure, may be applied to solve this problem. To do so, the unknown charge density functions are expanded in terms of well-behaved basis functions with unknown coefficients, even though the actual charge densities may be very complex. In the C calculation, for example, the electric charge density function may be expressed in terms of known basis functions f_k of finite series, such that $\rho_e(x,z) = \sum_{k=1}^K \alpha_k f_k(x,z)$, in which α_k are unknown coefficients. The purpose of applying a method of moments is to calculate the unknown coefficients, and then an approximate solution to the problem can be obtained. The L calculation can be made similarly. With the calculated L and C , the slow-wave velocity and characteristic impedance can be derived by applying Eqs. (7–9). The theory and applications of the method of moments can be found in the literature [27]. Details on applying the variational principle are described in Ref. 23, which also presents a number of typical theoretical and experimental results of single and coupled microstrip periodic structures.

6.3. Model for Planar MIS Structure

Various approximate models were proposed for modeling an MIS microstrip line and CPW, whose cross sections are shown in Fig. 3 with a unified equivalent circuit model, as described in Fig. 9. Details of these classic techniques are well formulated in technical papers and books, and they include the parallel-plate waveguide model for the microstrip line [21] and the conformal mapping technique for both the microstrip line and the CPW [26]. Valid use of these techniques is always subject to careful approximations or assumptions about geometrical dimensions and physical parameters. The Schottky-contact microstrip line, which is regarded as a special case of the MIS microstrip line, can be treated similarly to the MIS structure.

Figure 9. Unified equivalent circuit model for an MIS slow-wave structure including microstrip and CPW lines (see Fig. 3). In addition to the previously defined lumped-elements $RGLC$, Z_m is used to account for the conductor loss, which can be obtained by the calculating surface impedance Z_s , for example.

Of course, the MIS structure consists of an unavoidable lossy semiconductor layer and an extremely thin insulator usually with very narrow guiding strips. Therefore, the loss is a critical factor in analyzing and designing an MIS structure. There are three potential difficulties encountered in modeling planar MIS structures: (1) accurate characterization of conductor loss; (2) accurate calculation of fringing fields (usually in the case of the parallel-waveguide model); and (3) the quasistatic multilayer model.

Three different modes of propagation exist along an MIS structure as frequency varies [19,21,26], called “slow-wave mode,” “dielectric quasiTEM mode,” and “skin-effect mode,” respectively. Generally, these modes are roughly distinguished by three characteristic frequencies, namely, the dielectric relaxation frequency f_d , the characteristic skin-effect frequency f_s , and the relaxation frequency of interfacial polarization $f_p = f_d(\epsilon_s h_1)/(\epsilon_i h_2)$ in which the physical parameters are specified in Fig. 3. The lumped-element $RGLC$ depicted in Fig. 9 is easily derived from the quasistatic (TEM mode) models [19,21,26]. Table 1 summarizes quasistatic approximations of the lumped elements for the MIS microstrip (including Schottky-contact line) and CPW. In Table 1, ϵ_0 and μ_0 are the permittivity and permeability of free space, respectively, and F is a geometrical factor stemming from the conformal mapping model, which is approximated by

$$F = \begin{cases} \frac{\ln \left[\frac{2(1 + \sqrt{k})}{(1 - \sqrt{k})} \right]}{\pi} & \text{for } 0.707 \leq k \leq 1 \\ \frac{\pi}{\ln \left[\frac{2(1 + \sqrt{k'})}{(1 - \sqrt{k'})} \right]} & \text{for } 0 \leq k \leq 0.707 \end{cases} \quad (11)$$

in which $k = W/(W + 2S)$ and $k' = \sqrt{1 - k^2}$. The parameter K in Table 1, which can be numerically calculated by an exact static model, accounts for the effect of fringing fields, and its value is slightly greater than 1.0. The effect of conductor loss is reflected in its complex impedance Z_m . It can be derived by several techniques, such as the incremental inductance rule [7], phenomenological loss equivalence [28], and surface impedance approach [7]. Other parameters are described in Fig. 3.

Table 1. Basic Characteristic Frequencies and Lumped-Element Equations of the Approximate Quasistatic Model for MIS and Schottky-Contact Microstrip Lines and MIS Coplanar Waveguides (CPW)

Line Type	Lumped Elements						
	f^a	f^s	R	G	L	C	Z^m
MIS and Schottky-Contact Microstrip	$\frac{\sigma}{2\pi\epsilon_0\epsilon_s}$	$\frac{1}{\pi\sigma\mu_0 h_2^2}$	$\frac{3}{\sigma h_2 w}$	$\frac{w}{\sigma h_2}$	$\mu_0 \frac{(h_1 + h_2)}{w}$	$\epsilon_0 \epsilon_i \frac{w}{h_1}$	$\frac{Z_s}{w}$
MIS CPW	$\frac{\sigma}{2\pi\epsilon_0\epsilon_s}$	$\frac{1}{\pi\sigma\mu_0 (w/2 + s)^2}$	$\frac{1}{\sigma \delta w}$	$2\sigma F$	$\frac{\mu_0}{4F}$	$\frac{\epsilon_0 \epsilon_i w}{h_1} K$	$\frac{Z_s}{w}$

^aThe model validity may be subject to certain limiting conditions. Physical and electrical parameters refer to Fig. 3. The geometrical factor F is calculated by Eq. (11). The complex impedance of conductor Z_m can be derived from the surface impedance Z_s that can be modeled by several well-documented techniques (see relevant references and literature for more details). The K value, usually slightly greater than 1, is used to assess the effect of fringing fields, and it can be numerically calculated by an exact static model.

7. ACCURATE AND HYBRID-MODE FIELD MODELS

Accurate field models are usually required when approximate models are no longer valid or the operating frequency is too high to use a quasistatic approximation. In other cases, the use of hybrid-mode field techniques are mandatory because the slow-wave structures cannot support a quasiTEM mode propagation, such as the corrugated periodic waveguide and the fin line, to name two typical examples. Some physical approximations simplify or make a field model useful before its analytical development. Therefore, the choice of an appropriate field model is critically important for its expected accuracy and efficiency when applied to the structure of interest. There are many techniques available today, whose solutions are usually in numerical form. They include the method of moments and finite-difference and finite-element techniques. Readers are referred to other articles and literature for details on the numerical techniques. There is no “lumped-element” consideration in the field models to account for the spatial separation of electric and magnetic energy in contrast with the quasistatic models.

In the past, a number of efficient techniques were applied to various periodic waveguides (3-D problems) and MIS multilayered planar transmission lines (2-D problems). Earlier models for the waveguide problems were usually related to modal expansion or mode-matching techniques. Planar periodic structures were studied with a spectral-domain approach [24,29,30], which can also be applied to MIS slow-wave structures. In this case, the conductor thickness is usually assumed to vanish even though its effect may be included in the model. In fact, the conductor loss with a finite thickness in the field-based models can be evaluated by various techniques, such as the surface impedance scheme [7] and the self-consistent technique [31]. The semiconductor layer of an MIS structure may be inhomogeneous under certain circumstances, such as a depletion region of the Schottky-contact structures and partially doped MIS lines. Therefore, a generalized technique may be required to handle such complex topologies. In Sections 7.1 and 7.2, two typical techniques are presented narratively to showcase modeling using field theory.

7.1. Model for Planar Periodic Waveguide

Electromagnetic fields in a planar multilayered periodic structure are described by scalar electric and magnetic potential functions that also satisfy Helmholtz equations and boundary conditions [30]. Such potentials can be expanded as functions of trigonometric functions in their infinite summations by considering Floquet’s spatial harmonic representation in the periodic cell. Similarly to the static model, the infinite summation must be truncated. As detailed in Ref. 30, the Floquet harmonics can be regarded as “modal spectra” in the Fourier sense or as a “natural Fourier transform” in the half-periodic cell ($p/2$). As such, a double Fourier expansion is developed over the planar periodic fin line or slotline cell along the x - z plane, as shown in Fig. 10. The resulting formulation suggests that a procedure called “higher order resonant harmonic decoupling” can be readily applied, meaning that even and odd harmonics in the z -direction ($p/2$) can be separated regardless of the fundamental mode. This argument translates the Floquet’s theorem into a linear superposition of the spatial harmonics in a periodic cell with fictitious electric and magnetic walls defined at the periodic boundaries with the interval ($p/2$), as indicated in Fig. 10.

This decoupling procedure provides us with a powerful bidimensional Fourier transform tool in the x - z plane. In addition, this consideration allows predicting the existence of two modes: TM (even harmonics) and TE (odd harmonics). In this way, the Helmholtz equations can be transformed into y -dependent, ordinary differential equations that are solved analytically along the layered transverse direction. This corresponds to a set of transmission line equations in the spectral-domain. The use of the transmission line equations and additional boundary conditions leads to algebraic, spectral-domain-coupled, Green’s function $\tilde{\mathbf{Y}}$ in the form of a matrix at the periodic discontinuity:

$$\begin{bmatrix} \tilde{\mathbf{Y}}_{xx}(\alpha_m, \xi_n, \beta) & \tilde{\mathbf{Y}}_{xz}(\alpha_m, \xi_n, \beta) \\ \tilde{\mathbf{Y}}_{zx}(\alpha_m, \xi_n, \beta) & \tilde{\mathbf{Y}}_{zz}(\alpha_m, \xi_n, \beta) \end{bmatrix} \cdot \begin{bmatrix} \tilde{\mathbf{E}}_x(\alpha_m, \xi_n) \\ \tilde{\mathbf{E}}_z(\alpha_m, \xi_n) \end{bmatrix} = \begin{bmatrix} \tilde{\mathbf{J}}_x(\alpha_m, \xi_n) \\ \tilde{\mathbf{J}}_z(\alpha_m, \xi_n) \end{bmatrix} \quad (12)$$

Figure 10. Two-dimensional physical layout description (a) and spatial-harmonics representation (b) of a periodically loaded planar slotline or fin line whose periodic cell is defined by d (the spacing between two adjacent stubs along the axial direction), $2w$ (the gap between the inline stubs), and $2s$ (the distance between the two bottom lines). The cross section of this structure may be in the form of multilayer dielectrics, whereas the spatial harmonics are transformed into a linear superposition of even (magnetic) and odd (electric) harmonics in a single periodic cell for a hybrid-mode model.

Obviously, the elements in Green’s function are related to α_m (the x -oriented spectral variable), $\xi_n = 2\pi n/p$ (the z -oriented spectral variable), and the unknown β . Then, the unknown aperture fields E and currents J can be expanded in terms of bidimensional basis functions with unknown coefficients, and Galerkin’s technique is applied to derive a coefficient matrix equation in the spectral-domain.

A nontrivial solution for the propagative constant is obtained by setting the determinant of the coefficient matrix $M(\beta)$ equal to zero. Several algorithms may be applied to search for solutions of this resulting nonlinear equation (eigenvalue problems). As explained in Ref. 30, the basis functions can be defined as functions of two types, namely, “guided” and “stored” basis functions. The field quantities and other parameters can be calculated once the fundamental propagation constant is

obtained, leading to the visualization of the field profile over the structure.

7.2. Model for Planar MIS Structure

As the MIS structures are a class of typical planar lossy transmission lines with a multilayered dielectric, a broad range of field-based techniques can be applied. However, the spectral-domain approach, the method of lines, and the mode-matching technique are the widely accepted schemes for modeling these structures because the MIS structures have such special features that the ratio of thickness among the multiple layers is relatively large and also the line width may be critically small compared with other structures. In addition, an inhomogeneous doping profile is possible for improving line performance [32]. Therefore, those fine details must be efficiently taken into account if a successful model is to be obtained. These arguments recommend that a model free of space discretization from layer to layer is favored, which includes the previous schemes. The following presentation is limited to an overview of the method of lines [25], which is a popular alternative to the spectral-domain approach when applied to the same problem. In particular, this method has some unique features, and it allows handling complex cross-sectional geometries, as in an inhomogeneously doped layer.

To begin with, an ideal lossless guiding conductor of vanishing thickness is considered for simplifying the model description. The same field equations as in the modeling of planar periodic structures are used herewith with the two potential functions. The whole MIS structure depicted in Fig. 3 is sampled by a set of alternating electric and magnetic lines perpendicular to the conducting strip plane. The potentials of each of the sampling lines must satisfy the Sturm–Liouville and Helmholtz equations. The Sturm–Liouville equations allow one to account for an inhomogeneous profile [25]. Using finite-difference techniques, these partial differential equations are cast into spatially coupled ordinary differential equations for each layer of the MIS guiding structure. Then they can be decoupled by matrix diagonalization via matrix eigenvalue techniques to yield simple transverse transmission line equations.

In our model, the lower boundary is a perfect electric wall under the ground plane, whereas the upper boundary may be infinity, corresponding to a matched transverse transmission line. Starting from both boundaries with the aid of transverse transmission concepts, we enforce field continuity at each interface. Finally, by equating the upper and lower tangential field components at the entire interface of the conducting strip, a characteristic matrix relationship may be derived from the matrix transformation back in the original space-domain. Extracting the sampling lines that intersect the conductor over which the tangential electric fields are null, we obtain a smaller matrix. The complex propagation constant is obtained from its nontrivial solution.

In contrast with the spectral-domain approach, the method of lines is always formulated in the semidiscrete

space-domain. The underlying advantages are its rigorous approach, simple convergent behavior, and fast algorithm with small memory requirements.

8. SLOW-WAVE SUMMARY AND APPLICATIONS

The two classes of slow-wave structures discussed previously, periodic structures and MIS transmission lines, have their own distinct characteristics because the mechanism of generating slow-wave propagation differs in separating electric and magnetic energy in space. The difference between them can be largely seen from their parameters, such as the slow-wave factor, transmission loss, characteristic impedance, bandwidth, frequency response, dispersion, and power handling capability. Modeling strategies for both types also differ. In fact, different groups of periodic structures and MIS lines also exist, based on the fundamental building block's geometry. The hybrid periodic MIS structures (sometimes called cross-tie overlay MIS structures) are also interesting in their own right, because they share some of the common characteristics of both periodic and MIS structures.

Slow-wave structures are characterized theoretically and experimentally for design purposes. There are several experimental techniques available, such as classic measurement methods for both periodic and MIS structures [7,30]. Other alternative methods, such as the ring-resonator technique, electrooptical sampling, time-domain measurements, and on-wafer probing techniques are also useful. Figure 11 shows an example of the measurement test setups for periodic structures, which allow one to extract the slow-wave factor and transmission loss.

Slow-wave structures are very useful in practice and play roles of paramount importance in the electrical and electronic fields. They are used and will continue to be used in diversified applications, including a broad range of passive and active circuits and devices in radio-frequency, microwave and millimeter-wave, and lightwave technologies. Now, slow-wave structures are categorized in terms of guided-wave properties, and various applications are also presented to highlight the importance of slow-wave structures in high-frequency electromagnetic engineering.

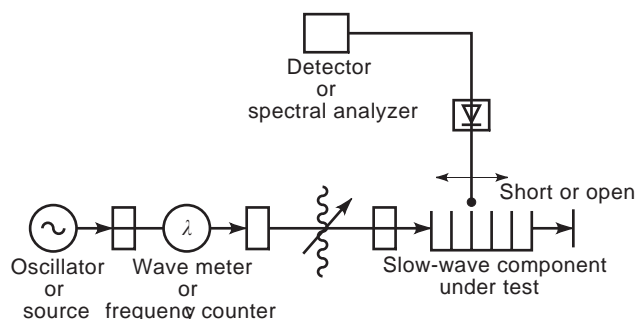

Figure 11. An example of the illustrative measurement setup of a conventional experimental procedure for a periodic structure in the frequency-domain.

8.1. Slow-Wave Structures and Properties

8.1.1. Periodic Structures. There are two classes of periodic structures: nonplanar and planar. The nonplanar structures include metallic waveguides, coaxial lines, and dielectric waveguides, whereas the planar structures are related to the integrated planar dielectric layers on which periodic metallic patterns are formed or printed. The periodic structures have quasiperiodic frequency response in the form of bandpass and bandstop (see Fig. 6 and Ref. 29 for an illustration), and they are quite dispersive. Low-loss, slow-wave transmission usually occurs in the bandpass region, and the structures may exhibit relatively high dispersion. A broad range of characteristic impedance and bandwidths are achievable on the basis of flexible and simultaneous separation of electric and magnetic energy in space. The nonplanar periodic structure may provide high-power handling capability and high Q (low loss) over its planar counterpart.

Three categories among the periodic structures in the form of nonplanar structures that have a relatively long history are the helix, the periodically obstructed waveguide, and the serpentine line. Planar structures may have similar periodic patterns, but they are formed on the 2-D plane, whereas the non-planar structures have 3-D features, and they are more flexible in structural design.

The helix (wire or tape) has continued to enjoy widespread use since its inception in a TWT. Three typical structures of the helix are the simple helix; the bifilar helix, also called the folded helix, made of two contrawound helices of equal but reversed pitches; and a ring-and-bar structure [14]. The last two helix-derived structures may have improved performance over the simple helical structure, such as higher allowable voltage, better thermal conditions, higher interactive impedance, and higher gain, when used in a TWT. However, the simple helix has the largest bandwidth. Similar helical patterns could also be realized by planar means, but very few examples are known to date because they are not useful for high-power applications.

Periodic waveguides supporting nonTEM modes usually behave as high-pass or bandpass filters, depending on the geometry of periodic obstacles or patterns. The topological form of such periodic obstacles characterizes the slow-wave properties. Typical examples include cavity-to-cavity chain structures. The intercavity couplings are made through capacitive or inductive schemes with various shapes, such as slot, cloverleaf, annular ring, and disk. Using the planar technique, the cavity can be easily made in the form of a patch or other geometry, and it can be coupled via gaps and other means.

Some typical examples of the serpentine line structure are the folded waveguide, including the meander-type line and the interdigital structure. Obviously, these structures can be realized easily by planar techniques. A number of these lines exhibit TEM-mode slow-wave propagation and usually the dispersion is low over a wide frequency range. Typical stationary field profiles and mode description over the periodic cell are shown in Fig. 12 for a fin-line structure at its fundamental resonance [30].

Figure 12. Typical electric field patterns or fundamental mode profiles in the $(x-z)$ section of a resonant periodic slow-wave structure (the periodic length p is equal to half of the guided-wave length $\lambda_g/2$ in this circumstance), which are generated by a hybrid-mode modeling technique. (a) TM_{11} mode; and (b) TE_{10} mode, in the case of a slotline or fin-line structure, as indicated in Fig. 10.

8.1.2. MIS Transmission Lines. The MIS structures consist of thin (several micrometers) and thick-film (several hundred micrometers) types on the basis of the thickness of the semiconductor (Si, GaAs, or InP) layer. The insulating layer (SiO_2 or Si_3N_4) is always kept very thin at around the order of less than $2 \mu m$. The fundamental characteristics of an MIS structure depend, first of all, on its line pattern. The thin-type MIS line was developed much earlier than its thick-type counterpart. Generally speaking, the thin-type semiconductor layer is less doped than the thick film for a much higher slow-wave factor, but its dispersion is also relatively high. The thick type is usually

heavily doped and has low dispersion over a wide frequency range. The low-loss propagation of a thick-film type may easily exceed 10 GHz with moderate slow-wave factors and easy-to-match impedance, whereas the thin-film type is limited to several GHz. There is also a difference between the normal MIS structures and Schottky-contact lines. Usually, the Schottky-contact line may require a voltage bias for practical use, and it is usually made of a microstrip line even though other lines are still feasible. The normal MIS structures may have any form of line patterns, such as microstrip, CPW, coplanar strip, fin line and slotline, and so on.

As mentioned in its lumped-element model, the MIS structure presents three basic characteristic frequencies with which it is convenient to design a “characteristic frequency map” in connection with the doping conductivity and frequency, as shown in Fig. 13. This map indicates the three possible modes of propagation identified in an MIS structure:

1. *Dielectric QuasiTEM Mode.* This is for the region where $f_d < f < f_s$. In this range, $\omega\epsilon_s > \sigma$, such that the doped semiconductor layer acts like a normal dielectric and confines most of the guided-wave energy in it. The propagation is usually lossy.
2. *Skin-Effect Mode.* When $f_s < f < f_d$, the doped semiconductor layer behaves as a lossy conductor wall to the wave because $\omega\epsilon_s \ll \sigma$. Hence, the depth of penetration or the skin depth $\delta = \sqrt{2/(\omega\mu_0\sigma)}$ becomes smaller than h_2 . The propagation is significantly dispersive.
3. *Slow-Wave Mode.* This is for the region where $f \ll f_d$ and $f \ll f_s$ as indicated in the map. In this case, f is perceived as not so “high” with the moderate value of σ .

Figure 13. $\sigma - f$ characteristic frequency map of a typical MIS slow-wave structure (TEM-mode type lines) that characterizes three modes: slow-wave mode, dielectric quasiTEM mode, and skin-effect mode. This symbolic map is useful in designing an MIS structure with preliminary consideration of parametric effects on its slow-wave factor and transmission loss.

The electric field is confined within the insulator, whereas the magnetic field penetrates freely over the cross section, resulting in energy separation in space.

The conductor loss is an important aspect in designing an MIS structure. The loss may be accurately calculated by a self-consistent approach [25,31]. In this case, the conductor of a finite thickness is modeled merely as a normal lossy dielectric layer with intrinsic conductivity. For an MIS line operating in the slow-wave mode, the conductor contributes largely to the total loss at low frequency, over which the semiconductor loss is relatively small.

8.2. Slow-Wave Applications

It is known that slow-waves are not limited to periodic and MIS structures. Other structures that generate slow-wave propagation may be competitive in finding applications. Conductors, including superconductors [31,33], for example, exhibit slow-wave effects at low frequency. In this case, the field may penetrate into the conductor, leading to a significant increase in line inductance. Complex media, such as chiral waveguides, may support slow-wave propagation with specially arranged and coupled electric and magnetic properties to separate electric and magnetic energy. A photonic bandgap structure presents merely periodic lattice geometry, which is also subject to slow-wave propagation. Nevertheless, most slow-wave applications known so far rely essentially on the periodic and MIS structures.

The basic applications for slow-wave structures are usually related to the following uses as passive circuits and active devices: circuit miniaturization, frequency-selective devices and filters, traveling-wave devices, antennas, time-delay lines, phase shift and equalization, impedance match, mode polarization, energy conversion, amplification, oscillation, pulse shaping, and signal synchronization. Table 2 presents a general comparison and summary of performance among the periodic waveguides

and MIS lines for slow-wave propagation based on the previous discussion. The table provides a critical choice of these structures for various applications, such as high-power traveling-wave devices, integrated microwave circuits, high-speed signal interconnects, optoelectronics, and superconducting devices. Selected devices and circuits are discussed following to highlight some uniquely useful features of slow-wave structures.

Phase Shifter and Delay Line. Both periodic and MIS structures can be used to design these devices as hybrids or monoliths. Usually, the periodic slow-wave structures present fixed-phase shifting and long time-delay lines. In this case, superconducting technology may be used to significantly reduce the intrinsic conductive loss, for example, a physically very long line required to achieve more than several nanoseconds of group delay. Delay-line concepts were developed much earlier with periodic waveguide structures, whereas the phase shifter has been a popular research topic using the MIS slow-wave structures, especially in designing tunable phase shifters [34].

Linear and Nonlinear Traveling-Wave Devices. Some classic slow-wave examples are high-power traveling-wave tubes, backward-wave oscillators, amplifiers, and linear accelerators using periodic waveguides. The planar technologies allow designing similar distributed devices based on transistors and nonlinear transmission lines (NLTL) for broad-band devices including broad-band impedance matching networks, field grating devices, and of course, broad-band amplifiers [35]. On the other hand, the velocity-match mechanism of electrical and optical signals can be realized by using periodic electrodes and also the control of MIS slow-wave guidance on traveling-wave electrooptical modulators and photodetectors for wideband applications [36].

Filtering and Pulse-Control Devices. A class of filters and multiplexer can be designed with periodic

Table 2. Critical View and Comparison of High-Frequency Electrical and Mechanical Characteristics of Periodic and MIS Slow-Wave Structures Judging from their Passive Circuit Applications

		Basic Characteristics				
		Maximum Limiting Frequency	Transmission loss	Slow-Wave Factor	Structural Size	Frequency Dispersion
Slow-Wave Structures	Metallic and dielectric periodic waveguides	Extremely high	Very low	Low to moderate	Large to very large	High
	Planar periodic waveguides	High or relatively high	Moderate to low	Low to moderate	Small to medium	Medium to high
	Thin-film MIS lines	Low (several GHz)	Medium to relatively high	Very high	Extremely small (hundred μm)	Relatively high
	Thick-film MIS lines	Medium (possibly up to 30 GHz)	Relatively low	Moderate	Miniaturized to several μm	Low

^aAs compared with the MIS lines, the periodic waveguides present usually bandpass and bandstop characteristics, thereby leading to high dispersion of frequency. On the other hand, the unavoidable lossy semiconductor layer in the MIS structures exhibits adversely higher loss of transmission. The performances of the MIS structures refer basically to the Si-SiO₂ building block. The thin and thick films are distinguished by the thickness of the doped semiconductor, which is in the range of several microns and several hundred microns in thickness of the doped semiconductor, respectively.

structures, using their bandpass and bandstop characteristics. Extremely low-loss and linear-phase narrowband filters are realized from superconducting slow-wave lines that have various periodic patterns [37]. Frequency-selective devices and some traveling-wave antennas can also benefit from the advantageous features of periodic slow-wave structures. Pulse-control lines, including pulse-shaping devices, are often seen in high-speed digital circuits and interconnects. In this case, the MIS structures may play an important role in designing low-dispersion and signal-synchronized-pulse routine lines [38].

SMALL ANTENNAS

KYOHEI FUJIMOTO
University of Tsukuba
Tsukuba, Japan

1. GENERAL

What is a small antenna? This question then leads to another question. How small is small in small antennas? When one looks at a millimeter-wave horn antenna of a palm size (Fig. 1), the antenna is said to be small, simply because the physical size is small. On the other hand, when one takes a look at a photo of Marconi's antenna used for the first transoceanic communication in 1901 (Fig. 2), the antenna is surely said to be "a quite big antenna." The Marconi's antenna had a vertical fan-like structure supported by a horizontal wire stretched between two masts about 48 meters high and 60 meters apart [1]. It is natural that smallness might be judged by its physical dimensions. However, smallness of an antenna is not only viewed by the physical size, but also the electrical size defined in comparison with the operating wavelength. When the aperture size of a millimeter-wave horn antenna is much larger than the operating wavelengths, it is not called small, but large in terms of the electrical size, although the physical size is small. In turn, the Marconi's antenna can be said to be small in terms of the wavelength, because it is measured to be about one-tenth of the operating wavelength. Use of the electrical size often is more meaningful than the physical size, because the antenna characteristics and performances are more reasonably dealt with in terms of the operating wavelength.

The smallness of an antenna can be viewed in other ways. For example, low-profile antennas such as the Inverted-L antenna [Fig. 3(a)], planar antennas such as the patch antenna, microstrip antenna (MSA) [Fig. 3 (b)], and so forth, may be classified into small antennas, as the height or thickness, one part of these antennas, is constrained to an electrically small size. In this case, the term "physically constrained small" is considered appropriate.

Another way to classify an antenna as being small is an attribute of its functions. When an antenna has attained either additional functions or enhanced performances without significant change in its dimensions, the antenna is said to be equivalently small, as the corresponding functions would not otherwise be obtained without enlarging the dimension. An example is a case where beam steering function (Fig. 4) is endowed to an antenna without any change in the dimensions; that is to say, the antenna of smaller dimensions is altered to give a beam

Figure 1. Microwave horn antenna.

Figure 2. Marconi's first transoceanic communication antenna.

steering function, which cannot be realized by smaller antennas. This type of antenna is classified into "functionally small antenna."

Then small antennas are categorized into four types [2]: Electrically Small Antenna (ESA), Physically Small Antenna (PSA), Physically Constrained Small Antenna (PCSA), and Functionally Small Antenna (FSA). Although one uses four categories, the classification is not necessarily distinct, so that one class of antenna can be classified into more than one class; for instance, when a patch antenna has the edge (radiating aperture) of one-fifth wavelength in its peripheral, the antenna is referred to as both ESA and PCSA.

Two major subjects exist in small antennas: (1) investigation of characteristics and performance of small antennas, and (2) exploitation of methods to attain small antenna, particularly ESA. The former is mainly concerned with fundamentals of electrically small antennas. The essentials of small antennas have long been studied by many investigators; however, many problems must still be solved. Among them, limitations of small antennas is the most significant and interesting subject remaining of the important problems. It is directly concerned with how to realize small antennas with reasonably high gain or broad bandwidth. The physical limitation was first discussed by Wheeler [3] and then Chu [4], in 1947 and 1948, respectively. Since then, small antenna problems have been discussed among many investigators, particularly regarding

Figure 3. Low-profile antennas. (a) Inverted-L antenna. (b) Patch antenna.

Figure 4. Beamsteering antenna.

antenna quality factor Q , gain, bandwidth, and efficiency [5–10] in conjunction with the limitation.

Meanwhile, various efforts to accomplish practically useful small antennas have continuously been made, and at the same time, attempts were made to realize antennas having performance as close as possible to the limitations. Among them, realization of ESA has been a continuously interesting one in the field of antennas and communications, because small antennas have been required for a variety of wireless systems and downsizing of systems subsequently demand downsizing of antennas rather urgently at the same time. Recent progress in miniaturization of electronic components, devices, and thus circuitries is notable, whereas antenna sizes have not necessarily followed it. The concept of downsizing in antennas is essentially different from that of other electronic components or devices, because antenna problems are inherently concerned with the physical nature of electromagnetic waves in open space, whereas circuitry is concerned with problems within closed space.

Nevertheless, there have been increasing demands for small antennas in a variety of situations. The most urgent requirements in recent years are for the fields of mobile communications, where the number of small terminals such as mobile phones has explosively increased and the antennas for such mobile terminals are required to be not only small, but also to be built into the unit, and yet to have higher or at least similar performance without appreciable degradation. In practice, gain and bandwidth should be maintained the same as that before the size reduction. Furthermore, with the advancement of systems, there have often been encountered the need for antennas that have capability for multiple-band or wideband operation for some systems. Other growing demands also have developed in various wireless systems, which are applied to transmission of not only information, but also data, video signals, and control signals. A typical example is the wireless LAN (Local Area Network) system, including indoor as well as outdoor networks. Another important requirement is for reception of the Digital Television (DTV) broadcasting. Small, wideband and yet reasonably high-gain antennas are demanded. The demands are not only outdoor and indoor antennas, but also vehicle-mount antennas, which should be as small and light as possible. Diversity or adaptive control function is inevitable for vehicle antennas.

Various types of small antennas have so far been developed. Planar and low-profile antennas are typical. Practical examples are Planar Inverted-F antenna (PIFA) [Fig. 5(a)], patch antennas, and microstrip antennas (MSA) [Fig. 5(b)], whereas examples of linear antennas are Normal Mode Helical Antennas (NMHA) [Fig. 5(c)], Meander Line Antennas (MLA) [Fig. 5(d)], Inverted-L antennas (ILA), and so forth. Materials such as ferrites and dielectrics are used to reduce the antenna size. Ceramic Chip Antennas (CCA) [Fig. 5(e)] and ferrite coil antennas [Fig. 5(f)] are practical examples. Among them, a very small Ceramic Chip Antenna exists made up with dimensions of several-millimeter square for applications to small mobile terminals in 1–5 GHz frequency regions, which is considered the physically smallest antenna to be used for small mobile terminals that can be produced by the present state of the art.

2. DEFINITION

“Small antennas” are categorized into four types according to the dimensions or the functions: Electrically Small Antenna (ESA), Physically Constrained Small Antenna

Figure 5. Various examples of small antenna. (a) Planar inverted-F antenna. (b) Microstrip antenna. (c) Normal mode helical antenna (NMHA).

(PCSA), Functionally Small Antenna (FSA), and Physically Small Antenna (PSA) [2].

- ESA is an antenna that has much smaller dimensions as compared with the wavelength. Conventionally, an antenna that has a much smaller volume than a virtual sphere, called “radian sphere” having radius r of $\lambda/2\pi$ (λ : wavelength) (Fig. 6), is referred to as ESA [11]. The radius of $\lambda/2\pi$ is significant in small antenna, because near space around a small antenna is occupied mainly by the stored energy of its electric field or a magnetic field, and the surface of the radian sphere is the transition region from where the energy flow produced by the small antenna changes mainly to the radiation energy.

However, two other terms were previously proposed to define ESA: (1) when an antenna has its greatest dimension less than one-tenth of wavelength [12] and (2) when it has less than one-eighth λ [13]. Although a radian sphere is referred to in the definition of ESA, an antenna may no longer be said to be ESA when it has a length equal to the diameter of the radian sphere; that is, $2 \times \lambda/2\pi$ (0.32λ). Thus, it is reasonable to say that an antenna having the size less than one-tenth λ should be classified to be ESA.

- PCSA is an antenna that is not necessarily categorized as an ESA, but has a shape that has considerably reduced size in one part of the antenna. A low-profile antenna with the height of say one-fiftieth λ or so, like a small MSA, can be classified into PCSA.
- FSA is an antenna that has additional functions or higher performance than an antenna with the same or smaller dimensions. FSA may not necessarily satisfy the above two categories, ESA and PCSA. For instance, an antenna accomplishing a beam steering function that would ordinarily be realized by an antenna of greater dimensions can be classified into FSA.
- PSA is an antenna that is not categorized in any of the above, but still regarded as small in a relative sense; that is, an antenna is judged to be small by its appearance. When the volume is bounded by 30 cm or

less in one length, the antenna can be called PSA. No strict physical meaning exists in the definition of PSA. An example is a microwave horn antenna, which can be placed on a palm. An MSA can be PCSA and also PSA.

These definitions cannot be analytically formulated in practice, because an antenna may be differently classified depending on the practical situation. For instance, when a short monopole categorized as ESA is placed on a rectangular conducting plate of one-quarter λ , as shown in Fig. 7, radiation performance of the monopole may be enhanced, as the effective length is extended by the addition of the conducting plate. Then one may consider that the addition of the conducting plate to the monopole antenna forms a new size-extended antenna system, which no longer belongs to ESA. In other words, performance of an ESA can be enhanced with assistance of a conducting material besides the antenna element. A small chip antenna placed on the ground plane in a small mobile terminal is a typical example.

3. REQUIREMENTS FOR SMALL ANTENNAS

General requirements for small antennas are listed below.

- (1) General
 - dimensions (small)
 - light weight
 - compactness
 - low profile
 - built-in
 - low cost
 - easy construction
- (2) Electrical performances
 - gain (high) *1
 - efficiency (high)*1
 - bandwidth (wide)*1
 - low interaction (desired)*1
 - radiation pattern (desired)*2
 - polarization *2

Figure 6. Radiansphere.

*1 as high/wide/low value as obtainable

*2 realization as is expected

4. MAJOR SUBJECTS RELATED WITH SMALL ANTENNAS

One of the practical and indispensable problems that concern small antennas is the study of the limitation of antennas and another is how to realize small antennas, especially ESA. Study of the limitation is particularly important because knowledge of the limitation is necessary as a guiding principle when development of a new antenna is attempted or small antennas are designed.

The physical limitation of small antenna was first discussed by Wheeler [3], and then by Chu [4], followed by Harrington [8], Hansen [9], McLean [10,11], and Grimes [12]. Recently, Geyi has shown an extended theory of limitation [13] from Chu's theory to include cases for arbitrary geometry and excitation of antennas and discussed the minimum Q and the largest G/Q in antennas.

The essential problem regarding Q is the relationships between antenna size and the lowest bound of antenna Q , which is the inverse of the bandwidth. Antenna designers often encounter practical problems asking how wider bandwidth or how higher efficiency could be obtained with a given size of small antenna. Thiele treated problems of Q based on the superdirective theory, as a small antenna is essentially a superdirective antenna. He obtained a lowest bound of Q in practical point of view and verified why practical antennas do show much higher Q than the theoretically lowest Q by showing some examples of typical antennas [14].

Recent needs for small antenna are urgent, as the downsizing in wireless systems has advanced rapidly and antennas to be applied to these systems should also meet the requirement that is downsizing. It is well known that the smaller the antenna size, the lower the radiation efficiency and narrower the bandwidth. The practical problem is how to keep the antenna performance unchanged or equivalent, even though the size is made smaller. Antenna designers must design antennas that satisfy the requirements, even when the size becomes smaller. With knowledge of the limitation, antenna design turns out to be an effort on how to approach a limitation as closely as possible, for instance, how to obtain wider bandwidth with a given small-sized antenna.

The fundamental concepts of making an antenna small in practice are (1) filling space (two or three dimensionally) effectively that encloses the antenna, (2) realizing uniform current distributions on the antenna element, (3) increasing radiation modes, (4) making self-resonance within an antenna system, and (5) adding functions.

The concept of filling space is based on Chu's theory, in which he derived minimum Q of a small antenna enclosed in a radian sphere. In practical antennas, the minimum Q can hardly be realized without fully using the volume of the sphere. As small dipoles or loops do not use the spherical volume effectively, their lower bound of Q is relatively high and, hence, the theoretically obtainable wideband characteristics can never be realized. In order to overcome the inherent narrow bandwidth problem in small anten-

Figure 8. A uniform current distribution on a small dipole antenna.

nas, filling space effectively enclosing an antenna as much as possible is significant and useful. Space is not necessarily three dimensional, but also two or one dimensional depending on an antenna structure. For example, fractal antennas may have fairly wide bandwidth, as they can occupy the space two dimensionally surrounding the antenna.

Chu also had shown that the ideal current distribution to attain the maximum gain is uniform (Fig. 8) [4]. However, uniform distribution on a dipole cannot ordinarily be realized by a small antenna structure, because current distribution goes to zero toward the end of an antenna element. The current distribution on a small dipole is assumed to be a triangular shape with zero at the end of the element (Fig. 9). One way to obtain uniform current distribution is to load an impedance component. The most popular example is top loading. The longer the linear antenna size is, the nearer the current distribution approaches to uniform, as the distribution is gradually changed more smoothly than a shorter antenna, which is usually assumed to be triangular. By using a traveling wave structure, an equivalently long antenna structure can be attained.

Integration technique, by which an antenna system is constituted with combination of devices or circuitry and an antenna, is another method to obtain uniform distribution, although it may not be perfect, but nearly uniform.

Increasing radiation mode is another important method. Hansen discussed in [9] that antenna Q will be reduced by half with excitation of TE and TM modes at the same time.

Achieving self-resonance in an antenna structure is an important concept of making an antenna small. If self-resonance is attained in a small antenna, one may increase radiation efficiency or avoid the degradation because of loss in the matching circuitry. Without using a reactive matching component with loss, connection between an antenna and the RF front end can be made simple and cost effective.

Self-resonance can be accomplished by (1) loading techniques, (2) using traveling wave structures, and (3) applying IAS (Integrated Antenna Systems) techniques.

Loading of an impedance component, including an antenna element, is essentially to change the current distributions on the antenna element so that the resonance condition is attained. Loading of a conjugate impedance is

Figure 9. A triangular current distribution on a dipole antenna.

to attain resonance for a wide frequency range, that is, wide bandwidth. Complementary structures do not only aim at achieving self-resonance condition, but also obtaining frequency-independent characteristics.

By adding function into an antenna, either enhancement of antenna performance or improvement of antenna characteristics can be expected. It depends on the functions to be integrated into an antenna system. If integration of amplification function could result in the increase of the antenna gain, it would conversely mean the reduction of an antenna size with the gain kept unchanged.

The integration technique may bring evolutionary antenna systems that cannot be realized by the conventional method. Either passive or active integration, or a combination, are possible, and either improvement of antenna characteristics or enhancement of antenna performance could be expected as a result of integration. Typical examples are enlargement of bandwidth, improvement of radiation efficiency, control of radiation patterns, and so forth. Enhancement of antenna performance or improvement of antenna characteristics may bring novel antennas with small size that cannot practically be realized by conventional antennas, although sometimes it would not be as easy as expected.

Application of nonmetallic materials to reduce an antenna dimensions and/or enhance antenna performance is also another important method, by which not only realizing very small antennas, but also having high-efficiency small antennas would be possible.

Realizing small antennas is, in other words, achieving either wider bandwidth or higher efficiency while maintaining the antenna size unchanged.

The practical systems sometimes require a very small antenna to fit to the unit having very small size. Antenna designers thus should attempt to realize an antenna having the practically obtainable performances for the required size, although some difficulty may still exist.

5. PROPERTIES OF SMALL ANTENNAS

5.1. General

Small antennas have some characteristics that distinguish them from ordinary antennas. A very small antenna can be considered essentially as an electric dipole or a magnetic dipole, and the reactive impedance is highly capacitive or inductive, whereas the resistive impedance is very small. With this impedance characteristic, particular care must be taken for small antennas. If the length of a dipole is shorter than one-tenth λ , a perfect match to the load of $50\ \Omega$ is very difficult. However, it is interesting to note that the effective aperture of it is about $0.119\ \lambda^2$ [Fig. 10(a)], when the antenna is perfectly matched, which is only an 8.5% smaller value than that of the one-half λ dipole, the effective aperture of which is $0.13\ \lambda^2$ [Fig. 10(b)] [15], which can be understood by inspecting the flow of the Poynting vector into a small antenna, as shown in Fig. 11 [16]. The figures illustrate cases for when (a) a short dipole is not matched, so the energy passes through the antenna, resulting in no energy absorption, (b) a very

Figure 10. Effective aperture. (a) A small dipole. (b) A half-wave dipole.

short dipole is perfectly matched and the incoming energy is efficiently absorbed, and (c) a matched one-half λ -dipole is used.

In practice, however, matching of a small antenna to the load of $50\ \Omega$ is not so easy, because the input impedance has inherently very low radiation resistance and very high reactive impedance. Matching to the load of $50\ \Omega$ thus needs a high conjugate reactance component to compensate the high antenna reactive impedance and a transformer to transform the low antenna resistance to $50\ \Omega$. When a small antenna is a type of electric dipole, high radiation efficiency may not be expected even if perfect matching could be attained.

The radiation efficiency η is given by

$$\eta = R_{\text{rad}} / (R_{\text{rad}} + R_{\text{loss}}) \quad (1)$$

where R_{rad} denotes the radiation resistance and R_{loss} is the loss resistance, which is composed of $R_{\text{L}a}$ and $R_{\text{L}c}$ existing in the antenna and the matching circuit, respectively. In a small electric dipole antenna, the reactive component of the input impedance is capacitive, so an inductive impedance is required for matching. When the dipole is a short stub of $0.16\ \lambda$ with thickness of $3.3 \times 10^{-4}\ \lambda$, R_{rad} is $0.1\ \Omega$ and X_{rad} (input reactance impedance) is $-2071\ \Omega$. In order to achieve matching, an inductive component of $2071\ \Omega$ is used. When Q_{L} of this component is 100, $R_{\text{L}c}$ is $20.7\ \Omega$. The radiation efficiency η in this case is about 0.005, or 0.5%. With Q_{L} of 400, η increases to 0.019, or 1.9%, which is still very low. A loss resistance because of the inductive component, which is used for the matching circuit, may far exceed the radiation resistance and, consequently, causes low radiation efficiency. It will become a serious problem in designing a small dipole antenna, as very small size is required.

Meanwhile, when a small magnetic dipole of the circumference $0.1\ \lambda$ with the same thickness as the above dipole is used, η is 9.28% with $Q_{\text{L}c}$ of 1000. If $Q_{\text{L}c}$ is 4000, η becomes 21.1%. As a capacitive component can give higher Q than that of an inductive component (a coil), a small

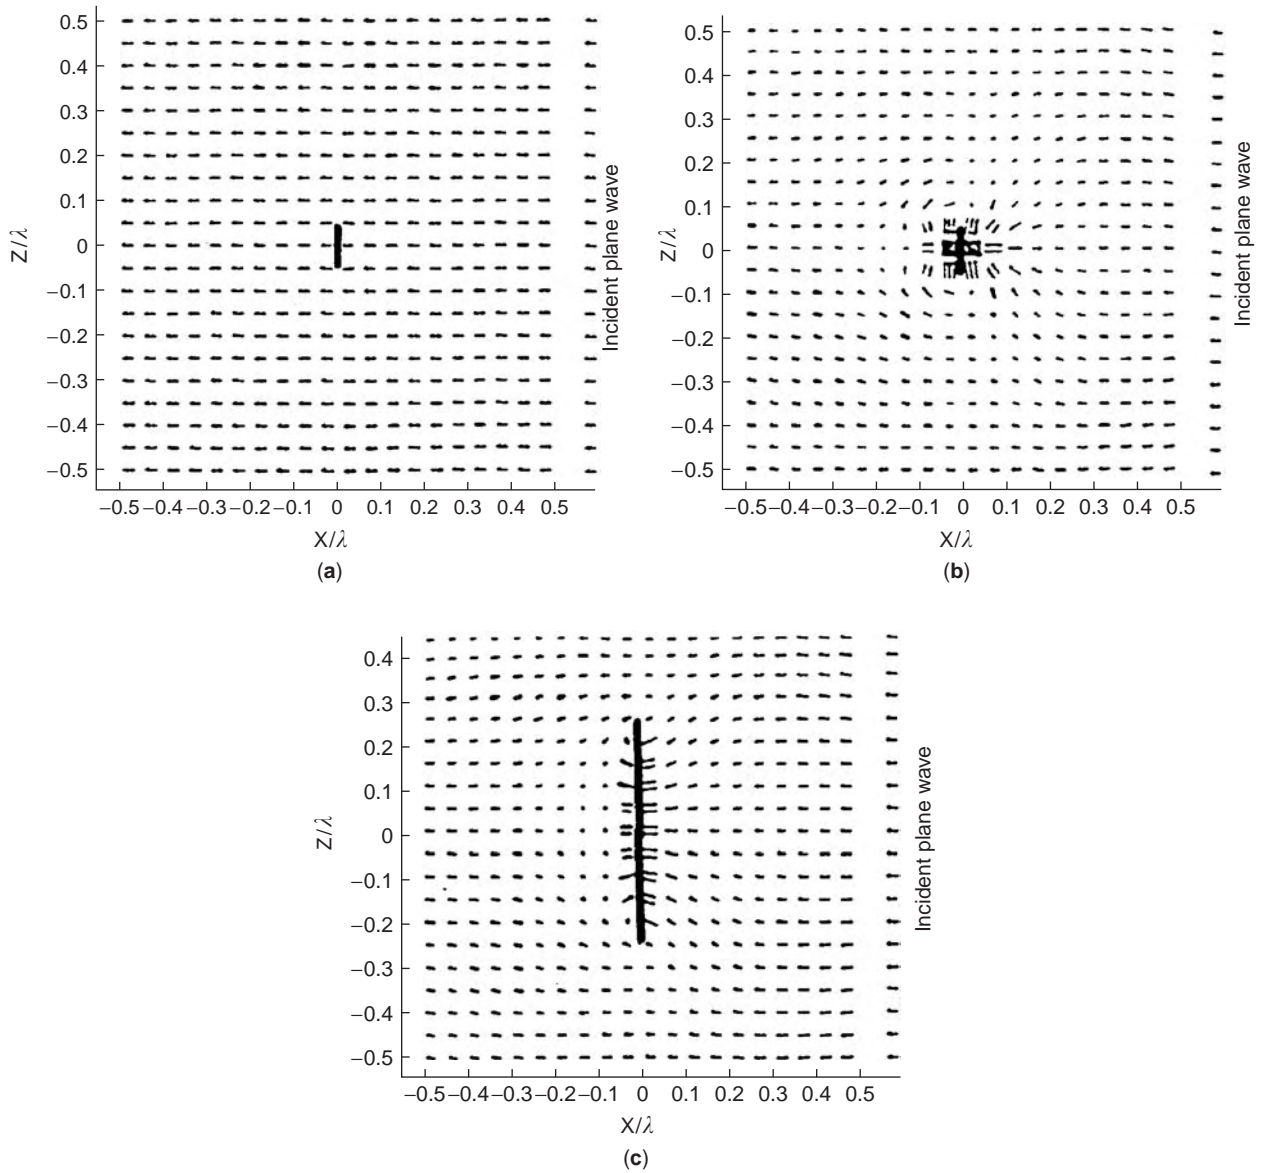

Figure 11. Poynting vector flow in the vicinity of a dipole antenna. (a) A small antenna is not matched. (b) A small antenna is perfectly matched. (c) A half-wave dipole is matched. (From Ref. 16 with permission from Wiley and IEICE.)

magnetic dipole is preferred in order to obtain higher radiation efficiency when about the same size of small antenna is required.

Gain G of an antenna is defined by

$$G = \eta D M \mathbf{p} \tag{2}$$

where D is the directivity, M is the impedance matching factor, and \mathbf{p} is the polarization matching factor. M is given by using the reflection factor Γ at the input terminals as

$$M = 1 - |\Gamma|^2 \leq 1 \tag{3}$$

$$= 4S / (1 + S)^2 \tag{4}$$

where S is VSWR and related with Γ by

$$S = (\Gamma + 1) / (\Gamma - 1) \tag{5}$$

The polarization factor \mathbf{p} is given by

$$\mathbf{p} = |\rho_H, \rho_E|^2 = |\cos \phi_p|^2 \leq 1 \tag{6}$$

where ρ_H and ρ_E are unit vectors of the wave with horizontal and vertical polarization, respectively, and ϕ_p is the angle between the two vectors. Here, the electric fields E_H and E_E of incoming waves, respectively, are described as

$$\mathbf{E}_H = \rho_H E_H \tag{7}$$

$$\mathbf{E}_E = \rho_E E_E \tag{8}$$

Gain of a very small antenna is determined almost by η and M , because D is 1.5 [4] without regarding the size, and p is usually taken as unity, because polarization matching is made in almost all cases. The radiation efficiency η of a dipole shown above was for cases where $M = 1$. If $M \neq 1$, the gain G is lowered as M decreases.

Another important factor in small antennas is Q . Q , in general, is defined as

$$Q = 2\omega X / \text{Prad} \tag{9}$$

where X denotes the reactive energy stored in an antenna, $\omega = 2\pi f$ (f : frequency), and Prad expresses the radiated power from an antenna. When Q is smaller than 10, the reverse of Q can be taken to be the bandwidth B . Either Q or bandwidth B is an essential factor in small antenna design, because in small antenna, Q rapidly increases, and as a consequence, bandwidth B decreases rapidly, as the size of antenna reduces. The lowest Q or highest obtainable B , and the highest possible G/Q have been studied by many investigators. Chu calculated G and Q of a linearly polarized omnidirectional antenna by using spherical mode expansions, by which the fields around the hypothetical antenna enclosed by a sphere of radius (a) are expressed [4]. He discussed about the possibility of wide bandwidth with an antenna of the maximum dimensions of $2r$ when the gain is equal to or less than $4r/\lambda$, which is the gain obtained by a current distribution of uniform amplitude and phase along a line of the length $2r$. He also mentioned that efficient use of the volume of the hypothetical sphere is essential for realizing the minimum Q , thus the wide bandwidth. Chu showed the directivity of a small antenna was 1.5, independent of the size. Later, Hansen discussed the limitation of antennas [9] and mentioned that the minimum obtainable Q shown by Chu could only be approached and never be equaled. He illustrated minimum obtainable Q with respect to the size (kr) of an antenna, as Fig. 12 shows. In the figure, Q 's for dipoles of both thin and thick radius and Goubau's antenna are shown for comparison with the Chu's results. Limitation problems will be described in Section 5.3.

Specialty in small antennas is observed in not only its properties but also the evaluation of the properties, particularly when the size becomes very small. The instrument itself for the measurements may disturb the antenna characteristics or the performance when the size is similar or larger compared with the antenna size. Errors in the measurement may often be observed especially when a small antenna has complicated structure, as proper connection of instrument to the antenna may hardly be made. These problems will be discussed in Section 5.3.

5.2. Characteristics of Small Antennas

5.2.1. Impedance. Theoretical input impedance Z_{dip} of a thin linear short dipole antenna having the length $2h$ and the thickness $2a$ is given as function of kh by [17]

$$Z_{\text{dip}} = R_{\text{dip}} + jX_{\text{dip}} \tag{10}$$

Figure 12. Minimum obtainable Q with respect to antenna dimensions kr . (From Ref. 9 with permission from Wiley and IEEE.)

where

$$R_{\text{dip}} = 20(kh)^2 \tag{11}$$

and

$$X_{\text{dip}} = -j120\{\ln(h/a) - 1\}/kh \tag{12}$$

R_{dip} and X_{dip} with respect to kh are drawn in Fig. 13 [18], where a parameter $\Omega = 2\ln(\frac{2h}{a})$ is used. The resistive component R_{dip} decreases rapidly as kh decreases, whereas the reactive component X_{dip} increases rapidly. When kh is 0.314, i.e., $2h = 0.1\lambda$, R_{dip} is 1.97Ω and X_{dip} is $-3.8 \times 10^3\Omega$.

Theoretical input impedance Z_{loop} of a thin small circular loop antenna having radius (a), and the thickness $2d$ is given by [19]

$$Z_{\text{loop}} = R_{\text{loop}} + jX_{\text{loop}} \tag{13}$$

where

$$R_{\text{loop}} = 20\pi^2(\beta a)^4 \tag{14}$$

$$X_{\text{loop}} = \omega L \tag{15}$$

and

$$L = \mu_0 a [\ln(8a/d) - 2] \tag{16}$$

Figure 13. Input impedance of a small dipole. (After Ref. 18.)

Resistive component R_{loop} and inductive component L are shown in Fig. 14 (a) and (b), respectively. When (a) is 0.05λ and the thickness is 0.005λ , R_{loop} is 15.8Ω , and X_{loop} is 202Ω .

Figure 14. Input impedance of a small loop.

Figure 15. Relationships between Q , η , and kr modified from the graph in Fig. 12.

5.2.2. Bandwidth. The bandwidth Δf is the range of frequencies on either side of a center frequency, at which the antenna characteristics, such as impedance, gain, radiation efficiency, and so forth, are within an acceptable range of those at the center frequency. For narrowband antennas like small antennas, a ratio of $\Delta f/f_0 = B$ is defined as

$$B = \Delta f / f_0 = (f_1 - f_2) / f_0 \tag{17}$$

where f_1 and f_2 , respectively, are the higher and the lower frequencies at which the power declines 3 dB from the

Figure 16. Antenna volume V , relative bandwidth B , and efficiency η of a practical PIFA.

Figure 17. Radiation Q with respect to antenna dimensions (βa and L/λ): McLean's curve is the lower bound for an ideal dipole, which has a uniform current distribution. Far-field Q is the lower bound for a dipole with sinusoidal current distribution. Top curve is a typical radiation Q for a thin wire dipole. (From Ref. 14 with permission from IEEE.)

maximum and f_0 is the center frequency of the bandwidth Δf . This B is referred to as the relative bandwidth and is practically used instead of the bandwidth Δf . The center frequency f_0 is given by

$$f_0 = (f_1 + f_2)/2 \tag{18}$$

Quality factor Q can be used instead of the relative bandwidth B when the bandwidth Δf is narrow ($B \ll 10\%$),

$$B = 1/Q \tag{19}$$

Q of an antenna is generally defined as [20]

$$Q_A = 2\omega W_e / Pr, \quad W_e > W_m \tag{20a}$$

or

$$Q_A = 2\omega W_m / Pr, \quad W_m > W_e \tag{20b}$$

where ω is the radian frequency $2\pi f$, Pr is the radiated power, and W_e and W_m , respectively, are the time average

Figure 18. A wire type bow-tie antenna. (From Ref. 14 with permission from IEEE.)

Figure 19. Radiation Q with respect to antenna dimensions (βa): McLean's curve is the lower bound for a ideal dipole, which has a uniform current distribution. Far-field Q is the lower bound for an dipole with sinusoidal current distribution. Top curve is Q for a thin wire dipole obtained by using X/R . nonpropagating stored electric energy and the time average nonpropagating stored magnetic energy.

As the size of antenna decreases, Q increases greatly and the bandwidth Δf becomes smaller. Q of a small dipole is expressed by [10]

$$Q = (kr)^{-3} + (kr)^{-1}, \quad kr < 1 \tag{21}$$

where r is the radius of a virtual sphere, which encloses the antenna.

The relationships between the antenna size kr , the relative bandwidth B , and the efficiency η are illustrated by Fig. 15, which is modified from Fig. 12 in [9]. In practical small antennas, variation of Q with respect to the size is

Figure 20. An end-loaded dipole with wire.

not necessarily the same as that of Q shown in Figs. 12 and 15. Figure 16 illustrates an example, showing variation of B and η with respect to the size (volume V) of a practical PIFA (Planar Inverted-F Antenna). In practice, $B(Q)$ increases (decreases) as the volume V of antenna increases (decreases), which seems somehow in conflict with the tendency shown in Fig. 12. The reason for it is that efficiency varies with change of the antenna size as well as the bandwidth, in contrast with the curves shown in Fig. 12, where curves are drawn with constant efficiency.

5.2.3. Radiation Patterns. As the size of antenna becomes small, directivity D_{\max} approaches 1.5, which implies the radiation pattern fills two-thirds of the entire solid angle of a space, and the pattern is simply a donut-shaped $\sin \theta$ pattern.

5.3. Limitation of Small Antennas

The reduction of antenna size imposes a fundamental limitation on the antenna performance. Antennas such as ESA having dimensions much less than the wavelength are subject to the limitations. Fundamental properties of small antennas were first treated by Wheeler [3], as was mentioned previously. Wheeler used the radiation power factor Pr , which was defined as a measure of radiation of a small antenna by taking a ratio of the radiation power to the reactive energy. In his treatment, a small antenna was assumed to have dimensions much smaller than the wavelength and, at most, less than one radiansphere ($= \lambda/2\pi$) in space. In small antennas, because the reactive energy exceeds the radiation power, an antenna is equivalently expressed by either a capacitance C or inductance L , both of which occupy a volume V . He discussed that Pr is proportional to volume and also concerned with antenna shape factor. Radiation efficiency η , which is defined as $Pr/(Pr + P_{\text{loss}})$, where P_{loss} is loss power factor, decreases with antenna size, because Pr is small whereas P_{loss} relatively increases with the size reduction.

Chu showed a fundamental limitation in small antennas by using spherical function expansions, expressing fields with a sum of spherical modes [4]. The antenna was assumed to be enclosed by a virtual sphere (Fig. 6), and the electromagnetic (EM) fields produced by the antenna located in the sphere were expressed with modes in a spherical harmonic series. By using the spherical functions, fields in open space can be treated with radial modes as well as the fields in a closed space like a circular waveguide. In his treatment, no azimuthal variations exist, i.e., the radiation is omnidirectional in the azimuth plane. An equivalent circuit was derived based on the field expressions obtained from mode expansions, from which mode impedance can be derived as a ratio of the mode voltages to the mode currents in the equivalent circuit. The antenna quality factor Q is then obtained for each mode with respect to the antenna dimensions, and the lowest limitation of Q was discussed.

As in small antennas bandwidth is the inverse of Q , the largest bandwidth can be found for antenna dimensions. Chu also showed maximum obtainable gain G and then a ratio of G to Q .

Chu's treatment of small antennas was followed by many investigators, and problems regarding limitations of antenna were subsequently discussed.

Fante worked on the antenna Q based on the spherical wave function expansion for the fields outside the circumscribing sphere of the antenna [21], along with Collin and Rothschild's idea, by which the stored energy was treated as the difference of total field energy and the asymptotic limit of the energy density at infinity [22]. Hansen also discussed limitations of small antennas essentially based on Chu's theory and illustrated relationships between antenna Q and antenna size taking radiation efficiency as the parameter [9]. He had shown that when both TE and TM fields are considered at the same time, Q will become one-half of that of the single mode. McLean improved Chu's theory by deriving an exact result for the antenna Q using the field for TM_{01} mode directly. His results were similar to Chu's; however, he found a slightly higher lower bound on Q for antennas, the length of which is approaching to a length of one-third λ .

Chu and McLean's results provide the lowest Q , however, as this lower bound Q can hardly be realized by a practical antenna, because uniform current distributions on the antenna system should be presumed and also the sphere enclosing an antenna should be used fully by the antenna. Foltz and McLean attempted to overcome this problem by expanding the fields around an antenna using prolate spheroidal functions, instead of spherical functions, and obtained a little higher Q , which was a more practical value than Chu's results. This result can be understood in that a dipole can be better represented by a prolate spheroidal volume than a spherical volume, as it occupies higher fraction of the volume inside the prolate spheroid than a sphere.

Thiele took a different approach to find a lower bound on the radiation Q_A for ESA [14]. His approach is based on the concept of superdirectivity R_{SD} [23], which is defined as the ratio of an integration of the far-field pattern function over all space (i.e., visible + invisible) to an integration over visible space as follows:

$$R_{SD} = \frac{\int_{-\infty}^{\infty} |f(u)|^2 du}{\int_{-\frac{\pi L}{\lambda}}^{\frac{\pi L}{\lambda}} |f(u)|^2 du} \quad (22)$$

where $f(u)$ is the normalized far-field pattern function in u space, $u = (\beta L/2) \cos \theta$, and L is the length of the linear source. Here it is assumed that the source is along the z axis with constant phase and the main beam direction is broadside. R_{SD} is equal to $(Q_A + 1)$ [14] if

$$Q_A = \frac{\int_{-\infty}^{-\frac{\pi L}{\lambda}} |f(u)|^2 du + \int_{\frac{\pi L}{\lambda}}^{\infty} |f(u)|^2 du}{\int_{-\frac{\pi L}{\lambda}}^{\frac{\pi L}{\lambda}} |f(u)|^2 du} \quad (23)$$

However, he discussed validity of using $f(u)$ only in Eq. (22) and then added the element pattern function

Figure 21. Minimum possible Q and minimized Q. (From Ref. 13 with permission from IEEE.)

Figure 22. G/Q for antenna with and without directivity. (From Ref. 13 with permission from IEEE.)

Figure 23. A planar bow-tie antenna.

Figure 24. An example of fractal structure.

Figure 25. An example of self-complementary structure.

$g(u)$ to $f(u)$ in Eq. (23), whereby consistency with Q_A defined by Eq. (21) is kept. Q_A is then expressed by

$$Q_A = \frac{\int_{-\infty}^{-\pi/L} |E_n(u)|^2 du + \int_{\pi/L}^{\infty} |E_n|^2 du}{\int_{-\pi/L}^{\pi/L} |E_n|^2 du} \quad (24)$$

where $E_u = f(u)g(u)$ normalized field pattern. For a dipole of arbitrary length L along the z axis with a sinusoidal current distribution,

$$E_n(u) = \frac{\cos u - \cos\left(\frac{\beta L}{2}\right)}{\left[1 - \cos\left(\frac{\beta L}{2}\right)\right] \sqrt{1 - \left(\frac{2u}{\beta L}\right)^2}} \quad (25)$$

Examples of radiation Q_A 's obtained by Eqs. (24) and (25) are shown in Fig. 17. A curve on top in the figure is typical radiation Q_A of a thin linear dipole obtained as a ratio of antenna input reactance to antenna input resistance, by using the method of moment. A curve at bottom shows the lower bound Q_A for an ideal or Hertzian dipole, which has uniform current distribution. McLean derived this Q_A by using the lowest order TM mode and that mode only. TM_{01} mode generates fields equivalent to the fields produced by a dipole of uniform current distribution, which corresponds to an ideal dipole. When the current distributions are sinusoidal, the lower bound of radiation Q_A is higher than that of antennas with uniform current

Figure 26. A capacitor plate-loaded dipole.

Figure 27. Various examples of loaded monopole on the ground plane. (a) Inverted-L, (b) Inverted-F, (c) T-shaped, (d) Umbrella type, (e) Loop-loaded, (f) Spiral-loaded, and (g) Device integrated.

distributions, which is considered to be a more practical case. The middle curve, denoted “far-field Q_A ,” is obtained by using Eq. (25) for a dipole of a sinusoidal current distribution. The curve is in between the top and the bottom ones. Q_A of a bow-tie dipole, which fits into the spherical volume of radius $L/2$ as shown in Fig. 18, has slightly higher values than the far-field Q_A , as Fig. 19 shows by a curve plotted with \square -symbols. An end-loaded dipole, shown in Fig. 20, has nearly uniform current distribution on the radiating element, so its radiation Q_A lies between McLean’s curve and the typical radiation Q_A , as shown by a curve plotted with \circ -symbols in Fig. 19. With increasing size, current distribution gradually varies to sinusoidal from uniform, and then the Q_A approaches to McLean’s curve. The top two curves show effects of antenna thickness, that is, increasing Q_A with decreasing the

thickness of a dipole antenna. Thiele also discussed Q_A with variation of radiation efficiency.

When an antenna is excited by both of the lowest modes TM_{01} and TE_{01} , the lowest Q , which is one-half that for either mode alone, is obtained [9]. In this case, the field is circularly polarized. The practical example is a case where both a small electric dipole and a small loop are used for the circular polarization. Q of this two-antenna system is one-half that of either the dipole or the loop alone. However, when circular polarization is generated by a cross dipole system with a $\pi/2$ phase difference, the Q will differ from the dipole-loop system and also differ from the Q of either element alone.

Grimes and Grimes have shown that Q of a crossed-Hertzian electric dipole approaches one-third that of a single dipole as the dipole becomes electrically small [12].

Figure 28. Connection of unbalanced line to balanced line. (a) Direct connection of a coaxial cable to a two-wire transmission line.(b) Equivalent expression of unbalanced mode. (c) Equivalent expression of balanced mode.

Figure 29. A dielectric material-loaded small monopole antenna used for evaluation of very small radiation resistance. (After Ref. 25.)

They used a time-dependent Poynting theorem. This factor one-third cannot be obtained by using frequency-domain approaches, because the near fields of the two dipoles are coupled and a phase difference exists between them.

Geyi further extended Chu’s theory to include antennas of arbitrary geometry and excitation. He has first derived the minimum possible antenna Q and then the maximum possible ratio of gain G over Q, based on the spherical mode theory. Fante had shown Q for directional antennas previously; however, Geyi examined Fante’s approach and pointed out that was incorrect. He discussed fundamental limitation of antenna by showing minimum possible Q and

maximum possible G/Q for both omnidirectional and directional antennas. They are expressed by [13] for directive antennas,

$$\max \frac{G}{Q}_{dir}^{small} \approx \frac{6(ka)^3}{2(ka)^2 + 1} \quad (26)$$

$$Q_{dir}^{small}|_{small} \approx \frac{1}{ka} + \frac{1}{2(ka)^3}, G_{dir}^{small}|_{small} \approx 3 \quad (27)$$

for omnidirectional antennas,

$$\max \frac{G}{Q}_{omn}^{small} \approx \frac{3(ka)^3}{2(ka)^2 + 1} \quad (28)$$

$$Q_{omn}^{min} \approx \frac{1}{ka} + \frac{1}{2(ka)^3}, G_{omn}^{max}|_{small} \approx 1.5 \quad (29)$$

For small antennas, which are considered here as antennas with the length less than one-eighth λ, the max G/Q and min Q can be achieved simultaneously. Gmax, given by Eq. (27), corresponds to the directivity of an infinitesimally small dipole. Therefore, an omnidirectional antenna, which can achieve maximum bandwidth, has the same directivity as that of an infinitesimally small dipole.

Figure 30. Measured results. (a) Radiation resistance vs. relative permittivity of loaded material. (b) Inverse of input reactance vs. relative permittivity of loaded material. (After Ref. 25.)

Figure 31. Wheeler-cap method for the radiation efficiency measurement. (From Ref. 24 with permission from Artech House.)

Figure 32. Variation of current distribution on an inverted-L element under the effect of Wheeler-cap. (From Refs. 24,27 with permission from Artech House.)

$Q_{\min}|_{\text{dir}}$, $Q_{\min}|_{\text{omn}}$, and minimum Q are shown in Fig. 21, where it is observed that $Q_{\min}|_{\text{dir}} > Q_{\min}|_{\text{omn}} > \text{minimum } Q$, excepting for $Ka < 1$. $G/Q|_{\text{dir}}$ and $G/Q|_{\text{omn}}$ are depicted in Fig. 22, where $G/Q|_{\text{dir}}$ is seen always larger than $G/Q|_{\text{omn}}$, which can be easily understood that a directional antenna may have higher gain even when Q is kept near the same value.

6. REALIZATION OF SMALL ANTENNAS

Various practical ways exist of making an antenna small.

First, applying the space-filling concept to an antenna structure is the most significant. Chu discussed this concept, stating that gain increase with minimum Q can be accomplished by effectively filling space within which an antenna is enclosed. He also showed that uniform current distribution on a dipole antenna leads to achieving maximum gain. The concept is not only associated with three-

Figure 33. A planar-cap loaded small monopole on the ground plane.

Figure 34. Various models of top-loaded monopoles.(a) A bar loaded at one side. (b) A bar loaded at both side. (c) T-bar loaded. (d) L-bar loaded. (e) Cross-bar loaded.

dimensional structures, but also one- or two-dimensional structures. A planar structure is a simple case in which the problem is how to constitute an antenna that can occupy the space to the greatest extent possible. A bow-tie antenna is an example (Fig. 23). More effective space filling is seen in fractal structures (Fig. 24), by which space to be filled will be increased by increasing the number of modes. Recently, much attention has been paid to the fractal structure by many investigators in great expectations of developing small antennas having wide bandwidth.

Second, accomplishing self-resonance in an antenna structure is significant. In a small dipole, for example, the shorter the antenna size becomes, the harder achieving the resonance within the antenna structure becomes, as the radiation resistance decreases to very small values, whereas the capacitive reactance increases greatly. Then a very high inductive reactance is required for matching. This high inductive reactance, which introduces a higher loss resistance than the radiation resistance, will degrade the radiation efficiency. On the contrary, if self-resonance condition can be satisfied in the antenna structure, such a loss can be avoided and achievement of appreciable radiation efficiency can be expected.

Self-resonance can be attained by integrating conjugate components into an antenna structure, as the reactive impedance is compensated. A composite antenna structure, for instance, a combination of a small dipole and a small loop, produces the self-resonance condition in the antenna system by compensating their reactance components against each other. If an antenna adopts complementary structure, self-resonance for a wide frequency range may be attained. The complementary structure (Fig. 25) has inherently frequency-independent property when it is constituted on an infinite platform.

Third, realizing uniform current distribution is another important concept for obtaining small antenna. However, in a practical antenna system like a dipole, uniform current distributions can hardly be realized, as the current diminishes at the end of the dipole element. One way to realize nearly uniform current distribution on an element is to load an impedance component or an antenna element

Figure 35. Input impedance characteristics of top-loaded monopoles shown in Fig. 34. (After Ref. 51.)

within the antenna. Top loading is an example. A capacitor plate is attached on top of a monopole standing on the ground so that the current on the monopole can be adjusted to have nearly uniform amplitude, as shown in Fig. 26. Loading of wire elements on top of a monopole, as Fig. 27 shows, is another method. The figure shows various types of top-loaded antennas; (a) inverted-L, (b) inverted-F, (c) T-shape, (d) umbrella-shape, (f) loop-loaded, and (e) spiral-loaded. By integrating some devices or circuitry into the antenna structure, current distributions may be modified to realize distribution of as near to uniform as possible [Fig. 27(g)].

Fourth, a more significant concept is to increase the modes. Gain increase or bandwidth enhancement can be expected with increase of modes. Two radiation modes can be produced by exciting an antenna with both TE and TM modes. A practical example is combination of a dipole and a slot. If they have complementary structure and are constructed on an infinite platform, it has frequency-independent characteristics. In practice, however, because an antenna structure can hardly be constituted on an infinite platform, perfect frequency-independent characteristics

cannot be accomplished. Nevertheless, an antenna with fairly wideband characteristics, and yet small size, can be realized, even with imperfect complementary structure.

Fifth, integration of devices or circuitry into an antenna structure is a useful technique to obtain either improvement of the antenna characteristics or enhancement of the antenna performance. By means of this technique,

possibility of gain increase, bandwidth enhancement, or improvement of radiation efficiency in a small antenna may exist. It does not mean, however, that these improvements and/or enhancements cannot always be accomplished, but it is dependent on antenna structure, integrating devices, method of integration, operating frequency, and so forth.

7. MEASUREMENTS [24]

7.1. Considerations Necessary Prior to the Measurement of Small Antennas

It seems no essential difference exists in small antenna measurement from the ordinary antenna measurement. However, the difference of small-antenna performance from that of ordinary antennas gives rise to the difference in their measurement. The reduction of antenna size presents various problems to the antenna designers because of the performance penalties in antenna characteristics, such as impedance, efficiency, bandwidth, and so forth. As far as the small antenna is concerned, the problems are not only associated with antenna design, but also with its measurements. The smaller the antenna size, the

Figure 42. Equivalent expression of pager antenna system. (a) Balanced mode (loop mode). (b) Unbalanced mode (dipole mode). (From Ref. 29 with permission from Research Studies Press.)

harder is the determination of its performance. The difficulty in small antenna measurements is attributed to the performance penalties as well as the antenna structure, which may have an asymmetric configuration. Problems will become complicated when a small antenna is mounted on or built into a platform in a unit of wireless systems. The antenna system then assumes a composite structure of an antenna and the unit body as an antenna system, and thus the measurement must perform to evaluate the performance of such composite antenna system. Special care is necessary to obtain a reliable determination of small antenna performance. Some typical cases to which particular attention should be paid are as follows:

- a. When the size of the antenna is very small compared with the wavelength or the size of nearby conducting materials.
- b. When the antenna structure is asymmetric.
- c. When some proximity effects exist on the antenna.

Although particular considerations are given to the measurement of small antennas, some cases may exist where no effective method is found for the accurate determination of antenna characteristics. For example, when the size of the antenna is extremely small, the resistance becomes too small to be determined. Another case is where the antenna structure is so complicated that precise measurement becomes very difficult to perform. When the antenna size is very small, difficulty in the measurement develops from not only the specific antenna performance, but also subjects related to antenna structure, proximity effect, and so forth.

Antenna measurements are often made by using an image plane as the ground plane (GPL). With an image (ground) plane, measurements can be made simpler and more accurate as compared with measurements without an image (ground) plane. When an antenna under test has simple and symmetric structure, half the antenna structure can be replaced by an image plane, and convenient measurements may then be made on one-half of the antenna. By using a GPL, a coaxial cable can be used for feeding of a test antenna. As almost all of the instruments have unbalanced mode output terminals, a coaxial cable is

Figure 41. Schematic of pager input terminals. (From Ref. 29 with permission from Research Studies Press.)

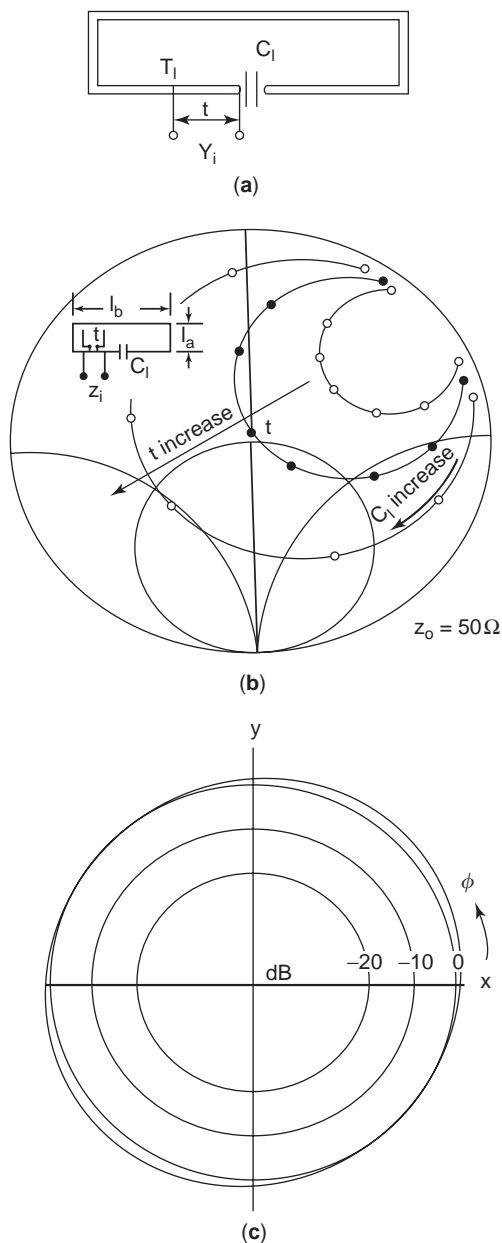

Figure 43. Receiving patterns. (a) Pattern produced by a balanced mode. (b) Patterns produced by unbalanced mode. (c) Combined pattern resulted in omnidirectional pattern. (From Ref. 29 with permission from Research Studies Press.)

used in ordinary measurements. Use of a coaxial cable is convenient and simple, and no Balun (balanced-unbalanced transformation) is necessary. In addition, a stable measurement can be performed, as noise and interference can be isolated from the antenna feed. The feature of using a coaxial cable feed behind the GPL is not concerned about the unbalanced current that disturbs the measurement.

When an antenna has balanced feed terminals and is connected by an unbalanced cable to feed, an unbalanced current may be easily produced on the feed cable. Similar situations are encountered when a small antenna is composed of asymmetrical, irregular, or complicated struc-

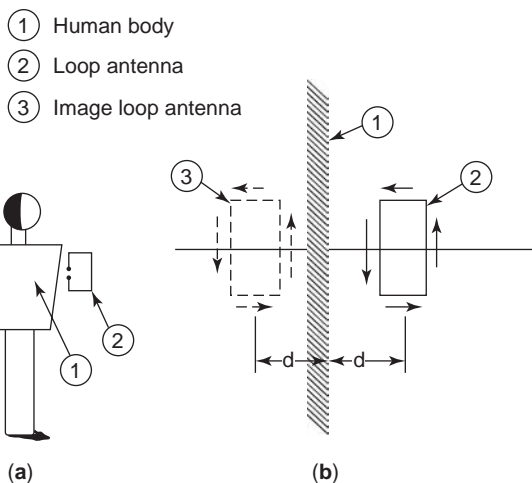

Figure 44. Self-resonance of a small loop antenna. (a) Variable parameters; feeding gap t and series capacitor C . (b) Variation of input impedance with variation of t and C .

tures. Use of a Balun is a must, and every means must be taken to avoid coupling, proximity effects, and so forth.

As a practical GPL cannot be made with infinite size, an undesired unbalanced current may be induced on the plane and further flow behind the plane. Thus, the determination of the antenna impedance becomes uncertain and radiation patterns are distorted. Hence, a usual compromise is to use a conducting plane of several wavelengths or more to obtain antenna performance nearly that of free space. For this purpose, use of a high-impedance ground plane (HIG), designed based on the electronic bandgap (EBG) concept, is recommended. However, one should be careful about the frequency dependence of the HIG.

7.2. Antenna Structure

When the size of antenna under test is comparable with or smaller than that of the instrument connected to the test antenna, electromagnetic coupling is likely to exist between the antenna element and nearby objects, including cables, instruments, and so forth. Such coupling effects may disturb the measurement. For example, if a coaxial cable is connected to an antenna element, the cable couples electromagnetically with the antenna element, and the impedance of the antenna may be measured with an error.

Figure 45. Complementary structure. (a) A planar element. (b) A complementary slot.

Figure 46. A typical complementary antenna; a monopole and a slot.

Environmental condition may likely affect antenna performance, and thus some errors will be produced in the measurement. When an antenna has a complicated structure, such environmental conditions may likely affect the antenna performance. A typical example is a case where an antenna is used for small mobile terminals, where the

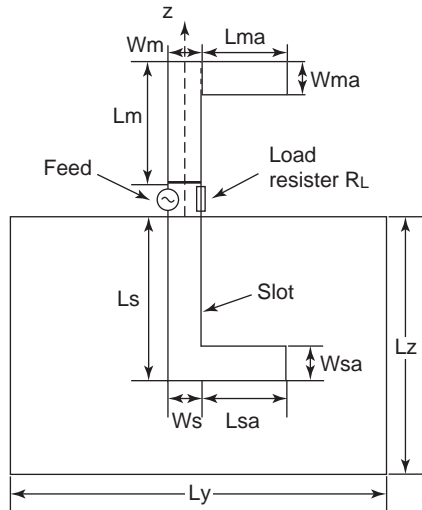

Figure 48. Normal mode helical antenna (NMHA).

mobile unit effectively acts as a part of radiator, as the antenna element excites the conducting materials in the unit. In this case, a combination of the antenna element and the unit constitutes an equivalent antenna system, and the measurement will be on the equivalent antenna system.

When undesired mode current exists in the antenna systems, uncertainty of the measurements is increased and exact antenna performance cannot be determined.

Figure 49. Equivalent expression of NMHA.

7.3. Balanced and Unbalanced Transformation

When a coaxial cable, which has an unbalanced mode, is connected directly to a two-wire line, which has a balanced mode [Fig. 28(a)], the system is equivalently expressed by two parts: an unbalanced mode [Fig. 28 (b)] and a balanced mode [Fig. 28(c)]. The unbalanced mode current I_u contributes to produce radiation, whereas the balanced mode current I_b does not. If the unbalanced mode current exists on the outside of the outer conductor of the coaxial cable, it may produce undesired radiation and may cause an error in the measurement of impedance and radiation patterns.

7.4. The Effect of Nearby Conducting Materials

The effect of nearby conducting materials on an antenna system, which is called the proximity effect, is an undesired phenomenon for small-antenna measurements. The usual attempt is to remove the proximity effect or to keep it as small as possible in the measurement system. If any proximity effect exists near a feed point, antenna current may be varied so that antenna characteristics such as impedance and efficiency are varied as well.

When some materials are located very near to an antenna element, removal of the proximity effect is not feasible. If an appreciable amount of radiation current flows

Figure 50. A model of normal mode helical antenna. (From Ref. 33 with permission from Research Studies Press.)

on the materials, the materials are considered a part of the “radiator,” and the antenna element and the materials together are considered as a combined radiator. In this case, the measurement is performed for the combined radiator. A typical example is a mobile phone unit, in which the mobile phone body and antenna element act as an antenna system.

7.5. The Accuracy, Precision, and Stability of the Instrument

If the antenna under test has such small size that its resistance is, for example, several ohms, the instrument to be used should have high enough accuracy and precision to measure such a low resistance value. A typical case is where the efficiency of an ESA that has dimensions on the order of one-tenth λ or less is determined. When an antenna impedance in the VHF-UHF ranges or higher is less than 0.5Ω , for example, no way to determine the true impedance may exist because an instrument with high enough accuracy to determine such a small value may not be available.

A successful measurement for such small impedance with reasonable accuracy was reported in [25], in which very low impedances of dielectric material-loaded dipoles (Fig. 29) are introduced. The results are shown in Fig. 30, where small values of radiation resistance and inverse of input reactance with respect to the relative permittivity of loaded dielectric material are shown. Efficiency-bandwidth ratio, which corresponds to Wheeler’s radiation power factor, is used to evaluate small values of radiation

Figure 51. Input impedance of a NMHA. (From Ref. 33 with permission from Research Studies Press.)

Figure 52. Radiation efficiency η versus pitch P . (From Ref. 33 with permission from Research Studies Press.)

resistance along with Wheeler-cap method for efficiency measurement.

Stability of the instrument is also important because, if the instrument is not stable enough, errors because of fluctuation in the measurement system become involved in the measured results. For instance, when a small impedance of an ESA, e.g., about $1\ \Omega$ is measured, stability of the instrument must be high enough to determine one-tenth of $1\ \Omega$ or so. The results obtained by the measurement with an unstable instrument are meaningless.

7.6. Measurement of Radiation Efficiency

There are three typical methods to determine the antenna efficiency: pattern integration method, Q-factor method, and Wheeler method [26].

The pattern integral method determines Prad from the integration of the radiation pattern intensity, which is obtained from the far-field measurement. Although pattern integration method is considered the most accurate available, especially when the absolute efficiency of an antenna is desired, it usually takes a rather long time, because it needs to measure radiation patterns and to perform integration of the radiation patterns over a spherical surface completely enclosing the antenna.

On the contrary, Q-factor and Wheeler methods have the advantage of being quick and easy to employ, as compared with the pattern integration method. These two methods relate with antenna efficiency to the input impedance rather than the far-field pattern integration. The two methods have the advantage that the measurement does not require any particular system, but can employ ordinary methods and also be performed in ordinary laboratory rooms. However, there is a tradeoff between the accuracy and ease of the measurement because the accuracy of the antenna efficiency obtained by these two methods is relatively lower than by the pattern integration method.

Figure 53. Design chart of NMHA. (a) Dh vs. P with respect to number of turns MT . (b) Dh vs. P with respect to resonance resistance R . (From Ref. 33 with permission from Research Studies Press.)

The Q-factor method is based on a measurement of two antenna Q values; one is the Q_{RL} of the test antenna and another is the Q_R of an ideal antenna. Q_{RL} can be determined by measuring the impedance of the test antenna. Q_r can be determined from calculations based on Chu's theory. If the Q of an antenna is high, it can be interpreted as the reciprocal of the relative bandwidth B. The B can be known from the impedance-frequency characteristics. B is defined as the bandwidth for the half-power frequencies that occur for a power reflection coefficient of 0.5 (VSWR = 5.83). As a result of the inherent difficulty in determining

Figure 54. Model of meander-line antenna. (From Ref. 34 with permission from IEICE.)

Figure 59. Radiation efficiency η with respect to length l/λ . (From Ref. 34 with permission from IEICE.)

Figure 60. Meander-line antenna composed of two strips in parallel. (From Ref. 35 with permission from IEICE.)

Q_R , the Wheeler method is recommended because it is simpler in practice.

In the Wheeler method (Fig. 31), the antenna resistance is measured in two ways: R_{in} of an antenna reradiating into free space and R_{loss} of an antenna placed within a Wheeler cap, which eliminates radiation from the antenna. By using these two resistances, R_{loss} and R_{in} , R_{rad} can be found, because $R_{in} = R_{rad} + R_{loss}$. Then the efficiency η is calculated from

$$\eta = R_{rad} / (R_{rad} + R_{loss}) \tag{30}$$

The dimension of a cap is recommended to be about $\lambda/2\pi$ or less, although no exact theories to prove this idea exist. From the experimental results, no severe limitation in the cap size seems to exist unless it does not greatly exceed $\lambda/2\pi$. For the shape of a cap, either a hemisphere or cubic shape can be used. The shape somehow depends on the size and type of test antennas. For a thin, short monopole, both hemispheric and cubic shapes can be used. A cubic shape seems to be better for antennas, such as an inverted-F antenna, because it has elements parallel to the sides of the cap, and the distance between the antenna element and the cap can be made nearly equal; thereby, variation

Figure 62. Equivalent circuit of two-strip meander-line antenna. (From Ref. 35 with permission from IEICE.)

in the antenna current is made small after the cap covers the antenna.

In any case, care must be observed for the resonance or antiresonance of the antenna, cap, or both. Note that the principle of the Wheeler method is based on the measurement of the series resistance or the parallel conductance at or near resonance or antiresonance frequencies; resistance or conductance becomes very low or approaches an infinitely large value, and no consistency in the measured values can be expected.

The inner surface of a cap should be plated to reduce the ohmic loss. Usually, the interaction of the cap surface current with the antenna current is ignored because it can be assumed to be very small. However, it may become an appreciable value when the antenna element approaches the inner surface of the cap because the cap surface current may interact with antenna current. Then the cap surface loss becomes included in the antenna loss. Plating the cap surface with gold is best.

Another problem in the Wheeler method lies in an assumption that the antenna current is not changed in the Wheeler cap, which is not really true. Figure 32 shows that the antenna current of an inverted-F antenna varies because of a Wheeler cap [27]. Variation of the current depends on the shape and the size of the Wheeler cap as well as the type and the size of the antenna. Errors in the measurement are greatly increased, especially at the frequency of resonance or antiresonance, which depend on the type and size of the antenna as well as the shape and size of the Wheeler cap.

8. PRACTICAL SMALL ANTENNAS

8.1. ESA

8.1.1. Self-Resonance Structure

8.1.1.1. Short Monopole with Capacitor Cap Top-Loading. A capacitor cap is placed on top of a monopole standing on the ground plane (GPL) (Fig. 33) in order to increase the radiation resistance of a short monopole. With assistance of an image presumed below the GPL, the antenna system is considered as a dipole with end-loading. The input resistance R_r is one-half that of the dipole, which is given by [17]

$$R_r = 1000(h/\lambda)^2 \quad (31)$$

8.1.1.2. Short Monopole with Wire Top-Loading. Figure 34 depicts a top view of various top-loaded antennas: (a) a bar one-side loaded, (b) a bar both-side loaded, (c) L-bar loaded, (d) T-bar loaded, and (e) cross-bar loaded.

The impedance characteristics of these antennas are shown in Fig. 35 [51].

8.1.2. Material Loading

8.1.2.1. Ceramic Chip Antenna. This example may be the world's smallest antenna at present; the size of the ceramic substrate measures 1.6 mm wide, 3.2 mm long, and 1.3 mm high, as depicted in Fig. 36. Figure 37 illustrates an exploded view of the antenna structure. The thin ceramic substrate is composed of multilayered thin ceramic sheets. The type of antenna is a normal mode helix, which is formed in the substrate by connecting printed patterns on the top layer and bottom layer via wires. This antenna has been practically used for small mobile terminals, in which the antenna is placed on a corner of the ground plane (GPL), as shown in Fig. 38. It is usual that a small part of the ground plane beneath the antenna

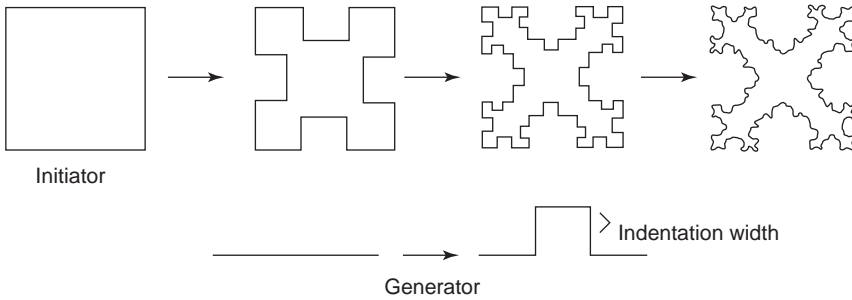

Figure 66. The iterative-generation procedure for a Minkowski island fractal. (From Ref. 36 with permission from IEEE.)

element is taken out in order to avoid excessive loss because of the GPL. However, the antenna needs the help of the GPL. In other words, this antenna actually excites the GPL so that the small antenna and the GPL work as a combined antenna system. Thus, the antenna performance depends on the size of the GPL and how and where the antenna element is placed on the GPL. Some examples of antenna applications are shown in Fig. 39, in which antenna mounting; operating frequency; and antenna performance, such as gain, bandwidth, and radiation patterns are presented.

This type of antenna has features in having a resonant frequency controlled by an easily adjustable structure, has reasonably high gain and wide bandwidth, in addition to being very small in size and very lightweight. Typically, it has the gain of -5 to $+10$ dBi and the bandwidth of about 100 MHz in 5 GHz regions.

8.1.3. Composite Structure

8.1.3.1. Small Rectangular Loop Antenna. This is an example of an ESA with composite structure, consisting of a small loop and an equivalent dipole structure [28]. The size of this antenna is 0.007λ . The design of this antenna was based on the important concepts of realizing small antennas, which are (1) increasing modes, (2) accomplishing self-resonance, and (3) use of magnetic current source and its image. The antenna was practically applied to a small pager unit, as shown in Fig. 40. A rectangular small loop antenna is directly connected to the receiver input as Fig. 41(a) shows. Without using a Balun for the connection between the loop and the receiver input, both balanced and unbalanced currents are produced at the feeding

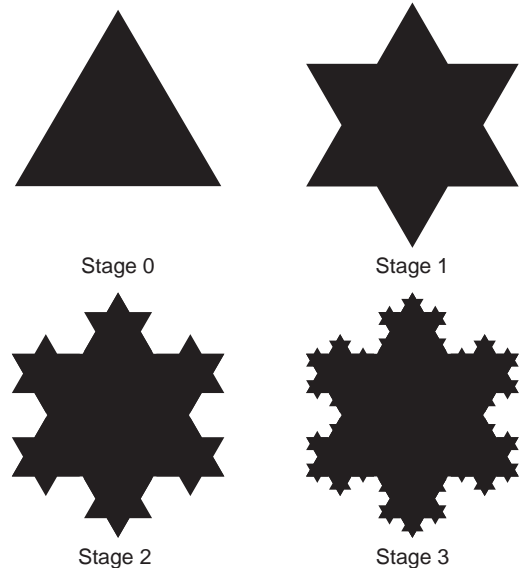

Figure 68. The first three stages of Koch snowflake. (From Ref. 38 with permission from IEEE.)

Figure 69. The first three stages of a Sierpinski gasket fractal. (From Ref. 38 with permission from IEEE.)

Figure 67. Three successive iteration of a Koch fractal. (From Ref. 39 with permission from IEEE.)

Figure 70. Experimental model of a first iteration of a Minkowski fractal. (From Ref. 36 with permission from IEEE.)

terminals, as shown in Fig. 41(b) and (c), respectively, resulting in creating two modes, a loop mode and a dipole mode, in the antenna system. The balanced part is the original loop antenna, whereas the unbalanced part forms

an equivalent dipole, being composed of the ground plane as one part and the loop structure as another part. Then the combined antenna system performs combined performances of both loop and dipole. The receiving patterns, for example, are nearly omnidirectional, as shown in Fig. 42, where (a) shows the loop pattern, (b) shows both the loop and the dipole patterns, and (c) shows the combined pattern of these. It is interesting to know that the pattern on the plane normal to the receiver unit is omnidirectional. With a single loop antenna, the pattern is only a figure 8-shaped pattern. The omnidirectional pattern is favorable, because a pager should have sensitivity without regarding direction of the signal incidence while moving.

Self-resonance was attained by integrating a capacitor C in series near the loop input and adjusting the gap t of input terminals [Fig. 43(a)], so that matching to the load of $50\ \Omega$ can be attained. Figure 43(b) shows how self-resonance, and thus matching conditions, can be attained by adjusting C and t .

Another point is that the loop element is placed normal to the wide side of the unit so that the loop faces normal to the human body when the unit is placed in a chest pocket [Fig. 44(a)]. By this means, image of the loop presumed inside the human body produces the additive magnetic field on the surface of the human body [Fig. 44(b)], so that the receiver sensitivity can be made about 3 dB higher as compared with that of a receiver in free space.

Figure 71. The input match characteristics. (a) A corner-fed square loop \square . (b) The first iteration Minkowski fractal loop \square . (From Ref. 36 with permission from IEEE.)

Figure 72. The far-field patterns of the first-order Minkowski fractal loop antenna: measured and computed results. (a) XY plane. (b) ZX plane. (c) ZY plane. (From Ref. 36 with permission from IEEE.)

The design concepts of this type of composite antenna, such as realization of self-resonance, utilization of unbalanced component, and use of magnetic current source as an additional radiator, can be applied to any other type of small antennas.

8.1.3.2. Complementary Antenna

8.1.3.2.1. general. The principle of the self-complementary antenna (SCA) was first introduced by Mushiake in 1948 [29,30], where SCA had shown to be an antenna system having constant input impedance, independently of the source frequency and shape of the antenna. The concept of SCA has been applied to create various types of wideband antennas, and subsequently practical applications have been made so far.

8.1.3.2.2. theory. Here, we assume a pair of mutually complementary antennas, as shown in Fig. 45, where (a) depicts an arbitrarily shaped planar antenna and (b) its complementary slot antenna. The electromagnetic fields E_1, H_1 for Fig. 45(a) and E_2, H_2 for Fig. 45(b) satisfy the duality relationship as follows:

$$E_2 = \mu H_1 \text{ and } H_2 = \pm \gamma E_1 \tag{32}$$

where $\gamma = (j\omega\epsilon + \sigma)/(j\omega\mu)$, ϵ , μ , and σ are permittivity, permeability, and conductivity of the medium, respectively. The input impedance Z_1 and Z_2 of the planar antenna and slot antenna, in Fig. 45(a) and (b), can be expressed by the ratio of the input voltages and input currents at the

(a)

(b)

Figure 73. Impedance of the Euclidean loop antennas. (a) Resistance. (b) Reactance. (From Ref. 39 with permission from IEEE.)

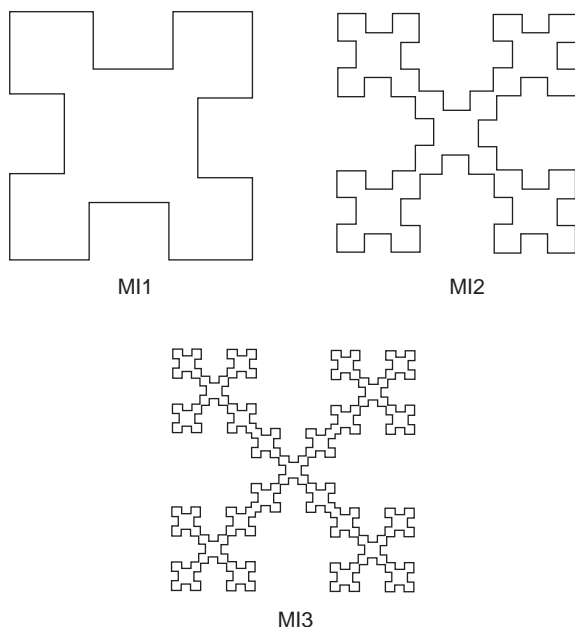

Figure 74. The Minkowski fractal loop antennas. (From Ref. 39 with permission from IEEE.)

respective feeding terminals a–b and c–d as follows:

$$Z_1 = \int_b^a E_1 \cdot dl / 2 \int_c^d H_1 \cdot dl \tag{33}$$

$$Z_2 = \int_d^c E_2 \cdot dl / 2 \int_b^a H_2 \cdot dl \tag{34}$$

where dl denotes the line element, and the integral is performed in the vicinity of the feed terminals. From Eqs. (32)–(34), the following relationships can be derived:

$$Z_1 Z_2 = (Z_0 / 2)^2 \tag{35}$$

where Z_0 is the intrinsic impedance of the medium, which is approximately equal to 120π ohms in free space. If an antenna is identical to its complementary structure, the antenna is referred to as the self-complementary antenna (SCA). The input impedance Z_1 of the original structure is equal to that of its complementary structure Z_2 , and is assumed to be Z , then

$$Z_1 = Z_2 = Z = Z_0 / 2 = 60 \pi \tag{36}$$

which is referred to as Mushiake’s relationship [27], which means that input impedance is a constant, independent of the source frequency and of the shape of the structure.

In other words, SCA has infinite bandwidth in terms of the input impedance. However, in practical antenna systems, infinite structure can never be realized so that constant impedance would only be approximate in practice. Thus, truncation effect because of the finite structure will always bring more or less deterioration of the bandwidth. However, study has shown even with finite dimensions, antenna systems having self-complementary structure have fairly wide bandwidth that can be used practically for various wideband wireless systems [31].

A typical example of SCA with small size is depicted in Fig. 46, where a monopole and its complementary slot are used to compose an SCA. Three antenna models shown in Fig. 47(a) are introduced here. In Fig. 47(a), the antenna dimensions and other parameters are also given. The antenna performances such as VSWR, radiation efficiency, and radiation patterns are illustrated in Fig. 47(b). As can be seen in the figures, the antenna has fairly wide bandwidth that cannot be obtained by other antennas of similar size.

8.1.3.3. Traveling Wave Structure

8.1.3.3.1. normal mode helical antenna (NMHA). Normal mode helical antenna is a helical antenna that radiates in the direction normal to the helical axis and the radiation patterns are essentially the same as that of a short dipole (Fig. 48). The dimensions of the helix are usually taken much smaller than the operating wavelength, the length of an individual turn being a small fraction of a wavelength λ and the axial length being also much less than a one-quarter λ . With this structure, an NMHA is equivalently expressed by an array of small loops and short monopoles (Fig. 49) [32]. Inductive imped-

ance is increased by the array of loops and compensates the capacitive impedance of short monopoles. As a consequence, the helical structure can be arranged to have self-resonance property, although the antenna length (in the axial direction) is considerably shorter than that of a conventional resonant monopole or dipole antenna. Then the antenna efficiency can be improved, and extension of the antenna length may lead to increased bandwidth. The NMHA has been used in modern mobile phones worldwide.

An antenna model shown in Fig. 50 is considered. The impedance characteristics of an antenna having dimensions of the helical diameter $Dh = 0.018\lambda$, the pitch

$P = 0.006 \lambda$, and the wire diameter $2a = 0.0002 \lambda$ are shown in Fig. 51, where number of turns MT is taken as the variable parameter. Figure 52 shows the radiation efficiency with respect to the pitch. The design chart, by which design parameters can be found, are provided in Fig. 53 [33], where relationships between Dh and P are given. In Fig. 52, the parameter used in (b) is the number of turns MT, whereas that in (c) is the radiation resistance R at resonance.

8.1.3.3.2. meander line antenna. A meander line antenna is an antenna that has a periodical array structure of alternative square patterns as shown in Fig. 54. With this pattern, the extended wire length can be made much longer than the initial antenna (dipole) length so that the self-resonance can be attained. The resonance frequency is then lower and radiation resistance is higher than that of a dipole with the same length, which in turn implies that the antenna is effectively made small.

Here, a meander line dipole antenna shown in Fig. 54, where dimensional parameters are given, is considered [34]. Figure 55 shows the equivalent expression of the antenna, which is composed of a series connection of shorted two-wire transmission lines (a) and a monopole (b). By using this model, design parameters can be found. At first, a relationship between the resonance frequency f_0 and the wire radius B /pitch p is obtained, as Fig. 56 shows. Here, the planar line of width B is replaced equivalently by a

Figure 78. Normal mode helical antennas. (From Ref. 39 with permission from IEEE.)

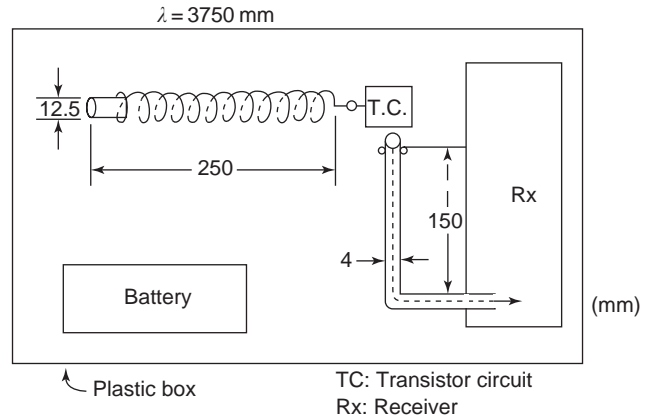

Figure 79. Inverted-L IAS. (From Ref. 40 with permission from Research Studies Press.)

wire of diameter d . When the resonance frequency f_0 is given, the number of turns N can be determined with prior knowledge of the wire radius B and the antenna width w by using Fig. 57. As the antenna length becomes shorter, the radiation resistance R_{rad} decreases. The ratio of the R_{rad} to that of a half-wave dipole is shown in Fig. 58 as a function of the antenna length-reduction ratio R_e . Figure 59 shows radiation efficiency η and number of turns N with respect to the length l (el) of the antenna.

In order to enhance the bandwidth, a meander line antenna is constituted with two strips in parallel, as shown in Fig. 60, where dimensional parameters are also given [35]. The antenna, which stands on a ground plane, can be equivalently modeled by a shorted two-wire transmission line with one line shorted at the ground plane [Fig. 61(a)] and further divided into two parts: balanced and unbalanced modes, respectively, as Fig. 61(a) and (b) show. Thus, a meander line antenna composed of two strips can be treated by an equivalent circuit shown in Fig. 62, where Z_u denotes impedance related with the unbalanced mode and Z_b with the balanced mode (the subscript u denotes the unbalance mode and B the balanced mode). With this model, antenna characteristics can be found and parameters necessary for the design are determined. Fig. 63 illustrates VSWR S with respect to frequency f along with various values of radiation resistance R_{rad} . Here, parameter $u = Q(2\Delta f)/f_0$, where Q is the quality factor of the antenna and $\Delta f = (f - f_0)$. An example of the antenna admittance $Y (= Gu + j(Bu + Bb))$ is shown in Fig. 64, where Gu and Bu , respectively, are conductance and susceptance of the balanced mode and Bb is susceptance of the balance mode. Relative bandwidth $Bm (= 2\Delta f_m/f_0)$ vs. VSWR S_m is shown in Fig. 65, where Δf_m is the maximum Δf and S_m is the maximum VSWR required.

8.1.3.3.3. fractal structure. Fractal structure is applied to miniaturization of antenna by using its space-filling property. The fractal geometry is known as a structure having infinitely iterative intricate fine contour. Starting from a Euclidean square (the initiator), for example, and replacing each segment of the geometry with the generator, Minkowsky fractal island is generated, as shown in Fig. 66 [36]. Significance of application of a fractal

Figure 80. S/N gain performance of inverted-L IAS. (From Ref. 40 with permission from Research Studies Press.)

structure to antennas is two-fold; one is to endow the antenna with increased space-filling ability, attributed to the intricate shape to fit into a smaller physical area and bring an increase in the electrical length, by which resonance frequency can be lowered. Another is to increase the radiation resistance as a consequence of increase in the electrical length. These are effective ways to realize small antennas that have higher gain or lower Q as compared with the same size of conventional antennas.

The first example of how a fractal structure could be used for miniaturizing an antenna was the Koch fractal monopole (Fig. 67) [33], in which an antenna with better performance in terms of Q than the Euclidean monopole was demonstrated. Later, more intricate dipole structures have been analyzed [37]. These results have shown that the bandwidth of an antenna was improved when the antenna used more effectively the available volume of the virtual sphere that surrounds the antenna.

The geometrical configuration of the Koch fractal monopole antenna starts out as an equilateral triangle in a plane and forms snowflake shapes that are constructed by adding smaller and smaller triangles to the original structure in an iterative fashion, as Fig. 68 shows. Another popular fractal structure is Sierpinski gasket fractal, which is depicted in Fig. 69 [38]. This fractal is

constructed by removing smaller and smaller triangles, opposite to the Koch fractal, from the original structure.

Miniaturization of a loop antenna, as an example, is shown in Fig. 70, where the generation procedure starting from a square loop and the initiator are depicted [36]. The fractal is formed by displacing the middle third of each straight segment by some fraction of one-third, which is called the indentation width w that takes value from 0 to 1. The resulting structure has five segments for every one of the previous iteration, but not all of the same scale.

Antenna performance of a corner-fed small square loop and a first iteration Minkowsky fractal loop shown in Fig. 70 is compared in terms of input match, as shown in Fig. 71. It is observed that with the fractal structure the resonance frequency is lowered and better matching can be made, although the Minkowsky fractal has 15% smaller height than the small square loop. Radiation patterns are illustrated in Fig. 72, in which it is shown that the fractal structure produced an appreciable amount of horizontal

Figure 81. Ferrite IAS. (From Ref. 41 with permission from IEEE.)

Figure 82. S/N gain performance of Ferrite IAS. (From Ref. 41 with permission from IEEE.)

Figure 83. Inverted-L antenna.

patterns, as it has some horizontal components in its shape.

Various antenna performances have been studied for various types of fractal antennas [39]. For comparison, a square loop having a size of 2.66 m × 2.8 m and a circular loop having a radius of 1.704 m have been used. The impedances of these two antennas are shown in Fig. 73, whereas the impedance characteristics of fractal loops are shown in Fig. 74. Minkowsky fractals are shown in Fig. 75. The performances such as resonant frequency, feed point resistance, VSWR, radiation efficiency, dimensions, and so forth, are provided in Tables 1 and 2, where parameters are presented at the two lowest series-resonance frequencies. The progressive decrease in resonance frequency is observed; however, as the fractal iteration increases, the decrease in resonant frequency begins to converge to a lower limit, which implies that the benefit of lowering resonant frequency diminishes with a progressive increase in the fractal iteration.

Koch fractal monopoles shown in Fig. 76 have impedance properties presented in Table 3 and the resonant performance characteristics of other types of fractal structure, such as meander line (Fig. 77) and normal mode helix structure (Fig. 78), are shown by Table 4.

8.1.4. Integrated Antennas Systems (IAS)

8.1.4.1. Inverted-L Integrated Antenna System. A transistor circuit was integrated into the middle of an inverted-L element, by which a long monopole antenna previously used was replaced [40]. With the Inverted-L

IAS, about 10 dB higher S/N gain over the conventionally used monopole antenna of about a one-third wavelength was attained. Figure 79 shows the antenna installed inside an 80 MHz small portable receiver. Figure 80 shows receiver S/N gain improvement over that when the monopole was used. This IAS can be referred to functionally small antenna, because downsizing of the antenna was attributed to integration of amplification function.

Figure 88. A slot mounted on the side of a rectangular conducting box.(a) Initial model. (b)A half-wavelength slot mounted on a rectangular conducting body.(c) Planar inverted-F antenna.

8.1.4.2. Ferrite AIAS (Active Integrated Antenna System). Gain of a small ferrite antenna was drastically increased by integrating parametric excitation into a ferrite antenna [41]. Figure 81 illustrates the antenna structure along with signal, pump, and output circuits. By the parametric excitation to a rectangular ferrite bar with pumping of 3 MHz, signal input of 1 MHz is transformed into output of 2 MHz with higher S/N gain than that of the same size ferrite antenna. S/N gain performance obtained is shown in Fig. 82, in which about 10 dB higher S/N gain can be seen.

This ferrite AIAS is a real “active” antenna, whereas in general active antennas, the radiator is not really “active,”

Figure 89. Goubau antenna. (From Ref. 45 with permission from IEEE.)

Figure 90. Bandwidth characteristics of Goubau antenna. (From Ref. 45 with permission from IEEE.)

but inherently passive, although it is called “active antenna.” In this ferrite AIAS, the part that is concerned with radiation (receiving) performs like a real “active” radiator as a consequence of the parametric excitation.

This antenna can be also classified into an FSA, as the smallness of antenna was achieved by integration of amplification function.

8.2. PCSA

8.2.1. Inverted-L Antenna. Inverted-L antenna (ILA) is an antenna that is composed of a short vertical element and a little longer horizontal element attached to the vertical element, as shown in Fig. 83. The ILA is a class of low-profile antenna and is classified in a physically constrained small antenna, because the height of the antenna is, in almost all cases, constrained to a fraction of the operating wavelength. The horizontal element is not necessarily short, but the length is usually shorter than a quarter wavelength (Fig. 84).

This type of antenna was used in ships in the early days of wireless communications and later at home for reception of broadcasting, as the antenna is very simple and easily built by using thin wires. As ILA has a feature of low profile and simple structure, it has been applied to various communication systems, particularly mobile communications. ILA does not have, however, really favorable characteristics, because the radiation resistance is very low and reactive impedance is very high, as shown in Fig. 85 [42]. Then, in practical applications, various modified antennas have been developed and used. The typical one is the inverted-F antenna (IFA), from which the planar inverted-F antenna (PIFA) has evolved. PIFA and its variations have been widely applied to mobile phones.

8.2.2. Inverted-F Antenna (IFA). IFA shown in Fig. 85 can be treated by an antenna shown in Fig. 86 (a) with

Figure 91. Multilayered antenna. (From Ref. 46 with permission from IEICE.)

Figure 92. Bandwidth of the Multilayered antenna. (From Ref. 46 with permission from IEICE.)

its image. This IFA shown in Fig. 86(b) is equivalently decomposed into two parts: an ILA with its image and two two-wire shorted transmission lines, as Fig. 86(c) expresses. The two-wire transmission lines compensate capacitive

Figure 93. Radiation patterns of Multilayered antenna. (a) XY plane. (b) XZ plane. (c) YZ plane. (From Ref. 46 with permission from IEICE.)

impedance of the ILA and, at the same time, stepup the input impedance so that matching to the 50 ohm load is made feasible. The input impedance of IFA is expressed by

$$Z_{in} = 4Za \cap 2Zb \tag{37}$$

where Za denotes the input impedance of the antenna shown in Fig. 86(b), Zh is the impedance of the shorted two-wire transmission line having the length h and

Figure 98. Array of two-reactance component integrated dipole antennas. (From Ref. 49 with permission from Research Studies Press.)

the width S , and \square expresses parallel combination of impedances.

The input impedance of an IFA can be adjusted by selecting S and h appropriately. An example is shown in Fig. 87 [43].

Figure 99. Transistor-circuit integrated inverted-L antenna. (From Ref. 50 with permission from Research Studies Press.)

8.2.3. Planar Inverted-F Antenna (PIFA). PIFA is a modified antenna from IFA being composed of a short vertical element and a planar horizontal element. However, it should be noted that PIFA is not an IFA, from which the horizontal element is simply replaced by a planar element. The principle of the PIFA performance differs from that of the IFA, because the source of radiation of PIFA is nearly a half wavelength aperture formed along the peripheral of the horizontal element, whereas that of IFA is a short vertical element and a quarter wavelength horizontal element. PIFA has initially started with a slot antenna placed on the side of a rectangular conducting body, as shown in Fig. 88(a). The slot has the length nearly a half wavelength and is fed at a point near a shorted end. The idea was born in the process of development of handset antennas. The basic concept is based on the handset antenna having a small and low-profile structure, and magnetic current as a source of radiation is recommended. This slot antenna satisfies these requirements. Meanwhile, the microstrip antenna (MSA) had been known as a useful planar antenna, having a small and low-profile structure. Then an attempt was made to place that slot antenna on a ground plane to form a planar structure like an MSA [Fig. 88(b)], and the performance was confirmed to be satisfactory for handset use. Finally, the antenna configuration was arranged to have a structure, as illustrated in Fig. 88(c), in which the shorted part is shown with reduced size for making the antenna size small. In a PIFA, its peripheral aperture of a half wavelength contributes to radiation, whereas in MSA, a patch end of a quarter wavelength does to radiation.

An initial attempt was made for increasing the bandwidth of a linear IFA by replacing the linear horizontal element with a planar element; however, it was not successful, as the bandwidth increase obtained was only 1–2%, unless otherwise increasing the height.

8.2.4. Disk-Loaded Antennas. Goubau developed a multielement sectored-disk antenna [44], which had a VSWR bandwidth of about 2 to 1. Figure 89 illustrates the antenna configuration. Two of the posts are connected to the ground plane, whereas two other posts are used for feed connections. The wideband performance is shown in Fig. 90.

Friedman later demonstrated a simple disk-loaded antenna, which had shown wideband performance of 2 to 1 or 3 to 1 in terms of VSWR [45]. He developed a wideband matching method to achieve a low VSWR over a desired bandwidth for small antennas and applied it to a small disk-loaded antenna, obtaining comparative wide bandwidth with the Goubau antenna. The disk antenna is integrated with impedance matching circuits, consisting of two parallel side posts and a conductive biconical center post located in the space under the disk. The concept of the matching circuit is basically a wideband double-tuning to impedance match to a line resistance.

8.2.5. Multilayered Antenna. A multilayered antenna demonstrated by Tokumaru has a small, low-profile, and

lightweight structure, and yet features very wideband performance [46]. The wide bandwidth was accomplished by the two-layered plate structure, with which multi-resonance performance was attained. The antenna structure and its dimensions are shown in Fig. 91. The SWR performance is illustrated in Fig. 92, by which wideband performance can be observed to be about 48%. The radiation patterns at 1.5 GHz are shown in Fig. 93. Similar radiation patterns were obtained at 1.8 GHz but not shown here. The measure of size reduction is evaluated by using a size reduction ratio $S = V/\lambda^3$, where V is the physical volume of the antenna. S of various antennas are compared. S of this antenna is 0.0057 when the dimensions are $60 \times 60 \times 20$ (mm) (1.5 GHz), whereas 0.0004 for a Planar Inverted-F antenna when the dimensions are $45 \times 30 \times 10$ (mm) (0.92 GHz), and 0.0052 for a stacked-MSA when the dimensions are $3.8 \times 3.8 \times 1.8$ (mm) (20 GHz).

8.2.6. Folded-Loop Antenna. A wideband folded-loop antenna, depicted in Fig. 94(c), has been demonstrated in [47]. The antenna is originally a one-wavelength rectangular loop, as shown in Fig. 94(a), and is folded to constitute a small, low-profile antenna, as shown in Fig. 94(b). Three resonance modes exist in the antenna structure that contributes to make this antenna wideband. The wideband performance in the 1 GHz band is illustrated in Fig. 95, in which about 40% or wider bandwidth can be observed.

This antenna is not really an ESA; however, because this sort of wideband characteristics may not ordinarily be accomplished by the same-sized antennas, this antenna may be said to be a functionally small antenna.

This antenna is designed to be used as a builtin antenna in a handset unit. In Fig. 94(c), two feeding methods, with either balanced line or unbalanced line, are shown. Use of the balanced linefeed is meaningful for antennas used in a handset, because it is effective to avoid an operator's hand effect on the antenna system, as the undesired current flow on the feeding cable can be reduced. This antenna has, however, the self-balance property, and hence either balanced or unbalanced feed can be used.

8.3. FSA

8.3.1. Integrated Antenna System

8.3.1.1. Reactance Component-Integrated Dipole Antenna (RCDA). Beam shifting or steering realized by a single dipole was demonstrated by using a 0.8-wavelength antenna, into which one or two reactance components were integrated [48], which is a typical example of FSA, because beam shifting, which usually needs at least two antennas, was accomplished by a single dipole, although the length was a little longer than a half wavelength. Beam shifting is attributed to asymmetrical current distributions on the dipole that was accomplished by asymmetrical integration of reactance components, as shown in Fig. 95, where two different reactance components were used. An example of beam shifting pattern is shown in Fig. 96, where parameters used are also shown.

When one reactance component, instead of two, is integrated into a dipole element, the reactance component is placed symmetrically with respect to the feed point so that asymmetrical current distribution on the dipole element is achieved, thereby beam shifting is attained. Figure 97 illustrates an example.

When beam steering or scanning is required, it can be achieved by varying the integrated-reactance values through electronic means.

8.3.1.2. Array of RCDA. Two elements of reactance component-integrated dipoles are arrayed, as shown in Fig. 98(a), and beam shifting achieved is shown in Fig. 98(b) [49]. As two-dimensional pattern control is feasible by using a RCDA, three-dimensional pattern control may be possible by array of two RCDA's, which implies possibility of array thinning by using RCDA.

8.3.1.3. Transistor Circuit-Integrated Dipole Antenna. Electronic beam control can be realized by integrating a transistor circuit into a dipole antenna. Figure 99 depicts an example [50], where a transistor circuit is placed asymmetrically with respect to the feed point, so that asymmetrical current distribution is realized. By varying the bias voltage to the transistor circuit, the circuit parameters are varied, resulting in pattern control.

1. INTRODUCTION

Since the industrial revolution in the second half of the eighteenth century engineering has made enormous advances in the design and manufacture of machinery and systems. All these advancements were based on traditional materials, which do not have particularly special physical or chemical properties. The traditional materials included metals, such as steel and gold, and insulators, such as glass. The machinery and systems developed included the wooden wheel, steam engine, and gaseous electronics.

Contemporary research on new machines and systems, however, focuses on the development of new materials and engineered material structures that possess unique properties that may be utilized in new engineering applications. This research involves the tailoring of some special material systems and structures in order to realize a particular physical or chemical property needed for a certain application. Alternatively, the research involves the discovery of new properties in some special groups of materials; these properties may open up the door for several new and exciting engineering applications.

1. INTRODUCTION

Since the industrial revolution in the second half of the eighteenth century engineering has made enormous advances in the design and manufacture of machinery and systems. All these advancements were based on traditional materials, which do not have particularly special physical or chemical properties. The traditional materials included metals, such as steel and gold, and insulators, such as glass. The machinery and systems developed included the wooden wheel, steam engine, and gaseous electronics.

Contemporary research on new machines and systems, however, focuses on the development of new materials and engineered material structures that possess unique properties that may be utilized in new engineering applications. This research involves the tailoring of some special material systems and structures in order to realize a particular physical or chemical property needed for a certain application. Alternatively, the research involves the discovery of new properties in some special groups of materials; these properties may open up the door for several new and exciting engineering applications.

Traditional materials, on one hand, have very well established and limited physical properties that cannot be significantly altered. For example, metals have high electrical conductivities that change very slightly with temperature, and glass remains insulating over a wide temperature range. “Smart materials,” on the other hand, have properties that can be dramatically altered. For example, “semiconductors” are a special group of materials in which electrical conductivity can change by orders of magnitude as their temperatures and/or compositions are very slightly changed. Moreover, the optical properties of semiconductors can be significantly modulated by engineering a multitude of semiconductor structures incorporating different semiconductor films. Needless to say, these properties of semiconductors paved the way for a revolution in information technology, communication, and nanotechnologies. This revolution is fueled by advancements in nanoscale electronics, optics, and mechanics.

The group of smart materials reviewed in this article includes (1) semiconductors, (2) superconductors, (3) piezoelectric materials, and (4) shape memory materials. Our choice of these materials for review in this article does not limit the list of smart materials to this group of materials. Indeed, it is very well known by now that several other materials, such as liquid crystals and rheostatic materials, possess very interesting properties that are widely employed in many exciting engineering applications. However, the group of smart materials discussed here is particularly important to the advancement of the rapidly expanding fields of nanoelectronics and integrated circuits (ICs), nano/micromechanical systems (N/MEMS), optoelectronics, and communication.

2. SEMICONDUCTORS

To fabricate ICs or N/MEMS, many different kinds of bulk materials and thin films are used. We will refer to these bulk materials and thin films used in IC and N/MEMS fabrication as *electronic materials* [1]. The bulk materials are predominantly semiconductor materials. The most important semiconductors in IC fabrication are silicon and gallium arsenide. The thin films used in IC fabrication can be classified into four groups: thermal silicon dioxide, dielectric layers, polycrystalline silicon (poly-Si), and metal films. The dielectric layers include deposited silicon dioxide (sometimes referred to as *the oxide*), and silicon nitride. These dielectrics are used for insulation between conducting layers, for diffusion and ion implantation masks, for structural components in N/MEMS, and for passivation to protect devices from impurities, moisture,

and scratches. Poly-Si is used as a gate electrode in metal-oxide-semiconductor (MOS) devices, as a conductive material for multilevel metallization, as a contact material for devices with shallow junctions, and as a structural material in N/MEMS. Metal films are used to form low-resistance interconnections and rectifying metal-semiconductor barriers. The thermal oxide is usually a better quality oxide (compared to deposited oxide) and is used for the gate oxide layers in field effect transistors. It is, hence, apparent that semiconductors are the backbone for ICs and N/MEMS since they are used in both their crystalline and polycrystalline forms as well as they are used in the chemical growth of dielectric films needed for device operation and protection. The sections below focus on the properties of semiconductors and demonstrate the multitude of smart characteristics associated with these materials.

2.1. Electrical and Chemical Properties of Semiconductors

Semiconductors are inorganic materials made from elements in the fourth column (group IV) of the periodic table. Semiconductor materials from group IV elements in the periodic table include silicon, germanium, and carbon (diamond); semiconductors from group IV elements are called *elemental semiconductors*. Semiconductor materials can also be made from a combination of elements from either group III and group V or group II and group VI; these are called *compound semiconductors*. Examples of these are gallium arsenide and zinc telluride materials. The term *semiconductor* is given to these materials because above certain temperature regimes they are able to exhibit good electrical conduction properties, and below these temperature regimes they behave as insulators.

Among the elemental semiconductors, Si is by far the most commonly used semiconductor. Si is the most important material for nano/microelectronics and IC technology. Also, Si-based compounds and technologies are becoming the major cornerstones for the rapidly developing fields of N/MEMS and nanofabrication. For this reason we will be emphasizing Si and use it in demonstrating several semiconductor properties. Table 1 lists a few of the mechanical, electrical, and thermal properties of single-crystalline silicon. GaAs, on the other hand, is the most common of the compound semiconductors, and it is widely used in fabricating optical and high-speed devices.

The crystal structure of many semiconductors, including Si and GaAs, is the *diamond lattice* (Fig. 1a). Diamond structure is that of two interleaved face-centered cubic arrays with one array displaced a fraction of the interatomic distance from the other. In the GaAs type of

compound, one of the two arrays is composed entirely of Ga atoms, while the other array is composed of As atoms. This particular class of the diamond structure, called the *zincblende*, is shown in Fig. 1b for the II–VI compound semiconductor zinc sulfide. In the diamond lattice each atom has four nearest neighbors. In both elemental and compound semiconductors, there is an average of four valence electrons per atom. Each atom is thus held in the crystal by four covalent bonds with two electrons participating in each bond. In a perfect semiconductor crystal and at absolute zero temperature the number of electrons available would exactly fill the inner atomic shells and the covalent bonds. At temperatures above absolute zero some of these electrons gain enough thermal energy to break loose from these covalent bonds and become *free electrons*. This thermal energy relates to a quantum-mechanical property of the semiconductor crystal called the *energy gap*, often written as E_g and expressed in electronvolts (eV). The smaller the energy gap, the lower the temperature at which the semiconductor becomes conducting. Free electrons are responsible for electrical conduction across the semiconductor crystal. Some of the physical properties of selected elemental and compound semiconductor crystals are given in Table 2.

2.2. Growth and Deposition: Single-Crystalline and Polycrystalline Silicon

To demonstrate the methods of growing semiconductors we will consider growth of single-crystal silicon in details. We choose silicon since it is the most utilized semiconduc-

Table 2. Structure and Lattice Properties for Some Known Semiconductors^a

Material	Lattice Structure	Lattice Constant (Å)	Energy Gap (eV)
Ge	Diamond	5.66	0.66
Si	Diamond	5.43	1.12
InSb	Zincblende	6.46	0.18
InAs	Zincblende	6.04	0.33

tor in nano/microelectronics and N/MEMS. Basically, the technique used for silicon crystal growth from the melt is the *Czochralski technique* [2]. The technique starts from a pure form of sand (SiO_2) called *quartzite* placed in a furnace with different carbon-releasing materials such as coal and coke. Several reactions take place inside the furnace and high purity metallurgy-grade silicon (MGS) is produced. The Czochralski technique uses the apparatus shown in Fig. 2, called the *puller*. The puller comprises

Figure 2. A schematic view of the puller: the apparatus used in the Czochralski growth of Si [1].

three main parts: (1) a furnace that consists of a fused-silica (SiO_2) crucible, a graphite susceptor, a rotation mechanism, a heating element, and a power supply; (2) a crystal pulling mechanism, which is composed of a seed holder, and a rotation mechanism; and (3) an ambient control, which includes a gas source (usually an inert gas), a flow control, and an exhaust system. In the crystal growth process, MGS is placed in the crucible and the furnace is heated above the melting temperature of Si. An appropriately oriented seed crystal (e.g., [100]) is suspended over the crucible in a seed holder. The seed is lowered into the melt. Part of it melts but the tip of the remaining seed crystal still touches the liquid surface. The seed is then gently withdrawn. Progressive freezing at the solid-liquid interface yields a large single crystal ingot. Finally the ingot is sliced by diamond saw into wafers.

The method for growing single-crystal silicon layer on a substrate wafer is *epitaxial* process where the substrate wafer acts as a seed crystal. Epitaxial processes are different from crystal growth from the melt in that the epitaxial layer can be grown at a temperature very much below the melting point. Among various epitaxial processes, vapor-phase epitaxy (VPE) is the very common process for single-crystal silicon layer growth.

A schematic of the VPE apparatus is shown in Fig. 3. The figure shows a horizontal susceptor made from graphite blocks. The susceptor mechanically supports the wafer, and in induction-heated reactor it also serves as the source of thermal energy for the reaction. Several silicon sources are usually used: silicon tetrachloride (SiCl_4), dichlorosilane (SiH_2Cl_2), trichlorosilane (SiHCl_3), and silane (SiH_4). The typical reaction temperature for silicon tetrachloride is $\sim 1200^\circ\text{C}$. The overall reaction in the case of silicon tetrachloride is reduction by hydrogen [2]:

A competing reaction, which would occur simultaneously, is

In reaction (1) silicon is deposited on the wafer, whereas in reaction (2) silicon is removed (*etched*). Therefore if the

Figure 3. A schematic view of a typical VPE apparatus [1].

concentration of SiCl_4 is too high, etching rather than growth of silicon will take place.

An alternative epitaxial process for single-crystal silicon layer growth is molecular-beam epitaxy (MBE), which is an epitaxial process involving the reaction of a thermal beam of silicon atoms with a silicon wafer surface under ultrahigh vacuum conditions ($\sim 10^{-10}$ Torr). MBE can achieve precise control in both chemical composition and impurity (if introduced intentionally) profiles. Single-crystal multilayer structures with dimensions of the order of atomic layers can be made using MBE.

Polycrystalline silicon is often used as a structural material in N/MEMS. Poly-Si is also used in ICs and N/MEMS for electrode formation and as a conductor or high-value resistor depending on its doping level. A low-pressure reactor, such as the one shown in Fig. 3, operated between 600 and 650°C is used to deposit poly-Si by pyrolyzing silane according to the following reaction [2]:

The most common low-pressure processes used for poly-Si deposition are the ones that operate at pressures between 0.2 and 1.0 torr using 100% silane. Another process for poly-Si deposition involves a diluted mixture of 20–30% silane in nitrogen.

2.3. Doping

A pure semiconductor with insignificantly low concentrations of “impurities” is referred to as an *intrinsic semiconductor*. However, when impurities are intentionally added to a semiconductor the semiconductor is said to be “doped” with impurities. Figure 4a shows a hypothetical two-dimensional Si crystal in which one Si atom is replaced (or substituted) by an atom from group V elements in the periodic table, namely, phosphorus. Phosphorus has five valence electrons as opposed to Si, which has only four. The phosphorus atom will share four of its electrons with four neighboring Si atoms in covalent bonds. The remaining fifth valence electron in phosphorus is loosely bound to the phosphorus nucleus. Using the hydrogen atom model, one can estimate the ionization energy of E_d , an impurity atom in a semiconductor crystal as

$$E_d = \left(\frac{\epsilon_0}{\epsilon_s}\right)^2 \left(\frac{m_n^*}{m}\right) E_n \quad (4)$$

where ϵ_0 is the permittivity of free space, ϵ_s is that of the semiconductor, m is the electron’s mass, and m_n^* is its effective mass in the semiconductor crystal. When the phosphorus atom in Si is ionized, the released electron becomes a free electron, which is available for conduction. The phosphorus atom is, hence, called a *donor* atom since it donates a free electron to the crystal. All atoms with five valence electrons can potentially do the same thing done by phosphorus to the Si crystal, that is, donate a free electron to the semiconductor crystal; however, the amount of energy needed E_d for this process to occur may differ from one type of donor atom to another. Atoms

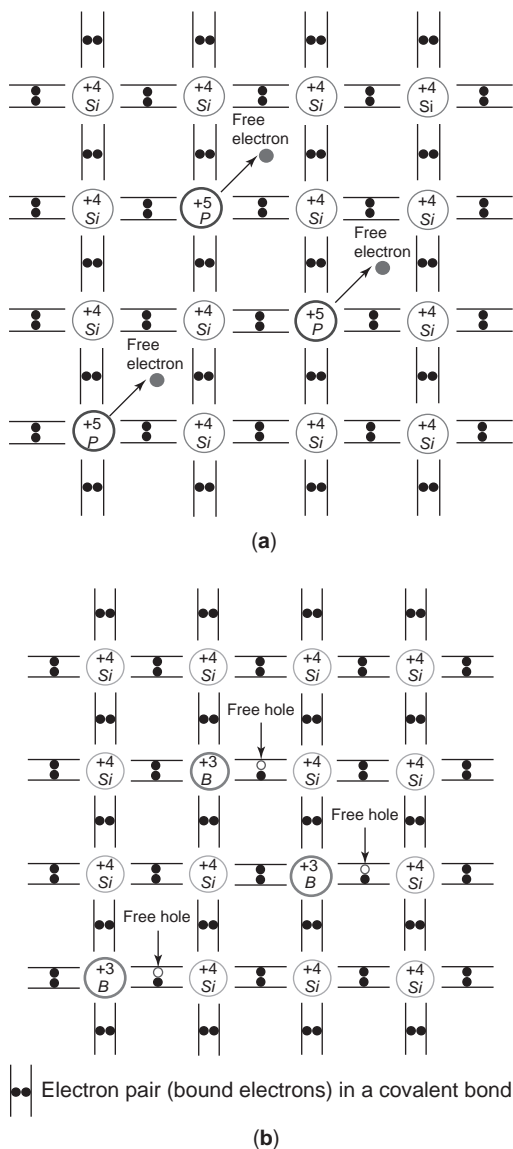

Figure 4. The effects of doping on a hypothetical two-dimensional Si crystal: (a) ntype; (b) ptype.

with five valence electrons are those in group V of the periodic table. These atoms will donate electrons if they substitute for host atoms in crystals of group IV elemental semiconductors. The atoms in group V of the periodic table, such as phosphorus or arsenic, are called *donor atoms* or simply *donors*, and the doped semiconductor is now called *extrinsic semiconductor*.

If one is able to introduce a large concentration of phosphorus atoms in an otherwise pure Si crystal, such as a phosphorus atom concentration of $\sim 10^{15} \text{ cm}^{-3}$, then with a minimal energy supply, these phosphorus atoms will donate each an electron to the crystal amounting to a concentration of electrons in the conduction band of the order of 10^{15} cm^{-3} at room temperature. This concentration of electrons is to be contrasted with the concentration of conduction electrons in an intrinsic Si at room temperature, which is of the order of 10^{10} cm^{-3} . With this doping level a five-order-of-magnitude increase in the free-electron

concentration is achieved. Note that in a solid there are $\sim 10^{22}\text{--}10^{23} \text{ atoms/cm}^3$ and a doping level of $\sim 10^{15} \text{ cm}^{-3}$ is equivalent to merely replacing one Si atom in every $10^7\text{--}10^8 \text{ atoms/cm}^3$ by a phosphorus atom. Clearly this level of doping introduces a very insignificant change in the overall crystal structure, but its effect on the free-electron concentration is apparently very significant. Therefore, conduction in phosphorus-doped Si is dominated by electrons. This type of extrinsic semiconductor, or more specifically Si, is called *n-type semiconductor* or *n-type Si*. The term *n type* indicates that the charge carriers are the negatively charged electrons. The example discussed above was specific to Si doped with phosphorus; however, the conclusions arrived at will generally apply to all elemental semiconductors doped with atoms of a group V element; thus, any elemental semiconductor doped with atoms from group V elements becomes an n-type semiconductor. The ionization energies E_d for several group V donors in Si are given in Table 3.

We now consider the situation where our elemental semiconductor is doped with atoms from an element in group III of the periodic table, specifically, atoms that have only three valence electrons. To be more specific, we will take as an example Si doped with boron as is shown in the hypothetical two-dimensional Si lattice in Fig. 4b. As can be seen from Fig. 4b, the net effect of having a boron atom substituting for Si is the creation of a free “hole” (an electron deficiency in a covalent bond). This hole, which is essentially a positively charged particle with the same charge magnitude as that in an electron, is generated as follows. Since boron has three valence electrons, three neighboring Si atoms will be bonded covalently with boron; however, the fourth nearest-neighbor Si atom has one of its four valence electrons sitting in a dangling bond—thus the whole system of the boron atom and the four neighboring Si atoms is missing one electron. An electron from a neighboring Si-Si covalent bond may replace the missing electron, thereby creating an electron deficiency (a hole) at the neighboring bond. The net effect is hence the generation of a *free hole* in the Si crystal. Therefore this type of extrinsic semiconductor, Si in this particular example, is called *p-type semiconductor* or *p-type Si*. It is p-type because electrical conduction is carried out by positively charged free holes. Common acceptor atoms to silicon are listed in Table 3.

Diffusion and *ion implantation* are the two key processes used to introduce controlled amounts of dopants

Table 3. Common Donor and Acceptor Atoms in Si Together with Their Ionization Energies

Atom	Atomic Number	Type	Ionization Energy in Si (eV)
Boron	5	Acceptor	0.045
Aluminum	13	Acceptor	0.057
Phosphorus	15	Donor	0.044
Gallium	31	Acceptor	0.065
Arsenic	33	Donor	0.049
Indium	49	Acceptor	0.160
Antimony	51	Donor	0.039

Source: Ref. 2.

into semiconductors. These two processes are used to selectively dope the semiconductor substrate to produce either n-type or a p-type region. In the diffusion method the dopant atoms are placed on the surface of the semiconductor by deposition from the gas phase of the dopant or by using doped-oxide sources. Diffusion of dopants is typically done by placing the semiconductor wafers in a furnace and passing an inert gas that contains the desired dopant through it. Temperatures for doping range between 800 and 1200°C for silicon. The diffusion process is described in terms of Fick's diffusion equation [3]

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} \quad (5)$$

where C is the dopant concentration, D is the diffusion coefficient, t is time, and x is measured from the wafer surface in a direction perpendicular to the surface. Typical values for D at $\sim 900^\circ\text{C}$ are of the order of $10^{-14} \text{ cm}^2/\text{s}$ [4].

Ion implantation is the process whereby high-energy ions are thrown at a semiconductor substrate. Typical ion energies used in ion implantations are in the range 20–200 keV, and ion densities could vary between 10^{11} and 10^{16} ions/cm² incident on the wafer surface. Commonly implanted elements are boron, phosphorus, and arsenic for doping elemental n- or p-type semiconductors. After implantations wafers are rapidly thermally annealed to electrically activate the dopants. Oxygen is also implanted in silicon wafers to form buried oxide layers.

2.4. Piezoresistivity in Semiconductors

Piezoresistivity is defined as the change in the resistivity of a material when subjected to a mechanical stress. The prefix *piezo* is Greek for “to press.” All materials probably have a piezoresistance effect to some extent, but it is particularly important in some semiconductors. Silicon exhibits piezoresistivity in either one of its p-type or n-type forms and because of this silicon is very commonly used in the fabrication of strain gauges and force/pressure sensors. The fact that Si crystal is anisotropic has made the relation between the change in resistivity and the applied stress more complex. For a three-dimensional Si crystal of resistivity ρ , the change in resistivity tensor $\Delta\rho$ and the stress tensor (σ values for the normal stress components and τ values for shear stress components) are related via a 6×6 piezoresistive coefficient matrix [π] as [5,6]

$$\frac{1}{\rho} \begin{bmatrix} \Delta\rho_{xx} \\ \Delta\rho_{yy} \\ \Delta\rho_{zz} \\ \Delta\rho_{xy} \\ \Delta\rho_{yz} \\ \Delta\rho_{zx} \end{bmatrix} = \begin{bmatrix} \pi_{11} & \pi_{12} & \pi_{12} & 0 & 0 & 0 \\ \pi_{12} & \pi_{11} & \pi_{12} & 0 & 0 & 0 \\ \pi_{12} & \pi_{12} & \pi_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & \pi_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & \pi_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & \pi_{44} \end{bmatrix} \begin{bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \\ \tau_{xy} \\ \tau_{yz} \\ \tau_{zx} \end{bmatrix} \quad (6)$$

where we notice that only three piezoresistive coefficients— π_{11} , π_{12} , and π_{44} —are nonzero for Si. π_{11} and π_{12} are associated with the normal stress components σ_{xx} , σ_{yy} ,

Table 4. Piezoresistance Coefficients for Si at Room Temperature

	ρ	π_{11} in $10^{-11}(\text{Pa})$	π_{12} in $10^{-11}(\text{Pa})$	π_{44} in $10^{-11}(\text{Pa})$
p-type Si	7.8	+6.6	−1.1	+138.1
n-type Si	11.7	−102.2	+53.4	−13.6

Source: Ref. 7.

and σ_{zz} , whereas the coefficient π_{44} is associated with the shear stress components. The values of these coefficients in Si at room temperature are given in Table 4. If we denote the piezoresistive coefficients of a piezoresistor along the longitudinal and transverse directions by π_L and π_T , respectively, then the relative change in resistance $\Delta R/R$ of the piezoresistor may be written as

$$\frac{\Delta R}{R} = \pi_L \sigma_L + \pi_T \sigma_T \quad (7)$$

where σ_L and σ_T are the longitudinal and tangential stresses, respectively. The piezoresistive coefficients for p-type Si piezoresistor in the longitudinal (x -axis) and tangential (y -axis) directions are given in Table 5.

2.5. Temperature Effects on Semiconductors

Thermoresistors are those materials for which the resistivity is a strong function of temperature. There are two types of thermoresistors: metal thermoresistors and semiconducting thermoresistors. The term *thermistor* is generally given to a semiconductor thermoresistor. The use of intrinsic semiconductors as thermistors is attractive because the resistivity's dependence on temperature is practically controlled by the carrier generation mechanism, namely, free-carrier concentrations n for electrons and p for holes as functions of temperature, rather than the “mobilities” of electrons and holes in the semiconductor. This is because the temperature-dependence of mobility in intrinsic semiconductors is much weaker than that of n and p . In an intrinsic semiconductor the dependence of resistivity ρ on temperature can be expressed as

$$\rho = A \exp \left[\frac{E_g(0)}{2k_B T} \right] \quad (8)$$

where T is temperature in kelvins, $E_g(0)$ is the energy bandgap at the absolute zero temperature, k_B is Boltz-

Table 5. Longitudinal and Tangential Piezoresistive Coefficients for Si

Crystal Plane	Orientation $\langle x \rangle$	Orientation $\langle y \rangle$	π_L	π_T
(100)	$\langle 100 \rangle$	$\langle 100 \rangle$	+0.02 π_{44}	0.02 π_{44}
(100)	$\langle 110 \rangle$	$\langle 100 \rangle$	+0.5 π_{44}	0
(100)	$\langle 110 \rangle$	$\langle 110 \rangle$	+0.5 π_{44}	−0.5 π_{44}
(100)	$\langle 111 \rangle$	$\langle 211 \rangle$	+0.66 π_{44}	−0.33 π_{44}

Source: Ref. 8.

mann's constant, and A is a preexponential factor that varies very slowly with temperature. If one defines the *temperature coefficient of resistivity* (TCR) α as

$$\alpha = \frac{1}{\rho_0} \frac{d\rho}{dT} \quad (9)$$

where ρ_0 denotes the resistivity at some reference temperature T_0 , often taken to be 0°C . From (8) we find out that for intrinsic semiconductors TCR is given by

$$\alpha \approx -\frac{E_g(0)}{2k_B T^2} \quad (10)$$

Unfortunately, silicon does not exhibit an intrinsic behavior that can be reliably utilized for temperature sensing. This is because the lowest concentration of electrically active impurities, and therefore dopant atoms obtainable in silicon is $\sim 10^{12} \text{cm}^{-3}$, which is two orders of magnitude higher than the intrinsic carrier concentration n_i in silicon at room temperature, which is $\sim 10^{10} \text{cm}^{-3}$. However, another elemental semiconductor, germanium, is successfully utilized in measuring cryogenic temperatures in the range 1–35 K [9].

2.6. Optical Absorption and Photoconductivity in Semiconductors

Radiation is absorbed by a semiconductor, and the degree of absorption varies with the material optical properties and the radiation energy. In this context the term *optical* does not necessarily imply that the photons absorbed are in the visible part of the electromagnetic spectrum. In fact, many semiconductors absorb photons in the infrared region, which is included in the term *optical absorption*. In semiconductors the major process that leads to the absorption of radiation is that of creating an *electron-hole pair*. Photons with energies greater than the bandgap of the semiconductor (i.e., $h\nu > E_g$) are absorbed by the semiconductor, whereas photons of energies lower than the bandgap (i.e., $h\nu < E_g$) are not absorbed and, instead, transmitted through the semiconductor. The electron and hole created are called *excess carriers*. The optical absorption is determined by the properties of the semiconductor via a parameter called *absorption coefficient*. The absorption coefficient α is a measure of the fractional decrease in incident radiation intensity I_0 with distance into the material x measured from the surface exposed to the radiation

$$I(x) = I_0 e^{-\alpha x}, \quad \alpha = -\frac{1}{I} \frac{dI}{dx} \quad (11)$$

where $I(x)$ is the intensity of radiation at x . Figure 5 shows a typical α/λ plot where we note that at long wavelengths ($hc/\lambda \ll E_g$) there is no significant absorption of radiation and considerable absorption of photons with larger energies ($hc/\lambda \geq E_g$).

Photoconductive cells are semiconductor resistor structures that are used as optical sensors that utilize the photoconductivity effect, in which light striking the resis-

Figure 5. A typical α/λ plot in a semiconductor.

tor reduces its resistance. The optical sensitivity of a semiconductor is assessed in terms of its optical generation rate G_{op} , the concentration of excess carriers generated per unit time. If the lifetimes, defined as the mean time each carrier spends before it is annihilated, is $\bar{\tau}_n$ or $\bar{\tau}_p$ for electrons and holes, respectively, one may write

$$\Delta n = G_{op} \bar{\tau}_n, \quad \Delta p = G_{op} \bar{\tau}_p \quad (12)$$

Accordingly, the photoconductivity change $\Delta\sigma$ in the semiconductor is

$$\Delta\sigma = eG_{op}(\mu_n \bar{\tau}_n + \mu_p \bar{\tau}_p) \quad (13)$$

This change in conductivity translates into a change in overall resistance ΔR of the semiconductor cell given by

$$\Delta R = \frac{1}{\Delta\sigma t} \left(\frac{l}{w} \right) \quad (14)$$

where t is the thickness and (l/w) is the aspect ratio of the cell.

2.7. Magnetoresistance in Semiconductors

Let us consider a slab of a semiconductor such as the one shown in Fig. 6 with the magnetic and electric fields orientations indicated in the figure. As they drift in the semiconductor, free carriers, namely, electrons and holes, will experience *Lorentz force*, which tends to deflect carriers to one of the semiconductor surfaces (top or bottom). This will continue until an electric field, called the *Hall field*, develops along the y axis. This field produces a force on the carrier that is exactly equal to the Lorentz force. Hence, in the steady state the total current in the y direction must be zero, and the Hall field will increase

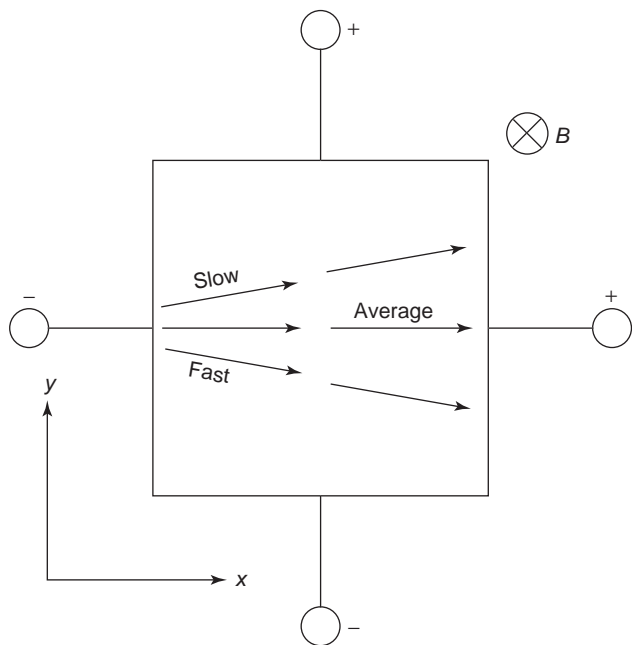

Figure 6. A slab of a biased semiconductor placed in a magnetic field.

until this is the case. However, we also note that the Lorentz force is directly proportional to the velocity of the carrier, and that not all carriers have the same velocity. In the steady state, for some charge carriers the Lorentz force is larger than the force due to the Hall field and for other carriers the opposite is true. This will cause some carriers to deflect upward and some to deflect downward, as shown in Fig. 6. The path of these charge carriers as they cross the slab is somewhat longer, and this leads to an increase of the resistance in the semiconductor. This effect is called *physical magnetoresistance*. Physical magnetoresistance is not severe in semiconductors as compared to metals. This is because the carrier mobilities in semiconductors are too small to induce any change in resistance for such a small change in the carrier's path. However, when coupled with the right geometry, magnetoresistance could be made significant in semiconductors. The dependence of the resistance of the semiconductor slab on the magnetic field is of the form [10]

$$R = R_0(1 + k_{ar}\mu^2B) \quad (15)$$

where k_{ar} is an aspect ratio parameter, R_0 is the resistance at zero magnetic field, and μ is the carrier mobility.

2.8. Chemical Interactions and Semiconductors as Chemoresistors

Back in 1953 it was discovered that the adsorption of some gases into the surfaces of some semiconductors could produce large changes in the resistivity. These semiconductors are primarily compound metal oxides such as ZnO, TiO₂, In₂O₃, or SnO₂. The latter is the most commonly used semiconductor in gas sensors, especially combustible gases, such as methane (CH₄). In an oxygen-rich

environment SnO₂ acts as a n-type semiconductor. However, oxygen can occupy a lattice vacant site in SnO₂ and acts as a single electron or double *electron trap*, in which the oxygen atom, once it occupies the lattice site, is able to bind one (to become O⁻) or two free electrons (to become O²⁻) to its core and therefore restricts the free motion of the electron or the two electrons. These trapped electrons are no longer free electrons, and the net effect is a reduction in the free-electron concentration n . This way the incorporation of oxygen in the crystal lattice of SnO₂ increases its resistivity. The electron-trapping process is reversed, however, by the exposure of the oxygen containing SnO₂ resistor to a gas such as CH₄. CH₄ reacts with the single negatively (O⁻) or double negatively (O²⁻) charged oxygen to produce CO₂. As this reaction is completed O⁻ or O²⁻ give back to the crystal of SnO₂ one or two free electrons, respectively. This reaction enhances the free-electron concentration and decreases the resistance.

A simple theory predicts an increase in the conductivity $\Delta\sigma$ of the semiconductor, which can be related to the increase in carrier concentration Δn and, from the reaction kinetics, to a fractional power m of the gas concentration [11]

$$\Delta\sigma = e\mu_n\Delta n \propto [X]^m \quad \text{where } 0.5 < m < 1 \quad (16)$$

where [X] represents the gas concentration.

2.9. Insulator-on-Semiconductor Structures: Oxidation/Nitridation of Silicon and Oxide/Nitride Deposition

2.9.1. Thermal Oxidation. Thermal oxidation is the method by which a thin film of SiO₂ is grown on top of a silicon wafer. It is the key method of producing thin SiO₂ layers in modern IC and N/MEMS technologies. Thermal oxidation of silicon in oxygen or water vapor can be described by the following chemical reactions [1,2]:

The silicon-silicon dioxide interface moves into the silicon during the oxidation process. Using the densities and molecular weights of silicon and silicon dioxide, one can show that growing an oxide thickness x consumes a layer of silicon that is $0.44x$ thick. Oxidation in high-pressure steam or oxygen can produce substantial acceleration in the growth rate and is often used in growing thick oxides. One advantage to high-pressure oxide growth is that oxides can be grown at significantly lower temperatures and at reasonable growth rates.

The basic structural unit of thermal SiO₂ is a silicon atom surrounded tetrahedrally by four oxygen atoms as shown in Fig. 7. The silicon-oxygen and oxygen-oxygen internuclear distances are 1.6 and 2.27 Å, respectively. SiO₂ or silica has several crystalline structures (e.g., quartz) and an amorphous structure. Typically amorphous SiO₂ has a density of $\sim 2.2 \text{ g/cm}^3$, whereas quartz

Figure 7. The basic structural unit of SiO_2 .

has a density of $\sim 2.7 \text{ g/cm}^3$. Thermally grown oxides are usually amorphous.

2.9.2. Silicon Oxide and Silicon Nitride Deposition.

Three deposition methods, all based on *chemical vapor deposition* (CVD), are commonly used in forming a thin dielectric film on a substrate: atmospheric-pressure chemical vapor deposition (APCVD), low-pressure chemical vapor deposition (LPCVD), and plasma-enhanced chemical vapor deposition (PECVD). The latter method is an energy-enhanced CVD method. The appropriate method from among these three deposition methods is based on the substrate temperature, the deposition rate and film uniformity, the morphology, the electrical and mechanical properties, and the chemical composition of the dielectric films.

CVD is used extensively in depositing SiO_2 and silicon nitride (Si_3N_4). CVD deposited SiO_2 does not replace thermally grown SiO_2 , which has electrical and mechanical properties superior to those of CVD oxide. However, CVD oxides are used instead to complement thermal oxides and in many cases to form oxide layers that are much thicker than thermal oxides in relatively very short timeframes. SiO_2 can be CVD-deposited by several methods. It can be deposited from reacting silane and oxygen in a LPCVD reactor at $\sim 300\text{--}500^\circ\text{C}$ [1,2]:

It can also be LPCVD-deposited by decomposing tetraethylorthosilicate, $\text{Si}(\text{OC}_2\text{H}_5)_4$. The compound, abbreviated TEOS, is vaporized from a liquid source. TEOS decomposes as follows:

Table 6 compares different SiO_2 films deposited by different methods and contrasts them with thermally grown oxides. Likewise, Si_3N_4 can be LPCVD-deposited by an intermediate-temperature process or a low-temperature PECVD process. In the LPCVD process, which is the more common process, dichlorosilane and ammonia react according to

3. SUPERCONDUCTORS

Superconductors are materials that exhibit no resistance to current flow. This definition implies that electrical resistance in these materials is zero, which suggests that once current is initiated in these materials, it continues to flow indefinitely without the need for maintaining the applied voltage that was necessary to produce the current. *Superconductivity* occurs in materials below a certain temperature that is specific for a given material. This temperature is referred to as the *transition* or *critical temperature* T_C .

3.1. Types of Superconductors

Superconductivity was discovered in 1911 by Kammerlingh Onnes in Leiden University in the Netherlands [12]. Kammerlingh Onnes cooled mercury down to liquid helium temperature (4.2 K) and found out that mercury loses its DC resistance below that temperature, which then becomes the critical temperature for mercury. Subsequent to Kammerlingh Onnes' discovery, several materials exhibited superconductivity at T_C , which is much higher than 4.2 K. Superconductors that have low T_C are often categorized as *low-temperature superconductors* (LTSs). The LTS category of superconductors consists mainly of metals and metalloids that show *some* conductivity at room temperature. They require extremely low temperature (in the neighborhood of 4.2 K) to slow down core vibrations sufficiently and inhibit electron scattering by phonon, which impedes electron flow.

Table 6. Properties of Deposited and Thermally Grown Oxide Films

Property	Composition	Step Coverage	Density (gm/cm^3)	Refractive Index	Dielectric Strength (V/cm)
Thermally grown at 1000°C	SiO_2	—	2.2	1.46	$> 10^{-5}$
Deposited from $\text{SiH}_4 + \text{O}_2$ at 450°C	$\text{SiO}_2(\text{H})$	Nonconformal	2.1	1.44	8×10^{-6}
Deposited from TEOS at 700°C	SiO_2	Conformal	2.2	1.46	10^{-5}
Deposited from $\text{SiCl}_2\text{H}_2 + \text{N}_2\text{O}$ at 900°C	$\text{SiO}_2(\text{Cl})$	Conformal	2.2	1.46	10^{-5}

Figure 8. The resistance dependence on temperature for an ordinary metal and low- and high-temperature superconductors (LTS, HTS).

In 1986 superconductivity was discovered in a new group of materials that have a significantly higher transition temperature ($T_C \sim 40$ K or above) [13]. T_C in this group of materials is at least 10 K higher than the highest T_C in LTS. Therefore, this group of superconductors are referred to as *high temperature superconductors* (HTSs). Except for a very few elements, HTS comprises metallic compounds and alloys. One prominent class of these compounds is the *perovskites*. Reported T_C values in HTS have reached ~ 140 K and are projected to reach 200 K or higher. The temperature dependence of the resistance in an ordinary metal is shown in Fig. 8 and contrasted with those in low-temperature and high-temperature superconductors. Also, Table 7 gives T_C for a selected group of superconductors.

3.2. The Meissner Effect

We now consider a hypothetical perfectly pure metal at $T = 0$ K in which the resistance is zero because of the absence of phonon scattering. This perfect conductor with a vanishing resistance is a perfect *diamagnet*; thus if placed in a magnetic field, the perfect conductor would expel the magnetic field and the magnetic field intensity within the perfect conductor would be zero. Conversely, if the hypothetical perfectly pure metal is placed in a magnetic field at $T > 0$ K (phonon scattering is present and the metal resistance is nonzero), a nonzero magnetic field develops within the metal. However, if the metal temperature is lowered to 0 K, at which point the metal becomes a perfect conductor, the magnetic field within the now perfect conductor remains trapped within. Both of these effects are derived from *Lenz' law*, which imply that current loops would be generated to exactly cancel the imposed field. Therefore, a solely zero resistance model for the superconductor in a magnetic field would behave similar to a perfect conductor.

However, the situation in a superconductor is found to be unexpectedly different from that in a perfect conductor. A superconductor in a magnetic field would have a nonzero magnetic field at $T > T_C$ as shown in Fig. 9a. In contrast to the perfect conductor, however, and when temperature is lowered to $T \leq T_C$ the magnetic field within the superconductor vanishes and the magnetic flux is expelled as shown in Fig. 9b; thus, the superconductor has a zero effective *permeability*. It was concluded that in a weak magnetic field and at $T \leq T_C$ a superconductor is a perfect diamagnet except for a thin surface layer of the body, which is ~ 100 nm deep. This effect is called the *Meissner effect* in superconductors [16].

The preceding discussion assumes a weak magnetic field. However, a superconductor loses its superconducting state at magnetic fields higher than a *critical field* value B_C . The critical field at any temperature is given as

$$B_C = B_C^0 \left[1 - \left(\frac{T}{T_C} \right)^2 \right] \tag{21}$$

Table 7. Properties of Some Selected Superconductors

where B_C^0 is a constant [17]. Table 7 gives the critical field for a number of superconductors.

3.3. Microscopic Theories of Superconductivity

The microscopic theory of superconductivity was developed by the trio Bardeen, Cooper, and Schrieffer (BCS) in 1957, and this theory is widely referred to as the BCS theory [18]. This theory describes the metal LTSs very successfully, and it leads to results that quantitatively agree with experimental results. Later in 1972 Bardeen, Cooper and Schrieffer were awarded the Nobel prize in physics for their BCS theory.

The basic hypothesis of the BCS theory of the superconducting state is that the electrons occupy the momentum states in pairs, which are attracted to one another. In a pair of electrons, referred to as *Cooper pair*, the two electrons occupy the momentum states \mathbf{k} and $-\mathbf{k}$ with opposite spins. In the superconducting ground state ($T=0$ K) the energy necessary to separate electrons in the pairs is called the *energy gap* Δ . The BCS theory relates Δ to T_C as

$$2\Delta = 3.52k_B T_C \quad (22)$$

where k_B is Boltzmann's constant. Also in the superconducting ground state ($T=0$ K) the probability of pair occupation of momentum states is reminiscent of the normal *Fermi-Dirac* occupation probability at $T=0$ K. At $T > 0$ K some of the pairs are separated and the generated single electrons obey Fermi-Dirac statistics. The energy gaps for selected superconductors are given in Table 7.

In spite of the remarkable success of the BCS theory in describing superconductivity in metal LTSs, there is, as yet, no acceptable microscopic theory for HTSs. The main

reason for this is that HTSs are highly anisotropic and their superconducting response depends very strongly in their crystallographic structure. Note that the BCS theory is based on the isotropic electron gas in a metal.

3.4. Superconductor Applications

The most obvious application of superconductors would be in power transmission lines. More than 10% of the generated electricity is dissipated as heat in the transmission lines, and the prospect of zero-loss superconducting transmission lines is appealing. However, the hurdle for such an application is the cooling below T_C requirement. Niobium-titanium with $T_C \sim 10$ K and $B_C \sim 15$ tesla is used in superconducting magnets applications. Superconducting magnets are essential to magnetic resonance imaging (MRI) of the human body. MRI requires very strong and uniform magnetic fields that can be generated only by superconducting coils.

Another prominent application of superconductors is in the *superconducting quantum interference device* (SQUID), which consists of two superconductors separated by insulating layers, thereby forming two parallel Josephson junctions. SQUID is able to detect minute magnetic fields such as the ones occurring in living organisms and animal brains.

4. PIEZOELECTRIC MATERIALS

4.1. The Piezoelectric Effect

Piezoelectricity is the development of electric polarization in a crystal produced by an applied mechanical stress (direct) and the converse process of development of mechanical elastic strain in a crystal by the application of an electric field (indirect). Piezoelectricity is therefore an electromechanical phenomenon that occurs in piezoelectric materials. In simple terms piezoelectric materials can produce a voltage if subjected to a mechanical stress. The reverse process, that is, the application of a voltage to a piezoelectric material, can change its shape.

For a crystal to be piezoelectric its structure must have no center of symmetry. Hence a stress applied to such a crystal will modify the separation between positive and negative charge sites and consequently results in a net polarization at the crystal surface. This polarization gives rise to the potential difference generated in the crystal. In piezoelectric materials, coupling between the electrical and mechanical parameters gives [1]

$$\sigma_{ij} = c_{ijkl}^E S_{kl} - e_{kij} E_k, \quad D_i = e_{ikl} S_{kl} + \epsilon_{ik}^s E_k \quad (23)$$

where σ and S are second order stress and strain tensors, respectively, and i and j assume values of 1, 2, or 3 (x , y , or z). The former tensor is expressed in pascals (Pa), and the latter is unitless. c^E , given in pascals, is the *elastic stiffness constant* at a given electric field E , measured in V/m , with the k th component E_k . e is the *piezoelectric constant* in units of C/m^2 and ϵ , given in F/m , is the permittivity of the piezoelectric material. D_i is the i th component of the electric displacement measured in C/m^2 .

The two equations in (23) are referred to as the *piezoelectric constitutive equations*. In matrix notation they take the form

$$[\sigma] = [c][S] - [e^T]E, \quad D = [e][S] + [\varepsilon]E \quad (24)$$

where $[e]$ is a 3×6 matrix with its elements depending on the symmetry of the piezoelectric crystal and $[e^T]$ is the transpose of the matrix $[e]$. With $e = 0$, Eqs. (23) and (24) reduce to the familiar *Hooke's law* and the familiar relation between electric field and displacement vectors $D = \varepsilon E$. Hence, D can be nonzero in the absence of any electric field ($E = 0$) provided that the crystal undergoes a strain, whereas the application of an electric field can result in strain in the absence of mechanical stress ($\sigma = 0$).

4.2. Piezoelectric Materials and Their Preparation

Piezoelectric materials are predominantly ceramic solids and a number of polymers. Piezoelectricity is exhibited by a number of natural crystals such as quartz, sodium potassium tartrate, and tourmaline. Among the synthesized piezoelectric crystals are the Rochelle salt, barium titanate ($BaTiO_3$), lead zirconate titanate (PZT), zinc oxide, aluminum nitride, and the polymer polyvinylidene fluoride (PVDF).

Piezoelectric films are commonly used in semiconductor sensor and N/MEMS applications. The most popular piezoelectric films for these applications are ZnO, AlN, and PZT. Advantages of these films over others include (1) high electromechanical coupling, (2) good adhesion to substrates, (3) stable and not significantly affected by environment, (4) compatible with CMOS processing, and (5) relatively low cost. Major applications of these films are in pressure and gas microsensors, acoustic resonators, accelerometers, filters, and microactuators. Several methods for the preparation of piezoelectric films are employed depending on which material and substrate are used.

The major preparation methods for piezoelectric films are vacuum deposition and solgel [19]. The latter method is used exclusively for piezoceramic films, such as PZT and PLZT, deposition. The solgel method involves the spinning of a chemical solution, which allows for a better control of composition and film homogeneity. Also solgel deposition is very low cost compared to vacuum deposition methods and is very suitable for large-area film preparation. However, solgel deposition may not be appropriate for the deposition of thick piezoelectric ($\geq 1\text{-}\mu\text{m}$) films because of localized microscopic cracks that could develop in thicker films, especially if subsequent thermal annealing of the film is part of the final device processing. Piezoelectric films with cracks have very low piezoelectric coupling and results in very poor device performance.

Vacuum deposition methods comprise sputtering and direct, indirect, or reactive evaporations [20–22]. Reactive evaporation is particularly important in depositing ZnO and AlN films. ZnO and AlN are also deposited using variations of sputtering: “triode sputtering,” “RF sputtering,” and “magnetron sputtering” [23]. ZnO sputtering employs a pure zinc target that is reactively sputtered in an oxygen/inert-gas mixture. Improved ZnO film deposi-

tions are obtained with triode sputtering at submicron pressures. Also higher sputtering rates and excellent film qualities have resulted from DC and RF magnetron sputtering. RF magnetron sputtering was also applied to AlN growth at low temperatures. Early preparations of AlN films have used metallorganic chemical vapor deposition (MOCVD) methods [24].

4.3. Piezoelectric Material Applications

Piezoelectric materials form essential components for transducer devices that convert mechanical signals to electrical ones. Likewise, piezoelectric materials form essential components for actuator devices, which convert electrical signals to mechanical ones.

To understand the electrical-to-mechanical energy conversion process and, hence, illustrate the actuation application of piezoelectric materials, we consider the hypothetical two-dimensional piezoelectric crystal in Fig. 10. Figure 10a shows the piezoelectric crystal in the absence of any applied stress or electric field with the vertical separation l between positive and negative charge centers. When an electric field E is applied in the direction shown in Fig. 10b, the positive and negative ion centers are displaced; positive ions are displaced upward, whereas negative ions are displaced downward. This increases the separation l between ions and results in crystal expansion—a net positive strain occurs in the crystal in this case. Similarly, by changing the applied electric field polarity, negative strain develops in the crystal as shown in Fig. 10c. This is a case of unidirectional loading, which is very common in many piezoelectric transducer applications. Instead of using the complex relations given in Eqs.

Figure 10. A piezoelectric crystal (a) in the absence of electric field, (b) with applied electric field, and (c) with applied electric field in a direction opposite that in (b).

(23) and (24) engineers often use the simple relation [25]

$$S = dE \tag{25}$$

where, as in Section 4.1, S and E are the strain and the magnitude of the electric field, respectively, and d is a *piezoelectric coefficient*, which is dependent on the piezoelectric material and is given in units of meters per volt. d relates to e in Eqs. (23) and (24) through c and ϵ .

Conversely, in sensor applications of piezoelectric materials and for unidirectional loading of the electric field, resulting from the application of a mechanical stress to the piezoelectric crystal, is simplified by the relation [25]

$$E = f\sigma \tag{26}$$

where f is another material dependent piezoelectric coefficient and satisfies the relation

$$\frac{1}{fd} = c \tag{27}$$

The effectiveness of the conversion of mechanical energy to electrical energy and vice versa is gauged via an electromechanical conversion factor K defined as follows [25]:

$$K^2 = \frac{\text{mechanical energy output}}{\text{electrical energy input}} \quad \text{or} \tag{28}$$

$$K^2 = \frac{\text{electrical energy output}}{\text{mechanical energy input}}$$

The piezoelectric coefficient d as well as the conversion factor K for common piezoelectric crystals are given in Table 8.

5. SHAPE MEMORY MATERIALS

5.1. Shape Memory Alloys

5.1.1. The Shape Memory Effect in Alloys. The *shape memory effect* (SME) is a property of a group of alloys that exhibit *martensitic transformation* [27]. The shape memory alloy (SMA) undergoes a deformation in the low-temperature phase and recovers its original shape on heating to a critical temperature called the *reverse transformation (RT) temperature*. Martensitic transformation (MT) is a diffusionless process in which atoms move collectively by a shearlike mechanism. Usually the *parent*

Figure 11. A martensitic transformation in a SMA showing the martensite and parent phases. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

phase, which occurs at a high temperature, is cubic; and the martensite phase, which occurs at a low temperature, has a lower symmetry. MT is schematically shown in Fig. 11, where as, the temperature is lowered, the parent phase yields the two martensites A and B, which have the same crystal structure but two different orientations. The two martensites A and B are called the *correspondence variants* (CVs). Since the martensite phase is of a lower symmetry than the parent phase, many variants could be formed from the parent phase. For example a MT in which the parent phase is face-centered cubic (fcc) and the martensite phase is body-centered tetragonal (bct) comes with three CVs. MT is normally accompanied by either slip or twinning, depending on the kind of alloys; this is why twins or dislocations are normally observed in martensites under electron microscopy. MT may occur as a result of temperature change; however, a uniaxial stress would always assist MT giving rise to a *stress-induced martensitic* (SIM) *transformation*. Now, if the temperature of the alloy is raised high enough to render the martensite phase unstable, a reverse transformation (RT) occurs, if it is crystallographically reversible, and the martensite reverts back to the parent phase, hence giving rise to SME.

Figure 12 illustrates the SME by showing the parent phase of a single-crystal SMA (Fig. 12a) transforming into a self-accommodated martensite phase (Fig. 12b) on cooling to a temperature T between T_M^s and T_M^f , where the former temperature is the martensite start temperature and the latter is the martensite finish temperature. As the

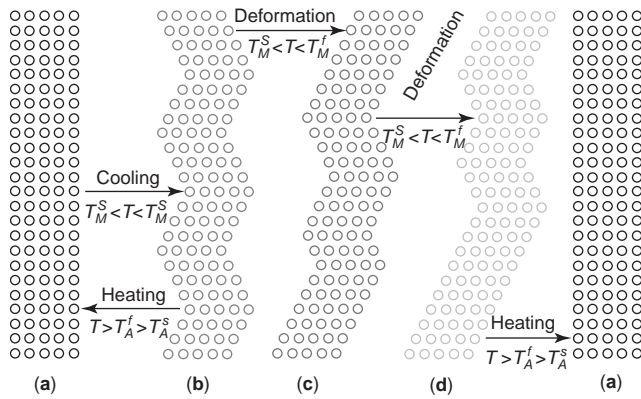

Figure 12. The SME effect and transformation paths over different temperature and deformation cycles in a SMA. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

temperature of the crystal is increased to $T > T_A^f > T_A^s$, where T_A^s and T_A^f are the start and finish temperatures of RT, respectively, the crystal regains its original shape. Also, a deformation in martensite (Figs. 12c and 12d), resulting from any kind of stress such as tensile, compressive, or bending, may proceed by the growth of one variant at the expense of the others (e.g., twinning or detwinning). As long as the strain is below some critical value, the deformed crystal reverts back to its original shape in Fig. 12a as the temperature is increased beyond T_A^f .

Figure 13 provides a tensile stress–strain behavior in a typical SMA. At $T_M^s < T < T_M^f$ the stress–strain curve is as shown in Fig. 13a: SIM occurs and is stable; hence a substantial strain remains on load removal and absence of stress. This strain is eliminated and the material returns to its original shape as indicated by the dotted line in Fig. 13a upon increasing the temperature to $T > T_A^f$. On the contrary, when the SMA is tensile-stressed at $T > T_A^f$, strains recover simply by unloading (Fig. 13b). One notes that often SMAs have another unique property called *superelasticity* at $T > T_A^f$. Superelastic materials are those materials exhibiting large ($\sim 20\%$) nonlinear recoverable strain on loading and unloading.

5.1.2. Shape Memory Alloys and Their Processing. Some selected SMAs are given in Table 9 together with their composition and structural change. TiNi-based alloys are the most prominent SMAs with good strength properties, ductility and resistance to corrosion, as well as excellent SME characteristics. However, TiNi-based alloys are expensive, which make them unsuitable for many applications. Cu-based SMAs, however, are rather inexpensive

Figure 13. A tensile stress–strain behavior in a SMA.

and have been extensively studied for several applications. They are superior to TiNi-based SMAs in electrical and thermal conductivities and in deformability. Among the Cu-based SMAs that are widely investigated are CuZn and CuAl.

The fabrication of commercial SMAs involves three major steps [28]: (1) melting and casting, (2) hot- and coldworking, and (3) shape memory treatment. The control of the alloy composition is very important to the SMA characteristics. In particular, room temperature is very sensitive to composition. For example, a 1% shift in Ni content results in 100 K changes in T_M^s and T_A^f of TiNi SMA. Melting is usually performed at high temperatures (~ 1500 K and higher) in high vacuum or an inert-gas atmosphere since the molten metals would often be very

Table 9. Properties of Some Selected SMAs

SMA	Composition	T_M^s (K)	T_M^f (K)	T_A^s (K)	T_A^f (K)

Figure 14. Elasticity–temperature behavior in a polymer.

reactive to oxygen. A high-frequency induction melting method is commonly used. Advantages of induction melting include the homogeneity and controllability of chemical composition throughout the ingot. Other melting methods utilize electron beams. Electron-beam melting comes with the lowest impurity content in the SMA; however, controllability of the composition is much less precise. Hot- or coldworking is used to forge and roll the ingot into a bar, a wire, or a slab with appropriate size.

5.2. Shape Memory Polymers

Certain polymers show SME; however, the mechanism involved is completely different from that in SMA. Rubberlike polymers show elastic behavior at room temperature; they exhibit large strains in response to applied stresses and completely recover their original shapes when the stresses are removed [28]. However, when the temperature of the strained rubberlike polymer is decreased to very low levels, the strained polymer may lose its elasticity and may not revert back to its original shape on the removal of stress. The low temperature at which this happens for a particular polymer is called the *glass temperature* T_g of the polymer (Fig. 14). When the temperature of the unloaded polymer is increased above T_g , the polymer returns back to its prestress shape, thus exhibiting a SME. Polymers that show the SME are referred to as the *shape memory polymers* (SMPs). The properties of SMAs and SMPs are compared in Table 10. Among SMPs are polynorbornene, polyisoprene, polyurethane, and polyethylene.

5.3. Applications of Shape Memory Materials

The most important applications of SM materials are in thermal actuation, which results in the generation of force and/or motion. The *thermal actuator* is a device that converts thermal energy to mechanical energy via the thermomechanical properties of a shape memory material. The most commonly used shape memory material element in an SM actuator is a coil spring since this form makes

Table 10. Comparison between SMA and SMP Properties

Physical Property	SMPs	SMAs
Density (g/cm^3)	0.9–1.1	6–8
Deformation (%)	250–800	6–7
Recovery temperature ($^{\circ}\text{C}$)	25–90	10–100
Stress required for deformation (MPa)	1–3	50–200
Recover stress (MPa)	1–3	150–300

possible the generation of high degrees of large force and motion. The major application of SM actuators is in thermally actuated valves. Other applications for SM actuators are the ones where the actuator is used as both a sensor and an actuator. These applications include thermal protection devices for domestic water filtration units, steam traps for passenger train steam heating units, and thermally actuated electric switches for diesel engine radiator fans.

SMAs and SMPs are also used in N/MEMS. These include robotic micromanipulators [29] and microgrippers [30]. Moreover, SME have more recently been used successfully in dental and medical fields. Examples of SME applications in dental fields are the use of TiNi alloys in dental arc wires [31], dental implants [32], and partial dentures [33]. In medical applications, however, bone plates made of TiNi alloys are attached with screws for fixing broken bones.

The origin of the Smith chart as a fast and accurate graphical design tool is rooted in the predigital computer era of the 1930s. The original paper chart format was routinely used to solve difficult transmission-line matching problems in a variety of broadcasting, microwave, circuit design, and telecommunication applications. While it has since evolved almost exclusively into a software format, the original paper forms remain a convenient detailed medium for print output of finished work from software implementations of Smith's graphical method.

Phillip H. Smith, inventor and developer of the Smith chart, was affiliated with Bell Telephone Laboratories for his entire engineering career after graduating from Tufts College in 1928. At Bell Labs, Smith repeatedly demonstrated his incisive, pragmatic, problem-solving abilities on a variety of technical problems. In his first decade on the job he developed the chart to its common present form through an iterative trial process of several more rudimentary forms Smith's original intended application was to simplify the tedious work of installing and matching open wire transmission lines for antennas. During this period he almost single-handedly developed and proved

the concept of using a graphical chart as a viable solution method. One can certainly appreciate his desire to minimize tedious slide-rule calculations required to solve transmission line equations involving hyperbolic functions. Smith [1] cited his routine need to obtain impedance solutions using Fleming's [2] telephone equation as a driving force to consider a graphical solution alternative. (Readers interested in greater detail on the life of Phillip Smith are referred to the Foreword section of Ref. 3 for a written transcript of the memorial session in Phillip Smith's honor presented at the 1990 IEEE MTT/S Symposium. An on-line IEEE source [4] also provides good detail on Smith's back-ground.)

The Smith chart was first published in a usable developmental form in 1939 by Smith [5]. A subsequent publication [6] in 1944 described the refined form known and used today. A standard preprinted paper chart in this format is shown in Fig. 1a, and Fig. 1b shows only the enlarged central portion around the normalized point $z = (1 + j0)$. In each of Smith's publications the fundamental equations and methods are provided along with demonstrations of the utility of the chart method. Certainly the ability to represent and mathematically manipulate a complete impedance data vector on a single compact graphical paper chart was a significant step forward at the time for the telecommunication and emerging electronics industries at the onset of World War II.

1. THE ATTRACTION OF A GRAPHICAL SOLUTION METHOD

The essential objective in using the Smith chart is stated simply. An impedance (or equivalent admittance) locus over a frequency range is systematically repositioned on the chart in well-defined ways by the progressive effects of series or shunt elements, thereby placing the passband portion of the impedance vector in the central area of the chart and the stopband portion at the outer periphery of the chart. The circuit elements commonly used include distributed elements such as transmission lines and quarter-wave stubs, discrete elements such as inductors and capacitors, and any combination of these and related elements. Resistance elements are seldom intentionally used.

There is no need for a graphical method as an aide to solve a straightforward equation such as Ohm's law. However, the more difficult general equation for the input impedance ("sending impedance" in early-twentieth-century parlance) of a transmission line with an arbitrary value of load impedance ("receiving impedance") is another matter. The presence of multiple hyperbolic functions in Fleming's equation is shown in Table 1, line 1. Figure 2a illustrates the concentric circular arc movement on the interior of the chart for a value of load impedance Z_L connected to a length l/λ of transmission line to produce an input impedance of Z_i . The input impedance

Figure 1. Full-size Smith chart grid; (b) enlarged center portion of the chart.

Figure 1. (Continued).

equations for transmission-line stubs (i.e., lengths of line typically less than a half-wavelength, with short-circuit and open-circuit load impedance values) are given by the equations of Table 1, lines 2 and 3, respectively. Figure 2b illustrates the concentric circular arc movement along the periphery of the chart for a value of load impedance ($Z_L = 0$ for the short-circuit stub and $Z_L = \infty$ for the open-circuit stub), connected to a stub with length l/λ , to produce an input impedance of Z_i .

The equation of Table 1, line 2 shows the effective parallel LC circuit tuning effect for a short-circuit stub, and line 3 illustrates the effective series LC circuit tuning effect for the case of an open-circuit stub. At relatively higher frequencies for which the length of the stub is greater than a half-wavelength, these tuning effects repeat unlike the effect of discrete (lumped element) parallel or series LC circuits.

The repetitive nature of these three equations when line length exceeds a half-wavelength is evident when one

Table 1. Distributed and Lumped-Element Components Commonly Used in Smith Chart Analysis and the Direction of Progression with Frequency on the Chart

Element Type	Defining Equation	Motion on the Smith Chart
Transmission line	$Z_{in} = Z_0 (Z_L + Z_0 \tanh \gamma l) / (Z_0 + Z_L \tanh \gamma l)$	CW along a circle centered at $Z_0 = 1 + j0$ (see Fig. 2a)
Short-circuit stub	$Z_{in} = jZ_0 \tan \gamma l$	CW along chart perimeter with region near ∞ especially useful ($l = \lambda/4$) (see Fig. 2b)
Open-circuit stub	$Z_{in} = -jZ_0 \cot \gamma l$	CW along chart perimeter with region near 0 especially useful ($l = \lambda/4$) (see Fig. 2b)
Inductance	$E = IX_L; X_L = j\omega L$	CW along constant- R circles (see Fig. 2c)
Capacitance	$E = IX_C; X_C = 1/j\omega C$	CCW along constant- R circles (see Fig. 2c)
Resistance	$E = IR$	To right along constant- X arcs toward $R = \infty$

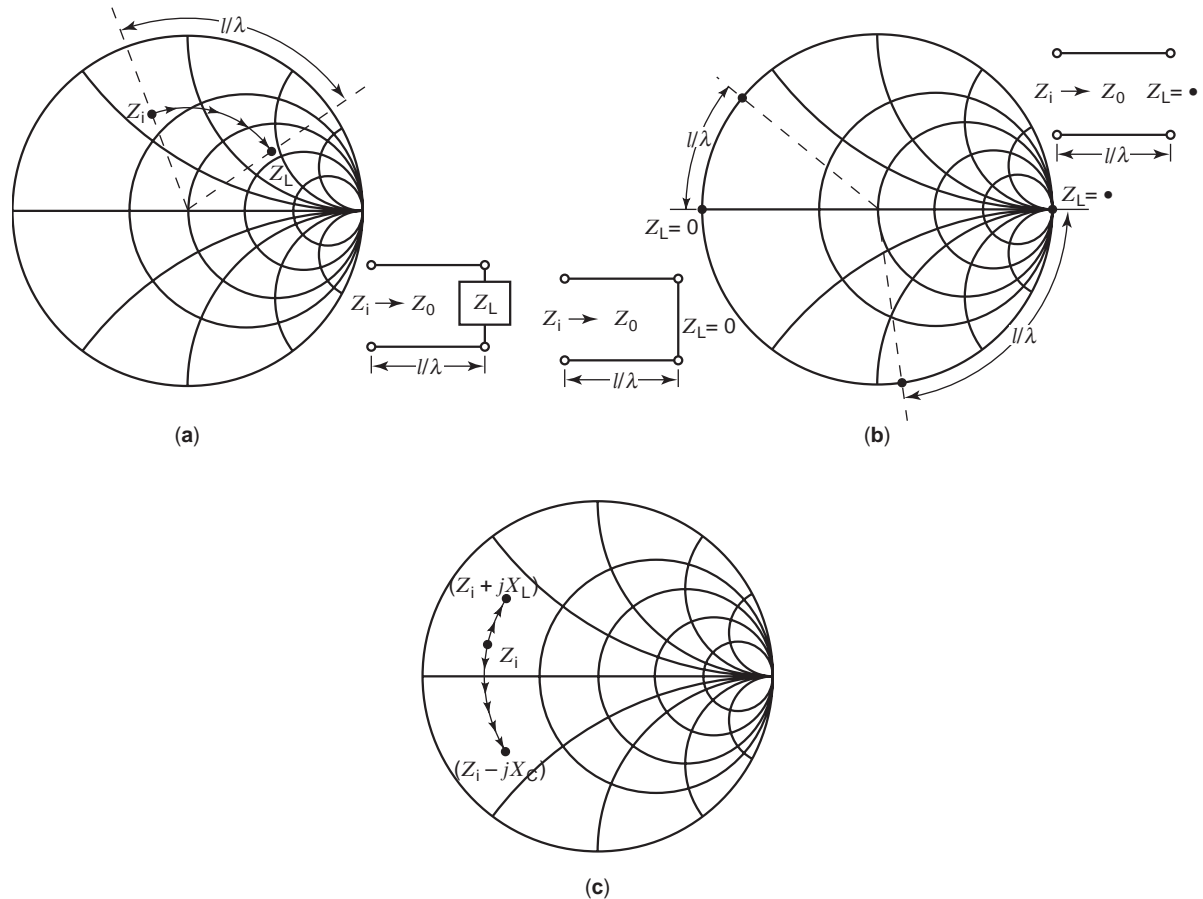

Figure 2. (a) Concentric circular movement along the chart interior to a value of input impedance Z_i resulting from addition of a transmission line to a load impedance Z_L ; (b) concentric circular chart movement along the chart periphery for the input impedance of a short-circuit ($Z_L = 0$) and an open-circuit ($Z_L = \infty$) stub; (c) movement along circular arcs of constant resistance for addition of a capacitance (downward) and inductance (upward) to a load impedance Z_L .

looks at them plotted on the chart. Likewise, the tuning effects of discrete elements is also calculable and treated on the chart. The inductor and capacitor are used especially in typical equalizer, filter, and matching circuits. The resistor element, while it can also be treated on the chart, is seldom used except in cases such as ultrabroadband (i.e., multioctave to decade bandwidth) tuning of electrically short antennas to meet a VSWR specification. The equations for the discrete elements and the relative motion of their locus on the chart is given in Table 1, lines 4, 5, and 6. Figure 2c illustrates the movement on the chart along arcs of constant resistance for some load impedance Z_L when a capacitance or inductance is placed in series.

The Smith chart's power as a graphical solution method comes from its versatility to design cascade and parallel circuits made up of any combination of distributed and lumped circuit elements defined by the equations given in Table 1. In addition, algorithmic methods such as the design of transmission-line impedance transformers can also be implemented directly on the chart. Design aids such as a voltage standing-wave ratio (VSWR) goal plotted as a circle concentric to the center of the chart and other geometric constructs such as forbidden areas and boundary circles make the design process straightforward. These

design aids as well as the line entries in Table 1 are discussed in greater detail in subsequent sections.

2. MATHEMATICAL STRUCTURE OF THE CHART

The mathematical basis of the Smith chart is a conformal bilinear transformation for which all data values approaching infinitely large values on the $\{(R, X)$ or $\{(G, B)\}$ complex plane map to a single uniquely defined finite point. In implementing the transformation, the simple, familiar, straight-lined, rectangular, impedance grid with resistance (or conductance) on the positive abscissa and reactance (or susceptance) on both positive and negative axes of the ordinate map into two families of circles that intersect orthogonally to one another. This holds true for charts scaled for impedance or admittance.

The equations that uniquely define the bilateral transformation between complex normalized impedance and complex reflection coefficient are given as

$$z = \frac{1+k}{1-k} \quad \text{and} \quad k = \frac{z-1}{z+1} \quad (1)$$

where z represents normalized impedance (Z/Z_0), k is the complex reflection coefficient at the point where z is measured, and Z_0 is the reference or normalizing value of impedance.

The generality of the underlying bilinear transformation is seen by plotting normalized impedance values (or analogously admittance values) on the right half of a Cartesian coordinate plane and evaluating the paired Eq. (1) for reflection coefficient loci that have constant values of magnitude with varying modulus as well as constant modulus (angle) values with varying magnitudes. Figure 3a illustrates normalized impedance plotted in a Cartesian frame, with the dashed lines indicating constant-resistance and constant-reactance values (hereafter referred to as constant- R and constant- X , respectively). Figure 3b

(a)

(b)

Figure 3. (a) Plots of normalized constant R and constant X on a Cartesian frame; (b) loci of constant- k (full circles) and constant- ϕ angle (circular arcs).

uses the same frame to depict loci of constant- k values as solid-lined full circles, and it uses loci of constant phase angle values for variable- k magnitudes as solid-lined partial circles. The constant angle value loci all intersect at the single point $z = (1 + j0)$ for which $k = (0 + j0)$.

Alternately, one can plot the complex reflection coefficient [$k = K \exp(j\phi)$] in two-dimensional cylindrical (i.e., polar) coordinates as shown in Fig. 4a, with $k = (0 + j0)$ located at the center and cylindrical angle representing the reflection coefficient angle ϕ . Then the transformation to complex normalized impedance using Eq. (1) results in loci for constant- R and constant- X values that are again full circles and partial circles, respectively, as illustrated in Fig. 4b. These circles and circular arcs have progressively offset centers located along the orthogonal axes defined by the horizontal line at $x = 0$ and the vertical line tangent to the outer circle at the right side point. Figure 4 illustrates the orthogonality features in both domains of (a) reflection coefficient and (b) normalized impedance.

(a)

(b)

Figure 4. (a) Two-dimensional cylindrical coordinate plot of loci of constant reflection coefficient magnitude and constant reflection coefficient angle; (b) loci of constant- R circles and constant- X circular arcs scaled to fit on the reflection coefficient loci plot of part (a).

The latter grid of circle and circular arcs represent exactly the chart solution method first proposed by Smith to the radio engineering community.

The radii and centers of the constant- R circles and constant- X circular arcs of Fig. 4b are derived relative to the center of the cylindrical coordinate plot of complex reflection coefficient. The radii are given by Eq. (2), where the value of either r or x is held constant. The geometric locations of the centers of the constant- R circles are given by Eq. (3), and the positions of the centers of the constant- X circular arcs are given by Eq. (4)

$$r_k = \frac{[(r^2 - 1 + x^2)^2 + 4x^2]^{1/2}}{(r+1)^2 + x^2} \quad (2)$$

$$(k_R^x, k_R^y) = \left(\frac{r}{r+1}, 0 \right) \quad (3)$$

$$(k_X^x, k_X^y) = \left(1, \frac{1}{x} \right) \quad (4)$$

where the subscripts R and X denote constant- R circles and constant- X arcs, respectively, and the superscripts x and y denote the directional components.

3. NORMALIZATION OF THE CHART

For commonality and other reasons, it is useful to deal with normalized rather than unnormalized charts. Both full-size and enlarged central area charts are normalized by dividing values of resistance (R) and reactance ($\pm X$) by the real reference value (Z_0). This scaling results in all real axis values to the left of the centerpoint having values between 0 and 1, and all real axis values to the right of the centerpoint represent values between 1 and infinity. Charts that plot admittance values are analogously normalized using the reference value $Y_0 = 1/Z_0$. The usage of normalized impedance values on the Smith chart grid facilitates the computation of reflection coefficient, VSWR, and return loss from the chart. Design examples given in subsequent sections for transmission-line problems illustrate the advantage of using normalized values for chart-based computation.

4. GRID-BASED FEATURES OF THE SMITH CHART

A number of useful design features result from the final form of the chart grid as derived by Smith. In addition to the interrelation of VSWR, return loss, and reflection coefficient, one is also able to read length ($1/\lambda$) along a transmission-line segment from the rim of the chart and use boundary circles as a design aid. These features are reviewed below, but the reader is referred to Smith's seminal text [7] for added detail on these and other features. This reference also contains an exhaustive bibliography on publications related to the Smith chart through 1969.

4.1. VSWR Circles

The relationship between VSWR and reflection coefficient is given by Eq. (5), where K is the magnitude of the complex reflection coefficient written as $k = K \exp(j\phi)$:

$$\text{VSWR} = \frac{1+K}{1-K} \quad (5)$$

On the Smith chart, loci of constant VSWR are concentric circles with all centers located at $K=0$, and radii are nonuniformly distributed between unity and infinity for values of K ranging from 0 to 1.

4.2. Chart Perimeter as Transmission-Line Length

The classical transmission-line equation (see Table 1, line 1) clearly illustrates that impedance, and hence VSWR, varies in a repetitive fashion every half-wavelength in distance along a lossless line. On the Smith chart this is equivalent to repeated values for reflection coefficients with every complete rotation around the chart relative to the center of the chart. The entire perimeter of the Smith chart calibrates uniformly as a \pm quarter-wavelength distance relative to a reference location. Clockwise rotation around the chart's periphery is equivalent to moving along the line in a direction toward the source (generator), and counterclockwise rotation around the chart is equivalent to moving toward the load.

4.3. Impedance and Admittance Locus Movement for Discrete Circuit Elements

Electronic circuit impedance matching is easily performed utilizing the Smith chart. Typically one desires to use only lossless components to accomplish a match. The addition of a discrete circuit element such as a capacitance or an inductance in a matching circuit has a well-defined effect on moving the locus of a load impedance vector on the chart grid. The four key discrete circuit elements commonly used in circuit matching are given as follows along with their effects on motion of an impedance locus (for series elements) or an admittance locus (for shunt elements):

- Series inductance rotates an impedance locus CW on a constant- R circle
- Series capacitance rotates an impedance locus CCW on a constant- R circle
- Shunt inductance rotates an admittance locus CCW on a constant- G circle
- Shunt capacitance rotates an admittance locus CW on a constant- G circle

Here CW and CCW denote clockwise and counterclockwise motion, respectively, on the specified circles.

4.4. Boundary Circles

The chart-centered circle for a finite value of VSWR leads directly to the useful design construct known as *boundary circles*, which serve as a visual aid to determine the correct value of a circuit element that will provide the proper

Figure 5. VSWR circle and its associated boundary circle pairs for a value $VSWR = 1.25$.

amount of rotation of an impedance or admittance locus for acceptable matching (i.e., that meets the VSWR requirement).

For a specified VSWR there are two related pairs of boundary circles. Each pair consists of two circles that are centered on the $x = 0$ line and are doubly tangent to both the VSWR circle and the periphery of the chart, where the magnitude of the reflection coefficient is unity. Figure 5 shows the combination of a $VSWR = 1.25$ circle along with its associated pair of boundary circles. Knowing the directions of rotation for an impedance or admittance locus caused by the addition of series or shunt elements, respectively, one immediately determines that impedance values over a very large portion of the chart—namely, the interior portions of both small boundary circles, as well as the upper and lower exclusion areas outside both of the larger boundary circles—cannot be matched to within a specified value of VSWR with a single matching element.

5. OTHER IMPORTANT OPERATIONS EXECUTABLE ON THE SMITH CHART

5.1. Two-Element Matching over the Entire Chart

In contrast to the case just shown where impedance values over much of the chart area cannot be matched with a single element, it can be shown that all single-frequency impedance values anywhere on the chart exclusive of the outer rim circle ($r = 0$) can always be perfectly matched to a value of $r = (1 + j0)$ by use of a two-element circuit. Smith [8] and a current software chart implementation [9] provide overlay diagrams of the eight possible ell-type circuits (four L - C , two L - L , and two C - C), each with its associated allowed area and supplementary forbidden area on the Smith chart. (The same diagrams are also illustrated in Ref. 10, p. 40.) Any point within an allowed area can always be perfectly matched using the associated ell circuit.

5.2. Transmission-Line Transformers

Frequently the design of an impedance-matching circuit must be implemented using distributed parameter ele-

ments such as transmission lines. Somlo [11] has shown how a single-frequency design for a transmission-line transformer is graphically implemented using a Smith chart. Narrow-bandwidth-matching designs are also achievable using the same method. The Somlo technique is implemented as a utility tool in the software implementations of Refs. 9 and 12.

The ability to graphically analyze the matching effects of a variety of transmission-line circuit elements (e.g., open- or short-circuit stubs as well as transmission-line sections and impedance transformers in both series and shunt configurations) gives the Smith chart more versatility than do software synthesis tools, which are typically unable to treat a full array of transmission-line elements.

6. EXAMPLE

A circuit-matching design exercise is described here to illustrate the methods used in obtaining a solution on the Smith chart. To keep the charts visually succinct, each of the intermediate plotting steps including $Z \rightarrow Y$ and $Y \rightarrow Z$ inversions as well as the effects of individual branch-by-branch circuit constructions are presented on a set of individual charts. The traces plotted on the charts use the convention of Z_N or Y_N for the driving point impedance or admittance when looking toward the load from branch N . Readers who wish to study a variety of antenna-matching problems executed in step-by-step detail can consult Ref. 13.

In this problem a device, such as an antenna, has a highly capacitive input impedance vector as given in Table 2 for the range of 850–925 MHz. The objective is to produce a matching circuit that meets a VSWR requirement of 2.5:1 over the reduced frequency range of 855–920 MHz with the restriction that no lumped circuit inductors be used in the matching circuit.

The bandwidth requirement of about 8.5%, the highly capacitive values, and the implementation restriction of no lumped inductors all imply that additional elements beyond a simple two-element L configuration will be required to implement a satisfactory matching circuit. The two solutions derived by use of a software chart method are described in Table 3, giving all the circuit element parameter values. The first solution uses transmission lines and short-circuit stub elements exclusively and is illustrated in the set of successive charts in Fig. 6. The second solution requires fewer elements but includes a capacitance and a short-circuit stub having a low value of Z_0 that is virtually impossible to implement. It is presented in the second part of Table 3 for purposes of contrast only.

Table 2. Load Impedance Values for Example Matching Problem

Frequency (MHz)	Load impedance (Ω)
850	$15.0 - j250$
875	$19.0 - j227$
900	$21.5 - j192$
925	$25.0 - j180$

Table 3. Component Types and Values for the Solutions of Example Problem

Element No.	Element Type	Parameter Values ($v/c =$ Group Velocity)
<i>Primary Solution^a</i>		
1	Transmission line	$Z_0 = 234 \Omega$, 2.60 cm, $v/c = 0.69$
2	Shunt short-circuit stub	$Z_0 = 10.1 \Omega$, 4.84 cm, $v/c = 0.69$
3	Transmission line	$Z_0 = 76.22 \Omega$, 0.70 cm, $v/c = 0.69$
4	Shunt short-circuit stub	$Z_0 = 6.53 \Omega$, 6.25 cm, $v/c = 0.69$
<i>Contrasting Solution</i>		
1	Transmission line	$Z_0 = 100 \Omega$, 4.91 cm, $v/c = 0.69$
2	Shunt capacitance	9.4 pF
3	Transmission line	$Z_0 = 42.8 \Omega$, 5.84 cm, $v/c = 0.69$
4	Shunt short-circuit stub	$Z_0 = 3.12 \Omega$, 5.91 cm, $v/c = 0.69$

^aSee Fig. 6 for associated chart traces.

The first element in the matching circuit must be either of the two inductive types: a short-circuit stub or a transmission line of sufficient length to rotate the load impedance trace toward the inductive reactance portion (i.e., upper half) of the chart. There is, however, a distinct observable difference in how the two candidate initial elements cause the load impedance trace to rotate on the chart. A series-wired short-circuit stub will move the load trace CW and upward along constant- R gridlines, causing

the rotated impedance vector to lie closer to the center of the chart, but extending it over the chart to a greater degree than would be caused by a series transmission line. Conversely, the series transmission line keeps the rotated load trace further out toward the chart periphery. A compromise for the initial element is to use a short length of transmission line with high Z_0 . This has an impedance-transforming effect in bringing the load trace toward the center of the chart, but the short length keeps the trace

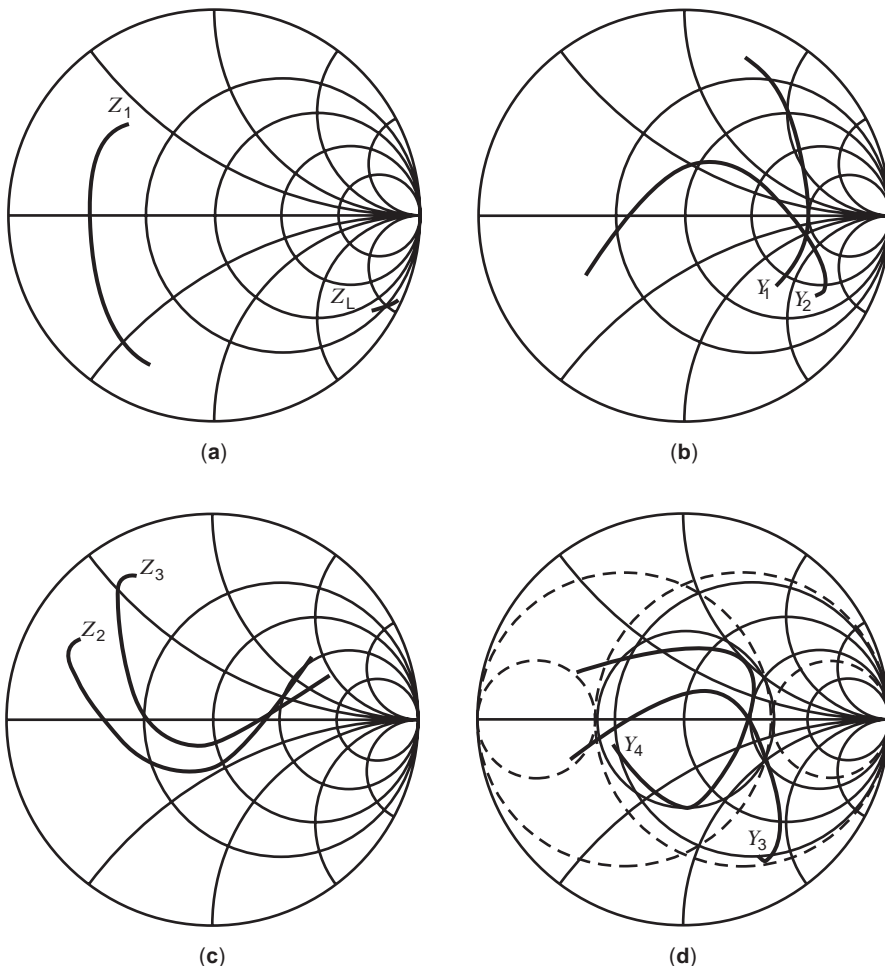

Figure 6. Solution to the example impedance-matching problem requiring no lumped-element inductors: (a) Z_L trace and Z_1 trace after adding series transmission-line section; (b) Y_1 trace and Y_2 trace after adding shunt short-circuit stub; (c) Z_2 trace and Z_3 trace after adding series transmission line section; (d) Y_3 trace and Y_4 trace after adding shunt short-circuit stub.

located mostly on the capacitive side of the chart. In this case the characteristic impedance and length of the transmission-line element are selected to rotate the impedance locus such that it approximately straddles the lower-left crescent of the boundary circles associated with the specified VSWR.

The second element, a shunt position short-circuit stub, rotates the Y_1 trace CCW and downward to position the ends of the Y_2 trace on the inductive susceptance side of the chart with the trace approximately surrounding the center of the chart. This begins the process of pulling the ends of the trace inward toward accomplishing the ultimate goal of collapsing the final trace into a loop configuration and positioning it inside the 2.5:1 VSWR circle.

The third element, a length of transmission line, rotates the Z_2 trace CW to an approximately vertical orientation with about half of the trace in each of the top and bottom halves of the chart. With the central portion of the Z_3 locus inside the VSWR circle, the sole purpose of the fourth and final element will be to complete the process of collapsing the trace into the needed loop and place it inside the VSWR circle.

The fourth element, a shunt-wired short-circuit stub, adds sufficient compensating susceptance (inductive susceptance at the low frequencies and capacitive susceptance at the high frequencies) to further close the loop. To provide the necessary magnitude of compensating susceptance given by $B_{\text{stub}} = -(\cot \gamma l/Z_0)$, the characteristic impedance required for the shunt short-circuit stub element is a small value. This also keeps the Y_4 trace tightly looped. In practice, this low value of Z_0 is typically accomplished with four equal-length stubs wired in parallel and each having a Z_0 of about 25Ω , which is a practical physical lower limit. Frequency interpolation is used to confirm that the VSWR specification is met for the frequency range of 855–920 MHz.

The contrasting solution listed in Table 3 follows much the same sequence used in the first solution. The primary difference in the two methods is that use of a capacitance for the second element places its associated Y_2 trace in a more vertical orientation with the extremes of the trace spread further out from the VSWR circle. That causes the value of characteristic impedance for the short-circuit stub used for the fourth element to be much lower than that for the first solution method, where more of the admittance locus for the third element is already within the VSWR circle. This second solution is clearly not a physically realizable situation. Hence, the associated chart traces are not shown.

7. REVITALIZATION OF THE SMITH CHART IN SOFTWARE

The original printed paper versions of the Smith chart were primarily used in industrial research and World War II development efforts through the 1940s. For the following three decades, these paper charts became a mainstay tool in every transmission-line course in academia as well as a broad-based industry design tool. Beginning about 1980 with the onset of a variety of numerical design tools such as the real-frequency method pioneered by Yarman

and Carlin [14] and implemented in commercial software [15], the paper version of the Smith chart fell into relative disuse. However, beginning about 1990, a number of software tools [9,10,12,16,17] became available that implemented the core operations of the Smith chart on a computer screen.

These software implementations of the Smith chart alleviated most or all of the key difficulties encountered with manual use of the paper charts. These advantages include (1) elimination of math errors since the software internally performs all the background calculations of branch impedance or admittance values including normalization, (2) elimination of errors due to using an incorrect rotation direction on the chart, (3) elimination of interpolation errors when plotting data onto or reading value off of the chart, (4) requiring the user to select a proper value of group velocity for a transmission line ($v/c < 1$), (5) having the software internally perform spline calculations to plot smoothly contouring line vectors on the chart, (6) the dramatic speed improvement factor over hand-drawn Smith charts, and (7) toggled screen presentation of VSWR and boundary circles as convenient design aids. In addition, an attractive feature of the software versions is their ability to plot the finished work in excellent detail on a preprinted paper Smith chart form for delivery or publication purposes.

With the availability of software-based Smith chart programs, the professional circuit designer, student, and researcher can take full advantage of the clarity and simplicity of graphical methods with a minimum investment of labor and time to obtain the needed solution. More important, one gains the value of personal insight into the process of design of a matching circuit when using this graphical method.

The value of the Smith chart as a potent graphical design tool was well stated by Carlin [18] at a 1983 IEEE MTT/S professional workshop on broadband matching: "So far the 'best' transfer functions analytic theory has to offer are based on Chebyshev polynomials and almost invariably these yield matching structures which can be surpassed in performance by significantly simpler equalizers. In effect the old-fashioned procedure of 'playing around' on the Smith chart may produce better results than sophisticated theory."

As software-based Smith chart tools evolve to include additional capabilities such as built-in circuit optimization functions and IEEE 488 interfaces to port measured impedance data from network analyzers, it is expected that they will enjoy continued future usage by a variety of technical practitioners and students.

SPACEBORNE RADAR

RONALD KWOK
SIMON H. YUEH
LEE-LUENG FU
California Institute of
Technology

Spaceborne remote sensing instruments allow the acquisition of global and synoptic information for Earth science investigations. In particular, active microwave observations have the added advantage of providing diurnal measurements and are relatively uncontaminated by the intervening atmosphere. Here, we review three different applications of active microwave remote sensing that have contributed geophysical measurements on a scale and accuracy that surpass what could be accomplished with airborne or in situ observations. These are synthetic aperture radar interferometry, scatterometry, and altimetry. For each of these areas, we describe the measurement princi-

ple, the current technology, the applications, and give a brief look into the future.

1. SPACEBORNE IMAGING RADAR INTERFEROMETRY

1.1. Background

Radar interferometry is a technique for combining coherent radar images recorded by antennas at different locations or at different times to form interferograms that permit the detection of small differences in range, to better than the wavelength (λ) of the signal, between the two points of observation. The measurements are extremely useful for construction of high-resolution topographic maps and surface change maps. The observational geometry of across-track interferometry is depicted in Fig. 1. For a given set of repeat-pass observations, from the i th and j th epochs, with baseline B_{ij} and look angle θ , the interferometric phase difference at each sample is

$$\begin{aligned} \Delta\phi_{ij} &= (4\pi/\lambda)B_{ij} \sin(\theta - \alpha_{ij}) + (4\pi/\lambda)\Delta\rho_{ij} \\ &= \phi_{\text{topography}} + \phi_{\text{displacement}} \end{aligned} \quad (1)$$

where α is the tilt of the baseline with respect to the horizontal. The difference in the slant range pathlength $|\mathbf{r}_i - \mathbf{r}_j|$ is approximated by $\mathbf{B} \cdot \mathbf{r}$. The first term $\phi_{\text{topography}}$ contains phase contributions from the topography of the Earth surface relative to the interferometric baseline. The sensitivity of the measurements to surface relief is directly proportional to the length of the baseline. If the scatterers are displaced by $\Delta\rho_{ij}$ in the range direction between the two observations, then the observed phase will include a second contribution of $(4\pi/\lambda)\Delta\rho_{ij}$ due to this displacement. This additional term $\phi_{\text{displacement}}$ is independent of the spatial baseline. When the i th and j th observations are acquired at the same time (single-pass interferometry), only the first term is relevant. If the i th and j th observations are separated by a time interval, it is generally referred to as repeat-pass interferometry. In the case where more than one observation is available, it is known as multiple-pass interferometry. The reader is referred to the following articles for a more detailed description of the principles of imaging radar interferometry [1–4].

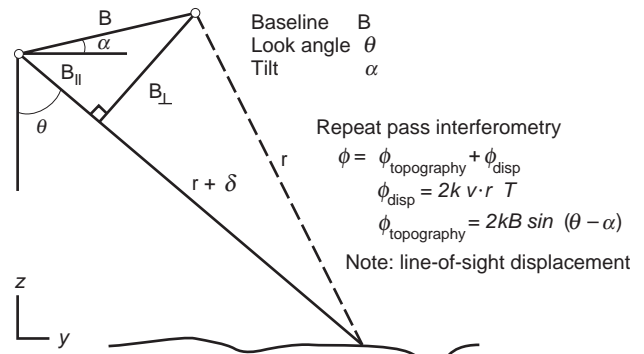

Figure 1. Radar interferometry—imaging geometry.

Here, we consider the more important practical limitations to the solution of Eq. (1) that affect the accuracies of the derived topography or motion field: phase unwrapping; baseline length/orientation; and phase noise. A digital interferogram is the product of two coregistered complex images I_i and I_j^* (* is the complex conjugate). The measured phases are modulo- 2π of the absolute phase $\Delta\phi_{ij}$ in Eq. (1). In order to create relative measurements, this phase field needs to be unwrapped to remove the 2π ambiguity. This is a difficult task, especially if the phase noise (introduced by the radar system) is high or if the phase field has high spatial frequency [2]. The unwrapped phase differs from the absolute interferometric phase $\Delta\phi_{ij}$ by an integer number of cycles for the entire phase field. Assuming $\phi_{\text{displacement}} = 0$ in the following discussion, a simple method to determine this constant would be to find one target in the interferogram with known position relative to the interferometer. Other methods for estimating absolute phase have been proposed and are used in different types of processing. Another significant error source results from errors in knowledge of the baseline length and orientation. It is impossible to separate an error in the baseline angle knowledge from a slope in the surface topography. Hence, the sensitivity of interferometer to surface relief is a function of baseline length and orientation. Extremely precise knowledge of the baseline geometry and length is required if absolute height estimates are needed. Phase noise results from various factors including thermal noise, sampling and processing artifacts, and the correlation of individual radar echoes before they are combined to form the interferogram. Uncertainties in baseline orientation cause slowly varying error whereas phase noise (expected to be random) describes the statistical variability of elevation estimates at each sample.

If an interferogram contains a mixture of topography and motion components in the observed phase, additional information is required to separate the two measurements. Much of it depends on the nature and magnitude of the motion field. For example, if a digital elevation model (DEM) of the region of interest is available, then the topographic phase could be removed. On the other hand, multiple interferograms could be used to estimate the two parameters. Some examples in the following sections illustrate several interesting uses of spaceborne interferometric datasets.

1.2. Evolution of the Technology

Imaging radar interferometry involves a mix of radar technology and data/signal processing techniques. Similar to most application technologies, the rate of development was limited by available datasets for experimentation and verification. Graham [5] of Goodyear Aerospace Corporation first demonstrated the feasibility of operating an airborne imaging radar system in the interferometric mode to generate elevation maps using optically processed data. Their interferometer consists of two antennas mounted one above the other on a side-looking moving gimbal. Subsequently, Zebker and Goldstein [1] at the Jet Propulsion Laboratory (JPL) refined these techniques using digitally processed complex data from a side-

looking synthetic aperture radar mounted on the NASA CV990 aircraft. Gray and Ferris-Manning [6] of the Canada Center for Remote Sensing (CCRS) also reported the results of a repeat-track implementation. The single-pass airborne systems of JPL and CCRS have generated extensive datasets for a number of years. Since then, there have been a growing number of interferometric systems developed for high-resolution topographic mapping and for studies in geology, glaciology, hydrology, and forestry. The current JPL TOPSAR system has two interferometers, both flush-mounted to the fuselage of the DC-8 aircraft and operating at L and C bands. The CCRS system uses the C-band channel of radar on the Convair CV-580 aircraft. Other airborne interferometers were developed by the following organizations: Environmental Research Institute of Michigan [7]; Norden Systems; and United Technologies. The Technical University of Denmark and Dornier of Germany both have operational airborne interferometers.

Researchers at JPL first demonstrated that interferometric procedures could be applied to satellite SAR data acquired on separate SEASAT passes [2,3]. Differential interferometry (using multiple interferograms) was used by Gabriel et al. [8] for detection of subcentimeter surface displacements over a large area. The SEASAT satellite, launched in 1978, provided a key source of satellite data for interferometric studies until the launch of the European Remote Sensing Satellite (ERS-1) in July 1991. The SEASAT SAR was operated at L band (25 cm wavelength) and the ERS-1 SAR was operated at C band. Both provided temporal baselines close to 3 days, but the longer wavelength of SEASAT makes that data less prone to temporal decorrelation. At shorter wavelengths, the data are more prone to temporal decorrelation, due to their sensitivity to small-scale changes in the scattering characteristics of the natural medium. The Japanese J-ERS1 radar, launched in 1992, has an L-band SAR, which also provided repeat-pass interferometric datasets. The repeat period of 44 days, however, was rather long for certain applications. Numerous Earth science studies have been carried out using these datasets.

The Spaceborne Imaging Radar (SIR-C/X-SAR) missions (both approximately 10 days) were flown in April and October 1994 and tested the technology of repeat-pass radar interferometry for topographic mapping of Earth and for detection of surface change. The multifrequency radars mounted in the shuttle bay were operated at L, C, and X bands. The L- and C-band radars had vertical and horizontal transmit and receive capabilities for collecting multipolarization observations. These radar datasets allowed an assessment of the relative merits of repeat-pass interferometers for mapping the Earth surface.

During late 1995 and early 1996, the ERS-1 and ERS-2 (launched in 1995) SARs were flown in tandem to collect a near-global dataset suitable for repeat-pass interferometric analysis. The orbits were maintained such that the repeat tracks of the two radars were separated by one day, thus providing 1-day intervals between data acquired for interferometry. Subsequently, ERS-1 was decommissioned as an operational sensor. Late in 1995, the Canadian RADARSAT (another C-band SAR with 24-day repeat) was

launched but the orbits were not routinely adjusted to the baseline tolerances required for interferometry. However, it still provided subsets of data suitable for interferometric studies.

These satellite systems have collected significant volumes of repeat-pass datasets. The use of these data for Earth science investigations has grown considerably.

1.3. Applications in Earth Science

We provide examples of three Earth science areas where the use of radar interferometry has blossomed: topographic mapping; measurement of glacial ice motion; and monitoring of earthquakes. The most direct application of radar interferometry is topographic mapping. Accurate DEMs are required by a number of Earth science disciplines, including hydrology, ecology, glaciology, geomorphology, and atmospheric circulation [9]. For example, the JPL/NASA TOPSAR system exhibits errors of about 1 m rms in flatter regions and 3 m in mountainous areas. By comparison, the standard United States Geological Survey (USGS) product generally available has a 30 m posting and a level of accuracy of approximately 7 m. The achievable accuracy is better than standard U.S. maps. For parts of the world that are relatively poorly mapped, topographic mapping using radar interferometry is an alternative to traditional photogrammetric surveys. This is especially attractive in regions where the cloud cover precludes the use of visible sensors.

Goldstein et al. [10] produced the first map of ice motion over the Rutford Ice Stream in Antarctica. In their demonstration, they used an image pair with very small baseline (~ 4 m) to avoid contamination due to surface relief. The sensitivity to line-of-sight motion is better than 1 m/year, and comparison of derived measurement with ground-based observations showed good agreement. Subsequently, Joughin et al. [11] and Rignot et al. [12] both demonstrated the observability of ice motion on the Greenland Ice Sheet after the removal of the topographic component of the signal. Kwok and Fahnestock [13] used a sequence of interferograms to separate the motion and topographic components of the measured interferometric phase with the assumption that the motion is constant over the observation period. Other studies have progressed further in the use of interferometric observations to produce maps of grounding lines and multiple

observations to derive three-dimensional velocities. As an illustration, Fig. 2 shows a map of the motion field of the Ross Ice Shelf in Antarctica just east of Roosevelt Island; the topographic component of the phase was removed. Flow patterns east of Roosevelt Island are explained by the flow of ice through the channel bounded by the Shirase Coast (400–500 m/year). The situation is more complicated west of Roosevelt Island, where large rifts extend away from the Bay of Whales and slice through the ice shelf. Eventually, these large blocks of ice will separate (an event known as calving) from the shelf ice and flow off as icebergs. Observations such as this have given glaciological investigators an unprecedented view of the velocity fields of the various regimes of glacial ice flow. By analyzing only a few synthetic aperture radar (SAR) images, these interferometric procedures can provide dense fields of observation that otherwise would require many years of extremely expensive fieldwork to compile.

The mapping of coseismic displacement of earthquakes was demonstrated by Massonnet et al. [14,15] and Zebker et al. [16]. Massonnet et al. [14] used two images (before and after an earthquake) and removed the topographic component using a simulated topographic phase field generated using an available DEM. Zebker et al. [16] used three complex SAR images: one before and two after the main Landers earthquake in June 1992. The topographic phase is removed by differencing two interferograms—one with surface motion and one without. Again, these techniques have been used routinely to monitor the effects of earthquakes in the past several years. Figure 3 shows a map of ground motion in the aftermath of an earthquake. This figure of the area around Kobe, Japan was created by combining two JERS-1 synthetic aperture radar images acquired 2.5 years apart to form an interferogram, which contains a record of the topography of the surface and the change in topography between the imaging times. Because the JERS-1 satellite imaged the area from nearly the same path on orbit (baseline = 0 m at the top of the scene and about 100 m at the bottom of the scene), there is very little sensitivity in the interferogram to the topography; the steep mountains north of the city of Kobe cannot be seen in the signature of the interferogram. However, the surface changed dramatically over the 2.5 years because the magnitude 7 Kobe earthquake occurred between imaging times. Most of the gray level variations on Awaji island and in the city of Kobe are the signature of strong

Figure 2. Ice motion of the Ross Ice Shelf, Antarctica near Roosevelt Island. This ERS tandem phase data was recorded at the U.S. McMurdo Reception Facility in Antarctica in January 1996.

Figure 3. Image showing surface displacement due to the magnitude 7 earthquake in Kobe, Japan derived from JERS-1 data. (Courtesy of Dr. P. Rosen, Jet Propulsion Laboratory, California Institute of Technology.)

displacement of the surface due to the earthquake. The distance that the ground moved is depicted as gray level contours, with 11.75 cm of distance shown as one cycle of color variation. It can be seen that the ground moved by greater than 1 m from before to after the earthquake. Very noisy signals along the port areas east of Kobe indicate massive surface disruption from liquefaction of the surface and collapse of structures.

1.4. Future Perspectives

Radar interferometry is rapidly maturing into a routine tool for providing important measurements for supporting Earth science investigations and other applications. There are a number of spaceborne radar systems on the horizon designed to provide interferometric observations as one of their primary missions.

In 1999, the Shuttle Radar Topography Mission (SRTM) was launched with the purpose of producing the most accurate and complete topographic map of the Earth surface. The SRTM mission is a joint project of the Department of Defence's National Imagery and Mapping Agency (NIMA), NASA, and the German and Italian Space Agencies. SRTM planned to build on the technology of the earlier SIR-C/X-SAR missions that were flown in

1994. The objective of the 1999 mission was to collect elevation measurements of nearly 80% of Earth's land surface. These observations were to be assembled into DEMs. These DEMs had a planimetric resolution of 30 m and a relative height accuracy of 10 m. Maps of this accuracy can be used for a large number of scientific, civilian, and military applications. The SRTM interferometer will operate at two frequencies (C and X bands). The interferometer had a baseline of approximately 60 m. A set of antennas were mounted in the bay of the shuttle, and another set were mounted at the end of a boom deployed from the shuttle bay after orbit insertion. The interferograms were obtained from complex SAR data collected from the two sets of antennas. In this case, we will have a C-band and X-band interferograms were provided for most of the Earth surface. The entire dataset was acquired in an 11-day mission. The bulk of the data processing to convert the radar signal data to DEMs took more than a year.

The European Space Agency (ESA) launched ENVISAT in late 1998 as a follow-up to the ERS satellites, and the Canadian Space Agency (CSA) launched RADARSAT II in 1999. The proposed NASA LightSAR was an imaging satellite that would use advanced technologies to reduce the cost and enhance the quality of images taken with SAR technology. All these spaceborne missions had an interferometry component. The data from these missions have provided quantitative measurements at an unprecedented spatial and temporal scale into the present century.

2. SPACEBORNE SCATTEROMETRY: OCEAN WINDS

2.1. Background

Wind scatterometers are radars specifically designed to measure wind velocities over the oceans. During the early 1960s, an aircraft radar measurement program conducted by the Naval Research Laboratory indicated that ocean radar clutter was dependent on windspeed and sea state [17,18]. Thereafter, NASA sponsored the development of airborne radars with extensive field programs to help interpret scatterometer measurements in terms of oceanic parameters. In 1966, Moore and Pierson [19] proposed a spaceborne scatterometer on a polar-orbiting satellite to obtain ocean surface wind measurements. During the 1970s, NASA sponsored improved aircraft (AAFE RADSCAT) and Skylab-193 scatterometer programs [20,21] that paved the way for a full-blown demonstration of a spaceborne sensor: the SASS experiment.

On June 28, 1978, SASS was launched on SEASAT to provide global measurements of ocean surface wind vectors [22,23]. Although SEASAT operated only for three months, SASS demonstrated the feasibility of ocean wind measurements from space. The scientific results can be found in the special issue of *Journal of Geophysical Research* [88(C3) (Feb. 28, 1983)].

Following the SASS experiment, the ERS series of satellites with onboard C-band microwave scatterometers [24] have provided surface wind measurements since 1991. The NASA Scatterometer (NSCAT) aboard the Japanese Advanced Earth Observation Satellite (ADEOS) was launched on August 17, 1996. Although ADEOS-1

ceased operation after June 1997, due to the solar paddle failure, NSCAT has been found to have had a significant impact on numerical weather forecasting, storm monitoring, and many other scientific applications. This prompted NASA to decide to launch a copy of the Sea Winds Scatterometer in early 1999 to fill in the data gap between the NSCAT and ADEOS-2/SeaWinds missions. Subsequent NASA and ESA satellite scatterometers were planned to extend the time series of satellite wind products to the twenty-first century.

2.2. Measurement Principle

Scatterometers measure ocean surface winds based on the dependence of radar backscatter (σ_0) on ocean surface roughness, which is a function of surface wind velocity. Here, σ_0 is defined as the normalized radar cross section of the sea surface. Wind-roughened surfaces in the form of gravity and capillary waves, breaking waves and foam, are due to the balance of wind input and dissipative processes. Changes in wind velocity cause changes in the roughness of these surface waves. Directional response of the ocean surface to wind forcing makes the profiles of gravity and capillary waves rougher in the along-wind direction than those across. Additionally, the nonlinear interaction of long and short ocean waves makes the short ocean waves rougher on the leeward faces of the long waves than on the windward faces [26,27]. These surface waves interact with radar waves, and the strength of the returned echoes is modulated by the windspeed and direction.

The typical dependence of microwave ocean backscatter on surface wind velocities is illustrated in Fig. 4. As shown, σ_0 is a monotonically increasing function of wind-speed at incidence angles above 20° , and has a few decibels (dB) of variation over azimuth angles. σ_0 is larger in the upwind direction than in the crosswind direction (upwind-crosswind asymmetry), and there is a small difference between upwind and downwind observations (upwind-downwind asymmetry). These asymmetries are caused by the preferential directional features of surface waves described in the foregoing. At small incidence angles ($<10^\circ$), the backscatter signal is dominated by the specular reflection by the surface, usually referred to as geometric optics scattering. Because the short ocean waves reduce the specular reflectivity of the surface, σ_0 has a negative wind speed sensitivity at near normal incidence angles. However, geometric optics scattering is insensitive to wave direction at less than 15° incidence angles. Hence, microwave scatterometers typically operate at above 20° incidence for near-surface wind velocity measurements.

To facilitate the retrieval of surface wind velocities from radar measurements, a geophysical model function (GMF) relating the microwave ocean backscatter to the surface wind velocity is required. In principle, if there is an accurate mathematical representation of ocean surface waves and an accurate scattering theory accounting for the interaction of electromagnetic waves with ocean surfaces, the relationship of σ_0 and ocean surface parameters can be established for any observation angles and fre-

Figure 4. The dependence of microwave ocean backscatter on surface wind velocities at Ku band derived from NSCAT-1 geophysical model function. 0° , 90° , and 180° azimuth angles correspond to upwind, crosswind, and downwind. Incidence angle is the angle between the direction of surface normal and the radar observation direction.

quencies. However, present hydrodynamic and electromagnetic theories are not yet mature enough to produce an accurate geophysical model function for operational considerations. An alternative approach for deriving the scatterometer GMF is to empirically correlate the radar measurements with in situ data. A variety of input winds, including numerical weather model winds and buoys, have been considered for the development of such an empirical function [28–30]. For example, the C-band geophysical model function [30] developed for the European Space Agency (ESA) is based on the colocated European Centre for Medium-Range Weather Forecasts (ECMWF) analysis field and ERS-1 scatterometer measurements. A similar approach using the National Center for Environmental

Prediction (NCEP) and ECMWF winds together with the Special Sensor Microwave/Imager windspeed products was employed to derive the first version of NSCAT model function (see Fig. 4).

Since σ_0 depends on both windspeed and direction, a single σ_0 measurement is inadequate for the retrieval of both variables (see Fig. 4). To retrieve the wind vector, multiple σ_0 measurements are made at several different azimuthal angles. Figure 5 depicts the measurement geometries of SASS, ERS, NSCAT, and SeaWinds scatterometers. SASS collected σ_0 measurements at two azimuth angles separated by 90° , and there are up to four possible wind directions for the SASS measurement geometry. To reduce the number of wind direction solutions (ambiguities), ERS scatterometers and NSCAT added one antenna beam to the SASS antenna geometry. Without measurement noise, ERS scatterometers and NSCAT measurements allow unique determination of the correct wind direction. However, the upwind and downwind asymmetry of ocean σ_0 are not significant, and, the correct wind direction (closest to the true) and the one in the opposite direction are often confused by noise. Hence, the ambiguity selection skill, which is defined as the probability that the correct wind direction solution is selected, is a very important parameter for scatterometer performance.

The scatterometer wind accuracy is limited by the accuracies of radar measurements and geophysical model functions. The sources of radar measurement errors result from uncertainties in instrument calibration, background and instrument thermal noise, radar integration time-bandwidth product, and propagation loss through the atmosphere. Instrument calibration errors typically appear

as biases and may drift as a function of time. Thermal noise and limited time-bandwidth product uncertainties are expected to be random and are important at low winds because of low signal-to-noise ratio. Atmospheric loss is expected to be smaller for ERS scatterometers operating at C band (5.3 GHz) than NSCAT operating at Ku band (13.995 GHz), but will introduce biases in the retrieved windspeed if left uncorrected. In particular, the error caused by atmospheric loss can be significant at high winds typically associated with thick cloud cover and rain. The other major error source for wind retrieval is the uncertainty of the geophysical model function, which may be influenced by many other geophysical parameters besides the winds, such as wave height and sea and air temperatures.

2.3. Current Technology

The NSCAT is a follow-on instrument to SASS. It operates at Ku band and employs antenna fan beams and Doppler filtering to determine the cell resolution. However, based on the study of SASS data, significant improvements have been made to address NASA science requirements. These include the addition of a third antenna beam for each side of the swath and an onboard digital Doppler processor to replace the analog filtering employed by SASS. The detailed design and implementation of each of these subsystems are described in Ref. 31.

The NSCAT antenna subsystem consists of two sets of three antenna fan beams. All NSCAT antenna beams are dual-polarized. The midbeam can transmit and receive vertical and horizontal polarizations, but NSCAT was

	SASS	NSCAT	SeaWinds	ERS-1/2
Frequency	14.6 GHz	13.995 GHz	13.402 GHz	5.3 GHz
Scan pattern				
Polarization	V-H, V-H	V, V-H, V	V, H	V only

Resolution	50/100 km	25/50 km	20/25 km	25/50 km
Swath				
Daily / 2-day coverage	Variable	77/97%	93/100%	41%
Dates	6/78 - 10/78	8/96 - 6/97	11/98 - 11/00 +, 8/00 - 8/03	91 +

Figure 5. Measurement geometries of SASS, ERS scatterometers, NSCAT, and SeaWinds.

designed to excite only the vertical polarization ports of fore and aft antenna beams. The baseline operation scans sequentially through these eight antenna ports in 3.746 s, leading to a sampling resolution of 25 km along the track. The scanning sequence is determined by a beam sequence table containing 8 beam numbers stored in the on-board computer. The addition of a third antenna beam to the SASS design is to improve the ambiguity selection skill of NSCAT. The results of postlaunch NSCAT calibration and validation studies have suggested that NSCAT multiple antenna measurements without additional meteorological information allow the selection of the closest solution more than 90% of the time, representing a significant improvement over SASS.

Another improvement of NSCAT over SASS is the use of onboard digital Doppler filtering. Due to the relative motion of spacecraft and Earth surfaces, the Doppler shift of the return echos varies across the swath. The onboard DSS divides the swath into 25 cells based on the Doppler shift. The Doppler center and bandwidth of each of these cells are adjusted as a function of spacecraft orbit location to maintain the swath location and across-track cell resolution. A table containing the constants necessary for the calculation of Doppler frequencies on orbit is called the "binning table" and is used by the NSCAT on-board computer for real-time calculations. Because the binning and beam sequence tables can be updated and uploadable to the satellite, the along- and across-track resolutions of each NSCAT cell are adjustable. For example, NSCAT has been configured to operate at 6.25 and 12.5 km measurement resolutions for about 2 days during the first three months of operation. The resulting high-resolution data have enabled the observations of the significant effects of land surface topography on coastal ocean winds.

SeaWinds is the follow-on to NSCAT. SeaWinds also operates at Ku band. The SeaWinds system represents a major design change of NASA scatterometers. Instead of using the fan beam design, SeaWinds uses a conically scanning reflector. This is due to the limited space available on ADEOS-2, which does not provide a clear field of view for NSCAT-like fan beam antennas with broad elevation antenna beam patterns. As mentioned earlier, the first copy of SeaWinds Scatterometer went on a U.S. satellite in early 1999. The second copy of SeaWinds will be aboard ADEOS-2 as planned for a year 2000 launch.

The SeaWinds reflector is illuminated by two offset antenna feedhorns, resulting in two spot beams illuminating the Earth surface at 46° and 54° incidence angles. The outer beam operates at vertical polarization, and the inner beam operates at horizontal polarization. Because the horizontally polarized ocean backscatter has a larger upwind-downwind asymmetry than in the vertically polarized response, the mixed polarization combination was determined to have a better ambiguity selection skill than the other combinations. The antenna reflector is mounted on a spinning assembly with a nominal rotation rate of 18 rpm. The antenna footprints produced by these two antenna beams will trace out two circles on the surface, enabling two to four azimuth radar observations for a given spot on the surface. The relative azimuth angles of these observations vary across the swath, unlike the fan beam

designs where the relative azimuth angles are essentially constant from near to far swath. The varying azimuth geometry degrades the measurement performance at outer swath and near nadir track where the fore and aft looks reduce to one or have 180° separation.

Because of the change of antenna design, the signal detection principle and hence the electronics design of SeaWinds is also different from those of NSCAT. The resolution of the SeaWinds radar footprints is basically defined by the size of the antenna reflector and is about 35 km in range and 26 km in azimuth. To improve the range resolution, the SeaWinds radiofrequency electronics were designed to chirp the transmit signal over 375 kHz in one pulse length (1.5 m). Onboard digital processing then applied range compression to divide the radar echo into range bins, resulting in about 5 km resolution in range. This makes the size of the SeaWinds measurement cell comparable to the nominal resolution of NSCAT.

Another important feature of the SeaWinds scanning geometry is that the measurement swath is contiguous without a gap near the subsatellite nadir track, which is present in fan-beam scatterometer designs. Although the accuracy of retrieved wind velocity near the spacecraft nadir track is not as good as that in the midswath, a contiguous swath does allow SeaWinds to image 90% of global ice-free oceans in 1 day compared with 2 days required for NSCAT.

The ESA has launched two ERS scatterometers since July 1991. ERS scatterometers are part of the Active Microwave Instrument (AMI) on ERS satellites. AMI operating at a frequency of 5.3 GHz (C band) consists of three operational modes: the image mode, the wave mode, and the wind mode. In the image and wave modes, AMI is configured as a synthetic aperture radar, while in the wind mode, it is configured as a scatterometer. These modes time-share the operation in orbit [24].

The ERS scatterometers employ a fan-beam antenna design with three vertically polarized antennas looking to the right-hand side of the satellite. The midbeam is perpendicular to the ERS-1 ground track and the fore and aft antenna beams are offset by 45° in azimuth with respect to the midbeam. The antenna beamwidths are 26° in elevation and 0.9° in azimuth for fore and aft beams and 24° in elevation and 1.4° in azimuth for aft beam. These antenna beams provide three radar images of the ocean surface with a swath width of 500 km. However, unlike SASS and NSCAT designs based on Doppler filtering, ERS scatterometers employ short transmit pulses and range gate the return echos to sharpen the resolution along the broad-beam direction. This design eliminates the complexity of Doppler filtering, but an on-orbit yaw steering of ERS satellites was required to compensate for the Doppler shift.

The other distinct feature of ERS scatterometers is the use of high transmit power. Because the traveling-wave-tube amplifier (TWTA) used for ERS AMI provides an output peak power of 4 kW, the transmit power of ERS scatterometers is much larger than the nominal 100 W output power used by SASS, NSCAT, and SeaWinds. Although 100 W transmit power has been shown to be adequate for fan-beam scatterometers as demonstrated by NSCAT performance, a significantly higher transmit power raises the

signal-to noise ratio (SNR) and reduces the signal detection uncertainties of low wind σ_0 at high incidence angles.

The difference in transmit frequencies between ERS and NASA scatterometers leads to several performance differences in geophysical retrieval. The lower operating frequency makes ERS scatterometers less sensitive to atmospheric water vapor and clouds than Ku-band scatterometers; hence C-band scatterometers are expected to outperform Ku-band scatterometers under severe weather conditions. However, C-band backscatter is less sensitive to wind direction, particularly at low winds, and has smaller upwind and downwind backscatter differences. Consequently, Ku-band scatterometers have better wind direction accuracy than C-band scatterometers. It was observed that ERS scatterometers are very inadequate in discriminating the upwind and downwind ambiguities.

2.4. Applications in Earth Science

As the largest source of momentum to the upper ocean, winds drive oceanic motions on scales ranging from surface waves to basinwide current systems. Winds over the ocean modulate air-sea fluxes of heat, moisture, gases, and particulates, regulating the crucial coupling between atmosphere and ocean that establishes and maintains global and regional climates. Figure 6 is an example of global ocean surface winds provided by satellite scatterometers, illustrating the wind velocities over the Pacific Ocean on September 21, 1996, acquired by NSCAT. Gray levels in the image represent windspeed in meters per second. Dark shading shows low speeds, and light shading shows high speeds. In the tropical areas just north of the

equator, called the Intertropical Convergence Zone, winds from the Northern and Southern Hemispheres collide and force an upwelling of air. In the subtropical areas, air sinks back, creating a zone of divergence and low winds that was long ago called the Horse Latitudes. To the south (north) of the Horse Latitudes in the northern (southern) hemisphere, there are strong, steady winds known as Trade Winds. At latitudes greater than the Horse Latitudes, the Coriolis force is strong. High vorticity in this area creates the cyclones characterizing Earth's weather system. The light spiral features in the upper left near Japan are typhoons Violet and Tom.

Measurement of surface wind velocities can be assimilated into regional and global numerical weather models, thus improving our ability to predict future weather. Satellite wind data, such as those from ERS scatterometers and NSCAT, have generated more accurate forecasts and extended the useful range of weather forecasts by more than 24 h in the Southern Hemisphere. The mapping of wind fields in the equatorial areas of the Pacific Ocean is particularly useful for the prediction of El Niño events, leading to changes of rain patterns and weather worldwide. The ability of satellite scatterometers in the prediction of El Niño and other seasonal and annual climate changes will benefit the management of global agriculture, fisheries, and water reserves.

Scatterometer wind data are also valuable for various commercial applications, including storm warning, ship routing, oil production, and marine food harvesting. In a collaborative effort with NASA/JPL, National Oceanic and Atmospheric Administration (NOAA) was able to measure surface winds from NSCAT data within 3 hours after data acquisition for operational use. The scatterometer data can pinpoint the location, structure, and strength of storms [32], as indicated in Fig. 6. Severe marine storms, including hurricanes near America and typhoons in the western Pacific, are among the most destructive of all natural hazards. The use of satellite scatterometer wind data facilitates the monitoring and forecasting of tropical and midlatitude storms. Captains of ocean ships can rely on regular scatterometer data with large-scale coverage to choose routes that avoid heavy seas, high head winds, and severe weather systems. As oil production is ongoing at many offshore platforms around the world, long time series of scatterometer wind data will be indispensable for the design of drilling platforms and warnings of impending storms. Because winds drive the ocean currents that transport heat and nutrients, scatterometer data together with other types of spaceborne sensors can be used to study the biogeochemical balance of the ocean-atmosphere system. Detailed wind data from satellite scatterometers can aid in the harvesting of natural seafood crops.

Figure 6. Ocean surface winds provided by NSCAT of the Pacific Ocean on September 21, 1996. The image represents windspeed in meters per second. Dark shading represents low speeds and light shading high speeds. (Courtesy of Drs. W. T. Liu and W. Tang, Jet Propulsion Laboratory, California Institute of Technology.)

2.5. Future Perspectives

As the use of scatterometers becomes more widespread in meteorology, oceanography, and operational weather forecasting, there are several challenges for the development and applications of spaceborne scatterometer technology in the twenty-first century.

Although satellite scatterometers have already demonstrated a significant impact on climate research and weather forecasting, the volume, mass, and cost of a spaceborne scatterometer mission remains high, creating a significant barrier for these instruments to be flown on operational weather satellites. For instance, the cost of NSCAT and SeaWinds science missions are in the range of 100–200 million dollars for a mission life of 3 years, and both instruments weigh about 300 kg. It is necessary to incorporate new technologies to reduce the size, weight, and power of scatterometers. For example, reducing the noise figure of low-noise amplifiers will enable the reduction of transmit power, hence leading to a smaller demand on spacecraft power. Advanced electronics technology will allow the use of fewer and smaller components, but with more capabilities, resulting in a decrease of size and weight. This in turn will allow the use of a smaller launch vehicle and make it easier to accommodate the instruments on the spacecraft. Furthermore, if the mission lifetime can be extended beyond 3–5 years through the use of more reliable components and technologies, spaceborne scatterometry will be more cost-effective.

The temporal coverage and spatial resolution of spaceborne scatterometers need to be improved to enable the study of many natural phenomena with high variability and resolution. The radar footprint size and sampling resolution of ERS scatterometers, NSCAT and SeaWinds are in the range of 25–50 km, which is inadequate for imaging high-resolution features in the weather fronts, wind fields with high vorticity near the eyewall of tropical cyclones, tropical convective cells, and coastal winds. In addition, NSCAT and SeaWinds require a few days to complete coverage of the tropical oceans, where there are significant diurnal-period variations. A more frequent coverage is needed to resolve these variations for investigating tropical air–sea interaction dynamics. These issues will demand a high-resolution scatterometer with an improved swath coverage or a constellation of low-cost instruments.

The main objective of spaceborne scatterometers is to provide surface wind measurements over the global oceans. However, scatterometers also acquire radar measurements over land surfaces and polar sea ice, together occupying more than 30% of the Earth surface. Recent investigations of ERS scatterometers and NSCAT data have indicated that scatterometers have a strong potential for studies of the dynamics and changes of land surface and polar regions, for example, tropical deforestation monitoring, glacier ice sheets, sea ice extent, and sea ice motion. The challenge is to come up with an accurate geophysical interpretation of scatterometer data collected over these targets and to develop algorithms for a consistent, quantitative retrieval of geophysical parameters.

3. ALTIMETRY: LARGE-SCALE OCEAN DYNAMICS

3.1. Background

Radar altimetry is used to measure the precise height of sea surface relative to the geocenter, a very useful variable for geophysical studies. Many physical processes affect the height of the sea surface. The dominant factor is the spa-

tially varying gravity field of Earth, making the sea surface follow Earth's gravitational equipotential surface, or the geoid. This effect creates a sea surface relief of hundreds of meters. For instance, the height of the Tropical Indian Ocean is lower than that of the western Tropical Pacific Ocean by more than 100 m. The reader is referred to McAdoo and Marks [33] for an example of the applications of altimetry to the study of Earth's gravity field. Apart from the geoid are sea surface variations of magnitude from centimeters to meters caused by various oceanographic phenomena, such as tides, waves, currents, and storm surges. Among these, the effect of currents is most interesting in the study of large-scale ocean dynamics that is key to understanding the Earth's climate. The application of altimetry to the measurement of sea surface height for the study of ocean dynamics is the focus of this section.

The fundamental relation between sea surface height and ocean current is the geostrophic balance [34], a balance between the pressure gradient at the sea surface and the Coriolis force resulting from the movement of water on a rotating Earth. The pressure gradient is derived from the ocean topography, defined as the elevation of the sea surface relative to the geoid. The ocean topography is directly related to the ocean surface current velocity as follows

$$u = -\frac{g}{f} \frac{\partial h}{\partial y}$$

$$v = \frac{g}{f} \frac{\partial h}{\partial x}$$

where u is the eastward velocity, v is the northward velocity, x is the east coordinate, y is the north coordinate, h is the elevation of the ocean topography, $f = 2\Omega \sin(\text{latitude})$; $\Omega = 7.29 \times 10^{-5} \text{ s}^{-1}$ (rotation rate of Earth), and g is the local gravitational acceleration at the sea surface. The velocity determined in this way is not the total surface velocity, but the important component that penetrates the deep ocean. There is a surface boundary layer of directly wind-driven current (called the Ekman layer; see Ref. 34) that has no signatures in ocean topography and hence is invisible to altimeters. This aspect makes altimetry particularly useful for the study of the circulation of the entire water column.

The relief of the global ocean topography is on the order of 1 m, a small signal to retrieve from space. This signal has to be measured with an accuracy of a few centimeters in order to calculate the precise change in the ocean circulation. For instance, a 1 cm tilt of the ocean topography implies the transport of up to several million metric tons of water per second, which is a significant fraction of the transport carried by the major ocean current systems. The challenge of altimetry is to achieve this centimeter accuracy for oceanographic studies.

For a general introduction to altimetry the reader is referred to Stewart [35], Wunsch and Gaposchkin [36], and Chelton et al. [37]. The basic concept is straightforward. The radar altimeter bounces microwave pulses from the sea surface and measures the round-trip travel time to

Figure 7. Altimeter pulse interaction with the sea surface and the characteristic return waveform generated by the altimeter electronics (From Zieger et al. [39]).

determine the altitude of the spacecraft above the sea surface. By subtracting this altitude from the distance between the spacecraft and the geocenter, a distance determined by the technique of precision orbit determination [38], one can thus obtain the height of the sea surface relative to the geocenter.

Shown in Fig. 7 (adapted from Ref. 39) is a schematic representation of the technique of pulse ranging by a radar altimeter. It shows the variation with time of area illuminated by a short, widebeam pulse. The power of the return pulse is proportional to the area of illumination and thus has a similar dependence on time. The time of the arrival of the leading edge of the return pulse is used to determine the range from the sea surface to the radar antenna. In the presence of ocean waves, the wave crests reflect the pulse back to the altimeter sooner than do the wave troughs, creating a further stretch of the leading edge. The extent of the leading edge of the return pulse can thus be used to determine the height of the waves. The frequency used by most radar altimeters is in the range of the Ku band (~ 14 GHz, which corresponds to a wavelength of about 2 cm). At vertical incidence in the case of a radar altimeter, the return signal strength decreases with the amplitude of these centimetric waves, which are extremely sensitive to windspeed. When the wind is weak, the sea surface is smooth and hence reflects more radar signals than does a rough sea resulting from a strong wind. A strong return pulse is thus related to low windspeed, and a weak return pulse is related to high windspeed. Therefore, an altimeter can also measure ocean windspeed.

To obtain the centimeter measurement accuracy, a host of technical challenges arises despite the apparent simplicity of the basic measurement principle of radar altimetry. For example, the radar pulse needs to be compressed to resolve travel time in nanoseconds; thousands of pulses need to be transmitted and received every second to average out the noise in the return signals; the delay of electromagnetic waves due to the dry and wet air mass in the troposphere as well as the free electrons in the ionosphere needs to be accounted for; the distance between the center

of mass of the spacecraft and the geocenter needs to be determined within a few centimeters (a precision of one in ten millions).

3.2. Evolution of the Technology

The early satellite altimeters were primarily flown for proving the concept of this potentially powerful remote sensing tool [40]. The noise levels of the altimeters on board Skylab (1974), GEOS-3 (1975–1978), and Seasat (1978) were 60, 25, and 10 cm, respectively. The Seasat altimeter [41] was the first to have reached a precision level useful for oceanographic studies. Unfortunately, Seasat lasted only slightly over 100 days. The next satellite altimeter was flown by the U.S. Navy's Geosat (1985–1989). This instrument has several improvements over the Seasat altimeter (42), notably the longer radar pulse ($102.4\ \mu\text{s}$ instead of $3.2\ \mu\text{s}$). This long pulse, plus some other hardware improvements, has reduced the peak power requirement from 2 kW (for Seasat and GEOS-3) to 20 W, making the instrument more robust. The Geosat altimeter has lasted for four years and generated a rich data set for oceanographic and geophysical studies [the Geosat special issues of the *Journal of Geophysical Research* **95**(C3,10): 1990 [43].

Despite the success of Geosat, it has several limitations. The altimeter has only one frequency channel (13.5 GHz) and hence is not able to retrieve the pulse delay caused by the ionospheric free electrons. This delay can create an error of 2–20 cm. An altimeter operating at two properly separated frequencies would be able to determine this delay from the difference in pulse travel time between the two signals. The pulse delay by the water vapor in the troposphere creates another source of error of up to 40 cm. This delay requires knowledge of the water vapor content of the atmosphere whose determination would require a microwave radiometer. Such a radiometer was missing in Geosat. Moreover, the uncertainty in the radial position of the Geosat orbit was determined only with an accuracy of 1 m, making the applications to large-scale ocean dynamics difficult.

Launched in August 1992, the United States/France joint TOPEX/POSEIDON Mission [44] has provided a state-of-the-art altimeter system that is specifically designed to meet the challenge posed by the requirement of measuring the largescale, small signals in sea surface height caused by ocean currents. There are two radar altimeters on board the satellite. The primary one (provided by the United States) operates at two frequencies (13.6 and 5.3 GHz) for retrieving the ionospheric pulse delay. The secondary one (provided by France) is a solid-state, single-frequency (13.65 GHz) system to demonstrate low-power, low-cost technology for future altimeter missions. The primary NASA altimeter has several improvements over the Geosat altimeter [39]. The 13.6 GHz channel has a pulse rate of 4000/s compared to Geosat's 1020/s, resulting in reduction of noise level to an RMS magnitude of 1.7 cm. The instrument software in waveform sampling and analysis is also improved. The French altimeter, using a different design, performs at a noise level of 2 cm. TOPEX/POSEIDON also carries a three-frequency radiometer for measuring the total columnar water vapor content along the altimeter line of sight. This measurement is used to determine the pulse delay caused by the water vapor. The total error in the altimeter range measurement is estimated to be 3.2 cm (RMS) at the rate of one measurement per second, covering an along-track distance of 6.2 km.

The precise location of the satellite in orbit is determined by three independent tracking systems [38].

Conventional laser tracking was performed by an onboard laser retroreflector array with a worldwide ground network of laser stations. A dual-frequency microwave Doppler system called DORIS (Doppler Orbitography and Radio-positioning Integrated by Satellite) was provided by the French, involving an onboard receiver and a worldwide, densely populated network of ground beacons. An experimental Global Positioning System (GPS) receiver was carried as the third system, which involves the constellation of the GPS satellites and a network of ground stations. The accuracy of the satellite radial orbital position calculated from these measurements with the use of a state-of-the-art model of Earth's gravity field [45] has reached a level of less than 3 cm. The total uncertainty in the measurement of sea surface height has therefore reached a level of 4 cm, making the signals created by the variability of basinwide ocean circulation detectable from space for the first time.

Radar altimeters are also part of the payload of the ERS satellite series [46]. Single-frequency altimeters were flown on both the ERS-1 (1991–1996) and ERS-2 (1995 to the present) satellites. The level of performance of these two altimeters was somewhere between Geosat and TOPEX/POSEIDON. The accuracy of the orbit determination for ERS-2 has been significantly improved by the Precise Range and Range-Rate Equipment (PRARE) system, which failed to work on board ERS-1. However, it has been demonstrated that by adjusting the ERS-1 data to simultaneous TOPEX/POSEIDON data it was possible to

Figure 8. Standard deviation (in centimeters) of the sea surface height variability over the global oceans based on the first year of the TOPEX/POSEIDON data. The white areas represent variabilities larger than 25 cm with peak values larger than 50 cm.

Figure 9. TOPEX/POSEIDON observation (lower) and computer simulation (upper) of the sea level in the Pacific Ocean during December 1994, when the 1994–95 El Niño event reached its peak. The excessive heat associated with the anomalously high sea level in the central equatorial Pacific altered the path of the atmospheric jet stream and caused unusual weather worldwide. (From Fu and Smith [52]).

minimize the orbit errors in the ERS-1 data [47]. A major disadvantage of the ERS system is the lack of a second channel for determining the ionospheric pulse delay.

3.3. Applications to Large-Scale Ocean Dynamics

TOPEX/POSEIDON has opened a new door to the study of large-scale ocean circulation and its governing dynamics. A wealth of results can be found in two special issues of the *Journal of Geophysical Research* [99(C12): 1994; 100(C12): 1995], as well as Wunsch and Stammer [48]. For the first time scientists can obtain snapshots of the global ocean topography every 10 days and monitor its changes over weeks to years. The ocean is turbulent on a wide range of scales from millimeters to thousands of kilometers, from seconds to years and decades. However, most of the kinetic energy of ocean currents is concentrated at the so-called mesoscales: 100 km in space and 100 days in time. This is the scale of ocean storms, or eddies [49]. Figure 8 shows a map of the global distribution of the sea surface variability associated with the ocean eddies. The map was constructed from data taken over one year. It

reveals the regions of energetic ocean currents such as the Gulf Stream, the Japan Current (the Kuroshio), the Brazil/Malvinas Current, and the Antarctic Circumpolar Current among others. This type of map is very useful for testing the performance of computer models of ocean circulation [50–52], which, when properly calibrated and validated, are powerful tools for studying Earth's climate system.

Altimetry data are often analyzed in the form of sea surface anomalies, which are deviations of ocean topography from its time average and represent the variations of ocean currents that are affecting climate variability. Shown in Fig. 9 is a comparison of the sea surface anomalies in the Pacific Ocean derived from the TOPEX/POSEIDON data and the simulation by a state-of-the-art ocean circulation model [52]. The degree of similarity is striking, although the amplitude of the anomalies is generally weaker in the model simulation. In December 1994, the 1994/95 El Niño (see Ref. 53 on the subject) reached its peak. Note the manifestation of the El Niño as high (dark area) in the central equatorial Pacific in both the data and the model, indicating the capability of the model in

simulating major ocean anomalies. However, the quantitative accuracy of the model still needs to be improved. One effective approach is to apply data assimilation techniques (54) to combining the data with the model such that the information of the sea surface height observation can be used to improve the model simulation of the circulation, as well as temperature and salinity at depths [55,56].

3.4. Future Perspectives

The accuracy and precision of the TOPEX/POSEIDON observation has set the standard for future altimetric missions. Since the ocean circulation and its effect on climate has timescales from years to decades and longer, we need to establish a long record of high-quality altimeter data to gain significant understanding of the ocean's role in climate and to improve its prediction. A series of follow-on missions to TOPEX/POSEIDON, called Jason, was developed by France and the United States to extend the TOPEX/POSEIDON-class data record into the twenty-first century. The first of these series, Jason-1, was launched in 2000. This was intended as a solid-state, dual-frequency altimeter based on the heritage of the French altimeter on TOPEX/POSEIDON. The satellite was also equipped with a three-frequency water vapor radiometer as well as DORIS, GPS, and laser tracking devices. The objectives were to achieve a performance at the TOPEX/POSEIDON level with a goal of approaching 1 cm accuracy in sea surface height. Some new challenges are to develop new algorithms that would allow (1) recovery of signals over extremely calm seas or rain cells that produce an impulselike return waveform, and (2) better determination of the electromagnetic bias (a sea surface height bias toward the ocean wave troughs) that needs to be removed from the data. Another important task is calibration and validation of the system for consistency with TOPEX/POSEIDON to ensure continuity of the data for detecting long-term sea level trends and global change.

Two other altimetry missions were scheduled for the next five years. The U.S. Navy's Geosat Follow-On (GFO), launched in 1998, was equipped with a single-frequency altimeter and a two-frequency water vapor radiometer. Its challenge was to make ionospheric correction using models and data from other sources such as GPS. The ESA's Environment Satellite (ENVISAT), launched in 1999, carried a dual-frequency altimeter and a water vapor radiometer among several other instruments. The measurement performance was probably be close to that of TOPEX/POSEIDON. However, the satellite flew in an orbit that was not optimized for large-scale ocean dynamics due to multiple mission objectives.

Given the missions noted above, the prospects of future altimetric observations are excellent. The bilateral commitment of France and the United States to the continuation of TOPEX/POSEIDON-quality measurement via the Jason series has laid the foundation for a global observing system for monitoring the ocean in the present century. The quality promised by the Jason measurements will underlie their utility in serving as a framework to integrate other satellite observations into a powerful datastream for assimilation by sophisticated numerical

models. Such a system of data and models will make routine scientific diagnosis and reliable prediction of the ocean and climate changes a reality.

SPATIAL AND QUASI-OPTICAL POWER COMBINING

Dr. JULIO A. NAVARRO
Boeing-Phantom Works
Seattle, WA

1. HISTORICAL BACKGROUND

During the first few decades of the twentieth century, operating frequencies of several hundred megahertz were mostly ignored and “microwaves” were not yet deemed necessary. It was not until the advent of World War II, where the detection of enemy ships and aircraft became the key to national defense and the method of radio detection and ranging (radar) was born. The British used longwave radar to detect German bombers approaching the English shore and then scramble fighters to intercept the aircraft. However, longwave radar was limited by poor resolution and large ground interference. As a radar’s resolution (i.e., the minimum object size that it can detect) is inversely proportional to the frequency of operation, shorter operating wavelengths are better suited to detect smaller objects. Although resolution improves with shorter wavelengths, higher operating frequencies require improved circuits, antennas, and sources. With respect to radiofrequency (RF) power sources, it was not until Randall and Boot developed the internal cavity magnetron [1] that shorter wavelengths could be used effectively in radar applications. A magnetron source demonstrated 10 kW of pulsed power at S-band (2–4 GHz). The technology was carried over to the United States and developed through the efforts of the Radiation Laboratory of the Massachusetts Institute of Technology. The development of the magnetron and similar tube-type devices in the early 1940s gave the allies a definitive edge in detecting enemy attacks and shortened the duration of the war considerably.

The MIT Radiation Lab also developed a wide range of waveguide circuits and antenna components that continue, nearly unchanged, to this day. These microwave circuits have since become an integral part of modern society used in many space, scientific, and commercial applications. The term *microwave* refers to that part of the frequency spectrum from 300 MHz to 300 GHz. Another more recent term, *millimeter waves* refer to the subset of the microwave range where the operating wavelength is one millimeter long (i.e., ≥ 30 GHz).

A radar’s performance is determined by its operating frequency, bandwidth, power output, antenna gain, and receiver sensitivity. Higher operating frequencies and higher output power combined with larger antennas, improved receiving, and processing circuits allow longer detection ranges, higher resolution, and improved perimeter protection. The success of microwave radar has enabled the development of a wide range of devices and components. The availability of these components has facilitated the introduction of many other applications such as point-to-point data communication links, telemetry, medical imaging, wireless local area networks, motion and presence sensing systems, remote sensing and imaging, selec-

tive heating of tumors, and spectroscopy for material identification. For example, police radar started at X-band (10.525 GHz) and later, with the improvement of components, moved to K-band (24.1 GHz), then to Ka-band (35.5 GHz), and Laser frequencies. At the same time, a new consumer market emerged to detect the presence of police radar with radar detectors. In a similar fashion, automatic door openers, perimeter surveillance, and detection systems have been successfully deployed at S-band, X-band, and now at K-band.

As more applications are introduced, overcrowding and interference tend to push new applications toward higher operating frequencies. Crowded spectrum has pushed many satellite communication systems from C- to X- to Ka-band. Higher operating frequencies provide larger instantaneous bandwidth, which can translate to faster data rate and larger information throughput. Higher operating frequencies also provide greater antenna directive gain for a given aperture size. At higher frequencies, however, devices perform poorly with respect to power and efficiency, distribution circuits have higher losses and require significantly improved and often complicated fabrication methods. Low-loss materials and complex fabrication methods also increase the cost of materials and components. Another problem is that high-frequency circuit models are often over-simplified and inaccurate, which leads to more design iterations, loss in delivery schedules, and higher system costs.

Over the last decade, many improvements in personal computing power, commercial software tools, and emerging consumer markets has propelled significant improvements in materials, processes, devices, components, and systems. Regardless of the specific application, complete low-cost system solutions require the successful combination of materials, mechanical parts, and electronic components as well as reasonable manufacturing, assembly, and test processes. Substrate material properties continue to improve in terms of dielectric constant, loss tangent, mechanical stability, and lot-to-lot repeatability. Mechanical parts are being fabricated in larger volumes with tighter dimensional tolerances at relatively low costs (i.e., casting, molding, plating, etc.). Electronic devices continue to improve in efficiency and frequency performance while the device packages are more robust, less expensive, and easier to handle with automatic pick-and-place machines. Similarly, printed wiring board fabrication methods are improving with respect to multiple-layer registration, laminations, via-plating, drilling, and routing. These improvements have resulted in reduced per unit component costs and improved performance, which has, in turn, opened up new markets and applications. The synergy between the various areas has contributed to an explosion of new products.

This article discusses various aspects of power combining techniques, including devices, integrated antennas, and methods for power combining. Section 2 briefly describes vacuum tube devices used in RF power generation and reasons for replacing them with solid-state devices. This description is followed by power combining classifications and descriptions of quasioptical and spatial power combiners.

2. RF POWER GENERATION

Types of devices used to generate RF power at millimeter wavelengths include magnetrons, klystrons, traveling-wave tubes (TWT), cross-field amplifiers (CFA), and solid-state devices. Tubes are very efficient at high power levels and continue to be used in many critical applications. However, tubes tend to be costly, bulky, and not as reliable as solid-state devices. Tubes require heaters for cathodes, finite warm-up time, high-voltage power supplies, oil-filling or encapsulation, and a large space for implementation.

Semiconductors, on the other hand, do not require heaters, are not limited by warm-up delays, can use low-voltage supplies, and can be implemented in relatively compact spaces. Tubes tend to operate in bandwidths less than 20%, whereas solid-state devices can operate over broader bandwidths (~50%). Solid-state devices are fabricated using photolithographic techniques and can be integrated monolithically within circuits of varying functions that exhibit consistent, repeatable performance and greater mean time between failures (MTBF).

However, solid-state devices, in general, provide relatively little power as compared with tube-type devices or similar high-power microwave sources [2,3]. Single solid-state electronic devices have thermal and impedance limitations that limit the RF output power and power-added efficiencies. These deficiencies get progressively worse with increasing frequency and limits their use in many high-power military and commercial applications.

Solid-state devices, however, continue to hold the promise of higher operating frequencies with lower costs, higher reliability, increased repeatability, and greater MTBF. To address and overcome the RF power and efficiency issues of combining many distributed sources [4], several techniques at microwave [5] and millimeter [6] wavelengths have been proposed and demonstrated in both industry and academia.

3. POWER COMBINING TECHNIQUES

Power combining techniques have been implemented at various levels such as chip, circuit, and spatial levels. In the area of spatial combiners, two references detail components and configurations implemented up to 1995 [7,8]. The references describe individual active antenna ele-

ments and grid configurations used in a wide range of applications, including spatial power combining.

In some applications, a component may employ several levels of combining to achieve the desired output power. Power combining classifications are listed below and shown in Fig. 1 [9].

1. Chip level [10,11]: Clustering or grouping of multiple devices in sub-wavelength lattices. Single wafer implementation is preferred, but chip devices can be diced and grouped together after wafer fabrication.
2. Circuit level (waveguides and planar media)
 - a. Resonant cavities [12–14]
 - b. Nonresonant [15–17]
 - i. N-way combiners [18–22]
 - ii. Corporate combiners [23]
3. Spatial Power Combining
 - a. Open resonator cavities [24–27]
 - b. Array of resonant radiators
 - c. Arrays of nonresonant radiators [28] and Grids [29]

Chip-level combining of solid-state devices can be accomplished monolithically on the wafer if yields and consistency throughout the process can be tightly controlled. If yields are not high, then good devices on the wafer can be diced and die-attached to a carrier plate for DC biasing, RF matching, and power combining. Chip-level combining has much tighter sub-wavelength lattice spacing over similar circuit-level combiners. Circuit-level combining has been used extensively in a broad range of media and combining configurations. As listed above, circuit-level combining can take many forms, including resonant cavities and nonresonant circuits. Resonant cavities may include rectangular and cylindrical waveguides or similar planar resonant structures. Nonresonant circuits include N-way and corporate combiners. N-way combiners include radial line, conical waveguide, and Wilkinson combiners, whereas corporate combiners include hybrid-coupled and chain-coupled circuits.

Circuit-level power combiners are limited by ohmic and dielectric losses, which increases proportionally with the number of devices combined. Overmoding is an issue with resonant combiners, and device-to-device isolation often limits the graceful degradation that distributed sources exhibit. Free-space combining provides an alternative

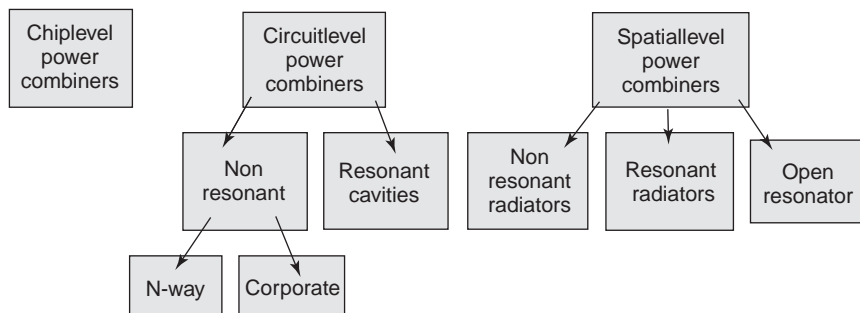

Figure 1. Power combining classifications.

method of power combining that addresses some of these deficiencies.

Spatial power combiners overcome circuit losses by combining in free space. Spatial combiners include open resonator arrays of resonant and nonresonant antennas (i.e., grids). Similar to chip-level combiners, grids tend to be tightly spaced, nonresonant individual devices clustered in a two-dimensional lattice. Several grids can be layered to develop many other components, such as filters [30,31], multipliers [32], oscillators [33,34], mixers [35], amplifiers [36], variable impedance surfaces [37], nonferrite isolators [38,39], polarization converters, and voltage-controlled frequency-selective surfaces [40].

4. OPEN RESONATOR SPATIAL POWER COMBINER

The open resonator was first proposed by J. Mink. It uses a spatial combining array within a quasioptical cavity. The distributed, self-running sources are injection locked to a quasioptical resonant mode of an open cavity as shown in Fig. 2 [41].

Open resonators are referred to as quasioptical because of the similarities with laser cavities at optical frequencies (i.e., Fabry–Perot). Open-cavity power combiners relax fabrication tolerances of typical circuit resonant cavities and avoid dielectric and ohmic losses of circuit-level combiners. Open resonators replace transmission line circuits with free space and use the open-cavity modes to synchronize all of the free-running sources. These open-cavity modes have high quality factors, which enhance stability and phase-spectra of the output signal. The large open-cavity dimensions allow the combination of many devices while avoiding multimode issues of circuit-level resonant cavities. A partially transparent reflector is used to maintain the open resonator mode while still coupling power out for system use. Open resonator combiners have been demonstrated using both two- and three-terminal devices that are clustered at the beam waist of the dominant mode. Partial reflector, which provides feedback for sustaining the open resonator mode, also allows transmission for energy radiation. DC biasing of the array of sources, thermal management, mode stability, and modulation are

Figure 2. Open resonator spatial power combiner from Mink.

issues that require some careful attention for this quasi-optical combiner.

5. ANTENNA ARRAYS IN SPATIAL POWER COMBINERS

Spatial power combiners using an array of free-running sources also relax fabrication tolerances of circuit cavity combiners and avoid dielectric and ohmic losses of circuit-level combiners. Spatial power combiners radiate freely as large planar arrays of distributed sources synchronized to produce a single higher output power signal. Unlike the open resonator, spatial combiners require alternative methods for synchronization, such as mutual coupling, external circuitry, partial reflection for external feedback, or an external source as shown in Fig. 3. Spectral purity and stability of the spatial combiner will depend on the injection locking method and the qualities of the injection locking source used.

Spatial power combiners are not limited to the open resonator beam waist dimensions, so many more sources can be injection-locked and combined in a larger area without open resonator moding concerns. The single, coherent transmitter spatial power combiner output has predictable EIRP, beamwidth, and bandwidth. Spatial power combiners can be designed and modeled using standard oscillator and planar array theory. The antenna element normally serves as a resonator, radiator, and the conduit to supply DC power to the active devices. As always, DC biasing and control must be carefully implemented to avoid degrading the co- and cross-polarization components of the active antennas. Thermal gradients across the aperture degrade the overall combining efficiency and performance of the spatial combiner by detuning individual sources.

Spatial power combiners require the design and fabrication of a large number of similar sources. However, many electrical and mechanical difficulties exist that

Figure 3. Methods for active antenna synchronization in a spatial power combiner.

work against the fabrication of nearly identical sources. The individual device parameters and package parasitics vary throughout the process. Similarly, assembly tolerances and die placement vary along with wire bonding and alignment. These variations create differences between the theoretical expectations and measured parameters. These differences are further compounded by mutual coupling in the array environment, which will vary as a function of frequency and element position within the array. The phase of an individual of active antenna synchronized within a spatial combining array depends on the difference between its self-oscillating frequency and the array injection-locked operating frequency. Mutual coupling tends to pull the oscillating frequency of individual active antennas and incur a phase offset on each of the sources. As mutual coupling varies with respect to array location, many identical sources could exhibit varying phase offsets across the aperture. These offsets, if not accounted for, can reduce power combining efficiency and overall array performance. On the other hand, these phase offsets have been controlled to develop a spatial power combiner with array beam steering capabilities [42–45].

The resulting spatial power combiner can be classified by its frequency stability, noise content, and spectral purity. The spatial combiner may also have issues like frequency jumping, pulling, or pushing and spurious signals. If the array of distributed sources remains locked, the spatial combiner should exhibit graceful degradation and have much higher reliability and MBTF than a comparable tube device.

6. ACTIVE ANTENNA OSCILLATORS

As active antennas are radiating oscillators, the same qualities used to describe circuit oscillators apply to active antennas used for spatial power combiners. There are several types of sinusoidal oscillators, including sub-harmonic, fundamental, and harmonic oscillators. Oscillators provide power at each of its harmonics. If the embedding circuit is designed to operate at the first harmonic and suppress others, it is called a fundamental oscillator. Similarly, sub-harmonic oscillators operate at fractional multiples below the fundamental, and harmonic oscillators operate at integer multiples above the fundamental. The performance of an oscillator can be gauged by several qualities listed below:

1. **Stability:** Ability of an oscillator to return to the original operating point after experiencing a slight electrical or mechanical disturbance.
2. **Noise**
 - Amplitude modulation (AM) noise: amplitude variations of the output signal.
 - FM noise: unwanted frequency variations.
 - Phase noise: unwanted phase variations.
3. **Quality (Q) factor**
 - Unloaded: accounts for resonator losses R_{loss} only.

- External: accounts for the load resistor R_{load} only and assumes $R_{loss} = 0$.
 - Loaded: accounts for both resonator losses and external loading.
4. **Frequency**
 - Jumping: Discontinuous change in oscillator frequency because of nonlinearities in the device impedance.
 - Pulling: Change in oscillator frequency vs. a specified load mismatch over 360° of phase variation.
 - Pushing: Change in oscillator frequency vs. DC bias point variation.
 5. **Spurious signals:** Output signals at frequencies other than the desired oscillation carrier.
 6. **Post-Tuning drift:** Frequency and power drift of a steady-state oscillator because of heating of the solid-state device.
 7. **Thermal stability:** Change in output power and frequency vs. temperature.

Each of these traits are applicable to active antennas and because the antenna serves as the resonant circuit as well as the radiator for the source, it will affect the overall performance of the spatial power combiner. A DC bias line delivers the proper voltage and current for the active device to generate electromagnetic energy. The resonator circuit provides the necessary reactive storage that compensates for the active device reactance. Oscillations occur at the frequency where the overall circuit reactance cancels out.

Figure 4 shows the Gunn diode equivalent circuit along with the imbedding circuit. The imbedding circuit could be a typical circuit resonator, an isolated antenna, or an antenna in an array environment. The imbedding circuit is depicted by $(Z_c = R_c + jX_c)$ and the Gunn diode by $(Z_d = R_d + jX_d)$. Similar schematics are applicable for three-terminal devices. Derivations and analysis for

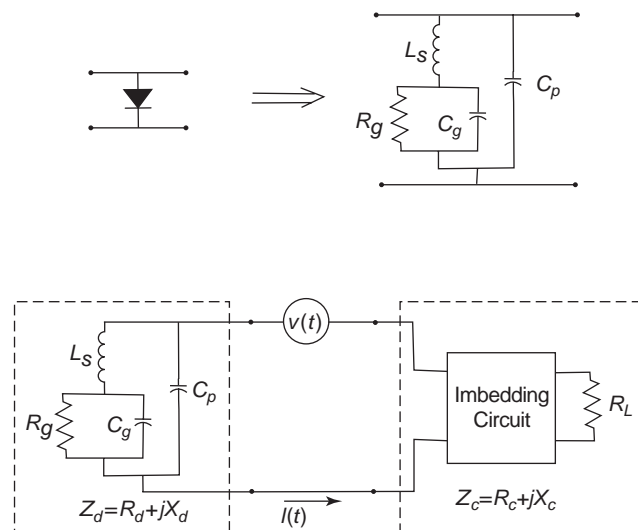

Figure 4. Gunn diode and active antenna equivalent circuit.

stability [46], noise in synchronized oscillators [47–49], external quality factors, and injection locking characteristics [50] have been derived and described in literature.

Oscillation start-up occurs because of noise or DC bias transients. The power level builds up until the active device is saturated. The device achieves steady-state equilibrium by continually restoring the power delivered to and dissipated within the circuit. As the device impedance is a function of the RF current, the oscillation frequency may change as the device reaches its steady state. At equilibrium, the oscillation frequency and amplitude remain unchanged.

For a free-running, steady-state oscillator, the sum of the circuit (Z_c) and device (Z_d) impedances must be zero at the device's operating point as shown by

$$Z_d(V_{dc}, I_{dc}, \omega_n, I_{rf}, T, \dots) + Z_c(\omega_n) = 0 \quad (1)$$

where the circuit impedance varies only with frequency and the device impedance is a function of its DC operating point (V_{dc} , I_{dc}), operating frequency components (ω_n), RF current amplitude (I_{rf}), and temperature (T). The subscript n refers to the harmonic or sub-harmonic frequency. The conditions for oscillation are then summarized as

$$\begin{aligned} R_c &\leq |R_d| \\ X_d &= -X_c \end{aligned} \quad (2)$$

where R_d is the device negative resistance and R_c is the resistance presented to the device terminals by the circuit. Similarly, X_d is the device reactance and X_c is the reactance presented to the device terminals by the circuit.

Figure 5 shows a typical circuit response presented to the device terminals at resonance. As shown, the real part of the imbedding circuit's impedance presented to the diode ($\text{Re}[Z_c]$) must be less than the real part of the diode's impedance ($\text{Re}[Z_d]$) to satisfy the oscillation condition in Equation (2). The figure also shows the zero cross-over points of ($\text{im}[Z_c] + \text{im}[Z_d]$). One of the two zero-crossings satisfies both conditions and serves as the oscillation frequency (f_0).

Figure 6 shows the Gunn diode I-V characteristics, including the threshold voltage (V_{th}), threshold current (I_{th}), DC operating current (I_{op}), and DC operating voltage (V_{op}). Impressed on the graph is an RF variation at the operating frequency ($f_0 = \frac{c}{\lambda}$) that simulates oscillation conditions.

7. SPATIAL POWER COMBINER FIGURES-OF-MERIT

Active antennas and spatial power combiners are measured in antenna ranges or anechoic chambers. Active antennas exhibit low Q-factor values and are easily affected by the environment. Care must be taken to ensure proper biasing and minimal load pulling as the antenna is rotated. Using standard gain horns, the Effective Isotropic Radiated Power (EIRP) of the active antenna or spatial power combiner can be determined through the use of the Friis transmission equation:

$$EIRP = \frac{P_{rec}}{G_{std}} \left(\frac{4\pi R}{\lambda} \right)^2 \quad (3)$$

where the receive horn gain is (G_{std}), power received at the horn is (P_{rec}), the range length is R , and the operating wavelength is (λ).

Figure 5. Imbedding circuit characteristics at resonance.

Figure 6. Gunn diode I-V characteristics.

The EIRP measurement and the estimated gain of the integrated antenna (G_a) is then used to determine the output power (P_o) of the integrated active device or array of devices:

$$P_o = \frac{EIRP}{G_a} \quad (4)$$

In the case of a spatial power combiner, the aperture gain (G_a) can be approximated by the total projected area of the array, which are typically rectangular or, as in the case of most open resonators, circular.

$$G_a = 4\pi \frac{\text{Array Area}}{\lambda^2} \quad (5)$$

Given the large number of distributed sources with varying power and phase levels, the spatial power combiner can be analyzed using array theory to determine directivity drop and sidelobe level increase from random amplitude and phase errors. Other key parameters of an active antenna include its locking gain (G_L) and its locking bandwidth (Δf), which determine the amount of injected power (P_{inj}) required to keep the active antenna synchronized to an external source.

Within the measurement chamber, an antenna of known gain (G_{std}) placed at a specified distance (R) is used to inject a signal on the active antenna at wavelength (λ). The Friis transmission equation is used again to determine how much power is injected (P_{inj}) at the active device terminals from a known source of power (P_{source}):

$$P_{inj} = G_a G_{std} P_{source} \left(\frac{\lambda}{4\pi R} \right)^2 \quad (6)$$

where the source power level (P_{source}) is varied to obtain different levels of injected power (P_{inj}) on the active device over a range of operating frequencies.

This data is used to determine the locking gain ($G_L = \frac{P_o}{P_{inj}}$) and locking bandwidth (Δf) of the radiating oscillator or spatial power combiner. With the values above, the external Quality-factor of the active antenna can also be calculated

$$Q_{ext} = 2 \frac{f_0}{\Delta f_{max}} \sqrt{\frac{P_{inj}}{P_0}} \frac{1}{\sin(\psi)} \quad (7)$$

where ψ is the angle at the intersection of the device line and the imbedded antenna impedance presented to the device terminals. Although there are no hard rules for comparison, the external Q-factor (Q_{ext}) and power-added efficiency ($PAE = \frac{P_{RFout} - P_{DCin}}{P_{RFIn}}$) are useful figures-of-merit that are used to compare the performance of active antennas spatial power combiners. In [51], Gouker presents a good review and suggestions on the development of figures-of-merit for more equitable comparisons between various spatial power combining oscillators and amplifiers.

As previously stated, a large number of relatively low-power active antennas are clustered and synchronized to develop a large high-power source with the benefits of semiconductor technologies and the graceful degradation afforded by distributed sources. To date, only certain aspects of true spatial power combining sources have been implemented commercially, and tube devices are likely to stay in use in many critical high-power applications for the next few decades.

Significant improvements in power densities, power-added efficiencies, and thermal management are required to reach power levels comparable with current high-power tube devices. Recent improvements in basic materials and device technologies continue to advance the attainable power levels from spatial power combining techniques. New technologies such as Gallium Nitride, ferroelectrics, reliable Micro-Electro-Mechanical Systems (MEMS), micromachining [52], and nanotechnologies continue to provide additional features that will improve the current state-of-the-art. Improvements in processing and assembly tolerances are also allowing the fabrication of a larger number of nearly identical sources that are more easily grouped and synchronized. As the power output levels increase, thermal dissipation and thermal gradients across the face of the combiner degrade performance and are also being addressed [53].

Grids and similar nonresonant arrays have shown great promise in monolithic integration and in the development of more compact, stable oscillators, higher power amplifiers [54], and many other quasioptical components previously referenced. Along with the advancement of sources, significant developments in spatial power combining amplifiers [55], phased arrays [56], retro-directive arrays [57,58], smart antennas, and active integrated transceivers [59] continue to increase in both functionality and quality. In time, these developments will increase both function and performance at reasonable costs for new products in emerging global markets.

SPICE

WILLIAM H. MORONG
Consultant

1. INTRODUCTION TO SPICE

Since the advent of electronic computers, programs have been developed to simulate physical phenomena. Electronic circuits are among the phenomena having thus been simulated. An enduring and popular electronic simulation program developed at the University of California, Berkeley, is SPICE, an acronym meaning “Simulator Program with Integrated Circuit Emphasis.” It is beneficial not to be misled by its name to believe that SPICE is limited to circuits destined for monolithic integration. SPICE simulates as easily as integrated circuits, discrete circuits, and even purely electrical circuits containing only such components as voltage and current sources, resistors, capacitors, and inductors.

SPICE is most useful when a need exists to simulate circuits at the component level. Many other simulation programs offer higher degrees of abstraction to free the user from handling a plethora of individual components. Cases where component-level simulation is helpful include, but are not limited to, analog circuits, the structures within digital circuits in which such analog behavior as transitions must be studied, RF circuitry, and the instruction of students in circuit theory.

SPICE includes such ideal components as independent and dependent voltage and current sources, resistors, capacitors, inductors, and transmission lines, and provides a means for assigning a numerical quantities to each instance of such components. It further provides for inclusion in circuits of externally supplied components as models or as subcircuits.

A SPICE circuit comprises a “netlist” that expresses the chosen components and their interconnections. The “netlist,” an example of which is shown in Fig. 1, is essentially an alpha-numeric text expression of a circuit diagram. Each component or external connection and each terminal thereof is assigned a name. Each group of uniquely interconnected component terminals is called a “node” and assigned a name. The SPICE simulation program, through extensive iteration in accordance with the netlist and components thereof, calculates the behavior of the circuit. This behavior approximately satisfies, often with great precision, the requirements of such fundamental circuit equations as Ohm’s law and Kirchhoff’s law. Adherence to such laws is implicit in SPICE simulation.

Until recently, the most common means of passing input to the SPICE application has been alpha-numeric text in a command line, or even Hollerith cards. The total input

NODE	REFERENCE	PIN #	PIN NAME	PIN TYPE	PART VALUE

Figure 1. Sample portion of a SPICE netlist. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

for a given circuit to SPICE is still often called a “deck.” Such entry has been language readable by computers, necessitated by the former inability of computers to economically process more humanly intuitive communications. However, in electronic engineering, far older and more comfortable language exists, in which most engineers are fluent. That language is the circuit (schematic) diagram. Undoubtedly, engineers who do not share a spoken tongue, or even an alphabet, can read each others’ diagrams. Recent advances in Graphic User Interfaces (GUIs) now render circuit diagrams computers readable. Modern SPICE applications offer “schematic entry” as the default input method. Figure 2 shows a typical SPICE schematic entry environment.

However tedious alpha-numeric text input may be, interpretation of nongraphical numeric output data seems even more difficult for humans. Therefore, SPICE has long included provisions for graphing the voltage at any node of a circuit or the current in a terminal of a component. Modern SPICE applications make this facility even more comfortable. The means of obtaining graphical output is now often a cursor resembling an oscilloscope probe, and the output often looks like an oscilloscope or spectrum analyzer output. Figure 3 shows typical SPICE output for the circuit of Fig. 2. The GUIs of some SPICE applications are now so good that it is possible for an engineer with decades of bench experience to forget that he or she is working in a virtual environment of which the soldering iron is no part. Figure 4 shows the SPICE GUI environment offered by a typical SPICE application.

In addition to schematic input and graphical output, many SPICE applications import and export netlists as .cir files, allowing a circuit generated in one SPICE application to be simulated in another. Some SPICE applications also filter and export their netlists in a number of proprietary formats readable by a number of popular Printed Circuit Board (PCB) layout applications. Moreover, some SPICE applications also provide easy graphical capture of on-screen diagrams and plots that can be easily picked up in popular graphics editing applications. Most of the files thus generated are of surprisingly modest size. All these facilities make it very easy for engineers to share designs and their outputs over networks, including the Internet.

SPICE is now available to operate under a variety of operating systems. Proprietary SPICE versions are often distinguished by their user interfaces and by the libraries they supply. The cost of a fully functional SPICE application varies from several thousand dollars to free. Some versions use standard Berkeley SPICE syntax, whereas others use similar syntax that is largely humanly understandable but not necessarily compatible. In addition, SPICE has been tailored for particular engineering disciplines. For instance, several software suppliers offer special versions directed toward RF design or power-conversion circuitry.

SPICE software may be accessed in a variety of ways. One may purchase a proprietary SPICE application. Complete SPICE applications are also offered as “freeware” [1] for download over the Internet. Such applications are usually less than 20 megabytes in size and will run reasonably quickly even on obsolete computers with

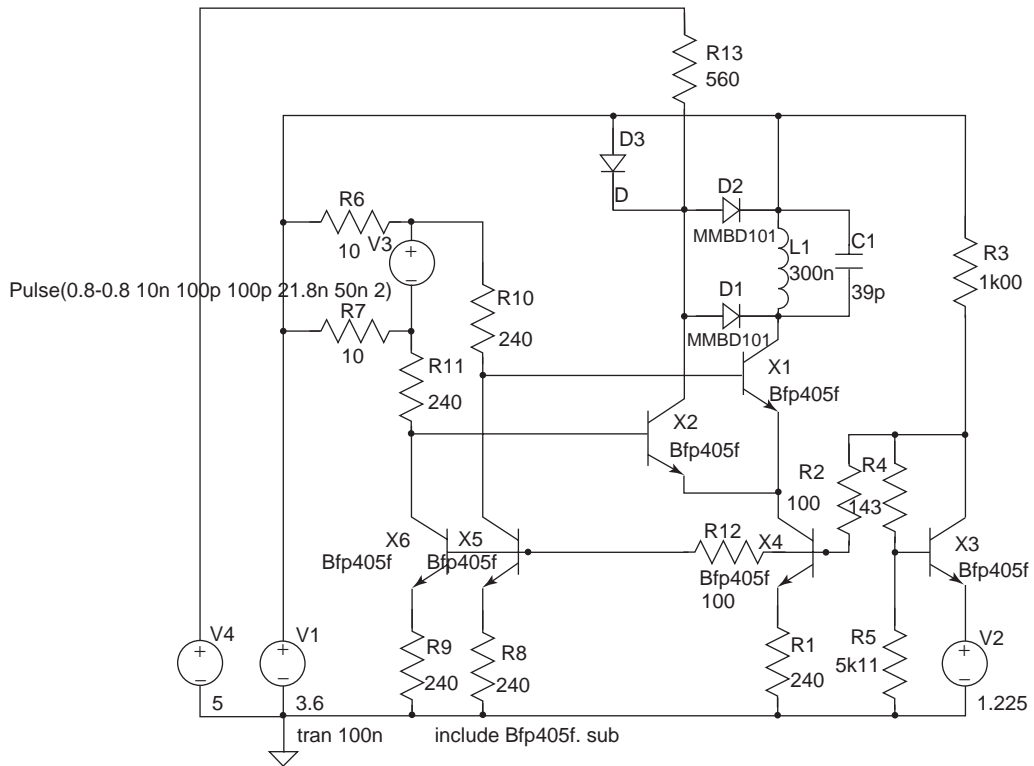

Figure 2. Schematic diagram image from SPICE GUI.

processor speeds below 200 Mhz. Free applications [2] sometimes include extensive libraries of the parts offered by the manufacturer supplying that application. Such libraries often do not encumber one's use of the program,

can be very convenient, and can easily be supplemented by models from other vendors. Some component vendors enter into arrangements with vendors of proprietary SPICE applications to provide applications largely dedicated to

Figure 3. Voltage and current waveforms from SPICE GUI. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

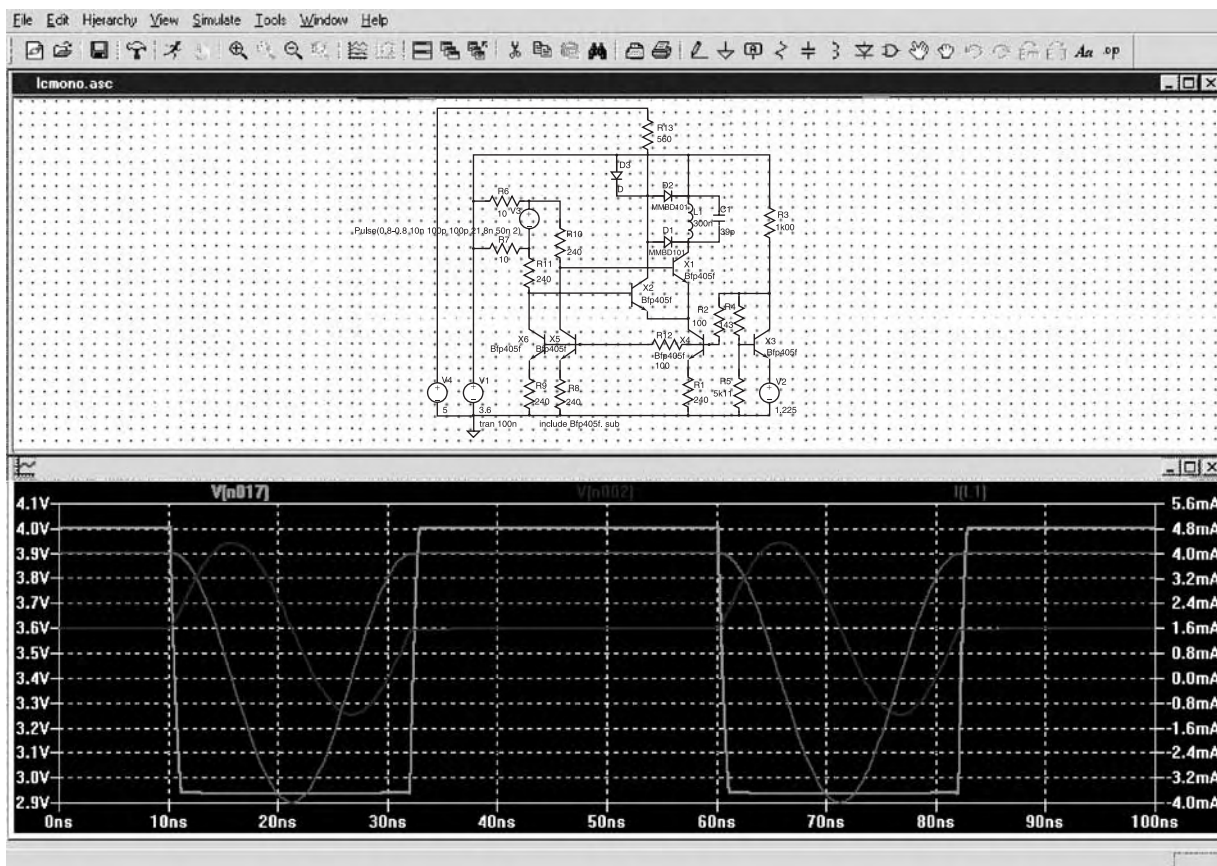

Figure 4. Typical SPICE GUI showing schematic and waveforms.

the components they offer or to limited applications such as power-conversion circuitry. Some of these dedicated applications are available for download [3], whereas others reside at the component vendor’s Website and are usable over the Internet [4]. It is wise to thoroughly explore these options without regard for the names of the applications. One offering named to indicate dedication to switching power supplies is actually a totally free, full-featured, and largely generic version of SPICE with a generous and convenient GUI, and operates under both Windows and Linux operating systems.

Although such primitive elements as resistors and capacitors are an integral part of SPICE, even the ubiquitous 2N3904 transistor is not. However, primitive frameworks of transistors are integral parts of SPICE. SPICE recognizes, as models, groups of parameters that together define the behavior of transistors. For each transistor type, SPICE requires a model that comprises parameters equated with corresponding numerical values. The transistors that SPICE is endowed to recognize are Bipolar Junction Transistors (BJTs), both NPN and PNP; Junction Field Effect Transistors (JFETs), both N and P channel; and Metal-Oxide Semiconductor Field Effect Transistors (MOSFETS), both N and P channel. SPICE also sets forth parameters for, and recognizes, models of semiconductor diodes.

A model is a brief text file that retains the alpha-numeric character of earlier SPICE inputs. Models begin

with the syntax “.model” followed by the name of the model, for example 2N3904. A primitive SPICE description follows, such as NPN for the 2N3904.

Its complement the 2N3906 would be “PNP.” SPICE recognizes .model and NPN and will associate these with the name 2N3904. Terminal numbers are assumed; in the case of a NPN BJT, these are usually 1, 2, and 3, the collector, base, and emitter, respectively.

Letters grouped with numbers follow, either in parentheses or on lines starting with “+” a list of parameters, each group containing “=”, for instance, “BF = 100.” Each group is a named quantity that SPICE has been endowed to recognize as a particular characteristic of device that it recognizes. Thus SPICE recognizes that the NPN called 2N3904 has a Beta Forward (BF) of 100. There are many SPICE-recognizable parameters for each device type. The mythical model below illustrates the typical syntax of a model.

```
.model XBT9999 NPN
+ Is = 7.931f   Xti = 3           Eg = 1.11           Vaf = 58.74
+ Bf = 76      Ne = 1.342       Ise = 5.911f       Ikf = 13.93m
+ Xtb = 1.5    Br = 1.297       Nc = 2             Isc = 0
+ Ikr = 0      Rc = 1.61        Cjc = 4.017p       Mjc = .3174
+ Vjc = .75    Fc = .5              Cje = 4.973p       Mje = .4146
+ Vje = .75    Tr = 4.687n          Tf = 820.4p        Itf = .35
+ Vtf = 4      Xtf = 7           Rb = 10
```

Complete lists of SPICE-recognizable parameters for diodes and transistors of all recognizable types are set forth in detail in literature published by UC Berkeley [5] and summarized [6,7] and published by other entities. Both the complete parameter descriptions and their summaries are freely available for download over the Internet. For MOSFETS, SPICE recognizes both electrical models, including electrical parameters and geometric models, the latter often including lengths and widths of MOSFET features expressed in microns.

Devices that are not single devices primitively recognizable to SPICE may also be similarly called. These are described as subcircuits. A subcircuit is brief text file including a plethora of SPICE-recognizable devices interconnected by a net list and having terminals like, and called like a single component. A subcircuit may contain many BJTs, resistors, capacitors, or other components. A subcircuit may encompass even a complex subsystem. The syntax is similar to that for models, beginning with ".subckt," followed by the name of the subcircuit, which is followed by several alpha-numeric expressions separated by spaces, representing the external nodes of the subcircuit. This opening is followed by a netlist of the subcircuit and any models included therein, finally ending with ".ends." Comments lines beginning with an asterisk may be included anywhere in the text. It is safest to completely include all models used in a subcircuit in its text to avoid corrupting a subcircuit when transporting it to a SPICE application with a different library. The filename of a subcircuit is usually the name of that subcircuit with the suffix ".sub." The syntax of a subcircuit is illustrated by the mythical subcircuit named DIFFECL.sub follows below.

```

Subcircuits have many uses. Subcircuits provide a way for SPICE to simulate both usual and unusual components. For example, it is unlikely that the authors of SPICE had vacuum tubes (valves) in mind when they wrote a program nominally having "integrated circuit emphasis." However, certain audio enthusiasts find that

subcircuits representing triode and pentode vacuum tubes are convenient for simulating their circuits. The monolithic IC designer may use subcircuits to abstract repetitive structures. The discrete analog designer will doubtless encounter manufacturers' macromodels of such devices as operational amplifiers, which are, in fact, subcircuits that mimic the behavior of such components. The HF RF designer may use models, but the very high frequency (VHF) and ultra-high frequency (UHF) designer must usually use models embedded in subcircuits representing the package parasitics of their devices.

Modern SPICE applications often include model and subcircuit libraries that SPICE searches by default for their contents. Additionally, many SPICE applications are endowed by their software authors with such libraries already supplied with common components. Models of devices are often supplied by manufacturers, and may usually be downloaded over the Internet. This is often the source of the most accurate models, although some manufacturers supply models with errors. Some users learn no more about models than how to download them and to install them in their SPICE libraries.

The RF designer and the high-speed analog and digital designer may need models of other circuit elements that neither SPICE nor device manufacturers can supply. At high frequencies and speeds, the parasitic, or stray, resistance, capacitance, and inductance of the interconnects between devices is often far from negligible and may even dominate circuit performance. Therefore, if SPICE is to simulate such circuits accurately, these parasitic elements must be included in the simulation. Obtaining models of parasitic elements can be challenging.

Other computer simulation programs may be used to provide models of parasitic elements. Some electromagnetic (EM) field solvers [8] provide for drafting entry of such geometric features as may occur on a PCB, in hybrid circuitry, or in a monolithic IC. Such programs also often provide import capability for graphics files. Some EM field solvers output both S-parameter and SPICE models that may be useful to the high-frequency SPICE user. Lacking an EM field solver, it is sometimes useful to treat interconnects as transmission line sections that are easily included in the SPICE simulation.

Another need for subcircuits and models develops with mixed-signal design. To simulate circuits containing both analog and digital devices, at least the input and output characteristics of the digital parts must be modeled in SPICE-recognizable format. One common format for digital interfaces is IBIS. IBIS-to-SPICE conversion applications [9] facilitate SPICE simulation including digital components. In the case of such digitally simple parts as buffers and inverters, the IBIS-to-SPICE conversion may be all the treatment that the digital components require.

2. USING SPICE

The first entry on a SPICE schematic diagram should be the ground (earth) symbol; SPICE will not correctly simulate any circuit lacking a ground.

SPICE will also balk at a circuit containing nodes for which it cannot compute a DC operating point relative to ground. A capacitor left with one open terminal is unacceptable. Analogous to the open capacitor is the shorted inductor, the current of which is unknown. Some SPICE applications will accept a resistor with one open terminal, whereas others will not. Despite the fact that coaxial cable, microstrip, or other transmission lines obviously exhibit longitudinal conduction, SPICE does not recognize what one may ordinarily take for granted. For simulation, circuits connected by transmission line may require resistors to ground at the far end of the line. Such resistors may be arbitrarily large, i.e., 1 gig-ohm. Other circuits inadvertently containing galvanically isolated nodes may require similar treatment. Examples of such are certain M-derived filters, isolation amplifiers, isolated DC-DC power supplies, and transformer-coupled RF circuitry. It is usually advisable to connect normally isolated circuit portions to the grounded parts of the schematic diagram using a resistor. Once the simulation is performed, one can examine this resistor for common-mode currents. If the circuit has been thoroughly modeled, it will contain the stray coupling elements between the isolated section and ground. In transformer-coupled circuitry, the common-mode potential imposed on a secondary winding may often have a peak voltage as high as the power supply on the primary side. The current in the connecting resistor should be commensurate with that which is to be expected. The discipline of examining this current is helpful in appreciating and controlling common-mode currents in RF circuits and DC-DC converters.

Although most SPICE applications have libraries of models and subcircuits, the manipulation of such files varies from application to application, and even within applications. For example, one application groups all semiconductors, models, and subcircuits alike into a single file. Another has a separate folder in which each subcircuit is a separate file. In the latter application, other components, passive and active, are grouped in files within another folder, a file for resistors, another for capacitor, yet another for inductors, a file for BJTs, etc. However, the latter application also includes other components not kept in such files, such as switches. In the latter application, switches are defined by a SPICE directive, a snippet of text edited in a dialog box and deposited on the schematic diagram.

A few words are needed about the use of the ideal components available in SPICE. Unless other inputs are given, SPICE components and sources are ideal! Resistors have no capacitance or inductance. Capacitors have no resistance or inductance. Inductors have no resistance or capacitance. Voltage sources can supply megaamps, and current sources have compliances of megavolts, whether dependent or independent sources. *If your simulation needs less than ideal components to be correct, you must explicitly add the necessary nonidealities to your schematic diagram, or in some SPICE applications, to the component descriptions!* At first, those unaccustomed to ideal components may experience some disorientation. For example, although a real current

source usually must be connected to a voltage more extreme than greatest compliance desired therefrom, an ideal current source needs no such connection. It may be connected to ground or to any appropriate return. Even more disconcerting is the fact that an ideal current source, unlike most real current sources, can swing to voltages beyond the power supply voltages provided in the schematic diagram. If one were to apply an ideal current source to the capacitor of a ramp generator, and then not reset that generator soon enough, one might see several kilovolts across that capacitor.

Additionally, diode and transistor models may not include breakdown voltages. In a real circuit, a positive current source applied to the emitter of an NPN BJT will merely cause zener conduction, but because the zener breakdown base-emitter junctions is commonly not included in SPICE models, the emitter voltage in simulation may increase to astounding levels.

The effects of ideal voltage sources are more misleading for SPICE users because they are seldom so dramatic. Build a DC-DC converter fed by an ideal voltage source and no ripple will be conducted to another connected circuit. Power the real version of the same circuits with a battery and the circuits sharing the battery may be inundated with noise. To obtain the truth, one must endow that ideal voltage source with battery-like nonidealities. If one remembers to observe the current in the ideal voltage source, the need for proper bypassing and decoupling becomes obvious.

Independent sources in SPICE may be made to provide a steady voltage or current, AC voltage or current for AC analysis, or waveforms with or without DC components. Available waveforms are pulse, sine-wave, exponential, piece-wise linear (PWL), and single-frequency FM. Although these sources largely correspond to what the engineer expects in bench instruments, a few accommodations are to be made. One accustomed to a function generator with sine-, square-, and triangle-wave outputs may at first miss the last. However, two triangle-wave sources are implicit in SPICE. The pulse source has programmable rise and fall time. A pulse consisting entirely of rise and fall is a triangle wave. One accustomed to the usual engineering practice of measuring pulses at their 50% points may at first not obtain the expected pulse waveforms from SPICE, in which the waveform is specified as having an implied off-time, a rise, an on-time, a fall, and a period. The second triangle-wave generator is the PWL source. Using this source, the times and levels at the tips of the wave may be defined.

In addition to independent sources, dependent sources are available in SPICE. These are four-terminal devices having either a voltage or a current input and a voltage or a current output. One must at least enter a value of gain or transconductance for these devices.

Another SPICE source is the nonlinear dependent (in some applications called behavioral) source. These are a two-terminal voltage or current sources, the output of which is a mathematical expression. The output of such a source might, for example, be a voltage twice the sine of the square of the voltage on some other node on the schematic diagram.

When any component or source is entered in SPICE, no error is entered with it. Some SPICE applications include Monte Carlo analysis, but, in the absence of that feature, one can be misled by inadvertent and unrealistic matching of components. If any question about such errors exists, it is wise to deliberately introduce appropriate errors and recheck simulation results.

Having entered a schematic diagram and incorporated in one's library, the models, and subcircuits it contains, one must direct SPICE to do the desired analysis. The time-domain oriented engineer will often choose transient analysis. The output of transient analysis is essentially the same as using an oscilloscope to probe a real circuit. In transient analysis, SPICE must be given at least a stop time at which to discontinue the simulation. During simulation, a dialog box may drop asking what node voltages or component currents are to be plotted. In many applications, one may, after simulation, examine these voltages and currents by clicking a probe-shaped cursor on a corresponding part of the schematic diagram. In transient analysis, a time to start collecting data to be plotted, a maximum step time (time resolution), and sometimes a minimum step time, may be entered.

Another engineer may choose AC analysis. In this case, the result after simulation of clicking the probe on a given node of the schematic is the generation of a Bode plot, as shown in Fig. 5. For this analysis, one enters a start frequency, a stop frequency, whether the output interval is to be in octaves or decades, and the number of points per interval. It does not matter at all to SPICE whether the circuit is operating from 1 to 10 MHz or 1 to 10 GHz, the computation is equally quick. For a given cir-

cuit, AC analysis is usually much quicker than transient analysis.

SPICE offers intuitive bridges between the frequency-domain and the time-domain. It is a trivial task to perform both transient and AC analysis of the same circuit. Making a habit of doing so can greatly sharpen one's intuitive grasp of the relationship between these domains. For example, one can observe the transient response of a feedback amplifier and then consider its Bode plot. Examination of the ripples in the transient response are easily related to discontinuities shown on the Bode plot. With a little practice of this discipline, it becomes difficult not to know how to compensate an amplifier. Were that not enough, many applications include FFT capability that is easily applied to the output data. Such capability, shown in Fig. 6, can be very useful for observing harmonics and intermodulation products.

Noise analysis is invoked similarly to AC analysis. The obvious difference is that for noise analysis the circuit itself provides the signal.

DC analysis is usually performed by default before more complex analyses are done, but may be separately invoked. Pole-zero analysis and sensitivity analysis are part of SPICE and are not explicitly accessible in many applications. Transfer function analysis is also part of SPICE, fully explicitly available in some applications and explicitly available only for DC in others.

Circuits capable of energy storage can require inordinate simulation times in SPICE. To overcome this problem, SPICE contains the ability to set initial conditions. For example, an L-C oscillator with a high-Q tank may take hundreds or thousands of cycles to attain the

steady state. If one is not interested in its turnon behavior, one may invoke an initial condition to start the circuit fully charged with energy. For example, one might use the syntax “.ic I(L1)=18m” (meaning the initial condition of L1 is to have a flow of 18 mA) to preload the inductor with 18 mA. If this current is correctly chosen in accordance with the equations governing the inductor’s peak current in the steady state, the oscillator may start immediately. In inductive circuits, it is not unusual to obtain plots indicating several KV, with power supplies of a few volts. This problem is often solved by setting an inductor initial condition to zero, or to some reasonable value. Likewise, if one has no interest in the turnon of an A-M envelope detector, one may precharge its filter capacitor with such syntax as “.ic V(n017) = 1.347 V,” where the terminal of the capacitor attached to node 17 needs to be charged to that voltage. The initial condition is almost indispensable for examining the ripple of DC-DC converters. When initial conditions are not specified and should be, not only does transient simulation often become lengthy, but also the SPICE iterations needed initially to establish DC conditions may become so slow as to strain one’s patience waiting for actual simulation to commence.

RF and power-conversion circuits often involve transformer coupling. Transformers in SPICE are simply coupled inductors. The windings to be coupled are entered having polarity dots if needed and their respective self-inductances. Remember that inductance varies as the square of turns; turns-ratio in SPICE is a dependent variable derived from the square root of the inductance ratio. One enters the windings on the schematic as if they were perfectly coupled. To implement less than complete

coupling, the syntax is usually something like “K1 L1 L2 0.5,” meaning that the windings L1 and L2 are 50% coupled. Many windings can usually be included in that syntax.

One might wonder how, without the expense of an EM field solver, to model parasitic elements. Free resources, some available online give, either as charts in text [10] or as calculators [11,12], the impedance of microstrip and other common structures given dielectric constant, or material, and dimensions. If one merely treats one’s interconnects as such structures, one can ascertain their impedances as transmission lines. The same facilities usually relate their timelengths to physical lengths. To convert timelength at a given impedance to lumped elements, use $C = T/Z_0$ and $L = T \cdot Z_0$, where T is the timelength, Z_0 is the characteristic impedance, C is the capacitance of the section, and L is the inductance of the section. Thus, one can approximate, for example, the stray capacitance and stray inductance of a run on PCB. The reason for simulating using lumped elements rather than transmission line sections for connections is that SPICE does not comprehend transmission lines as DC connections.

As SPICE may compute the characteristics of sections of transmission lines with far greater smoothness than is practically realizable, simulations involving transmission lines are often slow. More reasonable simulations are often obtained using lumped-element lines when the “lumpiness” is chosen to have little effect on circuit operation. Using many small sections can approximate the smoothness of a continuous line.

Although a few SPICE applications add some thermal capability, many do not. In the world of SPICE, simulated
