In practice, a conical structure on which simple antenna elements such as dipole, disk, cone, slot, or patch are mounted to excite a cone is often used. The infinite cone excited with an axial dipole at the tip has shown [14] that the strong radiation occurs along the small-angle cone unless the dipole length is about a half-wavelength. Figure 8 shows a finite wide-angle cone excited with a quarter-wavelength long and a half-wavelength long dipole [17]. Note that the maximum radiation can be directed toward the horizontal plane by proper choice of a and θ_0 at a desired frequency. A cone excited with an axially symmetric circumferential slot close to the tip [18] shows radiation characteristics similar to those of a dipole-excited cone, since a small circumferential slot (magnetic current loop) is equivalent to a small axial electric dipole. When the circumferential slot is not too close to the tip, that is, apart by 2.5 wavelength ($2\psi = 30^\circ$), the radiation pattern shows a rather complicated lobe structure [18]. The cone excited with a circular disk at the tip is called a *discone antenna* [19]. This antenna is fed with a coaxial

Figure 8. Far-zone electric field pattern of a tip-excited conical antenna, $\beta a = 50$: (a) $\theta_0 = 90^\circ$, $l = \lambda/4$; (b) $\theta_0 = 103.8^\circ$, $l = \lambda/4$; (c) $\theta_0 = 103.8^\circ$, $l = \lambda/2$; radiation beam can be directed to horizon by slanting a cone downward (from Ref. 17).

cable whose inner conductor terminates on the center of the disk and whose outer conductor terminates on the tip of the cone. The radiation pattern of the discone is similar

to that of a dipole antenna, but its input impedance bandwidth is exceedingly broad compared with an ordinary dipole antenna.

Figure 9 shows the measured input VSWR (for 57.6-Ω-cable) versus frequency of the finite conical antenna with different exciting elements at its tip [17]. The cone excited with a conical element (an asymmetric biconical antenna) indicates very broadband characteristics, particularly in

Figure 13. Directivity gain of a bowtie antenna in x direction (from Ref. 20).

lower-frequency regions, without affecting the radiation pattern.

3. TRIANGULAR (BOWTIE) ANTENNAS

A triangular plate antenna above a conducting ground plane and a bowtie antenna are shown in Figs. 10a and 10b. These antennas also possess broadband characteristics, though not as broad as a solid conical antenna. The theoretical characteristics of the bowtie antenna have been obtained numerically [20] by using the method of finite-difference time domain (FDTD). Figures 11a and 11b show the calculated input impedance. The input impedance of the triangular plate antenna above the ground plane is half of that of the bowtie antenna.

The far-zone electric field patterns in the x - y plane and in the x - z plane are shown in Figs. 12a and 12b, respectively. Note that the radiation is enhanced in the direction perpendicular to the antenna plate for the antenna length $2h \lesssim \lambda$, because the radiation from the antenna surface current is added in phase in that direction. The theoretical directivity gain of the bowtie antenna in the direction of the x axis is shown in dBi in Fig. 13 versus the antenna length $2h/\lambda$ for various cone angles [20]. It is noted here that the bowtie antenna can also be simulated by several radial wire rods as the solid biconical antenna.

1. INTRODUCTION

Coplanar stripline (CPS) is an attractive uniplanar transmission line offering flexibility in the design of planar microwave and millimeter-wave circuits, especially in mounting the solid-state device in series or shunt with no via holes. Its balanced structure is useful in applications such as printed dipole antenna feeding, rectennas, uniplanar mixers [1], integrated optic traveling-wave

DIELECTRIC LOADED ANTENNAS

1. INTRODUCTION

A transmit antenna converts the energy of a guided wave in a transmission line into the radiated wave in an unbounded medium. The receive antenna does the reverse. The transmission lines such as waveguides and coaxial and microstrip lines use conductors mostly to confine and guide the energy, but antennas use them to radiate it. Because the radiated energy is in unbounded region, phase control is often used to direct the radiation in the desired direction. Dielectrics play an important role in this process, and this article discusses a few representative cases. An important antenna parameter is its *directivity*, which is the measure of its control over the energy flow. To increase the directivity, the antenna size must be increased, and the influence of dielectrics on their performance changes considerably. Thus, in this article, the use of dielectrics in antenna applications is divided into two categories of large high-gain and small low-gain antenna applications.

In high-gain antenna applications, reflectors and lenses are used extensively [1]. They are passive and operate principally on the basis of their geometry. Consequently, they are relatively low-cost, reliable, and wide-band. Reflectors are usually made of good conductors, and thus have lower loss, and because of their high strength, can be made light. But reflectors suffer from limited scan capability. Lenses, on the other hand, because of their transparency, have more degree of freedom, specifically, two reflecting surfaces and the relative permittivity or refractive index. They also do not suffer from aperture blockage. However, lenses have disadvantages in large volume and high weight.

In microwave antenna applications, lenses have numerous and diverse applications, but in most cases they are large in size with respect to wavelength. Thus, physical and geometric optics apply, and most of the lens design techniques can be adopted from optics to microwave applications. The aperture theory and synthesis techniques can also be used effectively to facilitate designs. In addition, the use of an optical ray path in lens design makes the solution frequency-independent. In practice, however, the lens size in microwave frequencies is finite with respect to the wavelength, and the feed antenna is frequency-sensitive. Thus, the performance of the lens antenna also becomes frequency-dependent.

Natural dielectrics at microwave frequencies have reflective indices larger than unity and for collimation, require convex surfaces. However, artificial media using guiding structures, such as waveguides, are equivalent to

dielectrics with refractive index less than unity, and result in concave lenses. They are usually dispersive, resulting in variation of the refractive index with frequency, and have narrower operating bandwidths.

In small antennas dielectrics are used often to improve the radiation efficiency and polarization of the antennas, such as waveguides and horns. This is important in telecommunication applications, where polarization control is required to implement frequency reuse and minimize interference, especially in satellite and wireless communications. Horn antennas and reflector feeds are examples that incorporate dielectrics or lens loading to improve performance [2].

Another area of important dielectric use is insulated antennas in biological applications and remote sensing with buried or submerged antennas. The use of dielectric loading eliminates direct RF energy leak into the lossy environments, and ensure radiative coupling into the target objects. Often a full-wave analysis is needed to provide a proper understanding of their resonance property and coupling mechanism to the surrounding media.

The dielectric loading is also used for antenna miniaturization. Low-loss dielectrics with medium to high relative permittivities are now available and are used increasingly to reduce the antenna size. A number of important areas include dielectric-loaded waveguides and horn, and dielectric resonator and microstrip antennas. By aperture loading of waveguides and small horns, excellent pattern symmetry and low cross-polarization can be obtained, which are essential features of reflector and lens feeds. In addition, the dielectric loading reduces the size of the antennas and makes them useful candidates for multibeam applications, using reflectors and lenses. Miniaturization of the antenna is also an important requirement in wireless communications. Microstrip patch or slot antennas with high-relative-permittivity substrates play an important role in this area, and their derivatives are used in most applications. In dipole and monopole cases the dielectric loading is external and used for size reductions.

Finally, dielectric loading can also be used for gain enhancement, without shaping them such as lenses. Planar dielectrics can be used as radomes or covers to protect the antennas. By proper selection of the radome parameters, the antenna gain can also be increased significantly, while protecting the antennas from the environment.

2. DIELECTRIC LENS ANTENNAS

In optical terms, a lens produces an image of a source point at the image point, and lenses could be located anywhere in the space. As an antenna, this property means that the source and image points are focused at each other and the lens has two focal points. In turn, these focal points signify locations in the space, where rays emanating from the lens arrive at equal phases. This

property provides a mathematical relationship for describing the lens operation, and therefore its design.

To simplify the mathematics, the lens configuration is assumed to be rotationally symmetric, and the focal points are placed on its axis. A further simplification can be made for antenna applications, where the image point moves to infinity; that is, the lens focuses a nearby source point, on its axis, to another axial point at infinity. In such a case, all rays leaving the lens travel parallel to its axis, and their phasefronts are planes normal to the lens axis. This is shown in Fig. 1, where ϵ_r is the relative permittivity of the lens material, and $n = \sqrt{\epsilon_r}$ is its refractive index.

To design the lens, one is required to determine the geometry of its two faces, front and back, or the coordinates x_1, y_1 , and x_2, y_2 of points P_1 and P_2 (Fig. 2). There

$$n = \sqrt{\epsilon_r} \quad (a)$$

Figure 1. Geometry of lens antennas showing the feed and influence of lens on ray direction.

are four unknowns to be determined. The equality of the phase on the phasefronts requires that the electrical length between the focal points and the phasefronts be independent of the pathlengths. This provides one equation. Two other equations can be obtained from the ray optics at the lens interface points P_1 and P_2 , namely, the Fermat principle of minimum pathlengths. This enforces the well-known Snell law of refraction at the lens surface points. An additional relationship must be generated from the required lens properties, to enable a unique solution for the lens design.

To enforce the invariance of the ray pathlength, the central ray passing through points A, B , and C is selected as the reference and its length from S to C is compared with that of the ray passing through points P_1, P_2 , and P_3 . This provides the following equation

$$\overline{SP_1} + n\overline{P_1P_2} + \overline{P_2P_3} = \overline{SA} + n\overline{AB} + \overline{BC} \quad (1)$$

or

$$r_1 + nr_3 + L_1 = F + nT + L_0 \quad (2)$$

where in terms of P_1 and P_2 coordinates each length is given by

$$\begin{aligned} r_1 &= (x_1^2 + y_1^2)^{1/2} \\ r_3 &= [(x_2 - x_1)^2 + (y_2 - y_1)^2]^{1/2} \\ L_1 &= (x_3 - x_2) \\ L_0 &= x_3 - (F + T) \end{aligned} \quad (3)$$

and F and T are the lens focal length and axial thickness, and are therefore constant lengths defining the lens.

Enforcing the Fermat principle at points P_1 and P_2 results in differentiation of the pathlength in Eq. (1) in terms of its variables x_1, y_1 and x_2, y_2 and setting it to zero. This provides the slope of the lens surface profiles at each point P_1 and P_2 .

At point P_1 one obtains

$$\frac{d}{dx_1} [r_1 + nr_3 + L_1] = \frac{d}{dx_1} [F + nT + L_0] = \frac{d}{dx_1} L_0 \quad (4)$$

where the constants F and T are dropped and after simplifications one finds

$$\frac{dy_1}{dx_1} = \frac{x_1 r_3 - (x_2 - x_1) n r_1}{(y_2 - y_1) n r_1 - y_1 r_3} \quad (5)$$

At point P_2 , a similar differentiation in terms of x_2 gives

$$\frac{dy_2}{dx_2} = \frac{(x_2 - x_1) n - r_3}{(y_2 - y_1) n} \quad (6)$$

Equations (2), (5), and (6) are three fundamental equations to design the required lens. Without another relationship, x_1 may be selected as the independent variable. Then others, namely, x_2, y_1 , and y_2 , become dependent

Figure 2. Geometry of a lens indicating ray and surface coordinates.

variables to be determined in terms of x_1 . The solutions give the lens profiles in rectangular coordinates. If the lens profiles in polar coordinates are required, Eqs. (2), (5), and (6) can be obtained in terms of r_1, θ_1 and r_2, θ_2 , the polar coordinates of P_1 and P_2 . Differentiating Eq. (2) in terms of θ_1 and θ_2 gives

$$\frac{dr_1}{d\theta_1} = \frac{nr_1r_2 \sin(\theta_2 - \theta_1)}{r_3 - n[r_2 \cos(\theta_2 - \theta_1) - r_1]} \quad (7)$$

and

$$\frac{dr_2}{d\theta_2} = \frac{nr_1r_2 \sin(\theta_2 - \theta_1) + r_2r_3 \sin \theta_2}{r_3 \sin \theta_2 - n[r_2 - r_1 \cos(\theta_2 - \theta_1)]} \quad (8)$$

where use is made of the following polar coordinate relationships:

$$\begin{aligned} x_1 &= r_1 \cos \theta_1 \\ y_1 &= r_1 \sin \theta_1 \\ x_2 &= r_2 \cos \theta_2 \\ y_2 &= r_2 \sin \theta_2 \\ r_3 &= |r_1 - r_2| = [r_1^2 + r_2^2 - 2r_1r_2 \cos(\theta_2 - \theta_1)]^{1/2} \end{aligned} \quad (9)$$

Solutions of Eqs. (7) and (8) give the lens profiles in polar coordinates, which are often more compact in form. Also, for some simple lens configurations, they result in well-

known and easily recognizable parametric equations of the conic sections, generalizing the solution.

2.1. Examples of Simple Lenses

The lens design becomes considerably easier, if one of the lens surfaces is predetermined. This eliminates one of the differential equations, as the surface profile is already known. Among many surfaces to select the simpler ones are the planar and spherical surfaces, with the planar normal to the lens axis. Such selections give simple profile equations. The planar surface is described by a constant x coordinate and the spherical one by a constant polar coordinate r . These simplifications also assist in solutions of the other lens profile, for which an analytic solution can also be determined. Since either of the lens profiles can be predetermined as planar or spherical, four possible solutions exist. Only two, however, result in simple conical sections.

If the second surface S_2 is assumed to be planar, normal to the lens axis, the rays arriving from the right-hand side, parallel to the lens axis x , enter the lens unaffected and change direction only after the first lens surface S_1 . Then they focus at S ; that is, only the S_1 surface of the lens collimates the beam. Looking from the left side, spherical rays originating from the focal point S , enter the lens at S_1 and become parallel to its axis. Thus, after leaving the lens at S_2 , since they are normal to S_2 , their direction remains unchanged. In this case, the active surface S_1 of the lens is a hyperbola in cylindrical lens, and hyperboloid in rotationally symmetric lens.

If the surface S_1 is spherical, it becomes inactive, since the focal point is a point source and rays emanating from

it constitute spherical waves. Thus, when S_1 is predetermined as a spherical surface, they enter the lens unaffected. Their collimation is done entirely by the lens' second surface S_2 . Its surface is again a conic section, and its cross section is elliptic. In the other two cases, both surfaces S_1 and S_2 of lens participate in beam collimation and consequently are interdependent and more complex.

2.1.1. Lens with Planar S_2 . On S_2 , x is constant and slope is infinite (Fig. 3) and the surface is defined by

$$\begin{aligned} x_2 &= F + T \\ y_2 &= y_1 \end{aligned} \tag{10}$$

A consequence of this is $L_1 = L_0$ in Eq. (2), and using Eq. (10) it becomes

$$r_1 + nr_3 = F \tag{11}$$

which, using Eqs. (10), becomes a function of x_1 and y_1 . It can be solved directly to yield the profile of S_1 as

$$y_1^2 - (n^2 - 1)(x_1 - F)^2 = 2(n - 1)F(x_1 - F) \tag{12}$$

or in polar coordinates

$$r_1 = \frac{(n - 1)F}{n \cos \theta_1 - 1} \tag{13}$$

They represent rectangular and polar equations of a hyperbola, which is the lens profile on S_1 . They can also be used to determine the lens thickness on the axis. For this, one can use two extreme rays, passing through the lens tip and the axis. The equality of the electrical lengths gives

$$F + nT = r_1(\theta_{1 \max}) = \left[\left(\frac{D}{2} \right)^2 + (F + T)^2 \right]^{1/2} \tag{14}$$

Figure 3. Geometry of lens with a planar surface S_2 .

A solution of this equation gives the lens thickness T as

$$T = (n + 1)^{-1} \left[\left(\frac{(n + 1)D^2}{4(n - 1)} + F^2 \right)^{1/2} - F \right] \tag{15}$$

and

$$\begin{aligned} \theta_{1 \max} &= \cos^{-1} \left(\frac{1}{n} \right) \\ &= \tan^{-1} \left(\frac{(D/2)}{F + T} \right) \end{aligned} \tag{16}$$

Equation (16) shows that, for a given dielectric, the lens aperture angular size is limited by its refractive index n . In other words, with common dielectrics there is a limit on the compactness of the lens. That is, the focal length F cannot be reduced beyond the limit specified by Eq. (16).

2.1.2. Lens with Planar S_1 . In this case, both lens surfaces contribute to the beam collimation. Its surface can be determined similar to the case (in Section 2.1.1) by enforcing $x_1 = F$ and infinite slope for S_1 (Fig. 4). The results are [3]

$$x_1 = F$$

$$x_2 =$$

$$\frac{\{[(n-1)T - [F^2 + y_1^2]^{1/2}][(n^2-1)y_1^2 + n^2F^2]^{1/2} + n^2F[F^2 + y_1^2]^{1/2}\}}{[n^2(F^2 + y_1^2)]^{1/2} - [(n^2-1)y_1^2 + n^2F^2]^{1/2}}$$

$$y_2 = y_1 \left[1 + \frac{(x_2 - F)}{[(n^2 - 1)y_1^2 + n^2F^2]^{1/2}} \right]$$

$$T = \frac{1}{2} (n - 1)^{-1} [(4F^2 + D^2)^{1/2} - 2F] \tag{17}$$

Figure 4. Geometry of lens with a planar surface S_1 .

Note that, since the beam collimation is due to both surfaces, the coordinates of S_2 are now dependent on those of S_1 .

2.1.3. Lens with One Spherical Surface. When S_1 is a spherical surface, all spherical wave originating at the focal point S pass through it unaffected. The second surface, S_2 , collimates the beam. The geometry is shown in Fig. 5, and S_2 is an ellipse given as

$$r_2 = \frac{(n - 1)R}{n - \cos \theta_2} \tag{18}$$

where $R = F + T$ and other parameters are as defined in Fig. 5. Its equation in rectangular coordinates has the form

$$y_2 = \left[\left[\frac{x_2 + (n - 1)R}{n} \right]^2 - x_2^2 \right]^{1/2}$$

and

$$T = \frac{1}{2} (n - 1)^{-1} [2F - (4F^2 - D^4)^{1/2}] \tag{19}$$

$$\theta_{2 \max} = \cos^{-1} \left(\frac{1}{n} \right)$$

the last equation again sets a limit for the peak angular aperture of the lens for a given dielectric material.

When the surface S_2 is assumed to be spherical, then both lens surfaces participate in collimating the beam. The inner surface S_1 can be obtained from [3]

$$n^2 [r_2^2 + r_1^2 - 2r_1 r_2 \cos(\theta_1 - \theta_2)] = [(n - 1)T + r_2 \cos \theta_2 - r_1]^2$$

$$n^2 r_1 \sin(\theta_1 - \theta_2) = \sin \theta_2 [(n - 1)T + r_2 \cos \theta_2 - r_1] \tag{20}$$

$$T = \left[\frac{4(n - 1)F^2 - (n - 3)D^2}{4(n - 1)(n - 3)^2} \right]^{1/2} + \frac{F}{n - 3}$$

Figure 5. Geometry of lens with a spherical surface S_1 .

3. EFFECT OF LENS ON AMPLITUDE DISTRIBUTION

The lens equations (1) to (6) were based on the ray path analysis, or in antenna terms, the *phase relationships*. The amplitude distributions were not considered. In practical applications, however, the amplitude distributions are also important and will influence the aperture efficiency of the lens, sidelobe levels, and cross-polarization. To state it briefly, a uniform aperture distribution gives the highest directivity, but has high sidelobes because of its high edge illumination. Sidelobes can be reduced by tapering the field toward the edge. Excessive tapering, however, rapidly reduces the lens directivity. It is therefore useful to know the influence of the lens on the field amplitude as well.

Assume that $A(\theta)$ is the angular dependence of the wave amplitude radiating from the focal points and $A(\rho)$, with $\rho = r \sin \theta$, the amplitude distribution of the collimated beam. Then, using the conservation of power, and neglecting the reflection at the lens surface, the following amplitude relationships can be obtained [1].

Hyperbolic lens of case in Section 2.1.1

$$\frac{A(\rho)}{A(\theta_1)} = \frac{1}{F} \left[\frac{(n \cos \theta_1 - 1)^3}{(n - 1)^2(n - \cos \theta_1)} \right]^{1/2} \tag{21}$$

Elliptic lens of case in Section 2.1.3

$$\frac{A(\rho)}{A(\theta_1)} = \frac{1}{F} \left[\frac{(n - \cos \theta_1)^3}{(n - 1)^2(n \cos \theta_1 - 1)} \right]^{1/2} \tag{22}$$

An inspection of these equations shows that in Eq. (21) the amplitude ratio decreases with θ_1 ; that is, after leaving the lens the field is concentrated near its axis. The amplitude, in fact, drops to zero at the angle $\theta_{1 \max}$, given by Eq. (16). This lens, therefore, enhances the field taper of the source and is a good candidate for low-sidelobe applications. However, its aperture efficiency will be low. In contrast, the amplitude ratio in Eq. (22) increases with θ_1 ; that is, this lens corrects the amplitude taper of the source and enhances the aperture efficiency, but in the process, raises the sidelobe levels. Thus, it may be used in applications in which the aperture efficiency is more critical than the sidelobe levels.

For most common dielectrics the refractive index is $n = 1.6$, (i.e., $\epsilon_r \cong 2.55$). For these materials the limit of the aperture angle is $\theta_{1 \max} = 51.3^\circ$. Within this limit the amplitude ratios of Eqs. (21) and (22), normalized to axial values, are shown in Table 1. The amplitude tapering of hyperbolic lenses is clearly evident. A 35° lens adds another 10 dB to the aperture field taper, and beyond 40° , the lens is practically useless. For large-angle-lens applications, higher-dielectric-constant materials must be used. Table 1 also shows the amplitude enhancement of elliptic lens. A 35° lens improves the aperture field uniformity by as much as 6.3 dB. It increases rapidly thereafter and yields about 10 and 20 dB improvements for lens angles of 45° and 50° , respectively. These amplitude enhancements, however, must be accepted as theoretical

Table 1. Amplitude Distributions^a for the Hyperbolic and Elliptic Lenses of Figs. 3 and 5

Amplitude ratio $\frac{A(\rho)}{A(\theta_1)}$		Ray Angle θ_1 (degrees)							
		0	10	20	30	35	40	45	50
Hyperbolic lens equation [Eq. (21)]	Relative value (dB)	1.0	0.928	0.733	0.466	0.328	0.196	0.084	0.008
		0.0	-0.65	-2.70	-6.64	-9.70	-14.17	-21.5	-41.75
Elliptic lens equation [Eq. (22)]	Relative value (dB)	1.0	1.060	1.26	1.69	2.06	2.67	3.17	9.25
		0.0	0.51	2.01	4.55	6.29	8.54	10.03	19.33

^aWhere $n = 1.6$, $\epsilon_r = 2.55$, $\theta_{1\max} = 51.3^\circ$.

limits, since at these wide angles the lens surface reflectivity will reduce the practically attainable levels. Surface matching layers must be used to minimize the reflections.

3.1. General Lens Design

In the general lens of Fig. 2, both surfaces are profiled and participate in collimating the beam. Thus, a more versatile lens can be obtained. However, Eqs. (1)–(6) showed that there are at least four unknown coordinates, x_1, y_1 and x_2, y_2 , to be determined. But, the optical relationships provided only three equations, which are not sufficient to determine uniquely the coordinates of both surfaces S_1 and S_2 . Another relationship must be generated, which may be imposed on the amplitude distribution $A(\rho)$, to control the directivity or sidelobes. Alternatively, one may impose conditions on the aperture phase errors. An important case is the reduction of phase errors due to the source lateral defocusing. This will allow beam scanning without excessive degradation in efficiency and sidelobe levels. In most cases, however, the problem is too complex for analytic solution and a numerical approval must be used.

4. ABERRATIONS

The term *aberration*, which originated in optics, refers to the imperfection of lens in reproduction of the original image. In antenna theory, the performance is measured in terms of the aperture amplitude and phase distributions. The phase distribution, however, is the most critical parameter and influences the far field significantly. It is therefore used in evaluating the performance of aperture antennas such as lenses and reflectors. With a perfect lens and a point source at its focus, the phase error should not exist. However, there are fabrication tolerances, and misalignments can occur that will contribute to aberrations. Even without such imperfections, lens antennas can suffer from aberrations. Practical lens feeds are horn antennas and small arrays. Both have finite sizes and deviate from the point source [2]. This means that part of the feed aperture falls outside the focal point, and rays emanating from them do not satisfy the optical relationships. Thus, on the lens aperture, the phase distribution is not uniform. Similar situations also occur when the feed is moved off axis laterally to scan the beam. Again, aperture phase error occurs as a result of pathlength differences. A somewhat different situation arises when the feed is moved

axially, front or back. In this case, the phase error is symmetric, as all the rays leaving the source with equal angles travel equal distances and arrive at the aperture at an equal radial distance from the axis, that is, on a circular ring. But the length of the ray increases, or decreases, with radial distance on the aperture. The phase error is, therefore, quadratic on the aperture and reduces the aperture efficiency, while raising the sidelobes.

The general aberration (i.e., the lens aperture phase error) can depend implicitly on both feed and lens coordinates and be difficult to comprehend. However, like all other phase-error-related problems, it can also be represented as the pathlength difference with a reference ray. For rotationally symmetric rays, the natural reference is the axial ray. The pathlength difference can then be obtained by a Taylor-type expansion of the general ray length in terms of the axial one. For small aberrations the first few terms in the expansion will be sufficient to describe the length accurately. In terms of the aperture polar coordinates ρ and ϕ , the expansion becomes

$$L(\rho, \phi) = L_{\text{axial}} + \alpha\rho \cos \phi + \beta\rho^2[1 + \cos^2 \phi] + \gamma\rho^3 \cos \phi + \dots \quad (23)$$

where α , β , and γ are constants indicating the magnitude of each phase error. The leading term is linear in ρ and ϕ , then becomes quadratic, cubic, and so on, and the magnitude of each depends on the nature of imperfection causing the phase error. The even terms are caused by either an axial defocusing or an axially symmetric error. The odd terms can be due to a lateral displacement of the feed, or asymmetric errors.

The effects of each error can be investigated by its introduction in the aperture field and determining the far field using a Fourier transformation or diffraction integral. For one-dimensional errors (i.e., $\rho = x$ and $\phi = 0$), the effect can be understood easily, and has been investigated by Silver [1]. The first term is linear and in a Fourier integral shifts, the transform variable. It thus causes a tilt of the beam, but the gain remains the same. Using Silver's notation, if $f(x)$ is the aperture distribution and $g(u)$ the far field, that is, its Fourier transform with a linear phase error, one finds, with no phase error

$$g_0(u) = \frac{a}{2} \int_{-1}^1 f(x) \exp[jux] dx \quad (24)$$

and with phase error

$$g(u) = \frac{a}{2} \int_{-1}^1 f(x) \exp[j(ux - \alpha x)] dx = g_0(u - \alpha) \quad (25)$$

where $u = (\pi a/\lambda) \sin \theta$ and a is the aperture length. Equation (25) shows that the beam peak is moved from the $\theta = 0$ direction to θ_0 calculated by

$$u - \alpha = 0$$

or

$$\theta_0 = \sin^{-1} \left(\frac{\alpha \lambda}{\pi a} \right) \quad (26)$$

A quadratic phase error is symmetric on the aperture and does not tilt the beam, but reduces its gain. For small values of β , it can be calculated analytically [1] and is given by

$$\begin{aligned} g(u) &= \frac{a}{2} \int_{-1}^1 f(x) \exp[j(ux - \beta x^2)] dx \\ &\cong \frac{a}{2} [g_0(u) + j\beta g_0''(u)] \end{aligned} \quad (27)$$

where $g_0''(u)$ is the second derivative of $g_0(u)$. Because of this phase error, the gain decreases progressively with increasing β , and eventually the beam bifurcates and maxima appear on either side of the axis. It also raises the sidelobe levels. Figure 6 shows typical pattern degradation due to this error.

The next important phase error is the cubic one that has odd power dependence on the aperture coordinate. However, this error not only tilts the beam but also reduces the gain, and asymmetrically affects the sidelobes, raising them on one side while reducing them on the opposite side. Its effect is therefore a combination of the effects of linear and quadratic phase errors. For small

errors its far field is given by [1]

$$\begin{aligned} g(u) &= \frac{a}{2} \int_{-1}^1 f(x) \exp[j(ux - \delta x^3)] dx \\ &\cong \frac{a}{2} [g_0(u) + \delta g_0'''(u)] \end{aligned} \quad (28)$$

where $g_0'''(u)$ is the third derivative of $g_0(u)$. For a few small phase errors the far fields of this phase error are shown in Fig. 7. They show clearly the beam tilt, the gain loss, and raising the sidelobes toward the beam tilt. They are known as *coma lobes*, after the corresponding aberration in optics. Also, because this phase error causes more severe pattern degradation than others, it should be eliminated, especially as it manifests mostly in beam scanning. Feed lateral displacements to scan the beam can readily cause coma lobes. Fortunately, a number of lens surface modifications have been found to reduce the effects of this error [3].

5. ZONED LENSES

So far, the equations used for lens designs equalized the ray path lengths. The frequency of operation, or its wavelength, did not enter the equations. Thus, in principle, they should function at all frequencies. However, the directivity of a lens depends on the lens aperture size D , and is often used for high gain applications. This results in large lens sizes in wavelength, and at microwave frequencies, in large physical sizes, both the aperture diameter D and thickness T . It can, therefore, become excessively heavy and difficult to use. Since the thickness of the lens can be several wavelengths, it can be reduced along the ray path in multiple wavelengths without altering the relative phase change. The process starts at the edge, where the thickness is zero. Moving down toward the axis, the thickness increases progressively until it becomes one wavelength. This thickness can be made zero without

Figure 6. Effect of quadratic phase error on the far-field pattern, reducing the mainbeam and raising the sidelobes.

Figure 7. Effect of cubic phase error on the far-field pattern, causing beam tilt and asymmetry in the sidelobes.

altering the phase. The process can be continued K times until one arrives at the lens axis. In practice, one must maintain a small thickness t_m to provide adequate mechanical strength, the value of which will depend on the lens size, the material strength, and the application type.

With zoned lenses, and neglecting t_m , because the thickness does not exceed one electrical wavelength, its thickness is limited to $\lambda/(n-1)$. Including the minimum thickness t_m , the total thickness is limited to $t_m + l/(n-1)$ regardless of the number of zones. The pathlengths in wavelength, however, are not equal. With K zones, the ray path at the edge will be longer by a length equal to $(K-1)\lambda$. This causes the frequency dependence of lens operation, limiting its bandwidths. Enforcing the commonly used Silver criterion for this aperture phase error [1] (i.e. $> 0.125\lambda$), the useful bandwidth of a lens with K zones can be calculated from [1]

$$\text{Bandwidth} \cong \frac{25}{K-1} \text{ percent} \quad (29)$$

Equation (29) is valid for small variations of λ and uniform aperture distributions. For taper distributions, the effect of phase errors is smaller and the actual bandwidth can exceed that of Eq. (29).

Zoning the lens can cause one additional and severe problem due to shadowing. Two adjacent rays from the focus can travel through two separate zones, resulting in a dark ring zone on the aperture. This occurs in the transmit mode, and causes a loss of directivity and increased sidelobe levels. In the receive mode, the energy falling on the shadow zones never reaches the lens focus and diffracts into the space, again causing reduction of gain and increased noise temperature. Figure 8 shows the geometry of a three-zone lens and shadowing due to R_1 and R_2 rays.

Zoning without shadowing is also possible, but should be done on the nonrefracting surface of the lens. In a hyperbolic lens, this should be done on the planar

backsurface. Shadowing will be eliminated, but phase errors still occur at the transition lines due to diffraction effects.

6. REFLECTION FROM LENS SURFACE

Because the wave impedance in air and the dielectric medium of lens are different, reflections occur for all the rays. The reflection coefficient depends on both the wave polarization and the angle of incidence, namely, the angle of ray with the local normal on the lens surface. Neither can be avoided. With a linearly polarized wave, the relative polarization, with respect to the plane of incidence, changes from perpendicular to parallel, as the ray direction rotates on the lens surface. However, their reflection coefficient behaves differently. For perpendicular polarization, it increases progressively with the incidence angle but for parallel polarization, it decreases initially, and after vanishing at the Brewster angle, increases rapidly. Consequently, incidence angles must be kept small, less than 30° , to minimize the polarization effects on the lens aperture distribution.

The surface reflection effects can be reduced, when warranted, by utilizing an impedance-matching layer between the lens and free space. At normal and small angles of incidence, the refractive index of the matching layer can be found using a quarter-wavelength transformer rule. It is the geometric means of the refractive index of the lens dielectric and that of air. In practice, a different dielectric material may be used as the matching layer, or it may be synthesized by preferentially removing a fraction of the dielectric material from the lens surface, such as drilling $\lambda/4$ holes or cutting grooves [4]. However, care must be taken to determine their polarization effects.

The surface reflections also influence the impedance mismatch at its feed. The problem is most severe in cases where the lens surface is coincident with one of the

Figure 8. Geometry of a zoned lens with shadowing effects.

equiphase surfaces, namely, the wavefront. Then, the entire reflected wave travels back to the feed, the degree of which depends on the lens refractive index. At normal incidence, since the reflection coefficient is $|R| = (n - 1)/(n + 1)$, the reflected power is unacceptably large for all common dielectrics, and a matching surface should be used. In the event that a matching layer cannot be used, the reflection effects on the feed can be minimized by lateral defocusing of the feed, or retuning of the feed over a narrow bandwidth.

7. LENSES WITH $n < 1$

Lens equations (1) to (6) were developed without specifying the value of the refractive index, and are therefore valid for $n < 1$ cases as well. However, the lens surface becomes inverted. For instance, the hyperbolic lens equation [Eq. (13)] for $n < 1$ modifies to

$$r_1 = \frac{(1 - n)F}{1 - n \cos \theta_1} \quad (30)$$

and the lens surface becomes elliptical, concave toward the focus, similar to Fig. 1b. On the inner region a minimum thickness t is required to provide mechanical strength. Zoning is also possible and will cause shadowing when incorporated on the actively refracting surface. The bandwidth limitations due to n remains the same as the dielectric lenses with $n > 1$. However, the lens media for $n < 1$ such as metal plates and waveguides are usually frequency-sensitive and exhibit narrower bandwidths.

8. CONSTRAINED LENSES

The function of a lens is to modify the phasefront of an incident wave, say, from spherical to planar. In practice, this may be accomplished by means other than the dielectric lenses. In most general cases, the lens surfaces consist of a plurality of receiving and radiating elements, interconnected by processing elements. The received signals on one surface are modified in amplitude and phase and reradiated from the elements of the next surface. In passive designs, the interconnection is due to transmission lines, such as parallel plates, waveguides, and even coaxial lines. The design process is similar to the dielectric lenses and is governed by the pathlength equation. Snell's law, however, is not satisfied at all surfaces, and the problem of surface reflection and transmission must be solved using the wave equation. Nevertheless, lenses can be designed with similar surfaces, but with inverted curvature, as the dielectric lenses [3].

The simplest case uses parallel plates, with spacing a , between 1λ and 0.5λ . When the electric field is parallel to the plates, a non-TEM waveguide mode is excited and has a wavelength λ_p given, in terms of the free-space wavelength λ , by

$$\lambda_p = \frac{\lambda}{\left[1 - \left(\frac{\lambda}{2a}\right)^2\right]^{1/2}} \quad (31)$$

which can be used to define an equivalent refractive index as

$$n = \frac{\lambda}{\lambda_p} = \left[1 - \left(\frac{\lambda}{2a} \right)^2 \right] < 1 \tag{32}$$

In cylindrical lenses, when the plates and electric field are normal to the cylinder axis, Snell’s law of refraction governs the transition between the lens and outside media. But when they are parallel to the cylinder axis, the incident rays are constrained to pass between the plates and Snell’s law is not satisfied [1].

An example of the rotationally symmetric constrained lens is the planar-elliptic surface lens of Eq. (30). It is usually zoned to reduce its size and weight [4]. Other useful transmission media are the rectangular and square waveguides, operating in TE₁₀ or TE₀₁ modes. The waveguide dimensions must be such that only these modes can propagate and higher-order modes are suppressed. The square waveguide can be used for circularly polarized applications, otherwise, must be avoided to reduce cross-polarization.

9. INHOMOGENEOUS LENSES

In the lenses studied so far, the refractive index *n* was constant and the shape was profiled to satisfy the ray path condition. On the other hand, if the lens shape is kept fixed, then another parameter, such as the refractive index, must be allowed to change in order to help in collimating the beam. This is achieved in a family of lenses, the most important ones of which are spherical in shape, such as Luneberg lens, Maxwell’s fish-eye, and Eaton lenses. Their spherical shape provides a perfect three-dimensional symmetry, useful in applications such as the wide-angle scanning. They also have only a radial inhomogeneity, making them both physically and electrically symmetric.

9.1. Luneberg Lenses

The term *Luneberg lens* refers to a family of lenses with two axial foci. They can be both outside the lens or one inside and the other outside. The most useful case, however, is the lens with one focus on its surface, while the second one is at infinity. Thus, an axial point on the lens surface is focused to an axial point at infinity, on the opposite side of the lens. The refractive index of this lens is given by

$$n(r) = \left[2 - \left(\frac{r}{a} \right)^2 \right]^{1/2} \tag{33}$$

where *a* is the lens radius and *r* is the radial distance of a point inside the lens. At the origin, the refractive index is *n*(0) = √2, and on its surface it becomes unity. Both are practically significant. The refractive index values and variations are in reasonable range, and the lens can be synthesized. Moreover, the unity of its refractive index on the surface eliminates the impedance mismatch and, consequently, the surface reflections. The geometry and

ray paths of this lens are shown in Fig. 9, with a feed horn on its surface. Scanning the feed on its surface scans the radiated beam, without alteration. The scan limit is set only by the mechanical limitation of the feed horn motion. With a spherical conducting cap on its surface the lens also acts as a perfect reflector (i.e., a back-scatterer; Fig. 10). The main difficulty with this lens is its fabrication problems. Multilayer shells are normally used to synthesize the refractive index inhomogeneity. Figure 11 shows one case, where 10 layers are used to construct an 18-in. diameter lens. While the approximation to a continuously variable refractive index is reasonable, the wave scattering at the layer transitions reduces the lens efficiency.

With the abovementioned refractive index, the Luneberg lens performance is ideal at the geometric optics limits, when the lens diameter in wavelength is large. At microwave frequencies, the wavelength is large and the lens diameter in wavelength may not be large. Its performance, namely, directivity, and sidelobe levels deteriorate rapidly. In such cases, the refractive index profile can be modified to improve its performance. This can be done by determining the excitation efficiencies of various spherical modes and calculating its far field and directivity [5]. The new dielectric permittivity profile is defined as

$$\epsilon_r = n^2 = 2B - A^2 \left(\frac{r}{a} \right)^2 \tag{34}$$

the constant parameters *A* and *B* are determined to maximize the gain. Three different cases are identified and investigated. Their refractive index profiles are shown

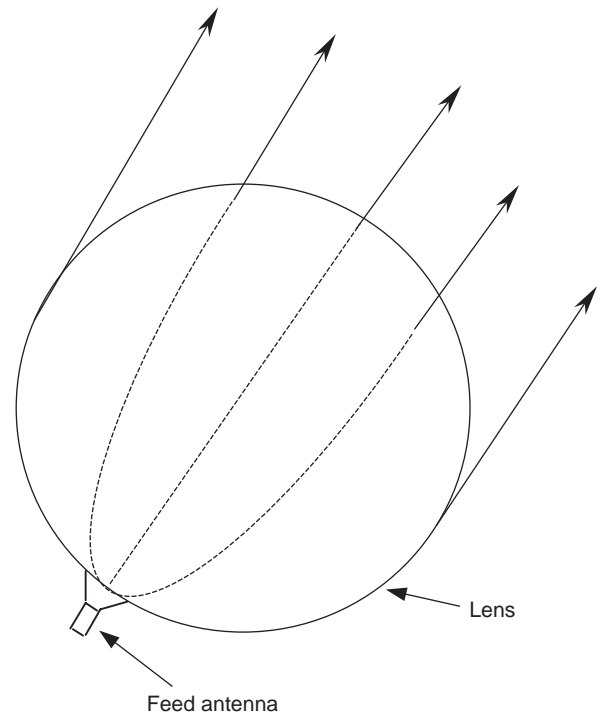

Figure 9. Typical ray paths in a Luneberg lens.

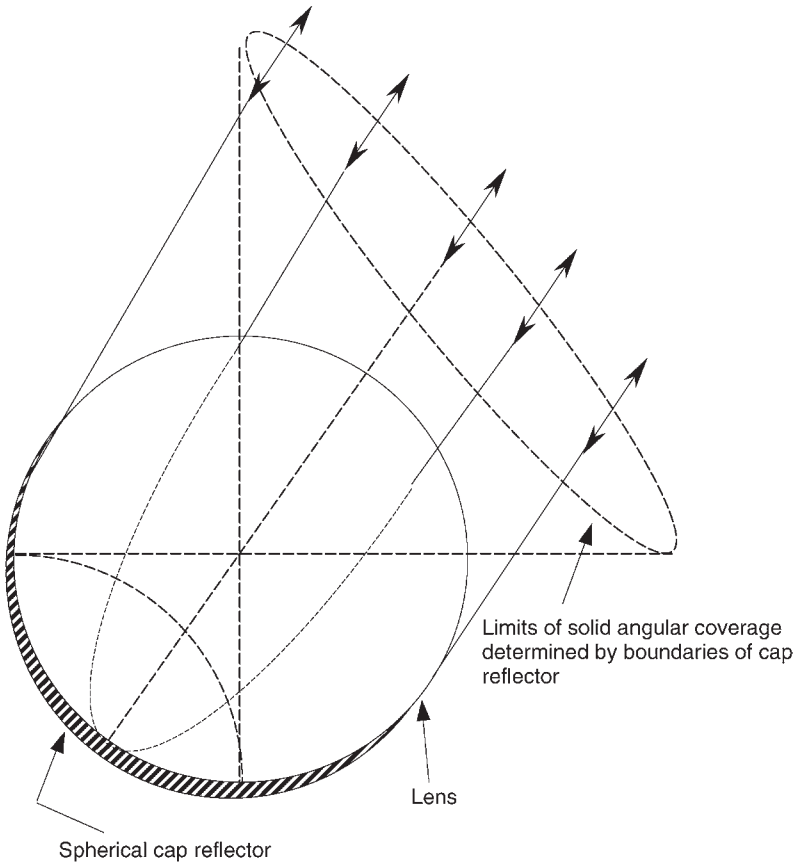

Figure 10. A passive Luneberg lens reflector returning the incident rays.

in Fig. 12. For case (a), $A=B=1$, which is the ordinary Luneberg lens. For profile *b*, $A=1$ and $B>0$, and the dielectric profile is the same as Luneberg lens with a constant increase given by $(2B - 2)$. In Fig. 12 profile *b* is for $B = 1.1$. For profile *c*, $B = 1$ and $A < 1$, which increases the lens permittivity at its surface ($A^2 = 0.95$ in Fig. 12). For profile *d* $A^2 = B$, and the dielectric profile falls between profiles *a* and *b*: ($A^2 = B = 1.1$ in Fig. 12). It gives a lens permittivity close to unity at its surface, which will

improve its impedance match to free surface. Profiles *b* and *c* give larger refractive indexes and are expected to perform better at lower frequencies. This is investigated

using the spherical harmonics, and the results for the directivity, sidelobe levels, and beamwidths are shown in Table 2.

9.2. Constant n Spherical Lens

The difficulty with fabrication of the inhomogeneous lenses encouraged investigators to search for quasi-ideal spherical lenses with constant refractive index. An interesting case is a lens with $\epsilon_r \cong 3$, studied earlier by Bekefi and Farnell [6] and more recently by Mason [7]. With a Huygen source feed at its surface, the computed phase distribution across its aperture, for different relative permittivities, is shown in Fig. 13. For $\epsilon_r \cong 3$, the phase error is below 10° , across about 60% of the aperture. It remains within acceptable range for gain calculated over at least 70% of the aperture, resulting in excellent gain performance over a wide range of frequencies. The only drawback seems to be the excitation of internal modes at their resonance. Their effect reduces with the loss tangent of the dielectric material.

10. DIELECTRIC-LOADED HORNS

Horn antennas are among the most useful and versatile antennas. They have a relatively simple shape and are easy to fabricate and use. They are used as test antennas, feeds for reflector and lens antennas, or independently as communication antennas. Because of their diverse applications, their electrical specifications vary considerably. As test antennas, they are used as gain standards and required to have good polarization isolation in the principal E and H planes. Rectangular horns are commonly used for this application to simplify the polarization definition and gain calculation. As a feed for reflector and lens antennas, the requirements are significantly different. While having a finite aperture size, they must behave as a point source, have small sidelobes and backlobes to minimize power spillovers, and have negligible cross-polarization in the entire radiation zone. To achieve such stringent requirements, their design must be precise and an accurate solution must be known to assess their performance. This is more so with circular horns and consequently have found more widespread applications as feeds than rectangular ones.

Electromagnetic analysis, however, has shown that conventional smooth-walled horns cannot provide radiation patterns with acceptable polarization purity and low spillover. Corrugated horns are developed for these applications, but are costly and narrowband. Dielectric loading of the horn has been shown to improve the performance and in certain applications may be used to replace corrugated ones.

In applications where horn antennas are used as independent communication antennas, gain and aperture efficiency may be the fundamental parameters to optimize. However, to obtain high gain, the horn aperture size must increase, which also increases the aperture phase errors. The phase errors can be maintained low by using small

Figure 13. Phase across aperture of a constant n spherical lens.

cone angles, but this increases the horn size. A convenient solution is then to use a lens at the horn aperture to reduce or eliminate the phase errors, by collimating the beam. Consequently, compact high-gain horns can be designed with controlled aperture phase and amplitude distributions, to improve the aperture efficiency and horn gain. Alternatively, lenses can be used to suitably modify the aperture distribution in both amplitude and phase to shape the radiation patterns.

In this section, initially the dielectric-loaded and lens-corrected horns will be discussed. Then, the use of dielectric in small antennas such as waveguides, microstrip antennas, and dipoles, will be considered, to improve their operation in specific applications.

10.1. Dielectric Loading

Historically, dielectric-cone loading inside smooth-walled conical horns was used by Clarricoats et al. [8], and Lier [9] to simulate the effect of corrugations. Corrugated horns, with quarter-wavelength corrugation depths, can support hybrid HE₁₁ mode. This mode radiates with low cross-polarization and can be designed to have negligible sidelobes. Introduction of the cone dielectric, with an airgap as shown in Fig. 14 inside a smooth-walled horn, was also shown to support hybrid modes and improve the performance. Clarricoats et al. [8] used low-dielectric-constant materials, such as foams with a relative permittivity of 1.13. But, in Lier’s work [9], solid-dielectric cones with a relative permittivity of 2.5 was used, again showing good performance. Both groups of investigators also analyzed these dielectric-loaded horns using modal expansions, and studied the effects of the airgap, horn permittivity, aperture diameter, flare angle, and the throat region. Airgap size was found to be strongly dependent

Figure 14. Geometry of a dielectric-loaded horn showing two possible dielectric insertions.

on the aperture diameter, and both are dependent on the dielectric permittivity. The airgap size generally increases with the horn diameter, and for a given diameter there is a minimum relative permittivity of dielectric to support the hybrid mode to minimize the cross-polarization. Both flare angle and the throat region have similar influences. Large flare angles, and asymmetric throat region design, excite higher-order modes and thus increase cross-polarization.

A variation of the conical dielectric-loaded horn is shown in Fig. 15. Its wall is profiled. A large flare angle near its throat reduces its axial length and results in a compact horn. Then, its small flare angle near the aperture improves the cross-polarization. The profile is described by the following equation

$$r(z) = r_{th} + 3\Delta r \left(1 - \frac{2z}{3L}\right) \left(\frac{z}{L}\right)^2 \tag{35}$$

$$\Delta r = r_{ap} - r_{th}$$

where r_{ap} and r_{th} are the horn radii at the antenna’s aperture and throat. A profile horn of this type was designed and optimized. Its performance is compared with the linear horn in Table 3. Its cross-polarization is improved by 4 dB. The effect of length reduction on the performance of the abovementioned profile horn is also shown in Table 4. It shows that the performance remains steady and comparable to a linear horn for length reductions by as much as 22%.

10.2. Lens-Corrected Horns

In high-gain horns, the aperture diameter in wavelength is large, and the horn length can be excessive, unless its flare angle is made large. But the combination of large aperture size and large flare angle can cause severe

Figure 15. Geometry of a dielectric-loaded profile horn.

Table 3. Performance^a of Dielectric Loaded Linear and Profiled Horns

Parameter	Linear Horn	Profiled Horn
3 dB beamwidth (deg)	14.8	13.7
10 dB beamwidth (deg)	26.9	24.8
Directivity (dBi)	22.1	22.5
Efficiency (%)	61.8	68.1

aperture phase error. This problem can be remedied by using a lens at the horn aperture. Figure 16 shows three possible options. These simple lenses and others, including zoned lenses, may be used, and would correct the horn aperture phase distributions. But each lens will have different influences on the aperture amplitude distribution. The properties of the first two lenses were investigated earlier, and Table 1 showed their effect on the amplitude distribution. Type (a) (in Fig. 16) increases the amplitude taper according to Eq. (21) and will reduce both sidelobes and the aperture efficiency. Type (b) will compensate for the amplitude taper, and according to Eq. (22), the lens permittivity can be used to control the aperture distribution, and thus the horn efficiency and the pattern sidelobes. For type (c), an analytic expression is not available and a numerical procedure must be used. However, as was indicated earlier with respect to this lens, both surfaces help in collimating the beam, but its second surface is similar to type (b) lens and its influence on the aperture distribution will be similar as well. With a hybrid-mode horn, corrugated or dielectric-loaded, the resulting aperture distributions for different lens relative permittivities are shown in Fig. 17, which shows that for ϵ_r around 1.22, the aperture amplitude distribution is nearly uniform.

11. DIELECTRIC-LOADED WAVEGUIDES

Waveguides have small aperture size and are not as efficient radiators as horns. Part of the energy leaks out and induces current on the outside wall, which radiates laterally and backward, causing large backlobes. The wave impedances of waveguide modes are also different from the free-space intrinsic impedance, and strong reflections can occur on the aperture, causing poor input impedance match. These problems can be partly overcome by

Table 4. Performance of Profile Horn with Length Reduction

Length (cm)	Peak Cross-Polarization (dB)	3 dB Beamwidth (deg)	Efficiency (%)
30.9	-36.0	13.7	68.1

15.0	-27.6	16.1	32.0

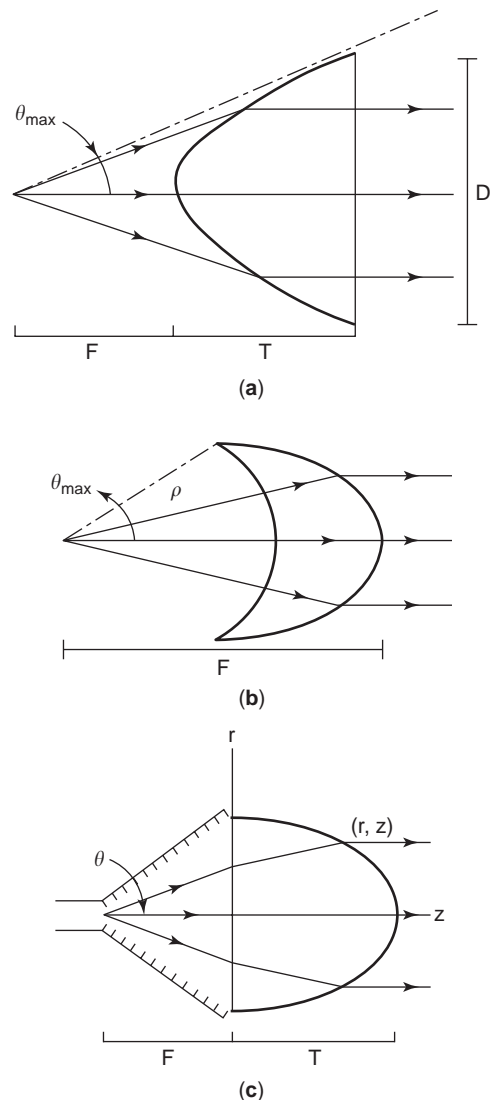

Figure 16. Three examples of lens types for loading horn aperture.

flaring the waveguide at its aperture. However, similar and even better performance can be obtained by loading the waveguide by a short section of a dielectric. The size and shape of the dielectric constant provide several parameters that can be used to shape the radiation patterns and tailor them to the desired specifications. Table 5 shows the results for three different end loadings, and the type of performance variations one could achieve [2]. Two other examples are shown in Figs. 18 and 19, with combinations of dielectric and cavity loadings [2]. In Fig. 18, the end geometry is optimized for nearly perfect pattern symmetry, with negligible cross-polarization. Figure 20 shows its copolar and cross-polar radiation patterns. In Fig. 19, the combination was again optimized for a heavily shaped radiation pattern, again with negligible cross-polarization in the forward direction. It is an ideal feed for deep parabolic reflectors with small $f/D = 0.25$. It provides high aperture efficiency of 81% due to its front pattern null, very low cross-polarization, and extremely

Figure 17. Aperture amplitude distribution for a lens corrected horn 30° semiflare angle hybrid-mode horn, type *c* lens.

low noise temperatures due to small f/D , the focal length : diameter ratio.

12. MICROSTRIP AND DIELECTRIC RESONATORS

Microstrip antennas are discussed in a separate article (see MICROSTRIP ANTENNAS), and usually consist of a conducting patch separated from a ground plane by a dielectric substrate. They are low-profile and increasingly popular antennas for practically any type of application. Their radiation patterns, however, are asymmetric with unequal *E*- and *H*-plane patterns. But, with careful optimization, the pattern symmetry can be achieved to

Figure 18. Geometry of a dielectric cavity-loaded waveguide feed.

minimize cross-polarization. Figure 21 shows a case of stacked patches with a side choke for equalizing the principal-plane pattern, low backradiation, and cross-polarization. Similar performance can also be obtained using a dielectric resonator in lieu of a microstrip patch. The dimensions of the dielectric resonator are related to the wavelength by

$$d = \frac{1.841\lambda}{4n\pi} \left[16 + \left(\frac{\pi d}{1.841h} \right)^2 \right]^{1/2} \tag{36}$$

The excited mode is the TM_{110} mode, and produces radiation similar to that of a microstrip patch. In Fig. 22, the resonator and the cavity are optimized for symmetric pattern in the principal planes to reduce the cross-polarization. They are shown in Fig. 23, with excellent symmetry. Both the microstrip and resonator antennas can be used as efficient reflectors and lens feeds with high aperture efficiency and low cross-polarization.

13. INSULATED ANTENNAS

Practically all antennas have conducting parts, but in certain families of antennas, especially small resonant

ones, the conduction current radiates directly. Typical examples are the wire antennas and microstrip antennas that are often half-wavelength resonators. In wire antennas, the current is excited by the applied voltage directly on the wire, which radiates in the surrounding space. In microstrip antennas, the currents are both on the patch and its ground plane, which are separated by a dielectric substrate. For this reason, only the patch current is

Figure 20. Radiation patterns of the waveguide feed of Fig. 18, showing perfect pattern symmetry and near negligible cross-polarization.

Figure 21. Geometry and radiation patterns of a stacked microstrip feed, with peripheral choke to minimize back radiation.

exposed to the surrounding medium. However, in either case, the physical constants of the medium are excessively lossy, and can short-circuit the antenna current and prevent its operation. In practice, this problem can occur in remote sensing and biological applications. In the former case, the antennas may be buried underground, or submerged in sea and ocean waters that have high electrical conductivities. In the latter case, the antennas are implanted into various types of body tissues that can have excessively high conductivities. In such cases, to ensure antenna operation, the conduction currents must be insulated from the surrounding conducting medium. A simple but effective method is to use a thin dielectric coating on the antenna conductor carrying the radiating currents. The coating will provide insulation between the

Figure 22. Geometry of a dielectric resonator antenna, showing a conducting cavity of height H and diameter D , with a dielectric disk of height h and diameter d .

Figure 23. Radiation patterns of the dielectric resonator antenna.

conducting antenna and the medium, thereby eliminating the conduction current. The excitation energy will then transfer into the pointing vector, leaving the antenna.

The behavior of the insulated antennas in a medium of complex permittivity differs considerably from that in free space, and should be analyzed carefully. For instance, consider a conventional dipole of length $2h$, as shown in Fig. 24. The wire is a good conductor and has a diameter of

Figure 24. Geometry of an insulated dipole antenna.

$2a$, insulated by a cylindrical dielectric region of diameter $2b$ and propagation constant k_1 , located in an infinite exterior region of k_2 . With a thin-wire approximation, the dipole current can be represented by a sinusoidal distribution of the form described in Ref. 10. The time factor is assumed to be $\exp(j\omega t)$

$$I(z) = \frac{-jV \sin k_L(h - |z|)}{2Z_{ca} \cos k_L h} \quad (37)$$

where

$$k_L = k_1 \left[1 + \frac{H_0^{(2)}(k_2 b)}{k_2 b H_1^{(2)}(k_2 b) \ln \frac{b}{a}} \right]^{1/2} \quad (38)$$

$$Z_{ca} = \frac{\varsigma_1 k_L}{2\pi k_1} \ln \left(\frac{b}{a} \right) \quad (39)$$

$$\varsigma_1 = \frac{\omega \mu_0}{k_1} \quad (40)$$

$$k_1 = \omega [\mu_1 \epsilon_1]^{1/2} \quad (41)$$

and $H_0^{(2)}$ and $H_1^{(2)}$ are Hankel functions of zero and first order. Note that with a perfect insulation dielectric k_1 is real but k_2 is complex due to the presence of Hankel functions in Eq. (38). It reduces to k_1 when b , the radius of the insulation, becomes infinitely large. In view of Eq. (38), the dipole current distribution, input impedance, as well as the radiation resistance, and the resonance frequency can depend strongly on the radius b and propagation constant k_1 , and k_2 , the propagation constant of the exterior region. The latter may not be fully known, or constant, during the application because of variations in moisture content and other variables. Thus, the insulation parameters should be selected appropriately to minimize the dependence of k_1 on k_2 .

14. MEDICAL AND BIOLOGICAL ANTENNAS

Another area in which insulated antennas play an important role is the biological and medical applications. They can be noninvasive (i.e., not penetrating the body) or invasive. In either case, the properties of insulated antennas can be significantly different from those in free space. Thus, care must be taken in their design and analysis to ensure adequate power transfer to the right tissue. Non-invasive radiators are often dielectric-loaded waveguides and horns, discussed in the previous section. The dielectric loading in this case is used to improve impedance matching and coupling to the body. Their design is not significantly different from those of other dielectric-loaded waveguides, except that the end shaping must prevent hotspots and improve penetration.

Microstrip antennas and arrays are other types of radiators suitable for noninvasive applications. However, their resonance property and power coupling to the body can be sensitive to the extent and nature of contact to the

skin. Dielectric coating over the radiating patch or slot can insulate the antenna and minimize the body's influence. This is due to the fact that, in microstrip antennas, the resonance depends on the effective dielectric constant, and not the actual substrate permittivity. With single-layer substrates of thickness h , this effective permittivity, for a conductor linewidth of W , is given by

$$\epsilon_{\text{eff}} = \frac{\epsilon_r + 1}{2} + \left(\frac{\epsilon_r - 1}{2}\right) \left(1 + \frac{12h}{w}\right)^{-1/2} \quad (42)$$

However, it can change significantly by introducing a higher permittivity layer over the substrate. Consequently, in biological applications, where the tissue relative permittivity can be excessively high due to the water content having $\epsilon_r \cong 80$, the nature of the proximity or contact with the body can alter ϵ_{eff} significantly [11]. Since microstrip antennas are narrowband, or at best not wide-band, the efficiency of their radiation and coupling to the body can be deteriorated. The effect can be reduced by introducing a superstrate layer over the microstrip antenna, to control the relative permittivity variations.

Invasive-type radiators can produce more uniform and controllable heating patterns, but they require implantation in the tissue. The most convenient types are the insulated needle radiator, basically the end of the coaxial line. However, this type of antenna can generate strong currents on the outer coaxial conductor and cause tissue heating behind the antenna. An improvement can be obtained by introduction of a quarter-wavelength choke over the coaxial conductor to form a sleeve antenna. Their analysis and sensitivity study can be carried out similar to the insulated dipole antennas. Figure 25 shows the geometry of needle and sleeve antennas.

15. NRD WAVEGUIDE ANTENNAS

A nonradiative dielectric (NRD) waveguide, shown in Fig. 26, consists of a dielectric slab sandwiched between two parallel conducting plates. It is known to have low resistive losses at high frequencies and useful structure for

design of low-loss circuit components, such as couplers, filters, and even amplifiers [12]. If an antenna can be designed using an NRD guide, it will be low-loss, and can be integrated with other NRD components. The resulting system of circuit-antenna combination will therefore be compact and provide high operating efficiency, useful in many high-frequency applications. However, in an NRD the field propagates within the dielectric slab and is cut off between the parallel plates outside the dielectric, where it attenuates exponentially. To cause radiation, therefore, one must expose its guided field to the external region. This can be accomplished in three different ways: (1) by cutting a slot on one of the conductors over the dielectric slab, (2) by terminating the parallel plates a short distance from the dielectric slab, and (3) by terminating the dielectric slab in free space.

In the first antenna type, cutting an aperture or slot on one of the conducting plates over the dielectric disturbs its guided field and causes the radiation [12,13]. However, the slot also causes discontinuities in the NRD guide that excites the dominant parallel-plate mode, which is not low-loss. In the second antenna type, the attenuating field between parallel plates leaks outside and radiates like a leaky-wave antenna [14,15]. This is a continuous radiation along the guide, and its radiation beam squints with frequency. The third antenna type radiates from the open end of the guide, and provided its termination geometry does not differ from that of the guide's cross section, it does not generate other modes [16]. It is therefore a well-behaved antenna and its radiation is due primarily to the guided mode of the dielectric. Its operation is discussed below.

Figure 26 shows the cross-sectional and end views of a conventional NRD guide [12]. The principal transverse field distributions are shown in Fig. 27, and in region I, which is the dielectric region, these fields are given by

$$E_{y1} = \frac{(K^2 \epsilon_r - \beta_y^2)}{j\omega\mu_0\epsilon_0\epsilon_r} \cos \frac{\pi x}{a} \cos(\beta_y y) e^{-j\beta_g z} \quad (43)$$

$$H_{x2} = \frac{j\beta_g}{\mu_0} \cos \frac{\pi x}{a} \cos(\beta_y y) e^{-j\beta_g z} \quad (44)$$

Figure 25. Implantable radiator types: (a) needle radiator; (b) sleeve antenna.

Figure 26. Geometry of NRD guide.

Figure 27. Fields in dielectric and air regions of NRD guide.

Between the parallel plates, in region II, the corresponding fields are

$$E_{y_2} = \cos\left(\frac{\beta_y b}{2}\right) \frac{(k^2 + \alpha_y^2)}{j\omega\mu_0\epsilon_0} \cos\left(\frac{\pi x}{a}\right) e^{-\alpha_y(|y|-b/2)} e^{-j\beta_g z} \quad (45)$$

$$H_{x_2} = j\cos\left(\frac{\beta_y b}{2}\right) \frac{\beta_g}{\mu_0} \cos\left(\frac{\pi x}{a}\right) e^{-\alpha_y(|y|-b/2)} e^{-j\beta_g z} \quad (46)$$

The guided field parameters in these equations are computed from the following transcendental equations:

$$\beta_g^2 = k_0^2 \epsilon_r - (\pi a)^2 - \beta_y^2 \quad (47)$$

$$= k_0^2 \epsilon_r - (\pi a)^2 + \alpha_y^2 \quad (48)$$

$$\beta_y \tan \frac{1}{2} \beta_y b = \epsilon_r \alpha_y \quad (49)$$

$$k^2 - \beta_y^2 = k_0^2 + \alpha_y^2 \quad (50)$$

Equations (43) to (46) can be used to define the equivalent electric and magnetic currents on the truncated aperture of Fig. 26, which can then be used to determine the radiation integrals [17]. The resulting far radiated fields in the principal planes are

$$\begin{aligned} E_{\theta(\phi=\pi/2)} &= E_{\theta}^0 [1 + \zeta_1 \cos \theta + \Gamma(1 - \zeta_1 \cos \theta)] \\ &\times \frac{b}{2} \left\{ \frac{\sin(b/2k \sin \theta + \beta_y b/2)}{b/2k \sin \theta + \beta_y b/2} \right. \\ &+ \left. \frac{\sin(b/2k \sin \theta - \beta_y b/2)}{b/2k \sin \theta - \beta_y b/2} \right\} \\ &+ E_{\theta}^0 [1 + \zeta_2 \cos \theta \\ &+ \Gamma(1 - \zeta_2 \cos \theta)] \left\{ \frac{2\epsilon_r \cos(\beta_y b/2)}{\alpha_y^2 + k^2 \sin^2 \theta} \right\} \\ &\times \left\{ \alpha_y \cos\left(\frac{b}{2k \sin \theta}\right) - k \sin \theta \sin\left(\frac{b}{2k \sin \theta}\right) \right\} \end{aligned} \quad (51)$$

$$\begin{aligned} E_{\phi(\phi=\pi/2)} &= E_{\phi}^0 \left\{ [\cos \theta + \zeta_1 + \Gamma(\cos \theta - \zeta_1)] \frac{1}{\beta_y} \sin\left(\frac{\beta_y b}{2}\right) \right. \\ &+ \left. [\cos \theta + \zeta_2 + \Gamma(\cos \theta - \zeta_2)] \frac{2\epsilon_r}{\alpha_y} \cos\left(\frac{\beta_y b}{2}\right) \right\} \\ &\times \left\{ \frac{\cos(ka/2 \sin \theta)}{(ka/2 \sin \theta)^2 - (\pi/2)^2} \right\} \end{aligned} \quad (52)$$

with

$$Z_{g1} = \frac{(k^2 \epsilon_r - \beta_y^2)}{k \epsilon_r \beta_g} \eta = \frac{\eta}{\zeta_1} \quad (53)$$

$$Z_{g2} = \frac{(k^2 + \alpha_y^2)}{k \beta_g} \eta = \frac{\eta}{\zeta_2} \quad (54)$$

where η is the free-space impedance. The parameter Γ is the reflection coefficient of the NRD guide radiating aperture, calculated using its wave impedance in Eqs. (53) and (54) and the free-space impedance.

An example of the radiation patterns is shown in Fig. 28. The dielectric region dimensions are 15×10.16 mm, and the relative permittivity is 2.55. At 9.5 GHz the impedance of the open-ended NRD guide is $z = 0.5940 + j0.5520$, which gives a reflection coefficient of $\Gamma = -0.1203 + j0.3380$. Other propagation parameters are shown in Table 6 [16]. Figure 28 shows an excellent agreement between the computed and measured radiation patterns, indicating that the single-mode operation of the NRD guide for this antenna type is a good assumption. The radiation patterns are also well defined and have a beam peak in the forward direction. The antenna is therefore a suitable candidate for single-element use or high-gain array applications.

16. ANTENNA MINIATURIZATION

Antenna miniaturization is an important issue in certain communication and mobile applications. Dielectric loading can be a useful tool for such applications, because for natural dielectrics the relative permittivity of the material is larger than unity. The velocity of electromagnetic waves

Table 6. Propagation Constants of NRD Guide

k_0	198.97
α_y	138.40
β_y	205.44
β_z	121.98

and their wavelengths within the dielectric medium, therefore, reduce by the square root of the relative permittivity. Since the waveguide and antenna dimensions are in terms of the wavelengths, they also become smaller inside dielectrics. Thus, the phenomenon can be used effectively for reducing the dimensions of the antennas. In certain applications, such as microstrip antennas, this is common knowledge, and for the case of dielectric resonators, it was discussed in Section 12. For other applications the case must be handled accordingly. An important issue is realization of the fact that the normal wavelength reduction by the square root of the relative permittivity occurs only inside infinite dielectric regions. In other cases, the effect is less and consequently an effective dielectric constant ϵ_{eff} is normally defined. For microstrip substrates this has been determined analytically, and was provided in Eq. (42). In most cases, however, the problem must be solved numerically. Here the case of a dielectric-coated monopole is discussed. Monopoles have a simple geometry and are important antenna candidates, but must be installed vertically, making them a tall structure. A reduction of their length can be very desirable in many applications.

Figure 29 shows the geometry of a dielectric coated monopole [18]. The dielectric material is a cylindrical ceramics of relative permittivity of $\epsilon_r = 38$, covering a conducting tube of diameter d_{in} and height 6.4 mm. The configuration is placed over an infinite ground plane and solved numerically using a finite-element method to determine its resonant frequency, impedance, return loss, and the bandwidth. The computed results are compared with measurements in Fig. 30 for the resonant frequency, and in Fig. 31 for the return loss.

Aside from a small frequency shift, the agreement is good. Figure 30 shows that, as the coating thickness

Figure 29. A cross section of the dielectric-coated antenna.

increases, the effect of the dielectric increases. This is manifested in the form of reduced resonant frequency as the monopole diameter is decreased, while keeping the coating diameter constant. In the limit of smallest monopole diameter, the resonant frequency is about 4.7 GHz, a reduction of about 2.4, as compared to its resonant frequency in free space. The effective permittivity is therefore about 5.8, which is much smaller than 38, the actual relative permittivity of the dielectric material. For larger effective permittivity values, one must either increase the dielectric thickness or increase its length beyond the monopole end. Since both of these solutions result in an increased size of the overall structure, a compromise must be made in any practical application.

17. GAIN ENHANCEMENT

Dielectric loading, when used judiciously, can be an effective means for increasing the gain of an antenna. The focusing effect of dielectric lenses was discussed in Section 2. This section addresses the case of planar dielectric loading. Lenses are not desirable solutions in some applications because of the high cost of fabrication or manufacturing tolerances at millimeter-wave frequencies. Simple planar dielectric layers are more desirable to

Figure 28. Measured and calculated radiation patterns of NRD guide.

Figure 30. Comparison of the calculated and measured resonant frequencies of antenna in Fig. 29.

use. They are natural in microstrip structures and cost-effective forms in most radome applications. When used properly, they can increase the antenna gain in proportion to their relative permittivity, compared to adjacent regions.

Figure 32 shows the geometry of a typical dielectric covered region. A planar dielectric layer of thickness t in region II is placed over another layer of thickness H in region I, which is over a conducting ground plane. Inside region I an antenna element is represented by an electric current I_0 , parallel to the ground plane and at a distance h . This problem was investigated by Jackson and

Figure 32. Antenna embedded in a two-layer planar dielectrics.

Figure 34. Variation of the cavity gain with its height H , $D = 2.0\lambda$, $\sqrt{\epsilon_r t} = 0.25$, $\epsilon_r = 10$.

Alexopoulos [18] using a transmission-line approximation. They have shown that the optimum thicknesses for maximizing the gain are given by

$$\frac{n_1 H}{\lambda_0} = \frac{m}{2}, \quad m = 1, 2, 3, \dots \quad (55)$$

$$\frac{n_2 t}{\lambda_0} = \frac{2n - 1}{4}, \quad n = 1, 2, \dots \quad (56)$$

$$\frac{n_1 h}{\lambda_0} = \frac{2p - 1}{4}, \quad p = 1, 2, \dots \quad (57)$$

and for this optimum thickness relationships the gain is approximately

$$\text{Gain} = 8 \frac{H}{\lambda_0} \left(\frac{\epsilon_2}{\epsilon_1} \right) \quad (58)$$

This indicates that, if region I is an air medium, then the antenna gain increases proportionally to the relative

permittivity of region II. For example, if the relative permittivity of region II is selected to be 100, then the antenna gain will increase by about 20 dB, over its gain without the presence of the dielectric layer. However, this gain increase is at the expense of the antenna gain bandwidth, which decreases inversely in terms of the relative permittivity.

The antenna spacing of Eq. (57) is not a hard rule and can be relaxed without a significant gain degradation. This allows the use of the other two parameters in Eqs. (55) and (56) to design radomes for gain enhancements. In an earlier study [19], the author placed a microstrip antenna at the bottom of a cavity that had a diameter $D = 2\lambda$. A radome was used to cover the cavity. From Eqs. (55) and (56) the optimum radome thickness is a quarter of a dielectric wavelength, and the optimum cavity height must be half-wavelengths. Figure 33 shows the antenna geometry, and Figs. 34 and 35 provide the variation of its gain with the cavity and radome thicknesses. The microstrip antenna gain without the radome was about 6 dBi, and the computed peak gains, in Figs. 34

Figure 35. Dependence of the cavity gain on radome thickness, $D = 2.0\lambda$, $H = 0.55\lambda$, $\epsilon_r = 10$.

and 35, are about 15.7 dBi, indicating an increase of about 9.7 dB, which is in good agreement with the prediction of Eq. (58). A set of measured gain patterns, in the principal E and H planes, are shown in Fig. 36. They confirm the predicted gain enhancement.

DIELECTRIC MEASUREMENT

R. BARTNIKAS
IREQ/Institut de Recherche
d'Hydro-Québec
Varenes, Québec
Canada

Dielectric measurements are concerned with the characterization of solid, liquid, and gaseous insulating materials over a wide range of DC and AC conditions at different frequencies, temperatures, field strengths, and pressures, under differing environments. The frequency range covered extends downward from the power frequency of 50 or 60 Hz through the ultralow frequency range from 10^{-2} to 10^{-6} Hz to DC and upward into the audiofrequency (AF), radiofrequency (RF), and microwave ranges and, finally, into the optical region for optically transparent dielectrics. It can be appreciated that a variety of specimen cells are required to suit the nature of the test and to act as containment vessels or holders for the specimens undergoing evaluation. The test methods and specimen containers used over the lower frequency spectrum differ substantially from those employed over the higher frequency spectrum (>300 MHz), because, at lower frequencies, the dielectric specimen behaves as a lumped circuit element, as opposed to its distributed parameter behavior over the higher frequency region, where the physical dimensions of the specimen become of the same order as the wavelength of the electric field. This delimiting difference necessarily requires other test procedures to be utilized at high frequencies, and constitutes perhaps the main reason for the bifurcation and the unfortunate, but often attending, isolation of the two fields of endeavor—even though the aim over the lower and upper frequency regions is identical, namely, the characterization of dielectric materials.

Space does not permit a detailed description of all the dielectric measurement procedures and, consequently, only a cursory presentation is made. Nor is it possible, within the given constraints, to delve into the various dielectric conduction and loss mechanisms in order to discuss the interpretative aspects of the measurement methods. Accordingly, the presentation is necessarily confined to a concise description of the most common methods of dielectric measurement employed currently. Wherever feasible, the methods given attempt to comply with the general guidelines of those specified in national and international standards, such as those by ASTM (American Society for Testing and Materials) and IEC (International Electrotechnical Commission), in order to put methods forward that are universally accepted and have withstood the test of time. The dielectric measurement methods presented here will deal principally with those of dc conductivity, dielectric constant and loss as a function of frequency, and voltage breakdown or dielectric strength.

1. DC CONDUCTIVITY MEASUREMENTS

1.1. Volume Resistivity (ρ_v)

Insulating materials employed on electrical equipment usually characterized by a high insulation resistance

and thus provide an isolating medium between adjacent components that are maintained at different potentials. In certain applications, such as for capacitor components, bushings, and cables, they must exhibit extremely low leakage current. In other applications, where partially conducting polymers are of interest, the insulation resistance values are substantially reduced. Insulation resistance measurements, which are generally carried out under DC conditions, yield not only data on the electrical conduction characteristics of a material, but may also provide an indication of the uniformity or impurity content of the insulating material. It is thus of considerable practical interest to classify the various insulating materials in terms of their DC insulation resistance, which can then be related to their DC electrical conductivity. The DC conductivity σ_{DC} of an insulating or dielectric material, is more fundamental property, as it bears a direct relationship to the conduction mechanisms taking place in the dielectric. It is defined as [1]

$$\sigma_{DC} = \frac{J_{iDC}}{E} \quad (1)$$

where J_{iDC} is the DC leakage or conduction current density in A/cm² and E is the direct electrical field in V/cm; the units of σ_{DC} are S/cm. If it is assumed that the DC conductivity arises from a drift of singly charged carriers e in the field direction, having a charge concentration n per cm³ and a mobility of μ in cm²V⁻¹s⁻¹, then Eq. (1) may be expressed as

$$\sigma_{DC} = e\mu n \quad (2)$$

The measured DC volume insulation resistance, R_v , is related to the DC volume resistivity of dielectric ρ_v by

$$\rho_v = \frac{A}{d} R_v \quad (3)$$

where A is the area of the measuring electrodes in cm² and d denotes the thickness of the dielectric specimen in cm; by definition, the DC conductivity is inversely related to the DC volume resistivity as

$$\sigma_{DC} = 1/\rho_v \quad (4)$$

such that the units of volume resistivity are in $\Omega \cdot \text{cm}$.

There are various specimen holder electrode systems and measurement techniques available for determining the volume insulation resistance R_v in terms of which the volume resistivity ρ_v may be computed, employing Eq. (3) [2–4]. For illustrative purposes, only the most prevalent ones in use will be considered. Figure 1 depicts a typical three-terminal electrode system with the dielectric specimen held between circular parallel-plane metallic electrodes. The electrodes are usually made of stainless steel, with the low-potential (guarded) electrode of diameter D_1 , having a diameter size less than the high-potential electrode, whose diameter D_3 is equal to that of the guarding electrode. The separation between the latter and the low-potential guarded electrode is equal to g , such that $g \leq 2d$,

Figure 1. Three-terminal electrode system for the measurement of volume resistivity (after ASTM D257) [3].

where d denotes the thickness of the dielectric specimen. The gap g between the low-potential and guard electrodes must be sufficiently large to prevent leakage over the surface of the dielectric from influencing the volume resistivity measurement; this is particularly important with high-input-impedance electrometers. A value of $g = 2d$ is most expedient, since it permits the measurement of both volume and surface insulation resistance with an identical electrode configuration.

The fringing of the flux lines essentially extends the guarded electrode edge into the gap region bounded by the measuring or low-potential electrode and the guard ring. Hence the area, A , in Eq. (3) is not the geometrical area of the low-potential electrode, but is approximately given [2] by

$$A = \frac{\pi(D_1 + g)^2}{4} \quad (5)$$

The determination of specimen thickness d in Eq. (3), does not present itself as a trivial problem [5]. Exact parallelism between the two opposite sides of a solid dielectric specimen is difficult to achieve, in practice. With polymers, it is common to make several thickness measurements along the specimen surface, either with a micrometer or a dial gauge, and then determine the average value of d . With most polymeric materials, the dielectric specimens will tend, in general, to conform to the surface of the measuring electrodes. However, with hard materials, the optically flat electrodes will generally not be contiguous with every portion of the surface of the dielectric. In such circumstances, the three-terminal electrodes must be either paint or vapor deposited on the rigid surfaces of the specimen. For this purpose, silver or aluminum is frequently employed, although aluminum is less desirable, because of its propensity to form nonconducting oxide films. Alternatively, tinfoil electrodes may be utilized, in conjunction

with a minute thickness of silicone grease, applied to ensure their adhesion to the specimen's surface. When liquid dielectrics are evaluated, permanently mounted three-terminal electrodes are employed, in conjunction with a cell container into which the liquid specimen submerges the measurement electrodes.

Figure 2 portrays a schematic three-terminal circuit diagram for the measurement of the volume insulation resistance R_v . Perhaps one of the most important considerations in the measurement of R_v is the time at which, following the application of the electric field, the actual measurement is made. When the voltage is suddenly applied across the specimen, the observed initial charging current is associated with the polarization of the dielectric; both the induced and permanent dipoles in the dielectric become aligned in the direction of the electrical field. Once this very rapid process is completed, the current commences a monotonic decline with time, as surplus free charge carriers are gradually swept out of the dielectric by the electric field. The nature of these charge carriers and their mobility are directly associated with the structure of the dielectric material. If the dielectric has an open structure, such as glass, the charge carriers may be ions; similarly, in a dielectric liquid such as an oil, where electrolytic contamination may be the source of the charge carriers, ions may be also responsible for the conduction current. In polymers, where the latitude of ionic motion is greatly restricted, the conduction process is frequently governed by electrons. Ideally, the R_v value should be measured when the conduction or the so-called leakage current attains a constant value, which is a function of the dielectric under test. For example, in a polymer, the value of constant current may be achieved when all excess free electrons have been removed from the dielectric and the residual leakage current is entirely determined by the trapping and detrapping rates of the electrons at the various traps (principally shallow traps). Thus, the number of migrating electrons at any one time approaches a constant value when an equilibrium is attained between the time each electron resides trapped in a well and the time it is free to migrate before it again becomes re-trapped. Since the complexity of the conduction process virtually ensures that different dielectrics are characterized by different times necessary for the leakage current to attain a constant value, it has been agreed *ad arbitrium* that all insulation resistance measurements should be made following a one-minute application of the electrical field.

Since the volume resistivity ρ_v of good insulating materials falls in the range from 10^{12} to $>10^{18} \Omega \text{ cm}$, the leakage current I_1 for such materials must be measured with a picoammeter, as indicated in Fig. 2. The guard circuit improves the accuracy of the measurement by reducing the influence of the leakage resistance. The effects of the coaxial cable resistance connected across the DC power supply can be greatly decreased by shunting the input of the coaxial cable to its shield, by means of an operational amplifier with unity gain; this feature is often incorporated in commercially available electrometer/ohmmeter instruments [6].

The volume insulation resistance R_v , in addition to being contingent on the time of the voltage application, is

Figure 2. Schematic circuit diagram for a three-terminal measurement of the volume insulation resistance.

also a function of the applied voltage V ; it is temperature-dependent as well. Thus, the value of V and the temperature must be specified; in general, the values of 100 and 500 V are most commonly employed [2,3]. Following one minute of voltage application, the value of R_v then calculated from

$$R_v = \frac{V}{I_1} \tag{6}$$

In the measurement of R_v an accuracy of 5% may be readily obtained. However, as the volume resistivity ρ_v is subsequently obtained in terms of Eq. (3), the accuracy of the ρ_v value is somewhat degraded, as a result of errors inherent in the measurement of the specimen thickness d and the estimation of the electrode area A [refer to Eq. (5)] when compensation for the field fringing effects is made.

1.2. Surface Resistivity (ρ_s)

Surface resistance R_s of solid insulating materials is, to a large extent, determined by the state of cleanliness or contamination of the surface of the dielectric under test. It is, as well, a strong function of surface moisture, particularly if the moisture film contains electrolytic impurities either intrinsic to the liquid film itself or as a result of solid ionic contaminants originally present on the solid dielectric surface. Surface resistance is thus a measure of the material's propensity to surface contamination and constitutes a useful indicator as concerns the surface tracking resistance of insulators when subjected to electric fields. It is common practice to condition the specimens prior to measurement in a dry atmosphere, before

performing the actual measurement at 50% relative humidity.

Surface resistance measurements may be carried out, either with two- or three-terminal electrode systems, although three-terminal electrodes are usually employed to eliminate stray leakage effects. The units of surface resistance are ohms or ohms per square. The latter refers to the arrangement of the electrodes, the configuration of a square, on the surface of the specimen, as depicted in Fig. 3 [2].

It is evident from the electrode arrangement in Fig. 3 that the surface resistance measurement also includes a contribution of the volume resistance. The magnitude of this contribution diminishes as the surface conductivity becomes increasingly greater than the volume conductivity. The procedure followed in measuring the surface resistance R_s is identical to that of R_v . The surface resistance is given by

$$R_s = \frac{V}{I_{s1}} \tag{7}$$

where I_{s1} is the surface leakage current and V is the voltage across the high-potential (H) and low-potential (L) electrodes. In Fig. 3, G represents the guard electrodes and g denotes the separation between the guard (G) and low-potential (L) electrodes. The surface resistivity ρ_s in ohms or ohms per square, is then determined from [2]

$$\rho_s = \frac{y}{x} R_s \tag{8}$$

where y denotes the length of the low-potential electrode (L) and x is the separation between the high- (H) and low- (L) potential electrodes. The electrodes may be applied with silver paint; alternatively, silver or aluminum electrodes may be deposited upon the surface under vacuum. Frequently, tinfoil electrodes are utilized with an extremely thin-layer film of silicone jelly applied on their underside, in order to provide adhesion on the specimen's surface.

Another approach is to employ the circular three-terminal electrode system of Fig. 2, but with the connections changed as portrayed in Fig. 4. Note that with this arrangement, the high potential is applied to the circular electrode (H) encompassing the center electrode, which

Figure 3. Schematic circuit diagram for the measurement of surface resistance with a three terminal electrode arrangement on the dielectric's surface [2].

Figure 4. Schematic circuit diagram of a three-terminal circular electrode arrangement for the measurement of the surface insulation resistance [3,6].

acts as the low-potential electrodes (L), while the upper electrode is connected to ground. In contradistinction to Fig. 2 (for volume resistivity measurements), the gap distance $g \geq 2d$; in analogy to Fig. 3, g is equivalent to the electrode separation distance, x . With circular electrode symmetry, the surface resistivity becomes [2,3]

$$\rho_s = \frac{\pi D_1}{g} R_s \quad (9)$$

where D_1 is the diameter of the low-potential electrode (L). The diameter of the upper grounded electrode (G) may be equal to or greater than that of the encompassing circular high-potential electrode (H).

2. PERMITTIVITY AND LOSS MEASUREMENTS ON LUMPED CAPACITANCE SPECIMENS

Under alternating voltages, dielectric materials are employed either as supports to insulate electrical components from each other and ground, or as dielectrics in capacitors. Some applications require dielectrics of low loss and low dielectric constant, while in others, high-dielectric-constant materials are desirable, to provide the highest possible capacitance for a given physical size. Thus two of the most important electrical properties of dielectric materials, in terms of which their use and application suitability at either low or high frequencies are assessed, are those of dielectric loss and dielectric constant.

The capacitance C of a parallel-plate capacitor containing a dielectric material having a relative real permittivity, ϵ'_r , may be expressed as

$$C = \epsilon'_r C_0 \quad (10)$$

where C_0 is the capacitance in vacuo and is given by

$$C_0 = \frac{\epsilon_0 A}{d} \quad (11)$$

where A is the area of the capacitor's plates in cm^2 , d the thickness of the dielectric, and ϵ_0 the permittivity in vacuo equal to 8.854×10^{-14} F/cm. By definition, ϵ'_r is equal to the ratio ϵ'/ϵ_0 , where ϵ' is the real value of the permittivity. Frequently, the relative real value of the permittivity ϵ'_r is simply referred to as the *dielectric constant*. The occurrence of loss in dielectrics, which may be associated with the migration of free charge carriers, space charge po-

larization, or the orientation of permanent dipoles, is manifest externally by a phase shift between the electric field (\mathbf{E}) and the displacement (\mathbf{D}) vectors [1]; consequently, the permittivity, ϵ , becomes a complex quantity of the form

$$\epsilon = \epsilon' - j\epsilon'' \quad (12)$$

where ϵ'' denotes the imaginary value of the permittivity. The total current density vector \mathbf{J} through the dielectric, composed of the leakage current density \mathbf{J}_l and capacitative or displacement current density \mathbf{J}_c vectors, may be expressed in terms of ϵ' and ϵ'' as

$$\begin{aligned} \mathbf{J} &= \mathbf{J}_l + \mathbf{J}_c \\ &= (\omega\epsilon'' + j\omega\epsilon')\mathbf{E} \end{aligned} \quad (13)$$

The phasor relationship between the current density vectors \mathbf{J}_l , \mathbf{J}_c , and \mathbf{J} is delineated in Fig. 5a with its corresponding RC equivalent circuit in Fig. 5b, in terms of which the dissipation factor ($\tan \delta$) of the dielectric specimen may be defined as

$$\tan \delta = \frac{J_l}{J_c} = \frac{I_l}{I_c} \quad (14)$$

where I_l and I_c are the corresponding current vectors. From Eqs. (14) and (15), it follows that

$$\tan \delta = \frac{\epsilon''}{\epsilon'} \quad (15)$$

Since the AC conductivity σ_{AC} is by definition, equal to \mathbf{J}_l/\mathbf{E} , then, in terms of Eq. (13), we obtain

$$\sigma_{AC} = \omega\epsilon'' \quad (16)$$

and

$$\tan \delta = \frac{\sigma_{AC}}{\omega\epsilon'} \quad (17)$$

The AC conductivity σ_{AC} must be distinguished from its DC value σ_{DC} because it may include permanent dipole

Figure 5. Current density phasor relationship in a dielectric (a) with its corresponding equivalent parallel RC circuit (b).

orientation losses, as well as frequency-dependent space charge polarization controlled carrier migration processes, which do not arise under DC conditions. It is readily apparent from the equivalent-circuit diagram, which represents the lossy part of a dielectric by an equivalent resistance, that

$$\begin{aligned} \tan \delta &= \frac{I_1}{I_c} \\ &= \frac{1}{\omega RC} \end{aligned} \tag{18}$$

where V is the applied voltage vector and I_1 is given by V/R and I_c by $j\omega CV$. It must be borne in mind that, the parallel equivalent RC circuit representation in Fig. 5b is valid only at one particular frequency, since both R and the capacitance C of the specimen are functions of frequency, as well as temperature and electric field. It must be further emphasized that, whereas some dielectric measurement circuits view the dielectric specimen as a parallel equivalent circuit with a large equivalent parallel insulation resistance R , others consider the dielectric as a series RC circuit, where the series resistance $R_s \ll R$. The $\tan \delta$ value for the series RC circuit representation becomes

$$\tan \delta = \omega R_s C \tag{19}$$

It is apparent that one can derive the primary dielectric parameters of σ_{AC} , ϵ'' , and ϵ' from the measured values of C and $\tan \delta$ by means of Eqs. (10), (15), and (17).

2.1. Measurements at Low Frequencies (from 10^{-6} to 10 Hz)

In studies related to the identification of charge carriers and space charge effects, it is desirable to carry out measurements in the frequency range between 10^{-6} and 10 Hz. For measurements below 10^{-1} Hz, it is common practice to apply a rapid risetime voltage step pulse across the specimen and subsequently observe the form of the charging or decay current. The arrangement for this measurement is very similar to that of the volume resistivity measurement in Fig. 2, with the exception that a switch is employed in conjunction with the DC power supply to abruptly apply a voltage step across the specimen [7,8]. Since the total charging current comprises all the frequency components contained within the voltage excitation step, Fourier transformation procedures can be utilized to derive the individual current distributions at the discrete frequencies. This procedure may be utilized irrespective of whether the specimen is charged or discharged. The relative real and imaginary permittivities ϵ'_r and ϵ''_r , respectively, may be expressed in terms of the resulting current as

$$\epsilon'_r(\omega) = \frac{1}{C_0 V} \int_0^\infty i(t) \cos \omega t \, dt + \frac{C_\infty}{C_0} \tag{20}$$

and

$$\epsilon''_r(\omega) = \frac{1}{C_0 V} \int_0^\infty i(t) \sin \omega t \, dt + \frac{G}{\omega C_0} \tag{21}$$

where V is the magnitude of the voltage step, C_∞ represents the lumped capacitance of the specimen at infinite frequency, and G is the DC conductance. Practical implications impose the upper and lower integration limits on Eqs. (20) and (21); the lower limit is fixed by the risetime of the electrometer employed (usually about 1 s) and the upper limit by the smallest value of current that the electrometer can measure (about 10^{-16} A) in the presence of extraneous noise. A numerical procedure is normally followed, to carry out these types of measurement [9]. For each frequency of measurement, the computer performs a numerical integration between the two integration limits to determine the values of ϵ'_r and ϵ''_r .

An automated precision time-domain reflectometer procedure is available that permits rapid measurements down to 10^{-4} Hz with an accuracy of 0.1% and a resolution of 10^{-5} in the $\tan \delta$ value [10,11]. Its schematic circuit diagram is depicted in Fig. 6.

Positive and negative voltage steps are applied across the specimen and the reference capacitors, C and C_{ref} respectively. The operational amplifier, in conjunction with the feedback capacitor C_f constitute a charge detector, providing an output that is proportional to the net charge injected [$Q_{ref} - Q(t)/C_f$] by the two opposite-polarity voltage steps of amplitude ΔV and $-\Delta V$, respectively. As the voltage across the specimen changes from 0 to ΔV , the charge $Q(t)$ flowing through the specimen is determined from

$$C(t) = \frac{Q(t)}{\Delta V} \tag{22}$$

where $C(t)$ denotes a time-dependent capacitance. Hence the complex capacitance of the specimen $C^*(\omega)$, as a function of frequency, may be expressed as

$$\begin{aligned} C^*(\omega) &= C'(\omega) - jC''(\omega) \\ &= \int_0^\infty C(t)' \exp[-j\omega t] dt \end{aligned} \tag{23}$$

where $C(t)'$ is the time derivative of $C(t)$. The relative real and imaginary permittivities, ϵ' and ϵ'' , are then deduced from

$$C'(\omega) \simeq \int_0^\infty C(t) \cos \omega t \, dt + C(0) + C_{ref} \tag{24}$$

and

$$C''(\omega) \simeq \int_0^\infty C(t) \sin \omega t \, dt \tag{25}$$

where $C'(\omega)$ and $C''(\omega)$ are the real and imaginary capacitances corresponding to $\epsilon'_r C_0$ and $\omega \epsilon''_r C_0$, respectively; $C(0)$ is the initial capacitance and the integration is

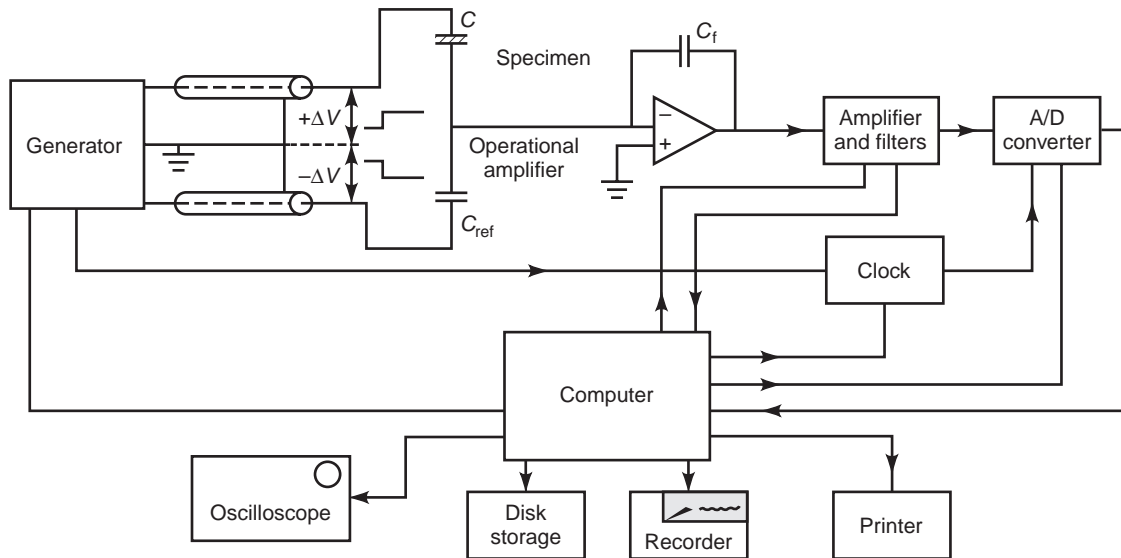

Figure 6. Schematic circuit diagram of time-domain system for measurements down to 10^{-4} Hz [10].

carried out for all times following the application of the voltage step at $t=0$. The minimum and the maximum feasible measurement times t_{\max} and t_{\min} determine the minimum and maximum measurement frequencies $\omega_{\min}/2\pi$ and $\omega_{\max}/2\pi$, respectively. The entire measurement is completed in less than one cycle at $\omega_{\min}/2\pi$.

A most useful instrument, which is frequently employed in the range from 10^{-2} to 10^2 Hz and occasionally up to 10^4 Hz, is the Thompson–Harris bridge [12,13]. A two-terminal specimen cell is utilized in conjunction with the bridge, so that a correction must be made to take into account fringing effects at the electrode edges. The schematic circuit diagram of the bridge, portrayed in Fig. 7, incorporates a specimen biasing feature [14], which is included to permit the determination of the depth of charge traps in the dielectric bulk and adjacent to the measuring electrodes.

The highly regulated frequency generator used in conjunction with the Thompson–Harris bridge must provide

exact in-phase and quadrature voltage outputs of V and jV , respectively. Operational amplifiers delineated in Fig. 7 provide the necessary voltage, phase, and impedance relationships. The capacitive current of the specimen is balanced by the injection of an out-of-phase voltage $-\beta V$ across a variable capacitor C_c ; injection of a quadrature voltage of αjV across C_R compensates for the conduction or leakage current in the specimen conductance G_x . Balance of the bridge is achieved by manipulating the capacitors C_C and C_R and observing the null point, in terms of the Lissajous figures displayed on the long-persistence oscilloscope. At balance, the conductance of the specimen G_x is given by

$$G_x = \omega \alpha C_R \quad (26)$$

and the capacitance of the specimen C_x is

$$C_x = \beta C_c \quad (27)$$

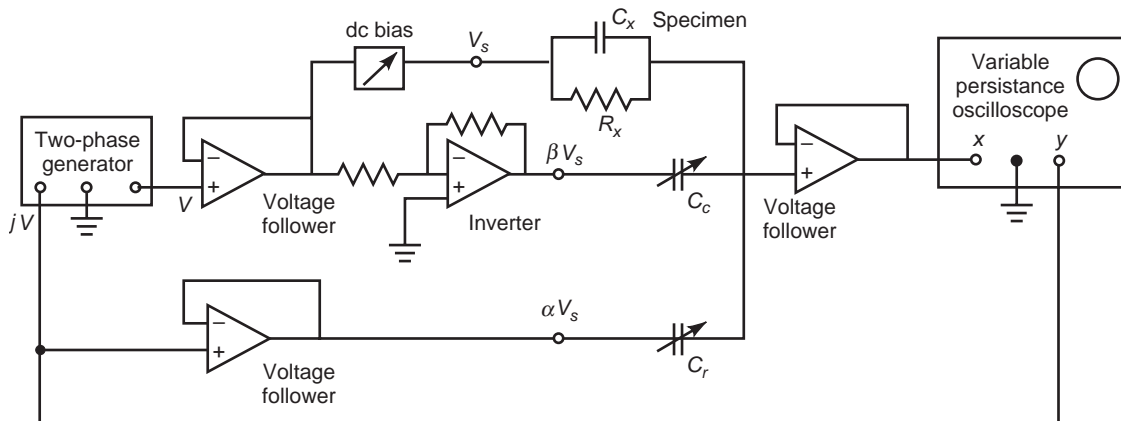

Figure 7. Thompson–Harris low-frequency bridge with specimen bias control feature [14].

from which the dissipation factor of the dielectric ($\tan \delta$) is obtained as

$$\begin{aligned}\tan \delta &= \frac{G_x}{\omega C_x} \\ &= \frac{\alpha C_R}{\beta C_c}\end{aligned}\quad (28)$$

Note that α and β are dimensionless quantities, representing the fraction of the voltage, V_s injected across C_R and C_c , respectively.

Not indicated in Fig. 7 is a zero-offset feature, which is utilized in routine measurements to compensate for the DC coupling circuitry, in order to prevent erratic shifts in the Lissajous figures while balancing is being carried out. The accuracy of the bridge is 0.1% with resolution ordinarily better than 0.1%.

Frequency response analyzer methods may also be employed for low-frequency measurements. These computerized techniques perform adequately well within the range from 10^{-4} to 10^4 Hz [15].

2.2. Power and Intermediate-Frequency Methods (10 Hz–1 MHz)

A considerable portion of the electrical insulating materials manufactured for use in electrical apparatus and cables are evaluated within the frequency range from 50 Hz to 1 MHz, employing primarily bridge type circuits. A further substantial portion of tests at high voltages are carried out at fixed power frequencies of 50, 60, and 400 Hz. The bridge circuits designed for power frequency applications, where measurements are normally made as a function of voltage, differ significantly from those involving measurements as a function of frequency at low voltage. Since most of these tests are performed by means of either Schering or transformer ratio arm bridges, the discussion here will be essentially confined to these types of bridges.

A common low-voltage Schering bridge arrangement, which employs the parallel substitution technique recommended in ASTM D150 [16], is depicted in Fig. 8 for the case where measurements are carried with a two-terminal specimen cell.

Figure 8. Low-voltage Schering bridge, employing the parallel substitution technique in accordance with ASTM D150 [16].

The capacitance C_3 is selected such that its negligibly small dielectric losses are approximately equal to those of the intrinsically low-loss standard capacitor C_s . Note that the Schering bridge views the specimen as an equivalent series $R_x C_x$ device, so that the variable arm composed of the parallel combination of R_1 and C_1 must be capable of compensating for the losses in the small series resistance R_x of the specimen. The null detector, which is normally an amplifier, is tuned to the frequency of the measurement, $f = \omega/2\pi$. Balance is first obtained by an adjustment of the capacitors C_1 and C_s , with the specimen disconnected. Then, with the specimen placed in parallel with the standard capacitor C_s , the bridge is rebalanced. The specimen capacitance C_x is thus determined from

$$C_x = C'_s - C''_s \quad (29)$$

and the dissipation factor from

$$\tan \delta_x = \frac{\omega R_1 C'_s (C''_1 - C'_1)}{(C'_s - C''_s)} \quad (30)$$

where C'_1, C'_s , and C''_1, C''_s denote the values of the variable capacitors C_1 and C_s at balance with the specimen disconnected and reconnected, respectively. The substitution technique eliminates the errors introduced by the coupling effects of the various stray capacitances, but it does not circumvent errors arising from connecting lead influences.

The procedures for the correction of lead and stray capacitance effects have been standardized and are explicitly enumerated in ASTM D150 [16]. It is the inductance, L_s , and the resistance R_s the leads, which contribute to the apparent increase of the capacitance ΔC and the dissipation factor $\Delta \tan \delta$ in accordance with the relations [16]

$$\Delta C = \omega^2 L_s C^2 \quad (31)$$

and

$$\Delta \tan \delta = \omega R_s C \quad (32)$$

where C is the true capacitance of the specimen; it is to be emphasized that, as the skin effect increases with frequency, the lead resistance R_s increases significantly with the square root of the frequency, $f = \omega/2\pi$. A standard practice for assessing the effect of the leads is to perform a measurement on a miniature sized capacitor, where the latter is first directly connected to the bridge terminals and then inserted across the far end of the leads. The difference between the two readings permits the calculations of ΔC and $\Delta \tan \delta$.

The appearance of an edge capacitance C_e and a ground capacitance C_g will lead to an increase in the measured apparent capacitance

$$C_a = C + C_e + C_g \quad (33)$$

and an apparent dissipation factor

$$\tan \delta_a = \frac{C \tan \delta}{C_a} \quad (34)$$

The relative real and imaginary permittivity ϵ'_r and ϵ''_r will then be given by

$$\begin{aligned} \epsilon'_r &= \frac{C}{C_0} \\ &= \frac{C_a - (C_e + C_g)}{C_0} \end{aligned} \quad (35)$$

and

$$\epsilon''_r = C_a \tan \delta_a / C_0 \quad (36)$$

For the normal type of specimen dimensions, where the parallel-plane cylindrical electrodes are smaller than the diameter of the specimen, the capacitance in vacuo C_0 with edge effect correction, may be expressed empirically in pF as [16]

$$C_0 = 0.006954 \frac{D^2}{d} \quad (37)$$

where d is the thickness of the specimen and D the diameter of the electrodes in mm. Exact formulas for the edge correction may be found in Ref. 17; the use of the exact formulas does not result in a significant difference for the correction. As with all dielectric measurements, the accuracy attainable is contingent not only upon the accuracy of the observed capacitance and $\tan \delta$ values, but also on the stray and edge effects of the electrodes employed, as well as the calculated interelectrode vacuum capacitance C_0 . In general, the permittivity is determinable to within $\pm 1\%$ and the $\tan \delta$ value to within $\pm(5\% + 0.0005)$ [16].

The circuit of a power frequency high-voltage Schering bridge, portrayed in Fig. 9, represents essentially an inverse arrangement of its sibling low-voltage bridge equivalent. The lower bridge arms of R_4 , C_4 , and R_3 constitute

Figure 9. Classical power frequency circuit of high-voltage Schering bridge with Wagner's Earth [2].

the balancing elements, while the upper arms of the series representation of the specimen, R, C , together with the standard capacitor, C_s , which have a high impedance in comparison with the lower resistive arms, assume the major portion of the voltage drop. This arrangement provides the bridge with an inherent safety feature, since the lower arms where balance manipulation of the bridge is carried out, remain at low potential. Figure 9, which represents the classical Schering bridge circuit, delineates also the guard circuit's balancing elements R_5 and C_5 , arranged in accordance with the so-called Wagner's Earth method. The guard circuit, which is implemented in order to eliminate the stray capacitance to ground, necessarily entails the use of a three-terminal measurement procedure. The solid dielectric slab specimen is placed in a three-terminal cell of the type depicted in Fig. 1, or if the specimen is a liquid dielectric, a concentric coaxial electrode cell [18] may be employed. Frequently, the specimen undergoing test may be a high-voltage power cable or stator bar, whose high-voltage terminated ends must also incorporate a guard circuit [19]. The standard capacitor C_s , which must be partial-discharge-free up to the maximum measurement voltage, is normally a 100 pF compressed-gas-filled unit with negligible dielectric loss. Note that the low-voltage arms are enveloped in grounded shields; the shield, screening the low-potential electrodes of the specimen and standard capacitor, including the detector that normally comprises an amplifier tuned to the power frequency, eliminates the stray capacitances to ground and between the components themselves. Thus, any capacitance current, which may develop between the detector and the high-voltage portion of the bridge, flows directly to ground via the auxiliary bridge arm of R_5 and C_5 . Since the latter are interposed between the shield and the bridge ground, their manipulation balances the guard or shield circuit. The switch SW , shown in Fig. 9, permits the necessary independent balancing steps for the bridge guard circuit and the bridge itself. At balance, the capacitance of the specimen [2] is given by

$$C = \frac{C_s R_4}{R_3} \quad (38)$$

and for equal self-inductances inherent with the resistive elements R_3 and R_4 , the dissipation factor reduces to

$$\tan \delta = \omega R_4 C_4 \quad (39)$$

Since high-voltage Schering bridges are normally designed to operate at one fixed power frequency, the dials of R_3 and C_4 are calibrated to read directly the capacitance and $\tan \delta$ values of the specimen, respectively. It is to be emphasized that, under high voltage conditions, should the specimen under test undergo partial discharge, then the indicated $\tan \delta$ value will reflect the power losses due to partial discharges, in addition to the dielectric losses occurring in the solid, liquid, or solid-liquid insulating system of the specimen [20].

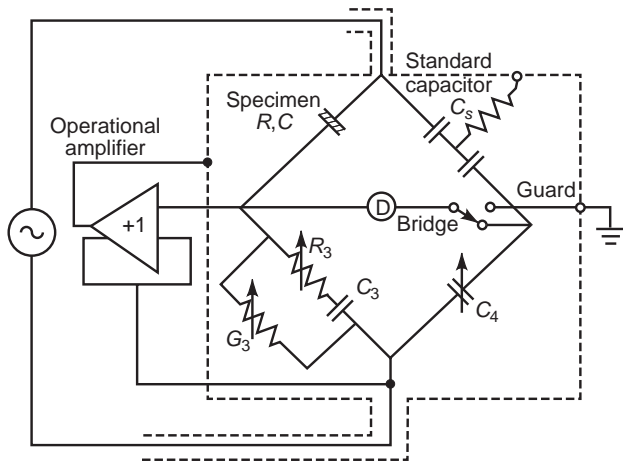

Figure 10. Schematic diagram of precision Tettex Schering bridge for measurements at power frequency [21].

Present high-voltage fixed power frequency Schering bridges employ a driven or active guard technique for balancing of the guard circuit in lieu of the classical Wagner’s Earth method. In this approach, the guard circuit and the detector, *D*, are maintained automatically, at the same potential, by means of a unit gain operational amplifier, whereby only a single balance step is required for the bridge. This feature, together with other improvements in the Schering bridge, is well exemplified in the Tettex precision Schering bridge, which has been designed for use on thin dielectric specimens up to 2 kV; its circuit is depicted in Fig. 10.

The bridge is limited in voltage, since now the lower arms are capacitive in nature, in order to attain a higher sensitivity as the stray capacitances are thus greatly reduced. The capacitance of the specimen, *C*, is obtained by

an adjustment of *C*₄ to yield

$$C = \frac{C_s C_3}{C_4} \tag{40}$$

and the value of $\tan \delta$ at the null is obtained by adjustment of *R*₃; the already low dielectric loss standard capacitor *C*_s is artificially reduced to zero, such that the $\tan \delta$ value of the specimen becomes

$$\tan \delta = \omega R_3 C_3 + \frac{G_3}{\omega C_3} \tag{41}$$

In the measurements carried out with Schering bridges, the capacitance and $\tan \delta$ values of the dielectric specimens are obtained in terms of the resistance and capacitance elements of the bridge. Hence, the precision and accuracy of the measurements are determined by the accuracy of these resistances and capacitances themselves. Precise dielectric measurements may also be performed by means of an inductively coupled voltage divider, utilizing a transformer arrangement, thereby circumventing some of the accuracy and stability constraints associated with resistive and capacitive elements [2,22]. Perhaps one of the finest precision/accuracy commercially available transformer ratio arm bridges for variable-frequency measurements in the range from 10 Hz to 100 kHz is that of Gen Rad, under the designation type 1621 transformer ratio arm bridge. Its schematic circuit diagram is delineated in Fig. 11. A 12-digit readout of the specimen capacitance *C*_x with a 10 ppm accuracy is provided within the range from 10⁻⁷ to 10 μF. A basic accuracy of 0.1% is attainable for conductance *G*_x measurements within the range of 10⁻¹⁰–10³ μS—that is, a $\tan \delta$ value of 10⁻⁷ at 1 kHz may be determined with a four-figure resolution.

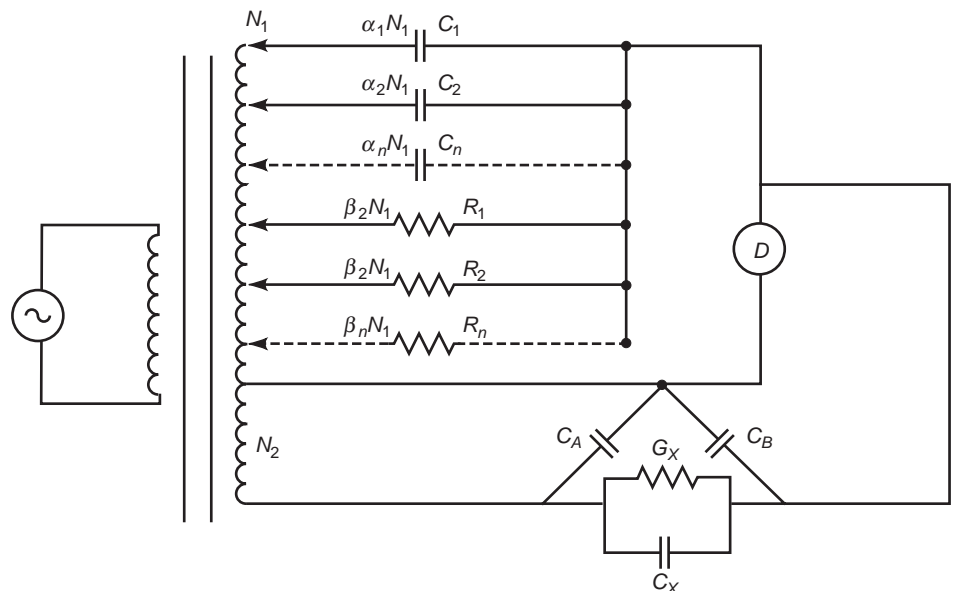

Figure 11. Basic circuit of Gen Rad type 1621 precision transformer ratio arm bridge [23].

The capacitances C_A and C_B shunting the transformer winding and the specimen, respectively, do not introduce any error into the measurement, since the former produces only a reduction of the voltage across the specimen, while the latter causes only a decrease in the sensitivity of the detector D . In balancing the bridge, the multiple tapped transformer principle is utilized in the course of the resistive and capacitive decade adjustments. Accordingly, the balance equation at the null of the bridge is given by

$$N_2(G_x + j\omega C_x) = N_1[(\beta_1 G_1 + \beta_2 G_2 + \dots + \beta_n G_n) + j\omega(\alpha_1 C_1 + \alpha_2 C_2 + \dots + \alpha_n C_n)] \quad (42)$$

Equating the real and imaginary terms yields the capacitance of the specimen

$$C_x = \frac{N_1}{N_2}[\alpha_1 C_1 + \alpha_2 C_2 + \dots + \alpha_n C_n] \quad (43)$$

and the conductance

$$G_x = \frac{N_1}{N_2}[\beta_1 G_1 + \beta_2 G_2 + \dots + \beta_n G_n] \quad (44)$$

The dissipation factor of the specimen as a function of frequency is obtained as

$$\begin{aligned} \tan \delta &= \frac{G_x}{\omega C_x} \\ &= \frac{[\beta_1 G_1 + \beta_2 G_2 + \dots + \beta_n G_n]}{\omega[\alpha_1 C_1 + \alpha_2 C_2 + \dots + \alpha_n C_n]} \end{aligned} \quad (45)$$

Note that the transformer ratio arm bridge views the dielectric specimen as an RC parallel equivalent circuit.

A computer-controlled automatic transformer ratio arm has been developed for measurements at power frequencies under high-voltage conditions [24]. The bridge circuit is delineated schematically in Fig. 12, in which the

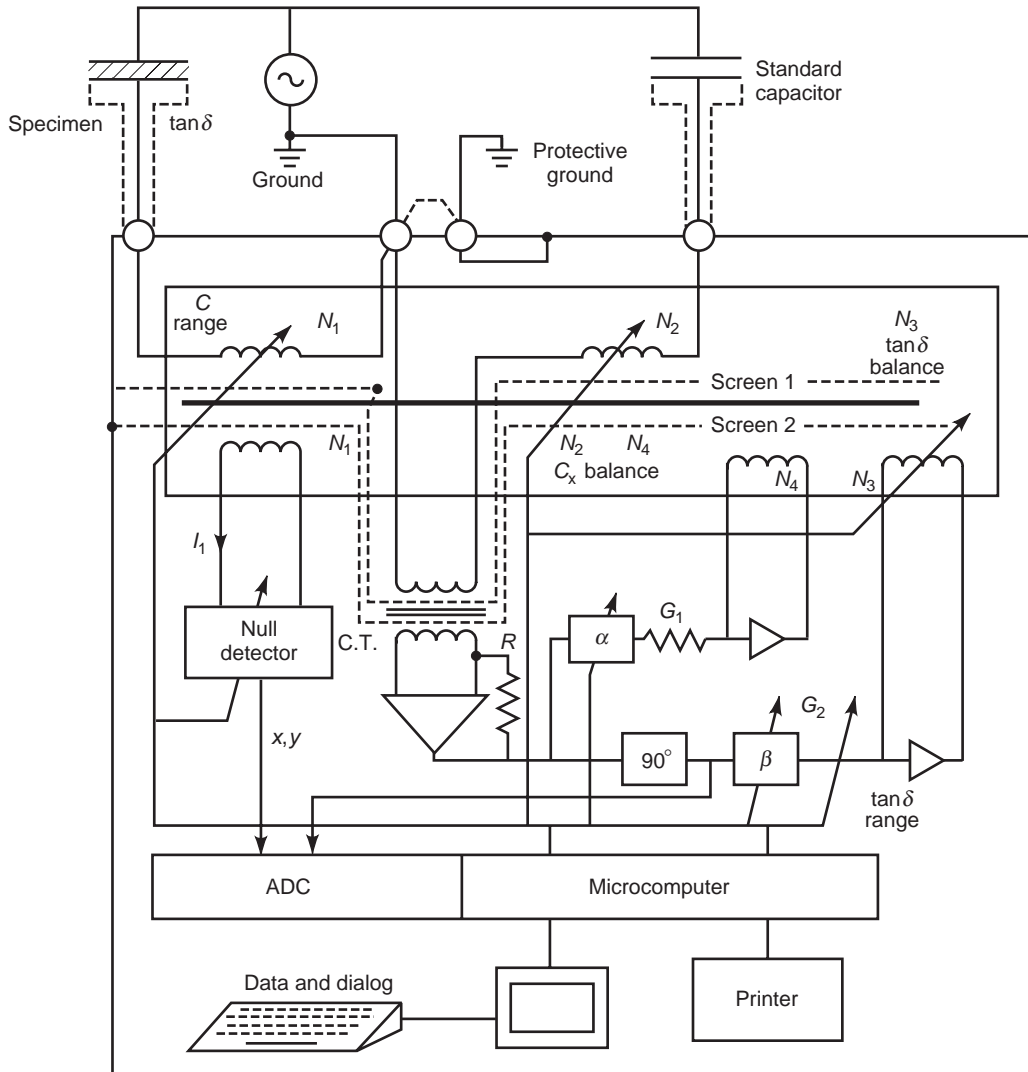

Figure 12. Automated power frequency transformer ratio arm bridge with computer control for measurements at high voltages [24].

coarse and fine balances are obtained by variation of the current comparator windings N_1, N_2 and N_3, N_4 , respectively. The currents in N_3 and N_4 are controlled by the multiplying analog-to-digital converters (ADCs), α and β , respectively, and are proportional to the current in the standard high-voltage capacitor C_s . The ampere turns equation for the balance condition at an applied voltage V across the specimen when the current I is equal to zero in the winding of the null detector N_1 is given by

$$V(G_x + j\omega C_x)N_1 = j\omega C_s V(N_2 + \alpha R G_1 N_4 - j\beta R G_2 N_3) \quad (46)$$

Equating the real and imaginary terms leads to the approximate expressions for the parallel, equivalent capacitance C_x and dissipation factor $\tan \delta$ of the dielectric [18,24]:

$$C_x = \frac{(N_2 + \alpha)C_s}{N_1} \quad (47)$$

$$\tan \delta = \frac{\beta R G_2}{1 + \frac{\alpha}{N_2}} \quad (48)$$

The automation of the power frequency transformer ratio arm bridge results in a reduction of the accuracy of the $\tan \delta$ measurement from $\pm 1 \times 10^{-7}$ to $\pm 1 \times 10^{-5}$.

2.3. Radiofrequency Methods (1–200 MHz)

Bridge techniques become unsuitable for measurements at frequencies beyond 1 MHz, because of the onset of inductance effects and, as a consequence, within the radio-frequency region of 1–200 MHz, resonance rise (Q meter) or susceptance variation methods must be employed [2,18]. Within these frequencies, three-terminal techniques become inapplicable cable and measurements must be carried out using two-terminal specimen holders.

The basic Q -meter circuit is shown in Fig. 13, in which the capacitance and $\tan \delta$ values of the specimen are determined in terms of a variable standard capacitor C_s and

the quality factor Q of the circuit. The coil L denotes a range of shielded fixed-inductance coils that are employed to establish resonance of the circuit with the specimen (G_x, C_x) inserted and removed. By definition, the Q value of the circuit is equal to the ratio of the peak voltage V_0 across the oscillator to that across the inductance, V_L such that

$$\begin{aligned} \frac{V_0}{V_L} &= \left(1 + \frac{\omega^2 L^2}{R^2}\right)^{1/2} \\ &= (1 + Q) \\ &\simeq Q \end{aligned} \quad (49)$$

for $Q \gg 1$. The voltmeter (V) of the Q meter is calibrated to read the Q values directly, since Q is given by V/IR . Representing the values of C'_s, Q' and C_s, Q as those obtained with the specimen disconnected and connected, respectively, yields the capacitance C_x and $\tan \delta$ values of the specimen as

$$C_x = C'_s - C_s \quad (50)$$

and

$$\tan \delta = \frac{1}{Q_x} \quad (51)$$

where

$$Q_x = \frac{C'_s - C_s}{C'_s} \frac{Q' Q}{Q' - Q} \quad (52)$$

When the measurements are carried out at high frequencies, a stiff short copper connecting wire should be employed between the specimen and the high-potential terminal of the Q meter, so that when disconnected, its same geometrical position, and configuration, a short

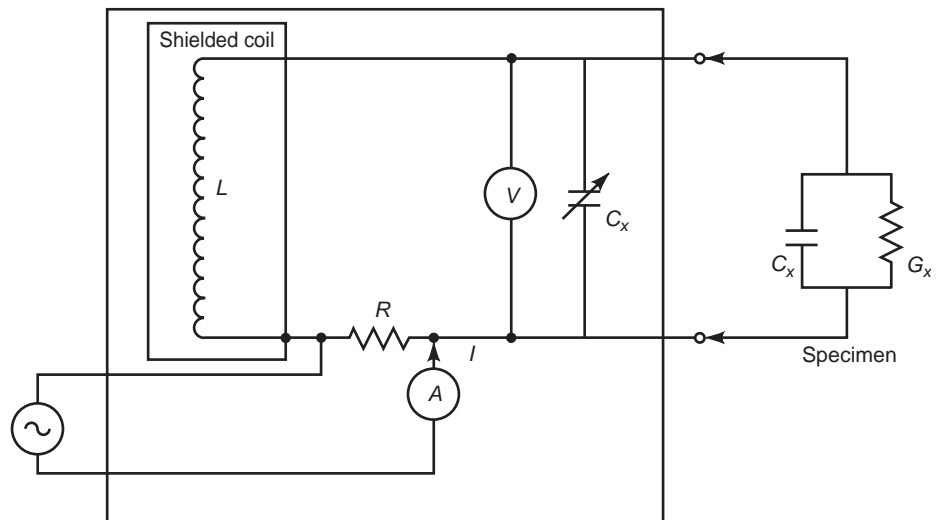

Figure 13. Q -meter circuit.

distance removed from the high-potential terminal, may be maintained, to ensure negligible change in the stray effects of the two positions of the connecting wire. With parallel-plane micrometer electrode specimen holders, accuracies of $\pm(0.1\% + 0.02 \text{ pF})$ and $\pm(2\% + 0.00005 \text{ pF})$, for the respective capacitance and $\tan \delta$ values of solid dielectric specimens may be achieved [16]. For solid specimens, an excellent precision reproducibility of $\pm 0.05\%$ and $\pm 5 \times 10^{-5}$ for C_x and $\tan \delta$, respectively, may be obtained by means of liquid displacement-type specimen holders [25]. A fluid displacement cell for use at 1 MHz, consisting of a fixed-plate, two-terminal, self-shielding capacitor, in which the edge and ground effects are taken into account, is depicted in Fig. 14.

The cell is most frequently employed for measurements at 1 MHz on polyethylene, although cell designs for frequencies up to 100 MHz are available. The fluid that is used in conjunction with polyethylene specimens is silicone with a kinematic viscosity of 1.0 cSt ($1 \times 10^{-6} \text{ m}^2/\text{s}$) at 23°C , whose dielectric constant matches that of polyethylene, and whose $\tan \delta$ value between 100 kHz and 1 MHz is negligibly small (about 5×10^{-5}). The separation between the fixed measuring electrodes of the cell design in Fig. 14 is $1.52 \pm 0.05 \text{ mm}$, thereby restricting the specimen thickness 1.27 mm , in order to allow for the formation of a finite liquid film thickness on both sides of the solid dielectric specimen adjacent to the central (high-potential) and outer (ground potential) plate electrodes or terminals. Two identical sizes ($68.3 \times 100 \text{ mm}$) of polyethylene sheet or slab specimens are employed, and measurements are made on the specimens inserted in the silicone fluid and then on the silicone fluid itself with the specimens removed.

The real value of the permittivity or dielectric constant of the polyethylene specimen ϵ' is obtained from the relation

$$(\epsilon' - \epsilon'_1) = \frac{\Delta C}{C_0} \left(\frac{d_0}{d} \right) \quad (53)$$

Figure 14. Fluid displacement cell with a fixed electrode separation equal to $1.52 \pm 0.05 \text{ mm}$ after ASTM Test Standard D1531 [25].

where ϵ'_1 is the real value of the permittivity of the silicone fluid at the measurement temperature, d_0 denotes the electrode separation, d represents the average thickness of the two specimens, and C_0 is the capacitance in vacuo of the double-plated capacitor within the fluid displacement cell, given by

$$C_0 = 2 \left[\frac{\epsilon_0 A}{d_0} \right] \quad (54)$$

where ϵ_0 is the permittivity of free space, A is the area of the center capacitor plate or electrode; the value of ΔC is obtained from

$$\Delta C = (C_2 - C_1) \quad (55)$$

where C_2 is the measured capacitance with the two solid dielectric specimens immersed in the silicone fluid and C_1 the corresponding value with the two specimens removed.

The dissipation factor, $\tan \delta$, of the two polyethylene specimens is defined by

$$\tan \delta = \tan \delta_1 + (\tan \delta_c - \tan \delta_1)[d_0/d] \quad (56)$$

where $\tan \delta_1$ the dissipation factor of the silicone fluid itself and is given by

$$\tan \delta_1 = C_T(Q_c - Q_1)/C_1 Q_0 Q_1 \quad (57)$$

where C_T represents the total capacitance of the tuned Q -meter resonant circuit prior to the connection of the specimen cell, Q_0 denotes the quality factor of the circuit at resonance prior to the connection of the ungrounded lead to the cell terminal, and Q_1 is the quality factor of the measuring circuit at resonance following the connection of the lead to the terminal of the cell containing the silicone fluid only, and C_1 the capacitance of the silicone fluid determined from the relation

$$C_1 = (C'_1 - C_1) \quad (58)$$

where C'_1 is equal to the capacitance reading following the connection of the leads to the circuit terminals before the connection of the ungrounded lead to the cell terminal. The value of the dissipation factor $\tan \delta_c$ obtained with the polyethylene specimens immersed in the cell, is determined from

$$\tan \delta_c = C_T(Q_0 - Q_2)/(\epsilon'_1 C_0 + \Delta C) Q_0 Q_2 \quad (59)$$

where Q_2 is the quality factor with the two solid specimens inserted in the cell.

The susceptance variation method originally propounded by Hartshorn and Ward [26] with subsequent refinements [27,28] is perhaps the most common method utilized for permittivity and loss measurements over the frequency region extending from 100 kHz to 200 MHz. The technique is based on the half-power point measurements of voltage across an LC resonant circuit, with the solid or liquid specimen inserted and removed from the test cell. A

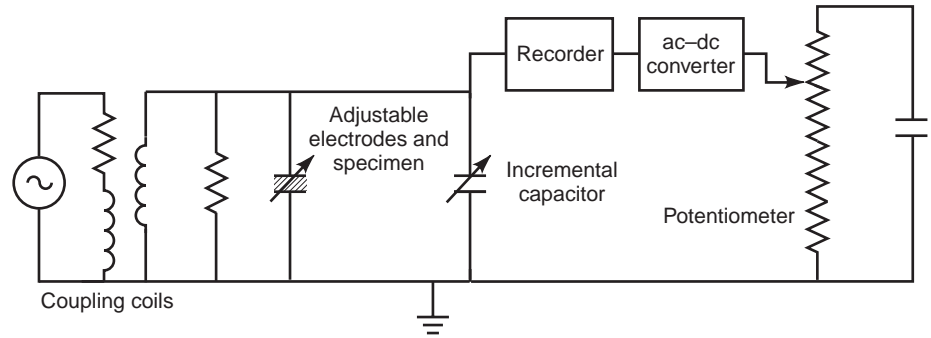

Figure 15. Schematic circuit diagram of modified Hartshorn-Ward susceptance variation circuit [27].

modified susceptance variation circuit and a cross-sectional profile view of the associated micrometer adjustable holder for solid specimens are depicted in Figs. 15 and 16, respectively. For liquids, the specimen holder is similar to that depicted in Fig. 16, except that two parallel concave electrodes are employed to permit containment of the liquid specimen.

The micrometer adjustable electrode system depicted in Fig. 16 portrays a solid dielectric specimen between plane-parallel electrodes. In the measurement procedure, resonance is first established with the specimen inserted between the electrodes and the maximum value of the voltage e_1 of the AC-DC converter is recorded. Thereafter, the specimen is removed and the separation of the electrodes is reduced until resonance is reestablished; this resonance point is characterized by a larger output voltage e_0 of the AC-DC converter. The capacitance of this air gap spacing is numerically equal to the capacitance of the specimen C_x and is obtained directly from the calibrated reading of the main micrometer setting. Manipulation of the main micrometer head, in conjunction with the small vernier or incremental capacitor, yields the half-power points of the resonance curve; the resulting width of the resonance curve is equivalent to a capacitance change, designated as ΔC_0 . It is the square law detection feature of the instrument that relates the ΔC_0 value directly to the recorded change of reading in the incremental capacitor. Hence the dissipation factor of the specimen [27] is

given by

$$\tan \delta = \left[\left(\frac{e_0}{e_1} \right)^{1/2} - 1 \right] \frac{\Delta C_0}{2C_x} \quad (60)$$

The real value of the permittivity ϵ'_r is normally obtained in terms of the thickness of the specimen d_s and the quantity, Δd

$$\epsilon'_r = \frac{d_s}{d_s - \Delta d} \quad (61)$$

where Δd represents the decrease in separation of the main electrodes in air required to restore the same capacitance as that obtained with the specimen placed between the electrodes. An accuracy of 1% is achievable on permittivity measurements and $\tan \delta$ may be determined to within $\pm 1.0 \times 10^{-6}$.

3. PERMITTIVITY AND LOSS MEASUREMENTS ON DISTRIBUTED PARAMETER SPECIMENS

Dielectric specimens behave as distributed parameter systems when the wavelength of the electromagnetic field becomes comparable to or is less than the physical dimensions of the specimen. The transition from lumped to distributed parameter behavior occurs generally within the frequency range from 300 MHz to 600 MHz. The high-frequency dielectric measurements represent a vast area of endeavor, which involves the use of resonant cavities of cylindrical and rectangular shapes, waveguides, or transmission lines, including quasioptical procedures, as well as optical methods requiring the use of spectrometers and interferometers. Since it would not be feasible within the space constraints to cover, even in a cursory manner, all test method variations over the millimeter and submillimeter wavelengths, the test procedures followed over this range of frequencies will be illustrated by a number of widely used and representative test methods.

3.1. Reentrant Cavity Method (300-600 MHz)

The reentrant cavity measurement technique constitutes, in essence, an extension of the Hartshorn-Ward method; it uses the same specimen cell arrangement, with the

Figure 16. Micrometer adjustable electrode for use in conjunction with the susceptance variation circuit [26].

Figure 17. Standing voltage wave pattern in a short-circuited coaxial waveguide containing a solid dielectric specimen [2].

exception that the inner walls are silver-plated, and the oscillator signal is admitted into the cell cavity via a coupling loop with a detector loop situated on the opposite wall of the concentric coaxial cell cavity [29]. The reentrant cavity is calibrated as a wavemeter, with the main micrometer adjustable specimen capacitor acting as the prime frequency control device and the vernier capacitor as an incremental control device (refer to Fig. 16). As in the case of the Hartshorn–Ward technique, the dielectric parameters are determined in terms of the width of the resonance curve with the specimen inserted between the measurement electrodes and then removed.

3.2. Coaxial Line–Waveguide Methods (500 MHz–50 GHz)

Waveguide or transmission-line methods are based on the shorted coaxial-line technique developed by Roberts and von Hippel [30]. Although for low loss dielectric solids and liquids, the technique yields optimum performance for microwave frequencies up to 50 GHz; the method has been used up to 95 GHz [31]. The confinement of the electrical field within the hollow waveguide’s circular or rectangular geometry eliminates stray capacitance and inductance effects. A standing-wave pattern results within the waveguide, from a reflection of the incident wave at the short-circuit termination adjacent to where the solid specimen is inserted as depicted in Fig. 17. When liquid specimens are tested, the waveguide is mounted in a vertical position [18]. Figure 17 indicates the position of the electrical nodes (position of the interference minima), with the width of the nodes, Δx , as indicated at the 3-dB points.

In terms of Δx , the voltage standing-wave ratio, abbreviated as VSWR, or r , may be expressed as

$$r = \lambda_{gs} / \pi \Delta x \tag{62}$$

where λ_{gs} is the wavelength of the slotted coaxial line; it is along the slot that a traveling probe is displaced to determine the VSWR. Since the value of Δx changes when the specimen is removed from the waveguide, the VSWR (r) also changes accordingly.

Perhaps one of the most common shorted coaxial transmission line arrangements in use is that described in ASTM D2520 [32], which is suitable for temperature-controlled measurements up to 1650°C, when utilized in conjunction with a platinum alloy with 20% rhodium as the material for the specimen holder; its schematic diagram is delineated in Fig. 18. A micrometer adjustable specimen capacitor acting as the prime frequency control device and the vernier capacitor as an incremental control device (refer to Fig. 16). As in the case of the Hartshorn–Ward technique, the dielectric parameters are determined in terms of the width of the resonance curve with the specimen inserted between the measurement electrodes and then removed.

$$\begin{aligned} \lambda_{gh}^{-2} &= \lambda_0^{-2} - \lambda_c^{-2} \\ &= \lambda_0^{-2} - (2a)^{-2} \end{aligned} \tag{63}$$

where λ_0 is the wavelength of the radiation in free space and is equal to c/f , where c is the velocity in free space and f is the frequency.

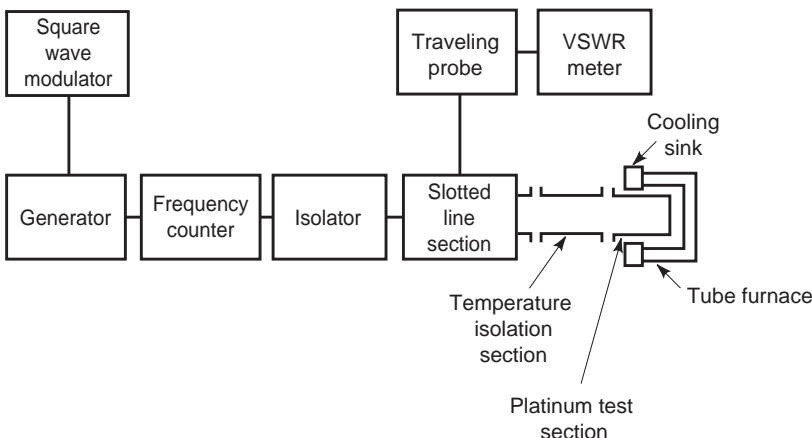

Figure 18. Schematic diagram of short-circuited rectangular waveguide with a temperature-controlled test specimen section (after ASTM D2520) [32].

With the specimen of thickness d_s inserted adjacent to the short in the waveguide, the impedance of the line at the specimen–air interface [33] is given by

$$Z_{in} = (j\omega\mu_0/\gamma_2) \tanh(\gamma_2 d_s) \quad (64)$$

where μ_0 is the permeability of the nonmagnetic dielectric material, which is identical to that in free space. Assuming negligible losses in the walls of the waveguide, the propagation constant of the coaxial waveguide γ_2 containing the specimen is given by

$$\gamma_2 = 2\pi(\lambda_c^{-2} - \epsilon'_r \lambda_0^{-2})^{1/2} \quad (65)$$

The load impedance at a phase distance φ from the observed electrical node for the value of the VSWR r given by Eq. (62), (34) is

$$Z_{meas} = f\mu_0\lambda_g[(1 - jr \tan \varphi)/(r - j \tan \varphi)] \quad (66)$$

where λ_g is the wavelength of the guide and is equal to $2\pi/\beta_2$; here β_2 is the phase coefficient of the waveguide with the specimen inserted; φ is the corrected phase distance, defined by

$$\varphi = 2\pi[(N/2) - (d_s/\lambda_{gh}) \pm (x_2 - x_1)\lambda_{gs}] \quad (67)$$

where N represents the smallest integer for which φ is positive, x_2 is the position of the traveling detector with the specimen inserted, as indicated in Fig. 17, and x_1 is the equivalent distance with the specimen removed.

Equating the impedances Z_{in} and Z_{meas} yields

$$\frac{\tanh \lambda_2 d_s}{\gamma_2} = \frac{\lambda_{gh}(1 - jr \tan \varphi)}{2\pi j(r - j \tan \varphi)} \quad (68)$$

Equating the real and imaginary terms yields the relative real value of the permittivity ϵ'_r of the specimen as

$$\epsilon'_r = [(\beta_2/2\pi)^2 + \lambda_c^{-2}]/\lambda_0^{-2} \quad (69)$$

and, for low-loss specimens [34], the dissipation factor simplifies to

$$\tan \delta = \frac{\Delta x(1 - \lambda_0^2/\epsilon'_r \lambda_c^2)(1 + \tan^2 \varphi)}{d_s\{[1 + \tan^2 \beta_2 d_s] - [(\tan \beta_2 d_s)/\beta_2 d_s]\}} \quad (70)$$

where the width of the node Δx that would be measured at the face of the specimen is given by

$$\Delta x = \Delta x_2 - \Delta x_1 \quad (71)$$

The principal factors affecting the accuracy of the measurements are associated with the assumption that losses at the walls of the waveguide are negligible and that the finite airgap between the solid specimen and the walls of the waveguide does not influence appreciably the results; evidently, the latter error does not arise with liquid specimens [18]. However, accuracies of $\pm 1\%$ for ϵ'_r and ± 200 radians for the loss angle δ are achievable.

3.3. Resonant Cavity Methods (about 500 MHz–60 GHz)

A resonating cavity may be viewed as a transmission line, which is shortened at both ends that are separated by an arbitrary multiple of one-half the operating wavelength. The insertion of a dielectric specimen into the cavity alters the wavelength and, as a consequence, the change in the quality factor Q of the cavity with the specimen inserted and removed can be used to derive the dielectric parameters of the specimen. Since resonant cavities have intrinsically high values of Q , they constitute an effective means for measuring low-loss dielectric materials. The specimens may have different geometrical configurations such as spheres, sheets, disks, rods, and so forth, and may fill the cross section of the beam, if necessary. The required specimen size becomes smaller as the cavity size diminishes with frequency, thereby also necessitating a redesign of the cavity with each octave increase in frequency. For frequencies above 60 MHz, the reduced cavity sizes, irrespective of their shape, rapidly approach a practical limit. Although open resonant cavities or interferometers may exceed substantially the frequency of 60 MHz [35] their applicability is confined to specimens having dielectric constants in excess of 5.

A coaxial waveguide shorted at one end becomes a resonant cavity when shorted at both ends. It may be resonated either by varying the frequency of the externally applied field or by varying the radial or axial dimensions of the cavity itself. A very widely used rectangular microwave cavity design for operation in the transverse electric field, TE_{10N} mode, is depicted in Fig. 19. Note that, in the mode designation code, the first subscript denotes the number of half-waves across the short-circuited waveguide, the second subscript refers to the number of half-waves from top to bottom of the waveguide, and the third subscript represents the odd number of half-waves along the waveguide. The closed cavity arrangement in Fig. 19 is identical to that given in the test method described in ASTM D2520 [32]. It is of paramount importance that the diameter of the iris holes in the transmitting and detecting ends be small to achieve high Q values. The particular design of the shown resonant cavity is intended for use with solid rod-shaped specimens, which are held suspended between the top and bottom holes that are drilled into the waveguide (refer to Fig. 19). The resonant frequency of

Figure 19. Closed rectangular resonant cavity for tests on solid rod-shaped dielectric specimens (after ASTM D2520) [32].

the specimen is defined by

$$f_0 = 15[(1/w)^2 + (N/d)^2]^{1/2} \quad (72)$$

where d is the physical length of the closed cavity and w its width (both in cm), N denotes the odd number of half-waves along the cavity, and the resonant frequency is in GHz. It is palpably evident, from Eq. (72), that higher test frequencies require closed cavities with increasingly reduced physical dimensions.

The measurements may be carried out either by means of the traditional VSWR meter utilizing a point-by-point approach or, for more rapidly obtainable results, a frequency sweep generator may be employed, as portrayed in the schematic test circuit of Fig. 20, in accordance with an IEC method [36]. The latter method may be computerized, in order to minimize errors, by recording simultaneously dual outputs from the signal generator and the cavity.

The measurements are carried out with the empty cavity and then with the specimen inserted. The quality factor Q_0 of the empty cavity is given by

$$Q_0 = \frac{f_0}{\Delta f_0} \quad (73)$$

where the half-power bandwidth of the empty resonant cavity is

$$\Delta f_0 = f_{02} - f_{01} \quad (74)$$

and f_{01} and f_{02} are the lower and upper frequency half-power (3 dB) points; the 3 dB points are established by means of a variable precision attenuator. When the specimen is inserted into the cavity, the quality factor Q_s becomes

$$Q_s = \frac{f_s}{\Delta f_s} \quad (75)$$

where f_s the new resonant frequency of the closed cavity containing the specimen and the half power bandwidth is

$$\Delta f_s = f_{s2} - f_{s1} \quad (76)$$

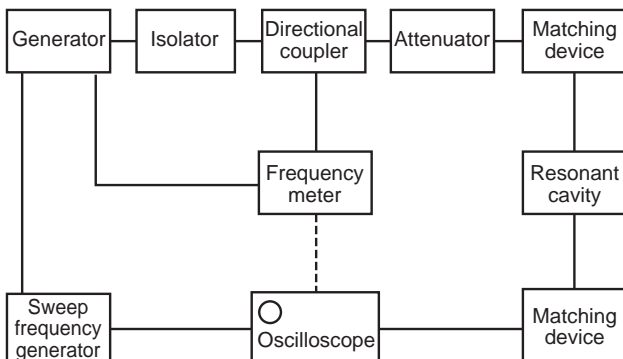

Figure 20. Microwave closed resonant cavity measurement system, using a sweep frequency generator technique (after IEC Publ. 377-2) [36].

where f_{s2} and f_{s1} are respectively, the upper and lower 3 dB point frequencies. The value of the relative real permittivity ϵ'_r and the dissipation factor $\tan \delta$ may now be determined from

$$\epsilon'_r = \left[\left(\frac{V_0(f_0 - f_s)}{2V_s f_s} \right) + 1 \right] \quad (77)$$

and

$$\tan \delta = \frac{\left[\frac{V_0}{4V_s} \left(\frac{1}{Q_s} - \frac{1}{Q_0} \right) \right]}{\left[\left(\frac{V_0(f_0 - f_s)}{2V_s f_s} \right) + 1 \right]} \quad (78)$$

where V_s and V_0 are respectively, the volumes of the specimen and the empty cavity. Note that the measured quantities are not contingent on the dimensions of the closed cavity. An accuracy to within 0.5% for the permittivity and approximately 5% for the dissipation factor are attainable. The specimen size and location within the cavity plays an important role; these two parameters influence the magnitude of the difference between Q_s and Q_0 on which the precision and accuracy depend. A high Q value for the cavity is thus important, since the 3 dB point frequencies become more clearly defined.

3.4. Quasioptical and Optical Methods (30–3000 GHz)

Dielectric measurements at microwave frequencies in excess of 60 GHz become increasingly arduous, as a result of the unduly small size of resonant cavity required. The difficulty is circumvented by employing for the microwave frequency range the same methods as those that are utilized in lightwave optics; such procedures are commonly referred to as *quasioptical* or *free-space techniques*. In analogy to an optical spectrometer, the collimator in a quasioptical microwave-type instrument consists of a parabolic reflector connected to a microwave generator, with the plane-wave source directed toward the dielectric specimen [37]. The latter is in sheet form and is mounted upon an object table, as in the case of an optical spectrometer. Another parabolic reflector (substituting an optical telescope), connected to a detector, receives the signal, which is either reflected from or transmitted through the sheet specimen. Thus, the resulting attenuation in the path between the transmitting and receiving parabolic reflectors constitutes a measure of the dielectric loss in the intervening dielectric sheet [38].

Quasioptical techniques also include the use of optical cavity resonators, which are suitable for measurements within the millimeter and submillimeter wavelengths of the electromagnetic spectrum. This differs from the usual closed cavity microwave resonator, in that the length of the resonator corresponds to a length number of wavelengths, while the specimen (in sheet form) assumes only a small fraction of the overall length [2]. There are three types of quasioptical resonator: the classical Fabry–Perot interferometer, the confocal resonator, and the semiconfocal resonator. The confocal resonator has the advantage that the electric field is more confined to the axis of the

Figure 21. Quasioptical confocal resonator arrangement [39].

resonator, resulting in Q values generally higher than 10^5 and lower diffraction losses. The Q of a semiconfocal resonator is approximately equal to half that of the confocal resonator.

For illustrative purposes, the measurement procedure followed with a quasioptical confocal resonator [39], delineated in Fig. 21, will be described, which has been successfully used at frequencies up to 343 GHz. As with any resonant cavity, the resonant frequency of the quasi-optical cavity is perturbed by the insertion of the specimen. The specimen is intentionally mounted at an angle, θ , to the vertical axis of the cavity, in order to eliminate standing-wave phenomena. The angle permits the waves reflected from the air–dielectric interface to escape from the resonator. The resonance is restored by reducing the distance ℓ between the two mirrors by an amount equal to $\Delta\ell$. The real value of the index of refraction n' of the specimen (39) is then given by

$$n' = (\epsilon'_r)^{1/2} = \left(1 + \frac{\Delta\ell}{d_s} - \frac{\varphi}{\beta_0 d_s}\right) \tag{79}$$

where d_s is the thickness of the dielectric specimen, β_0 is the phase factor in free space and is equal to $2\pi/\lambda_0$, and the angle φ is defined by

$$\varphi = \tan^{-1} \left[\frac{\sin 2n'\beta_0 d_s}{\left(\frac{n'+1}{n'-1}\right) - \cos 2n'\beta_0 d_s} \right] \tag{80}$$

For $\tan \delta$ measurements, the length of the empty quasioptical confocal resonator must be adjusted to an odd number of half-wavelengths at the resonant frequency for which the Q value is to be determined. The specimen must then be inserted at a position vertical to the axis of the resonator—that is, with $\theta = 0$, the Q value is maximized as the escape of the power from the resonator is minimized. With the resonant frequency restored as each mirror is moved inward a distance, $\Delta\ell/2$, the quality factor, Q_s , with the specimen inserted is then determined. The expression

for the dissipation factor [39] follows as

$$\tan \delta = \frac{\beta_0 \ell - \beta(\Delta\ell + d_s) \left[1 + \frac{\sin \beta_0(\Delta\ell + d_s)}{\beta_0(\Delta\ell + d_s)}\right]}{Q_s \eta^2 (\epsilon'_r)^2 \beta_s d_s \left[1 + \frac{\sin \beta_s d_s}{\beta_s d_s}\right]} + \frac{1}{Q_s} - \left\{ \frac{Q_0 \lambda_0 / 2\pi \ell}{\eta^2 (\epsilon'_r)^2 \beta_s d_s \left[1 + \frac{\sin \beta_s d_s}{\beta_s d_s}\right]} \right\} \tag{81}$$

where β_s is the phase constant in the dielectric medium and is equal to $2\pi/\lambda_s$; the value of η is

$$\eta = \left\{ \frac{[(n')^2 + \omega t^2 \beta_0 x_1] / (n')^2}{1 + \omega t^2 \beta_0 x_1} \right\} \tag{82}$$

where x_1 denotes the distance from the reflector to the dielectric sheet.

In the frequency range from 300 to 3000 GHz (wavelengths of 1 mm–100 μ m), true optical measurement techniques are employed. As this wavelength range overlaps the infrared region, infrared sources and detectors are utilized. If a broadband radiation source is employed, the component measurement frequencies, appearing at the output of an interferometer, are selected by means of a computer in terms of their Fourier components. Broadband radiation sources require more sensitive detectors; it is for this reason that laser sources, although monochromatic, appear to be more popular.

Figure 22 depicts an arrangement for the measurement of dielectric absorption at optical frequencies, utilizing a laser source [40]. The attenuation of the transmitted signal is obtained by comparing the amplitude of the signal transmitted through the specimen V with a monitored incident signal V_m . The method entails the use of different specimen thicknesses d_s , which requires adjustment of the polarizing attenuator, in order to maintain a constant transmission loss.

The dissipation factor is related to the absorption coefficient a_p , which obtained from the relation [40]

$$\ln A = a_p d_s + \text{constant} \tag{83}$$

the units of a_p are in nepers per cm; A is the reading of the attenuator, which is equal to $(\cos \varphi)^4$; here φ is the central polarizer angle of the attenuator. From the nature of Eq. (83), it is apparent that the absorption coefficient a_p can be obtained directly from a linear plot of $\ln A$ versus the specimen thickness d_s . The imaginary part of the index of refraction is equal to $ca_p/4\pi f$, where f is the frequency. Hence, the relative real value of the permittivity is given by

$$\epsilon'_r = (n')^2 - \left(\frac{ca_p}{4\pi f}\right)^2 \tag{84}$$

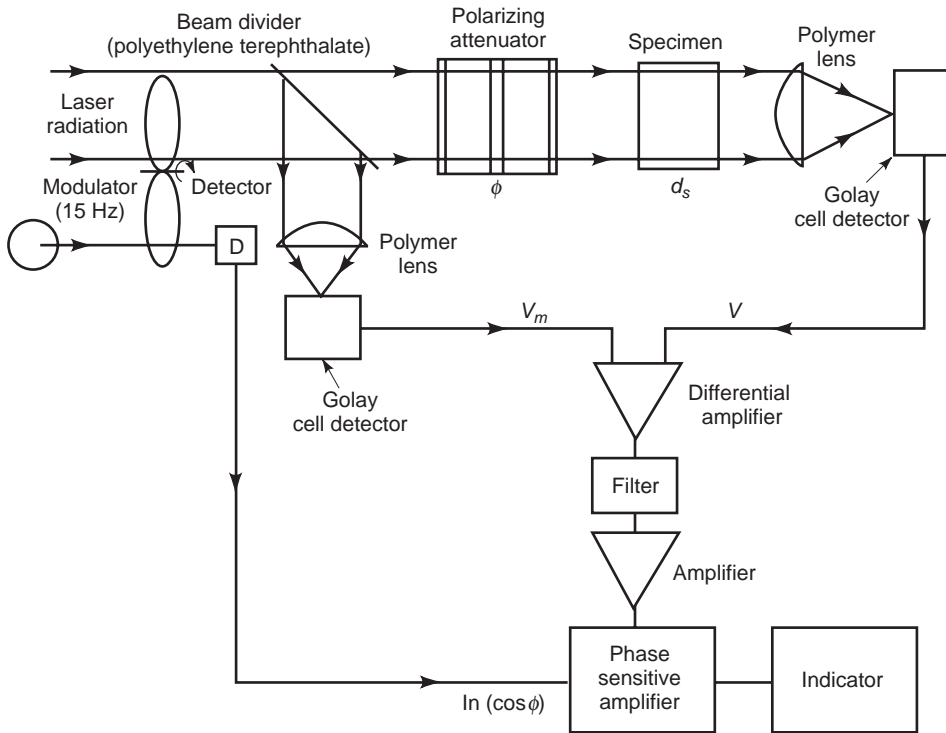

Figure 22. Dielectric absorption measurement system at optical frequencies with a laser radiation source [40].

and the relative imaginary value of the permittivity is

$$\varepsilon''_r = \frac{cn' a_p}{4\pi f} \quad (85)$$

The dissipation factor, which is equal to the ratio $\varepsilon''_r/\varepsilon'_r$ is then

$$\tan \delta = \frac{8\pi f n' c a_p}{(4\pi f n')^2 - (c a_p)^2} \quad (86)$$

The foregoing approach is based on transmission techniques, but laser source reflection arrangements are also available. It should be observed that there are a number of variations in the types of interferometers available for dielectric measurements, including the classical Michelson interferometer, which, in conjunction with a broadband radiation source, is suitable for measurements up to 3000 GHz. Laser, refraction measurements, based on the Mach-Zehnder approach, may also be employed to derive dielectric data. A comparison of the various optical measurement techniques at a large number of laboratories indicates that, whereas the real value of the index of refraction, n' , may be determined to an accuracy of 1%, the errors in the measurement of the absorption coefficient, a_p , may be as high as 37% [41].

4. VOLTAGE BREAKDOWN STRENGTH MEASUREMENTS

Voltage breakdown strength measurements are carried out on insulating materials to determine whether these materials can withstand certain operating stresses without failure. Since voltage failure is frequently initiated at

fault sites within solid insulating materials, the dielectric strength serves as an indicator of the homogeneity of the material. In liquid dielectrics, low dielectric strength values may be associated with moisture content, electrolytic contamination, and a high particle content. With gases for which the dielectric strength is a definite function of the composition of the gas (pure or mixture), dielectric strength data may be used to detect contamination from other gases, as well as determine the breakdown characteristics of intentionally combined gas mixtures.

The dielectric strength of insulating materials is highly contingent on the geometry of the test electrodes utilized. Sharp accentuated electrode edges lead to electrical field concentrations at the edges, which cause initiation of voltage breakdown of the material at voltages substantially below those that can be achieved under more uniform electrical field conditions. Thus voltage breakdown data are inextricably associated with the specific geometry of the test electrodes employed.

The true value of the breakdown strength or, more specifically, the intrinsic breakdown strength of the dielectric is obtained when the applied electric field is perfectly uniform. A uniform field can be achieved by means of Rogowski-Rengier profile electrodes; however, the application of such recessed-type electrodes to solid specimens requires the embedding of the electrodes into the solid dielectric by means of a suitable molding process when plastic dielectrics specimens are tested. Several relatively simple recessed electrode systems have been developed, which do not entirely produce a uniform field, but that improve the electrical field configuration appreciably, thereby permitting the attainment of dielectric strengths approaching the intrinsic value. One such simplified arrangement is depicted in Fig. 23 [42].

Figure 23. Spherical HV electrode with recessed solid specimen [42].

The recess in the rigid solid dielectric may be machined to form a highly stressed region in the specimen, with the electrodes vapor deposited on the dielectric to preclude any air gaps between the electrodes on the specimen. Alternatively, with nonporous solid dielectrics, conducting silver paint may be applied. Should sparkover occur at the edges prior to dielectric breakdown, the entire electrode assembly may be immersed in a mineral or silicone oil bath, provided the solid specimen is a nonporous material. The conductivity σ_m and dielectric constant ϵ'_m of the immersing medium must be selected such that under DC test voltages [43]

$$\sigma_m E_m > \sigma_s E_s \tag{87}$$

where E is the electric field and the subscripts “m” and “s” refer, respectively, to the oil medium and the solid specimen. Under alternating test voltages, we obtain

$$\epsilon'_m E_m > \epsilon'_s E_s \tag{88}$$

If the liquid is partially conducting, then

$$\epsilon'_m E_m \sec \delta_m > \epsilon'_s E_s \sec \delta_s \tag{89}$$

where δ is the loss angle.

Although the intrinsic strength of a dielectric material provides information on the maximum breakdown strength attainable for that material and thus is used to ascertain the nature of the mechanism responsible for the breakdown, it is, per se, of little consequence in practice. In fact, the intrinsic breakdown strength is usually one to several orders of magnitude higher than the electrical breakdown stress obtained with regular parallel-plane electrodes, or with the various electrical insulation configurations existing in different electrical apparatus. For this reason, the type of electrodes used in standard routine breakdown tests on materials are relatively simple to use, and are designed to provide reproducible results primarily for comparison purposes.

4.1. Electrode Systems for Routine Breakdown Tests on Solid Specimens

Present practice in assessing the breakdown strength and the quality of solid, liquid, and gaseous dielectric materials for use in electrical apparatus and cables involves the

Figure 24. Equal-diameter electrode system for dielectric strength measurement on sheet materials (after ASTM D149) [44].

use of a number of electrode systems, in accordance with national and international standards. For solid materials, the most commonly employed electrode system is the one-inch or 25-mm two-cylindrical electrode equal-diameter system portrayed in Fig. 24 [44]. The edges of the electrodes are rounded to a radius of 3.2mm, to minimize stress enhancement. In all dielectric strength tests, the thickness of the specimen must be specified, because the voltage stress, at which breakdown occurs, increases with a reduction of the specimen’s thickness. Thus, although very thin solid dielectric films may break down at low voltages, the corresponding breakdown stresses are appreciably higher than those for thick films of the same material, even though the latter may undergo breakdown at much higher applied voltages.

It is evident that equal-diameter electrodes systems must be concentric. This requirement may be circumvented by the use of two electrodes with different diameters, in accordance with IEC Publication 243, as depicted in Fig. 25 [45]. Note that the IEC (International Electrotechnical Commission) standard specifies dielectric specimen thicknesses equal to or less than 3.0 ± 0.2 mm. If tapes of reduced width are tested, then rod electrodes of the geometry delineated in Fig. 26 are utilized. When

Figure 25. Unequal-diameter electrode system for dielectric strength measurements on sheet materials (after IEC Publication 243) [45].

Figure 26. Cylindrical rod electrodes for dielectric strength measurements on thin narrow plastic tape or other narrow specimens (after ASTM D149) [44].

breakdown tests are carried out on thin inorganic films with application to electron devices, miniature counter electrodes are vapor deposited onto the surface of the specimen. For the evaluation of embedding compounds or greases, the standard procedure of ASTM D149 requires hemispherical electrodes, having an equivalent diameter of 12.7 mm [44].

The foregoing described electrode systems for solid dielectric specimens are suitable for tests under AC power frequency, DC, and impulse conditions. The electrode systems, for routine determination of the dielectric strength of liquids, differ from those described for solids. Routine acceptance tests on oils of petroleum origin for electrical apparatus and cables are carried out with an oil cup containing parallel-plane polished brass electrodes, with an interelectrode spacing of 2.5 ± 0.01 mm. The electrodes have a diameter of 25 mm and a thickness of 3 mm; they are square at the edges and are separated from the inner wall of the oil test cup by a distance of not less than 13 mm. The oil test cup assembly is shown in Fig. 27 [46]. The electrodes within the cell must be cleaned with a dry hydrocarbon solvent following each breakdown test; particular care must be taken to remove any carbonization

Figure 27. Parallel-plane square-edge electrode system for dielectric strength measurements on mineral oils (after ASTM D877) [46].

deposits on the electrodes, and the electrodes must be re-polished should any pitting of the surface manifest. Prior to admitting the liquid specimen into a cleaned test cell, the latter must be rinsed by the same liquid to remove any residues of the cleaning compound.

It is palpably evident from the geometric configuration of the square-edge electrodes in Fig. 27, that electrical stress enhancement occurs at the edges of the electrodes and that, therefore, breakdown is likely to occur there. For lower viscosity dielectric liquids (< 19 cSt or mm^2/s at 40°C), test electrodes, with the geometrical contour depicted in Fig. 28, have been found to be particularly effective in detecting decreases in the breakdown strength as a result of cellulose fiber contamination and absorbed moisture [47]. These electrodes are normally referred to as VDE (Verband Deutscher Electrotechniker)-type electrodes. Measurements of dielectric strength are performed with electrode separations of either 1 or 2 mm, with a gentle downward oil flow at the electrodes created by means of a rotating impeller located beneath the electrodes in the test cell.

Since oil-filled and impregnated electrical power equipment is subjected to lightning and switching impulses, it is important to assess the quality of the oil in terms of its impulse breakdown strength. Under nonuniform electrical field conditions, the dielectric strength of the oil is contingent on the polarity of the impulse in contradistinction to negligible differences observed under uniform fields. For this reason, nonuniform field electrode systems are frequently utilized for impulse tests. The electrodes may typically consist of either two 12.7 mm diameter brass or steel spheres or, for highly nonuniform fields, one such sphere and a steel needle point with a 0.06 mm radius of curvature at the needle tip [48].

The breakdown strength of gases is normally determined under quasiuniform AC field conditions. Typical electrodes utilized for this purpose consist of a sphere-to-plane geometry, wherein the electrical field is uniform directly underneath the sphere adjacent to the plane, becoming increasingly less uniform as the separation between the sphere and the plane increases. With a sphere-to-plane geometry, electrical breakdown tends to always occur in the uniform field region—that is, at the point where the separation between the sphere and the plane is least. The high-potential sphere electrode may

Figure 28. VDE electrode system for dielectric breakdown strength measurements on low-viscosity liquids [47].

be of steel with a diameter of 0.75 in. or 19.1 mm, and the ground potential electrode may be a cylindrical brass plane with a 1.5 inch or 38.1 mm diameter [49]. The tests are performed at 25°C at a standard pressure of 760 torr.

4.2. Voltage Breakdown Test Conditions and Procedures

The presence of lethal voltages in breakdown voltage tests necessitates strict adherence to high-voltage safety practices. Since the breakdown voltage may be a function of the ambient temperature, pressure, and humidity, depending on where solid, liquid, or gas specimens are tested, these parameters should be recorded at the time of the test; solid insulating materials should be conditioned prior to the breakdown test, so that they may reach thermal and moisture equilibrium with the environment. For more lossy solid and liquid specimens, the application of intense alternating electrical fields may result in cumulative heat generation due to dielectric losses, thereby leading to a thermal instability induced breakdown. Solid specimens may contain gas cavity inclusions, within which intense recurring partial discharges at elevated alternating fields may cause rapid deterioration of the adjacent solid insulation, thus leading to conspicuously lower breakdown strengths. Both thermal and discharge mechanism associated breakdowns account for the lower observed AC breakdown strengths, as opposed to those measured under DC and impulse conditions. Where the breakdown strength is controlled by the thermal and partial discharge mechanism, the breakdown process is a strong function for the time of voltage application. Accordingly, the rate of voltage rise in any voltage breakdown test is an important parameter.

For solid dielectrics, the rate of ac sinusoidal voltage rise is fixed usually at 500 V/s, though more rapid or slower rise rates may also be used. Breakdown or rupture of the dielectric is indicated by an audible voltage collapse across the specimen, as well as a visual burn at the tip of the breakdown. In order to minimize stress-induced aging effects in the insulation undergoing the voltage breakdown test, ASTM D149 stipulates that the duration of a short-time breakdown must not exceed 20 s. In the past, a voltage step test was employed, whereby the voltage was raised in steps; at each step it was maintained for a preset time, prior to the next-step increment in voltage, until the ensuence of dielectric breakdown event—that is, an abrupt voltage collapse across the specimen. The use of the step procedure was required in the absence of voltage sources with automatically regulated rate of voltage rise controls.

In DC dielectric breakdown strength determinations on dielectric material specimens, a single rate of voltage rise of 500 V/s is employed [50]. Under direct voltages, the initial breakdown event produces a minute channel in the volume of the solid dielectric, whose trace is not readily discernible. Reapplication of the direct voltage results in successively lower breakdown voltages, which confirm that a DC breakdown has already occurred. Also, the additional damage and burning produced within the breakdown channel renders it more visible.

Impulse tests on solid dielectric specimens are performed by increasing the peak voltage of the impulse gradually, from an initial peak value of 0.7 times the anticipated breakdown voltage [45,50]. The lightning impulse is simulated with an impulse waveform having a time to peak of 1.2 μ s and a decay time of 50 μ s to 50% of its initial peak value. Impulse breakdown is indicated by a voltage collapse at any point of the impulse waveform [2]; the peak voltage value of this impulse wave is considered as the impulse breakdown voltage. Location of the actual breakdown channel caused by an impulse may require, as in the DC case, several reapplications of the voltage pulse, to cause additional carbonization within the breakdown channel.

In the measurement of dielectric strength of liquid specimens at AC power frequencies using the parallel-plane square-edge electrodes, a fixed voltage rise of 3 kV/s is generally specified [46]. To avoid pitting of the test electrode surfaces, the short-circuit current at breakdown in the specimen is not permitted to exceed 10 mA/kV. For tests with the same electrode system under direct voltages, the same rate of voltage rise should be adequate. When the VDE-type electrodes are employed for low-viscosity liquids at power frequency, a much lower rate of voltage rise of 0.5 kV/s is preferred. Impulse breakdown tests performed on dielectric liquids are often carried out with both the simulated lightning impulse of the 1.2 by 50 μ s form and a switching surge impulse form with a 100 μ s risetime to peak and a decay time >1000 μ s. The impulse breakdown tests are carried out either at positive or negative polarities; often the measurements may be performed at both polarities. The measurement sequence at either polarity is begun at a voltage substantially below the expected impulse voltage breakdown level. Normally, three impulse waves are applied at each selected impulse voltage test level; it is an accepted practice to traverse at least three test levels prior to breakdown, with a fixed minimum time interval between each voltage level test. ASTM D3300 recommends a time interval of 30 s. The peak impulse voltage at breakdown is measured oscillographically across a calibrated resistive voltage divider. Whenever needle electrodes are employed, the geometry of the needle tip is altered, due to the energy released by the breakdown spark; this necessitates a change of the needle electrodes after each breakdown event.

Routine voltage breakdown strength measurements on insulating gases are normally performed under AC power frequencies, using a standard rate of voltage rise of 500 V/s [49]. The breakdown strength of gases is a function of gap spacing and gas pressure; since the value of the latter varies with the ambient temperature, both the pressure and temperature must be recorded for breakdown results obtained with a fixed gap setting.

It should be emphasized that, when the breakdown voltages are determined for solid, liquid, and gas specimens, the gap length or specimen thickness must be stated in each case. Even when the value of the voltage breakdown strength is provided in the units of voltage per unit specimen thickness, the specimen thickness must still be specified, because the breakdown strength is a function of the specimen thickness. Also, the dispersion in

the voltage breakdown data requires some form of statistical analysis. Breakdown strength data ordinarily refer to a mean measured value on 10 specimens. A low ratio (about 0.1) of the standard deviation to the mean value, derived from the ten measurements, is usually considered as an indicator of an acceptable probable error in the test results.

5. CONCLUDING REMARKS

The foregoing presentation of the measurement of conductivity, permittivity, and dielectric loss, and dielectric strength of electrical insulating materials has attempted to provide a concise cursory description of a number of the most common measurement techniques in use. Space limitations prevented a discussion on the various conduction and breakdown mechanism and their influence on the measured quantities. For a more in-depth discussion on the mechanisms involved and their determining inference on the measured quantities obtained with a variety of different test methods, the reader is referred to other literature [2,18,20,42].

DIELECTRIC PERMITTIVITY AND LOSS

D. K. DAS-GUPTA
University of Wales
Bangor, Wales

Dielectrics can be defined as materials with high electrical resistivities that conduct virtually no electricity at low DC electric fields. A large group of materials, including gases, liquids, semiconductors, ceramics, and organic and inorganic polymers, are classified as dielectrics. There are, however, no perfect dielectric materials.

The study of the electrical properties of dielectrics arises from their practical need for efficient electrical insulation requirements for long operational life. Many dielectric materials are classified by their electrical breakdown strength, dielectric loss, permittivity, and polarization, and these macroscopic properties are related to their atomic and molecular structures. Although dielectrics are widely employed in diverse applications (e.g., capacitors, cables, transformers, motors), the study of dielectrics has progressed very little since the early investigation of ferroelectric phenomena. However, the advent of microelectronics and complex control devices and components in defense and industrial applications has made dielectric research important in its own right.

The present article briefly reviews the electrostatic concepts that lead to time- and frequency-dependent dielectric phenomena together with the models of dielectric relaxation behavior in various materials. It also includes some explanations for the dielectric aging of insulating materials under high fields in humid environments.

1. DIELECTRIC POLARIZATION

1.1. Static Field

When an electric field is applied to a dielectric material, three processes can occur:

1. A steady flow of direct current (due to the DC conductivity σ_0) may occur if free charges are capable of moving throughout the volume without restraint.
2. Bound charges can form dipoles by aligning with the field and provide *polarization*. On removal of the field the dipoles may return to their original random orientations with the help of thermal energy, giving rise to *dielectric relaxation*.
3. Electronic and ionic charges may hop through the defect sites. These charges are neither free nor bound, and they give rise to an intermediate form of polarization, which involves finite charge storage.

Dielectrics may broadly be divided into nonpolar and polar materials. In nonpolar materials in an external field a dielectric polarization occurs when the positive and negative charges experience an electrical force that causes them to move apart in the direction of the external field. As a result, the centers of positive and negative charges no longer coincide. The molecules are then said to be *polarized*, and each molecule forms a dipole and acquires a dipole moment \mathbf{p} , defined thus

$$\mathbf{p} = e \mathbf{dl} \quad (1)$$

where e is the electronic charge and \mathbf{dl} the displacement ($\sim 10^{-10}$ – 10^{-11} m in magnitude) between the two charge centers. Note that \mathbf{dl} is a vector that points from the negative to the positive charge. Such dipoles are called *induced* dipoles. On removal of the field, the charges are redistributed and the dipole moment vanishes.

With polar dielectrics, which lack structural symmetry, the charge centers of opposite polarities do not coincide for a molecule even in the absence of an electric field. However, these molecular dipoles may be randomly distributed, thus summing to a zero dipole moment over any macroscopic volume element [1–9]. In the presence of an appropriate electric field, the molecules may align themselves in the field direction and thus provide a net dipole moment.

Macroscopically, the electric field in a dielectric is described [2] by the electric field strength \mathbf{E} (V/cm) and the electrical displacement density, also known as the electric flux density, \mathbf{D} (C/m²), where both \mathbf{D} and \mathbf{E} are vector quantities. Now the polarization can be defined as the dipole moment per unit volume, namely

$$\mathbf{P} = \sum_{i=1}^N \mathbf{p}_i / \Delta v \quad (2)$$

and is also a vector quantity. It should be noted that the normal component of \mathbf{P} at the surface equals the surface charge density per unit area. These three vectors, \mathbf{D} , \mathbf{E} , and \mathbf{P} , in a material medium other than vacuum, are related thus

$$\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P} \quad (3)$$

or

$$\mathbf{D} = \epsilon \mathbf{E} \quad (4)$$

where

$$\epsilon = \epsilon_0 \epsilon_r \quad (5)$$

where ϵ_0 is the permittivity in free space (8.85×10^{-12} F/m) and ϵ_r is the relative permittivity (dimensionless) or the dielectric constant of the material, which takes into account the polarization effect and is defined as

$$\epsilon_r = \frac{C}{C_0} \quad (6)$$

where C_0 is the capacitance of a capacitor with a vacuum between two conductors and C the capacitance when the same region is filled with the dielectric. ϵ_r is independent of the shape or size of the conductors and is entirely a characteristic of the particular dielectric medium. Table 1 [4] gives the values of ϵ_r for static or low-frequency (<1-kHz) fields of several materials. ϵ_r , which is a macroscopic and directly measurable parameter, is connected with the microscopic structure of a dielectric material and with its polarization behavior.

From Eq. (3), we have

$$\begin{aligned} \mathbf{D} &= \epsilon_0 \left(1 + \frac{\mathbf{P}}{\epsilon_0 \mathbf{E}} \right) \mathbf{E} \\ &= \epsilon_0 (1 + \chi) \mathbf{E} \\ &= \epsilon_0 \epsilon_r \mathbf{E} \end{aligned} \quad (7)$$

Table 1. The Relative Permittivity of Some Solid Dielectrics at 25°C

Dielectric	ϵ_r
Vacuum	1 (by definition)
Air (atmospheric pressure, 0°C)	1.0006
Amber	2.7
Borosilicate glass	4.0
Corning glass 0010	6.68

Beeswax (yellow)	2.73
Paraffin wax	2.3
Barium titanate	1200

Source: Ref. 4.

where

$$\epsilon_r = 1 + \chi \quad \text{and} \quad \chi = \frac{\mathbf{P}}{\epsilon_0 \mathbf{E}} \quad (8)$$

and χ is the dielectric susceptibility. Thus the parameter χ also provides a link between the macroscopic properties and the atomic molecular theory of dielectric materials.

We may also write a general relation between \mathbf{P} and \mathbf{E} thus (8)

$$\mathbf{P} = \epsilon_r \chi \mathbf{E} + \text{higher terms in } \mathbf{E} \quad (9)$$

where the higher terms in \mathbf{E} are applicable to the phenomenon of hyperpolarization. It should be noted that χ is the ratio of bound charge density to free charge density of a capacitor. A measurement of ϵ_r and hence χ provides the magnitude of the polarization \mathbf{P} of a dielectric material at any particular field \mathbf{E} .

One of the most useful methods of determining \mathbf{P} is to measure the current density $\mathbf{J}(t)$ as a function of time, as [8]

$$\mathbf{J}(t) = \frac{d\mathbf{D}}{dt} \quad (10)$$

It may be shown [3,8] that for noninteracting dipoles, χ is given by

$$\chi(0) = \frac{NP^2}{3\epsilon_0 kT} \quad (11)$$

where $\chi(0)$ is the static susceptibility in the zero-frequency limit, N the number density of polarizable molecules, k the Boltzmann constant, and T the temperature. χ is a dimensionless and scalar quantity in an isotropic medium.

2. MICROSCOPIC CONCEPTS OF POLARIZATION

We shall consider here the three cases of electronic, ionic, and orientational polarizations.

An isolated neutral atom in an electric field acquires a dipole moment when an external electric field produces a separation of the charge centers of opposite polarities. This is known as the *electronic polarization*, and it provides an induced dipole moment

$$p_{\text{ind}} = \alpha_e \mathbf{E} \quad (12)$$

where α_e is the electronic polarizability of an atom and is given by

$$\alpha_e = 4\pi \epsilon_0 r_0^3 \quad (13)$$

where r_0 is the radius of the spherical of an electron cloud surrounding an atomic nucleus. The molar polarizability Π of a monoatomic gas is given by

$$\Pi = N_0 \frac{4\pi}{3} r_0^3 \quad (14)$$

where N_0 is the number of molecules in a gram molecule (Avogadro's number). The lowest polarizability belongs to the noble gases with their completely filled outer electronic shells, which screen the nuclei from the effect of the external electric field. For hydrogen, with $r_0 = 0.53 \times 10^{-10}$ m, α_e is 1.66×10^{-41} F/m². Hence for a field E of 10^5 V/m¹, $\alpha E = 10^{-36}$ C/m. The length l of this induced dipole is $p/e = 10^{-17}$ m (where e is the electronic charge), which is indeed an extremely small distance compared with atomic dimensions [6].

Ionic polarization occurs in ionic substances, such as alkali halides, whose molecules are formed of atoms that have excess charges of opposite polarities. In an external field the relative positions of the positive and negative ions of a molecule may shift, thus introducing the dipole moment in addition to the induced electronic polarization. The ionic polarization p_i is given by

$$p_i = \alpha_i \mathbf{E} \quad (15)$$

where α_i is the ionic polarizability of the molecule, which arises from the ionic displacement. The alkali halides (halides of the group I elements) have the highest polarizabilities, possibly because of the single electron in their outermost shells. Table 2 [6] provides a list of values of contribution of ions to the molar polarization of typical alkali halides.

The third type of polarization, known as the *orientational polarization*, is associated with permanent dipoles in dipolar materials that possess a dipole moment even in the absence of an externally applied electric field. However,

Table 2. Ionic Polarization as a Fraction of the Total Polarization for Alkali Halides, and (in Parentheses) the Ionic Polarization of Each Compound Relative to that of LiF

	F	Cl	Br	I
Li	0.68 (1.0)	0.53 (3.22)	0.49 (1.96)	0.40 (2.09)
Na	0.65 (1.12)	0.50 (3.38)	0.44 (1.82)	0.39 (2.13)
K	0.65 (1.95)	0.49 (4.25)	0.46 (2.38)	0.38 (2.34)

Source: Ref. 6.

such a moment may not be observed macroscopically, as the thermal energy will randomize the dipoles so that the average moment will be zero over a small physical volume. On an application of an external electric field the dipoles will experience a torque, which will orient them in the field direction so that the average dipole moment will no longer be zero. It may be shown [3] that the orientational polarizability α_0 is given by

$$\alpha_0 = \frac{p^2}{3kT} \quad (16)$$

By adding the three polarizabilities mentioned above, the total polarization P can now be written as the sum of the three components

$$\mathbf{P} = p_e + p_i + p_0 = N \left(\alpha_e + \alpha_i + \frac{p_0^2}{3kT} \right) \mathbf{E} \quad (17)$$

where N is the number of contributing molecules or particles per unit volume.

Of course, not all atoms or molecules need display each of these three types of polarizability. Only the orientational polarization is temperature-dependent. Equation (17) is known as the *Langevin-Debye* formula, and we have

$$\chi = \epsilon_r - 1 = \frac{\mathbf{P}}{\epsilon_0 \mathbf{E}} = \frac{N}{\epsilon_0} \left(\alpha_e + \alpha_i + \frac{p_0^2}{3kT} \right) \quad (18)$$

Thus a measurement of ϵ_r as a function of temperature may help to distinguish the orientational polarization contribution from the sum of the components α_e and α_i , which are practically independent of temperature.

Figure 1 shows (9) a plot of $\epsilon_r - 1$ as a function of $1/T$ for the molecule of methyl amine (CH₅N). The intercept for the line at $1/T = 0$ and its slope are approximately 8×10^{-4} and 0.6 K^{-1} , respectively. From Eqs. (8), (9), and (17), we have (9)

$$\alpha_e + \alpha_i = \frac{8 \times 10^{-4} \epsilon_0}{N} \approx 6 \times 10^{-4} \text{ F/m}^2 \quad (19)$$

Figure 1. A plot of $\epsilon_r - 1$ as a function of $1/T$ for a molecule of methylamine (CH_5N) [9,10].

and

$$p_0^2 = \frac{0.6\epsilon_0 3k}{N} \approx 4.2 \times 10^{-30} \text{ C/m} \quad (20)$$

The further separation of α_e and α_i is not possible using this technique alone.

Table 3 gives the electric dipole moments of some molecules. The commonly used unit of dipole moment is the debye; $1 \text{ D} = 3.33 \times 10^{-30} \text{ C/m}$.

Table 3. Electric Dipole Moments of Some Molecules

Molecule	Dipole moment

CCl ₄	0.0	0
CH ₄ O	5.7	1.71

Space charge (interfacial) polarization generally arises from a presence of electrons and/or ions that have limited macroscopic motions in the bulk of a dielectric material. Eventually these charge carriers are localized at lattice defect sites, metal–electrode interfaces, impurity centers, and voids. As a result, the electric field in the dielectric may become distorted, thus producing an apparent increase in the dielectric constant. Space charge polarization is particularly evident in multiphase and inhomogeneous dielectrics, and its effect is dominant, particularly at low frequencies, in practical dielectrics such as impregnated paper, polymers, and sintered ceramics.

The study of dielectric polarization and susceptibility in liquids and solids is more complicated than in gases because of the interactions between the atoms and molecules in the condensed phase. These atoms and molecules will still exhibit electronic, ionic, and orientational polarizations. However, the effective local field E_1 on an atom or molecule in a liquid or a solid dielectric may not be the same as the externally applied field E . It is difficult to calculate the effective local field E_1 in the condensed phase except for the most symmetric crystals.

Since $P = \epsilon_0 (\epsilon_r - 1) E$, for the simplest case of a cubic crystal, the Lorentz equation for the local field E_1 (6) is

$$E_1 = (\epsilon_r + 2)E/3 \quad (21)$$

and $P = N\alpha E_1$, where α is the total polarizability and N the number of molecules per unit volume. Hence

$$P = (\epsilon_r + 2)NE/3 \quad (22)$$

and

$$\frac{N\alpha}{3\epsilon_0} = \frac{\epsilon_r - 1}{\epsilon_r + 2} \quad (23)$$

Equation (23) is the Clausius–Mossotti equation, which relates the microscopic property of the polarizability α with the macroscopic property of the relative permittivity or dielectric constant ϵ_r . Now we have

$$N = \frac{N_0\rho}{M} \quad (24)$$

where N_0 is the Avogadro number, M the molecular weight, and ρ the density. Substituting Eq. (24) into Eq. (23), we obtain the molar polarizability per mole:

$$\frac{N_0\alpha}{3\epsilon_0} = \frac{M}{\rho} \frac{\epsilon_r - 1}{\epsilon_r + 2} \quad (25)$$

Equation (25) should be used with caution, as it does not take dipolar interactions into account properly. Equation (23) may, however, be used to calculate the electronic polarizability α_e from the measured values of ϵ_r for dilute gases, for which $\epsilon_r \approx 1$ and $\epsilon_r + 2 \approx 3$. For such cases, we have

$$\alpha_r = \frac{\epsilon_0(\epsilon_r - 1)}{N} = \frac{\epsilon_0\chi}{N} \quad (26)$$

Table 4. Polarizability of Argon

Form	T (K)	Pressure (atm)	ϵ_r	$\alpha_e (10^{-40} \text{ F/m}^2)$
Gas	293	1	1.000517	1.83
Liquid	83	1	1.53	1.86

Source: Ref. 9.

Table 4 shows that the polarizability of the element argon does not vary significantly [9] between its dilute gas and liquid states. That may not be true for other gases with more extensive electronic structure when condensed to liquid or solid form.

The polarizabilities of α_e and α_i may be determined independently for ionic crystals in the solid state. The relative permittivities ϵ_r of ionic crystals are frequency-dependent. For an applied field at low frequencies the value of ϵ_r will be dependent on both α_e and α_i , whereas in the optical frequency range the lattice ions will not be able to follow the applied field and ϵ_r will only be ϵ_e . Table 5 shows the static (low-frequency) and optical (high-frequency) values of ϵ_r for some ionic crystals [9]. The difference between the values of ϵ_r in the second and the third columns is the contribution of the ionic polarization alone, whereas those in the third column characterize the contribution due to α_e .

The behavior of orientational polarization in dipolar molecules in the gas and liquid phases may be quite large if rotation of the dipoles is possible [10]. For such a case, the polarizability will have contributions from α_e , α_i , and α_0 , where the α_0 contribution will be temperature-dependent, where ϵ_r increases with decreasing temperature. However, as the temperature is lowered and the material solidifies, the value of ϵ_r will drop abruptly when the molecules can no longer rotate, and thus rotation cannot contribute to the polarization. Figure 2a [9,11] illustrates such behavior of ϵ_r for nitromethane. It may be observed that at 244 K, nitromethane freezes and ϵ_r drops abruptly from 45 to just under 5. At this temperature α_0 is zero for nitromethane and its polarizability arises from the α_e and α_i contributions, which are independent of temperature. However, there are some solids, such as HCl, that do not show this type of behavior. For HCl in the liquid state ϵ_r is large and increases with decreasing temperature, indicating rotational behavior of the molecules (see Fig. 2b). However, below 165 K, where HCl freezes, ϵ_r still continues to increase [9,12] because of the increase in the den-

sity of the material. At 100 K, the molecular rotation finally ceases and α_0 virtually becomes zero. The polarization contribution at this temperature in HCl originates from α_e and hindered rotation [9,12].

3. DIELECTRIC LOSS

3.1. Time-Dependent Dielectric Response

The dielectric behavior has been represented in the previous section by three vectors, \mathbf{D} , \mathbf{E} , and \mathbf{P} , which are assumed to be collinear in space and in the same phase in time. However, neither of these two assumptions is necessarily valid. We shall only consider the nature of the dielectric behavior with time for nonpolar materials and those containing permanent dipoles. Regarding the spatial collinearity, extensive treatment of crystal symmetry is necessary and will not be discussed here.

The time-dependent dielectric response may be synthesized [8] from three fundamental time dependences of the electric field: the delta function $\delta(t)$, the step function $1(t)$,

and the harmonic function $\sin \omega(t)$ or $\cos \omega(t)$, where ω is the angular frequency ($= 2\pi f$). Equation (3) may now be represented thus

$$\mathbf{D}(t) = \varepsilon_0 \mathbf{E} + \mathbf{P}(t)$$

where the first term on the right-hand side provides the instantaneous free-space contribution and the second the delayed polarization. We define a dielectric response function $\phi(t)$. The polarization response to a delta function excitation of strength $E \Delta t$ is [8]

$$\mathbf{P}(t) = \varepsilon_0 (\mathbf{E} \Delta t) \phi(t) \quad (27)$$

where E is the electric field, acting over a time period ΔT . From the principle of causality, we have

$$\phi(t) = 0 \quad \text{for } t < 0 \quad (28)$$

In the absence of any permanent polarization, we obtain

$$\lim_{t \rightarrow \infty} \phi(t) = 0 \quad (29)$$

Furthermore, from the principle of superposition, we have [8]

$$\mathbf{P}(t) = \varepsilon_0 \int_{-\infty}^t \phi(t - \tau) \mathbf{E}(\tau) dT \quad (30)$$

Equation (30) implies that the magnitude of polarization at a time t in a dielectric will depend on its past value; in other words, the material has a memory. On an application of an elementary step function field $E1(t)$, the dielectric polarization is given by

$$\mathbf{P}(t) = \varepsilon_0 \mathbf{E} \int_0^t \phi(\tau) d\tau \quad (31)$$

The charging current $I_c(t)$ is given by [8]

$$I_c(t) = \frac{d\mathbf{D}(t)}{dt} + \sigma_0 \mathbf{E} \quad (32)$$

$$\begin{aligned} &= \varepsilon_0 \frac{d\mathbf{E}(t)}{dt} + \frac{d\mathbf{P}(t)}{dt} + \sigma_0 \mathbf{E} \\ &= \varepsilon_0 \mathbf{E} [\delta(t) + \phi(t)] + \sigma_0 \mathbf{E} \end{aligned} \quad (33)$$

where the delta function $\delta(t)$ represents the instantaneous free-space response of the step function field, followed by the polarization current $d\mathbf{P}(t)/dt$ of the material. σ_0 is the DC conductivity, if any, of the dielectric at infinitely long time. Thus, we have [8]

$$\mathbf{P}(\infty) = \varepsilon_0 \mathbf{E} \int_0^{\infty} \phi(t) dt = \varepsilon_0 \chi(0) \mathbf{E} \quad (34)$$

where $P(\infty)$ is the polarization with a steady electric field E after an infinitely long time when the polarizing elements tend to be oriented along the field direction. On

removal of this step function field, a depolarization current $I_d(t)$ will follow as the thermal agitation randomizes the orientation of the dipoles with time. For this latter case there will be no contribution of σ_0 at $E = 0$.

3.2. Frequency-Dependent Dielectric Response

The polarization response to a harmonic field is known as the *frequency-domain response*. Taking the Fourier transform of both sides of Eq. (34), we get

$$\mathbf{P}(\omega) = \varepsilon_0 \chi(\omega) \mathbf{E}(\omega) \quad (35)$$

where $P(\omega)$ and $E(\omega)$ are the Fourier transforms of the time-dependent polarization and field, respectively. $\chi(\omega)$ is the frequency-dependent complex susceptibility, and it is the Fourier transform of the time-dependent response function $\phi(t)$:

$$\chi(\omega) = \chi'(\omega) - i\chi''(\omega) = \int_0^{\infty} \phi(t) e^{i\omega t} dt \quad (36)$$

The real part $\chi'(\omega)$ provides the magnitude of polarization in phase with the harmonic driving field $E(\omega)$ and does not contribute to the power loss, whereas the imaginary part $\chi''(\omega)$, which is in quadrature with the field, is referred to as the *dielectric loss*. $\chi'(\omega)$ and $\chi''(\omega)$ may be represented as odd and even functions of frequency, respectively:

$$\chi'(\omega) = \int_0^{\infty} \phi(t) \cos \omega t dt \quad (37)$$

$$\chi''(\omega) = \int_0^{\infty} \phi(t) \sin \omega t dt \quad (38)$$

In terms of permittivity, we may write

$$\mathbf{D}(\omega) = \varepsilon(\omega) \mathbf{E}(\omega) = \varepsilon_0 [1 + \chi'(\omega) - i\chi''(\omega)] \mathbf{E}(\omega) \quad (39)$$

For zero frequency, namely, the static case, we have

$$\chi'(0) = \int_0^{\infty} \phi(t) dt \quad (40)$$

and

$$\chi''(0) = 0 \quad (41)$$

Equation (36) shows that both $\chi'(\omega)$ and $\chi''(\omega)$ are functions of the dielectric response function $\phi(t)$, and these two parameters are Hilbert transforms of each other, through what are referred to as the *Kramers–Kronig relations*:

$$\chi'(\omega) = \frac{1}{\mathbf{P}} C \int_{-\infty}^{\infty} \frac{\chi''(x)}{x - \omega} dx \quad (42)$$

$$\chi''(\omega) = -\frac{1}{\mathbf{P}} C \int_{-\infty}^{\infty} \frac{\chi'(x)}{x - \omega} dx \quad (43)$$

where C denotes the Cauchy principal value of the integral. For the static case

$$\chi'(0) = \frac{2}{\pi} \int_{-\infty}^{\infty} \chi''(x) d \ln x \quad (44)$$

Equation (44) indicates that the variation of the dielectric parameters with frequency, specifically, the dielectric dispersion, is an essential property of dielectric materials [8]. It also shows that any mechanism that can lead to a strong polarization in a dielectric material must also lead to large losses in some frequency range. In other words, it is not possible to have a loss-free dielectric with a finite susceptibility [8]. In most dielectrics the loss is significant only in limited frequency ranges. Figure 3 [8] shows schematically two nonoverlapping loss processes at the low frequencies and a resonance process in the optical frequency range. In a limited frequency region we may define a *high-frequency permittivity* ϵ_{∞} , accounting for all the processes occurring at higher frequencies; thus [see Eq. (39)]

$$\epsilon(\omega) = \epsilon_{\infty} + \epsilon_0[\chi_x'(\omega) - i\chi_x''(\omega)] \quad (45)$$

from which we get

$$\epsilon_x'(\omega) = \epsilon_{\infty} + \epsilon_0\chi_x'(\omega) \quad (46)$$

and

$$\epsilon_x''(\omega) = \epsilon_0\chi_x''(\omega) \quad (47)$$

For an alternating voltage the frequency-dependent complex capacitance $C(\omega)$ is

$$C(\omega) = C'(\omega) - iC''(\omega) \quad (48)$$

where $C'(\omega)$ and $C''(\omega)$ are the real and imaginary parts of the complex capacitance. The loss angle δ is the angle between the electric field and the dielectric polarization. The

Figure 3. Schematic diagram of the frequency dependence of the real and imaginary parts of the complex susceptibility, showing three processes; the last one is a resonance process [8].

loss tangent

$$\tan \delta = \frac{C''(\omega)}{C'(\omega)} = \frac{\epsilon''(\omega)}{\epsilon'(\omega)} \quad (49)$$

is independent of the geometry of the dielectric material.

The existence of the polarization with respect to the field leads to the energy dissipation in the dielectric. Now the power dissipation \mathbf{P} per unit volume is

$$\mathbf{P} = I_{\text{phase}} \mathbf{E}$$

where I_{phase} is the part of the current in phase with \mathbf{E} , and is given by

$$\mathbf{P} = \omega \mathbf{E}^2 \epsilon_0 \epsilon' \tan \delta = \omega \mathbf{E}^2 \epsilon_0 \epsilon'' \quad (50)$$

Table 6 gives (6) typical values of the permittivity and loss factor of various dielectric materials at room temperature for different frequencies. Generally polar materials have larger permittivities and loss tangents than do non-polar materials. For many liquids the frequency at which maximum energy loss occurs at room temperature is approximately 1000 MHz (wavelength $\lambda \approx 0.3$ m), as shown [1] for three typical liquids in Table 7, where τ is the relaxation time ($= 1/f$).

Another type of energy loss occurs in a resonance absorption process at very high (i.e., IR, visible, and UV) frequencies. Although the real and imaginary parts of the complex permittivity vary in a manner similar to that for dipole relaxation, the origin of the energy loss is different in this process. At optical frequencies the permittivity of the dielectric is due almost entirely to the electronic polarization. In the absence of any external field a vibrating electron of charge e and mass m is elastically bound to its nucleus by a restoring force, and its equation of motion is

$$m \frac{d^2x}{dt^2} + kx = 0 \quad (51)$$

where k is the restoring-force constant and x is the displacement of the electron. This equation represents a simple harmonic motion, and its solution is

$$x = x_0 \sin \omega_0 t + A \quad (52)$$

where $\omega_0 = (k/m)^{1/2}$, A is the integration constant, x_0 the amplitude of oscillation, and ω_0 the natural resonance angular frequency of the oscillation. When an external alternating electric field is applied to this system, the resulting motion is a forced oscillation, represented by

$$m \frac{d^2x}{dt^2} + m\omega_0^2 x = e \mathbf{E} \cos \omega t \quad (53)$$

where \mathbf{E} is the amplitude of the field \mathbf{E} and ω is its frequency. Clearly the response of the oscillating system will now depend on both ω and ω_0 . The oscillations might be expected to build up without limit when $\omega = \omega_0$, although they are expected to be small at frequencies far away from

ω_0 . However, at resonance (i.e. $\omega = \omega_0$), the oscillations will in fact be limited (damped) by the emission of electromagnetic radiation by the oscillating charges, which dissipates energy. It may be shown that in a resonance absorption process [6]

$$\epsilon'(\omega) = \epsilon_0 + \frac{Ne^2}{m} \frac{\omega_0^2 - \omega^2}{(\omega_0^2 - \omega^2) + r^2\omega^2} \tag{54}$$

and

$$\epsilon''(\omega) = \frac{Ne^2}{m} \frac{r\omega}{(\omega_0^2 - \omega^2) + r^2\omega^2} \tag{55}$$

Table 7. Typical Relaxation Times of Three Liquids

where r is a constant of the material, called the *dissipation constant*. These quantities have the form shown in Fig. 3 at very high frequencies. For $\omega = 0$, which is the static case, we have

$$\epsilon'(0) = \epsilon_0 + \frac{Ne^2}{m\omega_0^2} \tag{56}$$

$\epsilon''(\omega)$ approaches zero for both $\omega \gg \omega_0$ and $\omega \ll \omega_0$, and it goes through a maximum value of $Ne^2/(mr\omega)$. Again $\epsilon''(\omega)$ represents an energy loss and the power loss \mathbf{P} is given again by

$$\mathbf{P} = \omega \epsilon''(\omega) \epsilon_0 \mathbf{E}^2 \tag{57}$$

As the characteristic values of ω_0 for electron clouds are very high, the resonance absorptions and their corresponding energy losses occur at very high frequencies in the IR-UV range.

For pure nonpolar dielectrics, whether solid, liquid, or gas, the polarization is of an essentially electronic nature. Some polar materials with a highly symmetric structure, like carbon tetrachloride (CCl₄), may also

exhibit electronic polarization. The presence of electronic polarizability may be verified with the Maxwell relation, $\epsilon^1 = n^2$, where n is the refractive index of the dielectric. Table 8 compares the ϵ^1 and n^2 values for a few marginally nonpolar materials [13,14].

4. MODELS OF DIELECTRIC RELAXATION

4.1. Models

The first model of the dielectric relation is due to Debye [3]. According to this model, the susceptibility function $\chi(\omega)$ for noninteracting polar molecules is given by [7]

$$\chi(\omega) \propto \frac{1}{1 + i(\omega/\omega_p)} \tag{58}$$

where ω_p is the angular frequency at which the maximum loss peak occurs. The real and imaginary parts of $\chi(\omega)$ are

$$\chi'(\omega) \propto \frac{1}{1 + \omega^2\tau^2} \tag{59}$$

and

$$\chi''(\omega) \propto \frac{\omega\tau}{1 + \omega^2\tau^2} \tag{60}$$

The corresponding time-domain response $\phi(t)$ follows the exponential function (15)

$$\phi t \propto e^{-t/\tau} \tag{61}$$

The loss peak occurs here at $\omega = \omega_p = 1/\tau$. Figure 4 shows the dependence of $\chi'(\omega)$, $\chi''(\omega)$, and $\phi(t)$ of Eqs. (59)–(61) [16] in log-log representation. The loss peak is symmetric about ω_p , and its width at half-height is 1.144 decades on the frequency scale. The Debye behavior has been observed in gases and in some polar liquids. The relaxation behavior of water and deuterium oxide closely

Figure 4. (a) The ideal Debye response in the frequency domain, with its characteristic frequency dependence of $\chi'(\omega) \propto \omega^{-2}$ and $\chi''(\omega) \propto \omega^{-1}$ above the loss peak. (b) The corresponding time-domain response, which is purely exponential, is plotted here in the somewhat unfamiliar log-log representation [16].

approximates that of the Debye form [17–19]. However, it is generally nonexistent in solids.

To account for the departure of the observed dielectric behavior, the following empirical expressions have been proposed. The Cole–Cole equation (20) is

$$\chi(\omega) \propto \frac{1}{1 + (i\omega/\omega_p)^{1-\alpha}} \tag{62}$$

where α is a fitting parameter in the range $0 < \alpha \leq 1$. Equation (62) provides a broader and symmetric relaxation spectrum than the Debye type. Furthermore, for $\omega > \omega_0$, $\chi'(\omega)$ and $\chi''(\omega)$ show parallelism in the log-log plot.

The Davidson–Cole equation has the form [21]

$$\chi(\omega) \propto \frac{1}{(1+i\omega/\omega_p)^\beta} \tag{63}$$

where β is yet another curve-fitting parameter in the range $0 < \beta \leq 1$. Equation (63) provides asymmetric relaxation profiles at $\omega \leq \omega_0$, whereas $\chi'(\omega)$ and $\chi''(\omega)$ remain parallel at $\omega > \omega_0$.

The Fuoss–Kirkwood model [22] for the imaginary part of the susceptibility is

$$\chi''(\omega) \propto \frac{2(\omega/\omega_p)^\gamma}{1 + (\omega/\omega_p)^{2\gamma}} \tag{64}$$

Another relaxation model is given by

$$\chi(\omega) \propto \sum_{s=1}^{\infty} \frac{\Gamma(\Delta s)}{(s-1)!} \left(\frac{\exp(-i\Delta\pi/2)}{\omega^\Delta \omega_p^{-\Delta}} \right)^s \tag{65}$$

This is an expansion into the frequency domain of the Kolrauch–Williams–Watts function [15] of time: $\exp[-(t/\tau)^\Delta]$. The parameter Δ in Eq. (65) has no physical

significance and is not based on the physics of dielectric interactions.

So far the models have had only one fitting parameter, namely, α for the Cole–Cole equation, β for the Davidson–Cole equation, γ for the Fuoss–Kirkwood equation, and Δ for the Kolrauch–Williams–Watt equation. The model due to Havriliak and Negami [23,24], the first one with two parameters, is given by

$$\chi(\omega) \propto \frac{1}{[1 + (i\omega/\omega_p)^{1-\alpha}]^\beta} \tag{66}$$

It should be stressed again that the fitting parameters α and β in this equation have no physical significance.

A classical form of presentation of the dielectric data is to plot $\chi'(\omega)$ or $\epsilon'(\omega)$ against $\chi''(\omega)$ or $\epsilon''(\omega)$, namely, the so-called Cole–Cole plot [20]. Figure 5 shows the shapes of the Debye, Cole–Cole, and Davidson–Cole equations for the susceptibility functions in Cole–Cole plots. It has been shown [20] that with the Debye model, a graph of $\chi'(\omega)$ against $\chi''(\omega)$ over the entire frequency range will be a semicircle and $\chi(\infty)$ or ϵ_∞ is obtained from the intercept at the horizontal axis (see Fig. 5a). Thus the relaxation time τ may be obtained from the slope of a straight line from the

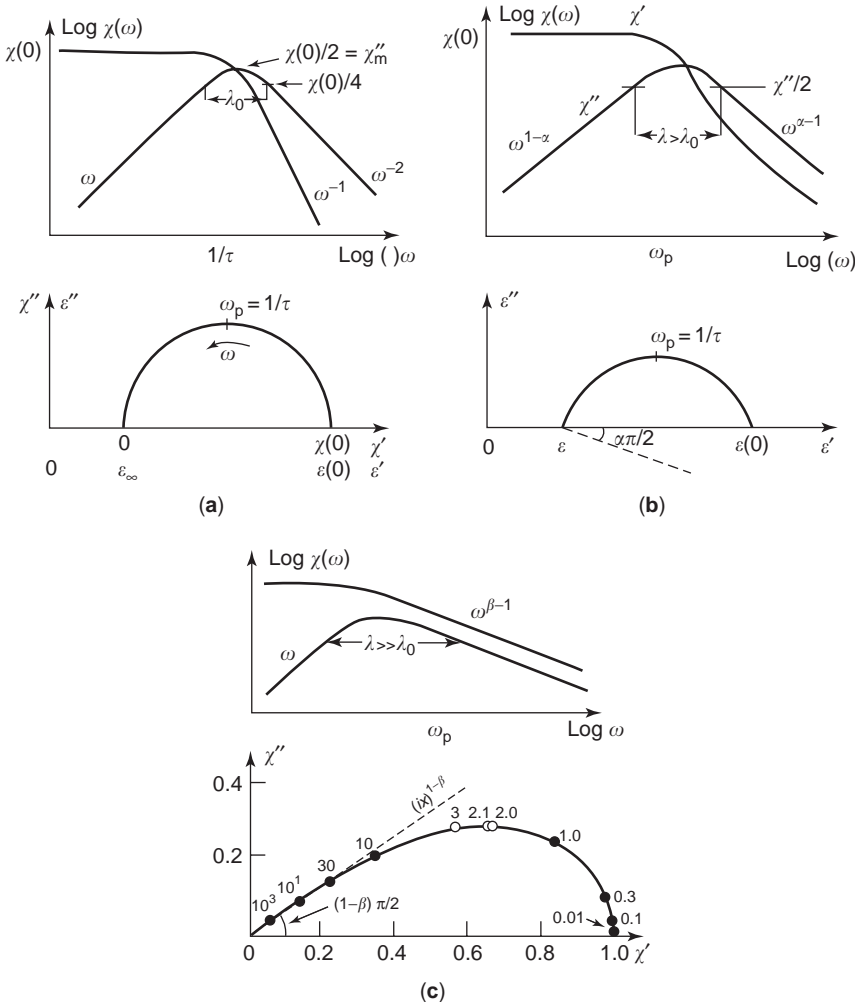

Figure 5. The frequency dependence of the real and imaginary parts of the susceptibility and the Cole–Cole presentation for (a) Debye, (b) Cole–Cole, and (c) Davidson–Cole systems [8].

origin to a point on the semicircle for which ω is known. Now the Cole–Cole relaxation model provides a symmetric but broader relaxation spectrum, and the corresponding Cole–Cole plot is still a semicircle. However, its center is depressed below the χ' or ϵ' horizontal axis (see Fig. 5b) with the angle $\alpha\pi/2$ between the radius of the circle and χ' or ϵ' axis. There is no molecular interpretation of this factor α , and it has been interpreted as a “spreading factor” of the actual relaxation time about a certain mean value. The magnitude of α must lie between zero and unity. The Cole–Cole plot for the Davidson–Cole model is a skewed plot (see Fig. 5c), representing a severe departure from the Debye relaxation behavior.

The Havriliak–Negami function [23,24] with two parameters, α and β [Eq. (66)], appears to provide the best results for the fitting of the measured dielectric data for most materials. However, none of these mathematical models that invoke a distribution of relaxation energies (25) or times offer any physical interpretation of material properties [26–29].

It has been suggested that a dielectric loss spectrum may be regarded as a mathematical summation of a distribution function $g(\tau)$ of Debye responses corresponding to a distribution of relaxation times [30]; thus

$$\chi(\omega) = \int_0^\infty \frac{g(\tau)}{1+i\omega\tau} d\tau \tag{67}$$

The distribution functions are always positive, and curves of $\chi''(\omega)$ or $\epsilon''(\omega)$ can be formed from them by the superposition of many single relaxation-time or frequency curves [31]. It has been shown [32] that the product of the elapsed time and the depolarization current is a convolution of the distribution function of relaxation frequencies with a weight function of an asymmetric bell shape. A similar relationship is also shown to exist for the imaginary part of the permittivity. The same work [32] also proposes a deconvolution procedure to determine the distribution function of relaxation frequencies from experimental data. A distribution of relaxation times from the frequency dependence of the real part of the complex permittivity has also been made with the inverse Fourier transformation [33]. As stated earlier, however, no distribution of relaxation times that can claim physical reality can be associated with relaxation systems in condensed matter [8,26,27].

A two-parameter model for the complex susceptibility function $\chi(\omega)$, known as the *universal relaxation law*, has been proposed [8,16], which states that all solid dielectrics follow fractional power laws in frequency. It is of interest to note that $\chi(\omega)$ may be expressed by a simple empirical expression [16,23]

$$\chi(\omega) = A[1 + (ix)^m]^{(n-1)/m} \tag{68}$$

where the exponents m and n lie between zero and unity and x is the normalized frequency. Equation (68) indicates that the experimental state of dielectric susceptibility can be fitted with two power-law exponents. The Debye function is a limiting form of this equation for $m = 1$ and $n = 0$.

For the symmetric loss peak at ω_p and $x=1$, we have $m = 1 - n$. Furthermore, the ratio $\chi''(\omega)/\chi'(\omega)$ decreases as m and $1 - n$ become smaller, thus providing broader peaks as in the case of the Cole–Cole function. This leads to the universal law, characterized by two fractional power laws in frequency respectively below and above the loss peak frequency ω_p [8,16]

$$\chi''(\omega) = \tan\left(\frac{m\pi}{2}\right)[\chi(0) - \chi'(\omega)] \propto \omega^m \quad \text{for } \omega \ll \omega_p \tag{69}$$

for $\omega \ll \omega_p$ and

$$\chi''(\omega) = \cot\left(\frac{n\pi}{2}\right)\chi'(\omega) \propto \omega^{n-1} \quad \text{for } \omega \gg \omega_p \tag{70}$$

where the exponents are in the ranges $0 < n < 1$ and $0 < m < 1$.

As a result, in the high-frequency range of the loss peak, the ratio of the imaginary to the real part of the complex susceptibility is a frequency-independent constant:

$$\frac{\chi''(\omega)}{\chi'(\omega)} = \cot\left(\frac{n\pi}{2}\right) \tag{71}$$

Hence, in a log–log plot $\chi''(\omega)$ and $\chi'(\omega)$ appear as parallel lines for $\omega \gg \omega_p$. It should be noted that for the Debye process this ratio is $\omega\tau$ and thus increases linearly with frequency, which is consistent with the idea that the process is a “viscous” phenomenon in which the dielectric loss is linearly related to the angular velocity [16].

For the low-frequency part of the loss peak ($\omega < \omega_p$), we have [8,15]

$$\frac{\chi''(\omega)}{\Delta\chi'(\omega)} = \tan\left(\frac{m\pi}{2}\right) \tag{72}$$

where $\Delta\chi'(\omega) = \chi(0) - \chi'(\omega)$ is known as the *dielectric decrement* and is the extent to which the polarization at any particular frequency falls short of the value of the equilibrium polarization in a static field. Equations (69) and (70) may be represented by the empirical law combining the two fractional power laws above and below ω_p [8]:

$$\chi''(\omega) \propto \frac{1}{(\omega/\omega_p)^{-m} + (\omega/\omega_p)^{1-n}} \tag{73}$$

The Fourier transforms of fractional power laws correlate the frequency-domain dielectric parameters with their time-domain behavior thus (16):

$$\omega^m \propto t^{-m-1} \quad \text{for } t \gg \tau \tag{74}$$

$$\omega^{n-1} \propto t^{-n} \quad \text{for } t \ll \tau \tag{75}$$

In the carrier-dominated low-frequency dispersion (LFD) or quasi-DC (QDC) systems, mobile charge carriers, such as ions and electrons, act as polarizing species and provide a broad dielectric response [16,34–36] in which no loss peak is observed. The LFD (or QDC)

Figure 6. The frequency dependence of a system dominated by LFD or QDC with $n_1 = 0.8$ at high frequencies and $n_2 = 0.5$ at low frequencies. The crossover point is deliberately shifted to high frequencies to show the LFD or QDC region [16].

relaxation is characterized by two independent processes, below and above a certain critical frequency ω_c , which may be represented by Eq. (70). The real and imaginary parts of the complex dielectric susceptibility steadily increase with decreasing frequency for small values of n_2 , at frequencies less than ω_c . This is followed by a flat loss behavior above ω_c with $n_1 \approx 1$ [8,16,28]. The frequency ω_c plays a role analogous to that for ω_p in a dipolar system.

Figure 6 shows [16] typical behavior of $\chi(\omega)$ for the LFD (or QDC) system. Figure 7 shows schematically the typical time-domain behavior of a dipolar LFD (or QDC) system together with the flat loss response corresponding to $n \rightarrow 1$ [15]. Note that the flat loss behavior is the limiting case of the dielectric response that occurs in low-loss materials with a very small value of the ratio $\chi''(\omega)/\chi'(\omega)$. The value

Figure 7. The time-domain response $\phi(t/\tau)$ of typical dielectric systems, including the Debye exponential response; the dipolar response with $n = 0.8$, $m = 0.6$; the carrier-dominated LFD response with $n_1 = 0.8$, $n_2 = 0.2$; and the flat loss with $n = 1$ [16].

of n_2 can never be zero, and hence n cannot actually have a value of 1, although nearly flat loss behavior has been observed experimentally.

There are few examples of solids, including single crystals of ferroelectrics, that show pure Debye relaxation behavior. A variety of solids (viz., low-loss dielectrics, dipolar materials, semiconductor p-n junctions, and biological materials) are known to show dielectric dispersions that may be fitted with the universal fractional power law [Eq. (73)]. Furthermore, dipolar systems exhibit loss peaks, whereas the carrier-dominated systems exhibit LFD (or QDC) behavior [8,34,35].

A stochastic model for the universal dielectric dispersion has also been proposed [37–39]. This probabilistic model is based on the assumption that individual dipoles and their environments interact during the process of relaxation and the dielectric response function is given by [37]

$$\phi(t) = \phi_0 \alpha \omega_p (\omega_p t)^{\alpha-1} [1 + k(\omega_p t)^\alpha] \quad (76)$$

where ϕ_0 is a constant of the relaxation function $\phi(t)$, and k is a positive real number. In the short-time limit this function is

$$\phi(t) \approx (\omega_p t)^{\alpha-1} = (\omega_p t)^{-n} \quad (77)$$

where $n = 1 - \alpha$ and $0 < n < 1$. The corresponding long-time limit is

$$\phi(t) \approx (\omega_p t)^{-(\alpha+k)/k} = (\omega_p t)^{-m-1} \quad (78)$$

where $m = \alpha/k$ and $0 < m < 1$ if $\alpha < k$. The exponents m and n of the universal fractional law [8] are thus related by [37]

$$m = \frac{1-n}{k} \quad (79)$$

where $k > 1 - n$ and $0 < n < 1$. If $1 - n < k \leq 1$, then $1 - n \leq m < 1$, and this is observed in most analyzed experimental results. For $k = 1$ we have $m = 1 - n$, and this is the Cole–Cole response. For $k = 1 - n$ we have $m = 1$, which is the Davidson–Cole response. If $k > 1$, then $0 < m < 1$, which is observed only in a small number of analyzed data [21,33,38]. In this case, $k \rightarrow 0$ and the Williams–Watts response is observed [15,40]. The probabilistic model [37–39] thus suggests a relation between the empirical parameters m and n , defining the low- and high-frequency regions of the complex dielectric susceptibility. It has been suggested [37] that the parameter (k) may be related to the waiting-time distribution of the relaxing dipoles, which may follow a Weibull distribution, namely

$$R(s) = \exp(-ks^\delta) \quad (80)$$

where $R(s)$ is the waiting-time distribution, k is a positive real number, and $0 < \delta < 1$. It has been shown [37] that for a particular waiting-time distribution function, the

solution for $\phi(t)$ can be obtained in a simple analytical form:

$$\phi(t) = \phi(t, 1-n, k), \quad 0 < 1-n < 1 \quad \text{and} \quad k > 0 \quad (81)$$

The relatively recent model [41,42] based on a cluster theory is perhaps the most sophisticated approach to the explanation of relaxation phenomena observed in imperfect materials. The theory has been derived in the framework of quantum mechanics and takes into account the manybody interactions present in condensed matter.

The dipoles in the condensed phase may be regarded as connected with other dipoles through their morphological structure, and it is unlikely that they can act independently as in the Debye model. Both solids and liquids are composed of spatially limited regions possessing partially regular structural order, and such regions may be called *clusters* [41]. In any material many clusters may exist, and in the presence of coupling between them an array may form displaying partial long-range order. Absence of coupling in the limit may lead to a *cluster gas*. In contrast, systems with strong coupling between these arrays will produce an almost perfect crystal. The model also considers two kinds of interactions—*intracluster* and *intercluster* exchanges—and each of these makes its own contributions to the final behavior of the complex susceptibility function.

A dipole in the intracluster motion may first relax exponentially ($d^{-t/\tau}$) as suggested in the Debye model. In doing so, it will affect the field experienced by other neighboring dipoles in the cluster. These neighboring dipoles, in turn, may also relax exponentially, thereby affecting the field experienced by the first dipole, and so on. As a result, the overall effect will be a process with an exponential single dipole relaxation of the form $e^{-t/\tau}$ and concomitant t^{-n} behavior for the relaxation of the cluster dipole moment. The intercluster exchange will have a range larger than that for the intracluster motion, and its origin will be in dipoles near the edge of the cluster interconnecting to a neighboring cluster [29,36,40]. It has been shown [41] that with the intracluster motion and with the progressive involvement of an increasing number of elements with the progress of time, a fractional power law (i.e., ω^{n-1} behavior) for the susceptibility function may be obtained. Furthermore, the parameter n ($0 < n < 1$) is related to the average cluster structure. Highly ordered structure has n values approaching unity, thus indicating an existence of completely correlated clusters. On the other hand, $n \rightarrow 0$ would signify a large degree of disorder, and the limit $n = 0$ would yield Debye-like relaxation behavior.

The intracluster-coupled mode may change to an intercluster mode as the spatial extent of the coupling (wavelength) increases beyond the cluster size. The mathematical derivation of the susceptibility function for the intercluster exchanges is similar to that of the intracluster motion, as the intercluster exchanges are now the perturbation of an ideal state. The result is also a fractional power law [41], giving an ω^m behavior for the susceptibility function. Once again the value of m is in the range $0 < m < 1$, and m represents the degree of structural order, this time on the larger scale of the cluster, namely,

the degree of ordering in the cluster array. Hence, $m \rightarrow 0$ indicates an almost ideal lattice structure, whereas $m \rightarrow 1$ may give rise to a wide distribution of clusters. The intracluster motion and the intercluster exchange mechanisms are schematically represented in Fig. 8 [28].

For the intracluster motion the susceptibility function is given by [41]

$$\chi(\omega) \propto \left(1 + i \frac{\omega}{\omega_p}\right)^{1-n} {}_2F_1\left(1-n, 1-m \frac{\omega_p}{\omega_p + i\omega}\right) \quad (82)$$

where ${}_2F_1$ is the Gaussian hypergeometric function. It should be noted that the asymptotic limits of Eq. (82) are the universal relaxation law [i.e., Eqs. (69) and (70)] [8].

The Dissado–Hill quantum-mechanical model [41] describes a QDC phenomenon as a partial conduction process that is equivalent to the LFD phenomenon [8] described above. In the QDC process considerations similar to those for the dipoles are given to systems containing charge carriers. The difference between a QDC process and DC conduction at low frequencies is that the latter phenomenon is characterized by

$$\chi(\omega) \rightarrow \text{constant} \quad (83)$$

and

$$\chi''(\omega) \propto \frac{\sigma_{dc}}{\omega} \quad (84)$$

where σ_{dc} is the frequency-independent DC conductivity. For the high frequencies, the Maxwell–Wagner interfacial polarization effect [1] may be used to predict a limiting

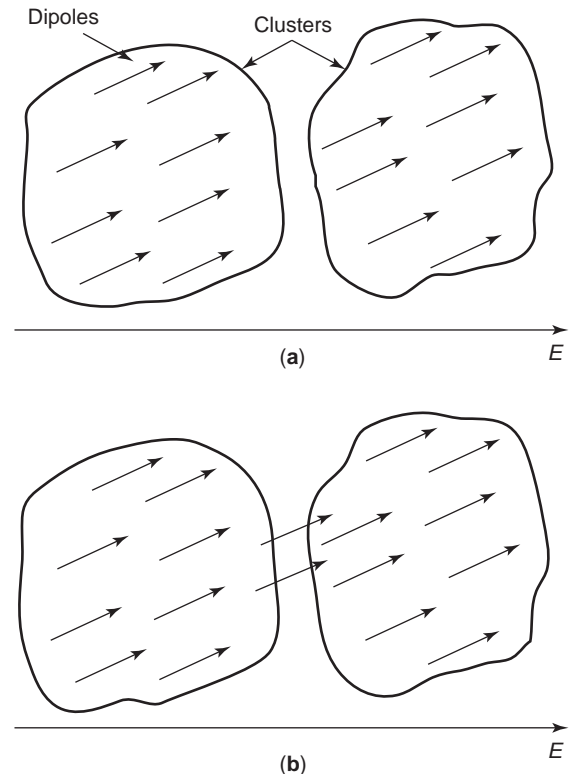

Figure 8. Schematic diagram of (a) intracluster motion and (b) intercluster exchange mechanism of Dissado–Hill model of dielectric relaxation [29,36].

behavior of the form

$$\chi'(\omega) \propto \omega^{-2} \quad (85)$$

$$\chi''(\omega) \propto \omega^{-1} \quad (86)$$

and

$$\chi''(\omega) \quad (87)$$

$$\chi'(\omega) \propto \omega$$

The Dissado–Hill model [41] suggests that the motion of all charge carriers within a cluster of correlation length is cooperative, that is, that the motion of a charge carrier to a neighboring site is limited to the vacancy of such sites and by other charges surrounding it. The model [41] divides the response into high-frequency (short-time) behavior above a critical frequency ω_c , where intracluster motion occurs, and low-frequency (long-time) behavior below ω_c , where intracluster motion exchange occurs. The intracluster motion, which is analogous to the flipping of dipoles, is now replaced by the hopping of charges between available sites within a correlation length ξ , which reduces the overall polarization of the cluster. The high-frequency response has the same functional form as for the dipoles: ω^{n-1} , $0 < n < 1$. Again the physical meaning of the exponent n is the average degree of structural ordering within a cluster, and small values of n will correspond to irregularities in a cluster such as might occur when an interstitial ion or a dislocation is present. The parameter n may also be related to the entropy density per cluster constituent. The value of n may be independent of temperature for thermally stable cluster structuring [41].

In the intercluster exchange there is a physical transport of charges between the clusters. The charge motion is no longer correlated with the available sites of the donor cluster, but rather with those of the acceptor cluster. For this case the susceptibility function is shown to be a fractional power law of the form ω^{-p} , with $0 < p < 1$ [41]. A small value of p indicates a set of clusters that are almost identical to each other, while a large value of p is associated with a broader distribution of clusters in which intercluster exchanges can carry the effective charge through many clusters over a long distance. In the presence of both the intracluster hopping and intercluster charge transport, the susceptibility function of the system is given by [42]

$$\chi(\omega) \propto \left(\frac{\omega_c}{\omega_c + i\omega} \right)^{1-n} {}_2F_1 \left(1-n, 1+p, 2-n; \frac{\omega_c}{\omega_c + i\omega} \right) \quad (88)$$

The asymptotic forms of $\chi(\omega)$ at high and low frequencies with respect to ω_c are [42]

$$\chi'(\omega) \propto \chi''(\omega) \approx \chi'(\omega_c) \left(\frac{\omega}{\omega_c} \right)^{-p} \quad \text{for } \omega \ll \omega_c \quad (89)$$

$$\chi'(\omega) \propto \chi''(\omega) \propto \chi'(\omega_c) \left(\frac{\omega}{\omega_c} \right)^{n-1} \quad \text{for } \omega > \omega_c \quad (90)$$

Once again, it may be noted that the asymptotic values of this model [41,42] are the same as those of the universal law model [8,15]. The relations between the exponents n and p of these two models are

$$p = 1 - n_2 \quad (91)$$

$$n = n_1 \quad (92)$$

where n_1 and n_2 refer to the values of the parameters of the universal law above and below ω_c , respectively [41]:

$$\chi'(\omega) \propto \chi''(\omega) \propto \omega^{n_2-1} \quad \text{for } \omega \ll \omega_c \quad (93)$$

$$\chi'(\omega) \propto \chi''(\omega) \propto \omega^{n_1-1} \quad \text{for } \omega > \omega_c \quad (94)$$

Summarizing the above, it appears that all dielectric materials commonly investigated have the following characteristics in terms of the indices n and m (41):

$n = 0, m = 1$ express the Debye limit of an ideal liquid with independent cluster constituents in the system.

$n = 1, m = 0$ occurs in an ideal crystal with no internal relaxation and zero loss.

For real liquids $n \rightarrow 0, m \rightarrow 1$, and the average clusters are weakly bound.

For plastic crystals, waxes, and viscous liquids, $n \approx \frac{1}{2}$ and $m \approx \frac{1}{2}$. These materials have clusters with restricted structural range.

For solids with interstitial impurities and ferroelectrics, $n \rightarrow 0$ and $m \rightarrow 1$. Ferroelectrics have weakly bound clusters of dipole reversals, thus yielding a small value of n .

For imperfectly crystallized materials with topographical impurities, glasses, and vitreous polymer systems, $n \rightarrow 1$ and $m \rightarrow 0$.

It may be noted that $n + m = 1$ will occur only when the intra- and intercluster displacements lie along the same coordinates, as in Lennard–Jones liquids [43] and hydrogen-bonded systems [44].

The cluster model [41,42] is in many ways the most rigorous description of relaxation of defects in a dielectric system, and it offers an ab initio derivation of the entire spectral shape of the frequency dependence of the susceptibility function.

Table 9 lists the theoretical concepts of dielectric relaxation models, discussed above.

4.2. Electric Equivalent Circuits for Dielectric Loss

A dielectric capacitor can be represented by an electrical circuit where the dielectric loss is reproduced mainly by an equivalent resistance R in series or in parallel with the capacitor and, occasionally, an inductance. A Debye system can be represented, for example, by a resistance and a capacitance in series, while non-Debye behavior of dielectric susceptibility may be constructed with more complex circuits.

Table 9. Theoretical Concepts of Relaxation Models

Function	Equation		Parameters
Debye	$\chi''(\omega) \propto \frac{1}{(\omega/\omega_p)^{-1} + (\omega/\omega_p)}$	(26)	$\alpha = 0$ $\beta = 1$
Cole–Cole	$\chi''(\omega) \propto \frac{1}{(\omega/\omega_p)^{\alpha-1} + (\omega/\omega_p)^{1-\alpha}}$	(27)	$0 < \alpha < 1$ $\beta = 1$
Davidson–Cole	$\chi''(\omega) \propto \frac{1}{(\omega/\omega_p)^{-1} + (\omega/\omega_p)^\beta}$	(28)	$\alpha = 0$ $0 < \beta < 1$
Havriliak–Negami	$\chi''(\omega) \propto \frac{1}{(\omega/\omega_p)^{\alpha-1} + (\omega/\omega_p)^{\beta(1-\alpha)}}$	(29)	$0 < \alpha < 1,$ $0 < \beta < 1$
Jonscher, Dissado, and Hill (dipolar peak)	$\chi''(\omega) \propto \frac{1}{(\omega/\omega_p)^{-m} + (\omega/\omega_p)^{n-1}}$	(21)	$0 < m < 1$ $0 < n < 1$
Jonscher, Dissado, and Hill (QDC process)	$\chi'(\omega) \propto \chi''(\omega) \propto \omega^{n_2-1}$ for $\omega \ll \omega_c$	(24)	$0 < n_2 < 1$ $0 < n_1 < 1$
	$\chi'(\omega) \propto \chi''(\omega) \propto \omega^{n_2-1}$ for $\omega \gg \omega_c$	(25)	
Weron (stochastic model)	$\phi(t) = \phi_0 \alpha \omega_p (\omega_p t)^{\alpha-1} [1 + k(\omega_p t)^\alpha]^{-(1+k)/k}$	(41)	$m = (1 - n)/k$ $1 - n < m < 1$

Source: Refs. 29,36.

For such cases, the concept of a *universal* capacitor [8] has been proposed, and the resulting frequency dependence of the dielectric parameters is

$$\chi(\omega) \propto C_n(\omega) = \beta(i\omega)^{n-1} = \beta \left(\sin \frac{n\pi}{2} - i \cos \frac{n\pi}{2} \right) \omega^{n-1} \quad (95)$$

It should be noted that for nonideal dielectric responses, the circuit elements will have frequency-dependent dispersive properties. Figure 9 shows schematic representations of simple circuit combinations of ideal, frequency-independent elements and some forms of presentation of dielectric data. The frequency response of lossy capacitors of the type represented by Eq. (89) is shown in Fig. 10 [8,36,45]. The association of universal capacitors and dispersive circuit elements is schematically represented in Table 10 [29].

4.3. Relaxation Behavior in Materials

The relaxation phenomena have been studied for a wide range of materials, from covalent, ionic, and van der Waals crystals at one extreme through glasses, liquids containing suspensions, solid synthetic polymers, and p-n junctions at the other [41].

The permittivity of nonpolar gases at normal pressure is close to unity, and the Clausius–Mossotti equation [23]

adequately describes its variation with moderate density changes [46]. At high pressures the molar polarization of gases deviates from the Clausius–Mossotti equation. The molecular polarizability is enhanced by the attractive forces between the molecules, whereas the repulsive forces decrease it.

Centrosymmetric molecules do not possess dipole or octupole moments, but quadrupole moments may be present in some gases, such as hydrogen, carbon dioxide, carbon disulfide, oxygen, nitrogen, benzene, and ethylene. Tetrahedral molecules, on the other hand, have zero dipole and quadrupole moments (e.g., methane and carbon tetrachloride) [46]. The presence of higher dipole moments in a molecule induces moments on its neighbors and produces deviations from the Clausius–Mossotti equation. Polar gases display temperature dependence of the orientational polarization, and their dielectric loss spectra follow the Debye relaxation behavior in which partial orientation of the permanent dipoles occurs under an externally applied field. Polar gases absorb energy in the microwave region through two processes: rotational absorption and unquantized molecular collision. The high-frequency dielectric properties of gases have been well reviewed [47,48] and will not be discussed further here.

There is as yet no exact theory of liquids, which have been treated either as dense gases or as disordered solids.

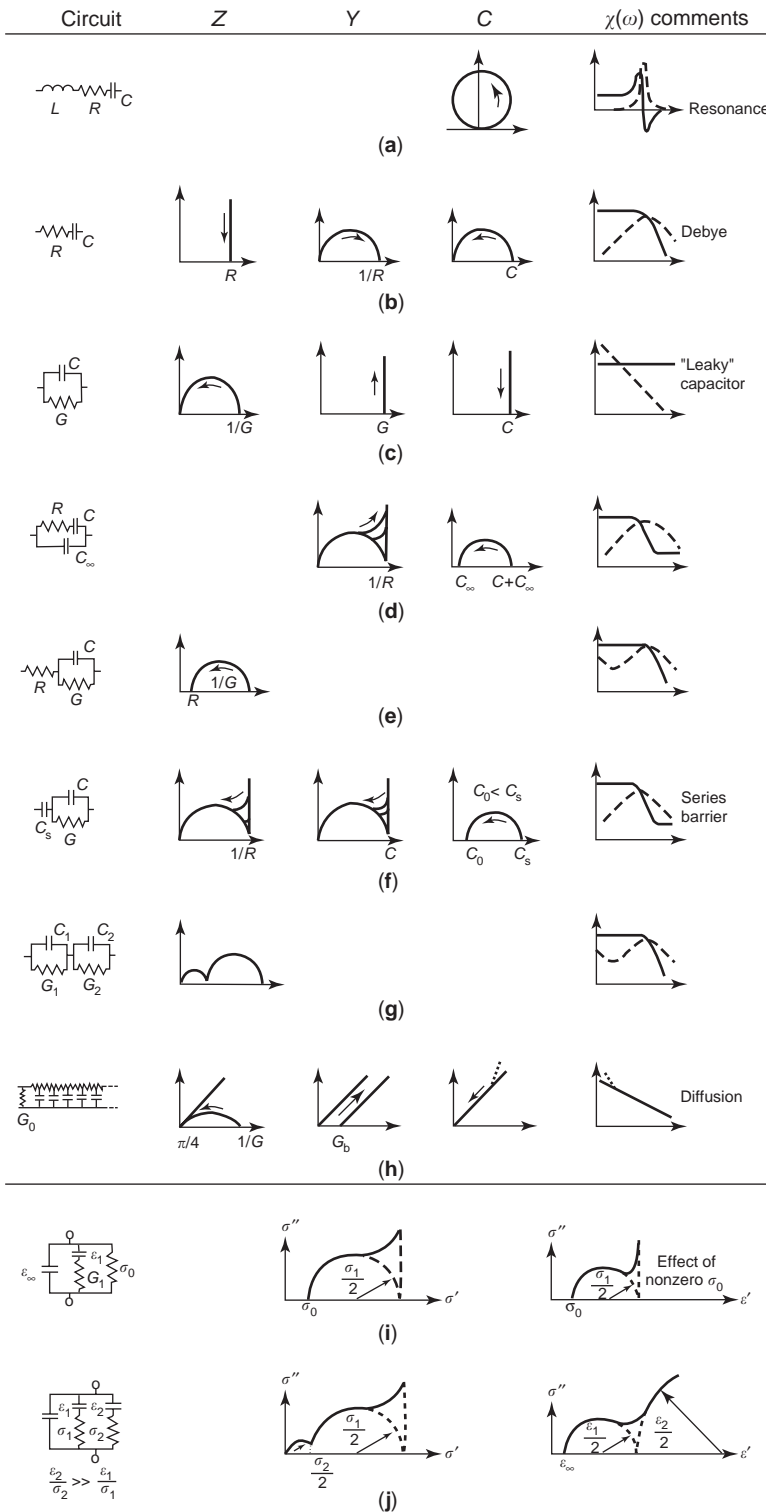

Figure 9. Schematic representation of simple circuits formed as a combination of ideal, frequency-independent elements (a-h) and some forms of presentation of dielectric data (i,j) [8,36,45].

The dielectric relaxation in polar liquids (dilute solutions) with spherical dipolar molecules can be interpreted in terms of the orientation of individual dipoles. In the Debye process, it is assumed that a spherical dipolar molecule obeys Stokes' law, which states that the relaxation time is proportional to the shear viscosity of the liquid and to r^3 , where r is the radius of the sphere. However, the relax-

ation time must depend on the viscosities of both the solvent and the solute. The molecular radius calculated from the relaxation time with the Debye model is usually too small. Improved fit to the relaxation behavior of liquids may be obtained with empirical formulas (Cole-Cole [20], Davidson-Cole [21], Havriliak-Negami [23,24]) and the universal law [8].

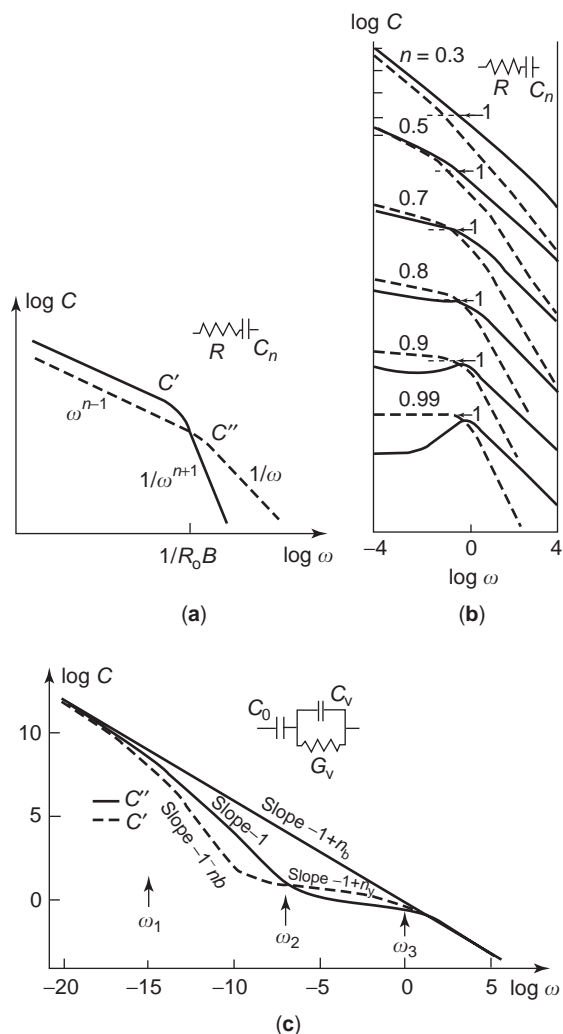

Figure 10. The frequency response of circuits involving universal lossy capacitors of the type $C_n = B(i\omega)^{n-1}$: (a) response of a series combination of C_n with a resistor R ; (b) calculated frequency dependences for a range of values of the exponent n ; (c) the response of the series-parallel circuit shown, with two universal capacitors, one of which corresponds to a series barrier region, while the other forms the equivalent of a volume region with its parallel conductance G_v . The values of parameters assumed in the calculation are as follows: $B_v = 1$, $G_v = 10^{-6}$, $n_v = 0.85$, $B_s = 1$, $n_s = 0.4$. At very low frequencies the volume behavior is dominated by the conductance, and the response is that of a series combination of C_b and G_v , which is therefore closely similar to that seen in (a) [8].

The intermolecular forces in associated liquids are stronger and perhaps more directional in some cases than in other liquids. Water is probably the most important associated liquid. The dielectric relaxation behavior of water agrees well with the Cole-Cole model [20] with $\alpha = 0.02 \pm 0.007$ [45,49]. It has been suggested [50] that the kinetic process responsible for the dielectric relaxation in water is cluster formation. Water is composed of fluctuating clusters of bonded molecules with unbonded molecules between them. Individual molecules are able to move frequently from one cluster to another, and their dipole orientation will depend on the number of hydrogen bonds they form [45,50]. It should be noted that the clustering is a

random process and that it is not possible to subdivide water molecules into groups that remain the same over a period of time longer than the average relaxation time, $\approx 9.6 \times 10^{-12}$ s, which is perhaps related to the OH stretching vibration at 1.10×10^{13} Hz. This vibration is affected by the hydrogen bonding. Alcohols have a wide distribution of relaxation times, which tend to follow the empirical Cole-Cole [20] and Davidson-Cole [21] models. The dielectric properties of liquids have been comprehensively reviewed elsewhere [45,50] and will not be discussed further here.

A perfect alkali halide ionic crystal such as NaCl can be polarized only by perturbing its thermal vibrations. However, in practice all crystals contain dislocations, specifically, polarizable flaws, which do not always distort the lattice, particularly when the ionic radii are similar [45]. The dielectric relaxation behavior in such materials is complicated by the presence of their ionic and electronic conductivities. For these materials the relaxation time τ tends to be long (≈ 1 s) at room temperature, and it obeys

$$\tau = Ae^{E_a/kT} \tag{96}$$

where E_a is the thermal activation energy and A is a constant. It is of interest to note that the mechanical relaxation time of these materials is often half the dielectric one, neglecting electrostatic interactions. This implies that the shear modes of polarization relax twice as fast as do the tensile ones [45]. The dielectric behavior of alkali halides with divalent cations has been reviewed extensively by Meakins [51].

Organic semicrystalline and amorphous polymers are practical electrical insulating materials that consist of macromolecules. Such molecular solids have both covalent and van der Waals bonds, which facilitate molecular motion in comparison with entirely covalently bonded solid dielectrics. The activation process in these materials also follows an Arrhenius relationship of the form of Eq. (90) except at the glass transition temperature T_g . The relaxation process at T_g is approximated by the William-Landel-Ferry relationship [52],

$$\tau(T) = \tau_0 \exp\left(\frac{C_1(T - T_g)}{C_2 + T - T_g}\right) \tag{97}$$

Figure 11. Schematic diagram of the temperature dependence of complex properties of polymers [54].

where τ_0 is a constant, and C_1 and C_2 are also constants with values ≈ 17 and ≈ 51 , respectively [46]. The relaxation time τ decreases with increasing temperature, as may be observed in isochronal plots of depolarizing current against temperature [53].

The relaxation behavior of polymers is related to several complex physical parameters—shear modulus, heat capacity, permittivity, and refractive index—which exhibit transitions with increasing temperature [54] (see Fig. 11). In an amorphous polymer the principal transition is the glass transition at a temperature T_g , which is labeled as the α transition at T_α in Fig. 11. Above T_g the free volume decreases to a critical value, thus severely restricting the segmental motions of the polymer chains. In a semicrystalline polymer there will be an additional transitional phenomenon at the melting temperature T_m . There are other secondary transitions, β and γ in order of decreasing temperature (i.e., $T_\alpha > T_\beta > T_\gamma$). For example, in polyethylene, the α , β , and γ relaxations at 1 kHz occur at 77, -13 , and -113°C , respectively. The α relaxation is attributed to motions in the crystalline phase, and the β relaxation arises from primary motions of the chain branches in the amorphous phase. The γ relaxation may be associated with a combination of processes including defect migration and the reorientation motion in the amorphous phase [55]. The α , β , and γ relaxations in polypropylene occur at 80, 0, and -80°C . Table 11 gives the glass transition temperatures T_g of some common polymers [54].

4.4. Experimental Evidence of Frequency Response and a Comparison with the Cluster Models

Although ideal Debye response in ferroelectric single crystals has been observed [56], there exist, in general, very few examples of such responses in condensed matter. Although water may be regarded as a classic dielectric, its dielectric behavior displays a broadened relaxation peak that departs from a true Debye relation [8,57]. Near-Debye relaxation responses have also been observed in silicon p-n junctions [8]. It may not be appropriate to

^aThese are approximate values; where two temperatures are given, the assignment of the glass transition remains doubtful. T_m is independent of chain length for high-molar-mass polymers, but falls somewhat as the chains become very short.

discuss experimentally observed dielectric dispersion data with the Cole–Cole, Davidson–Cole, and Havriliak–Negami models, which are basically empirical in nature. However, relaxation spectroscopy can provide considerable information on dielectric materials from the measurement of the shape of the loss peak as well as the relaxation rate and amplitude. The shape of a loss peak is clearly characterized by the parameters m and n of the Dissado–Hill [41,42] and universal law [8] models. This procedure has been employed to demonstrate the presence of cluster structure in (1) the viscous liquid produced from the glassy state above a glass transition [58], (2) plastic crystal phases [59], and (3) ferroelectrics [60,61]. The cluster size becomes strongly temperature-dependent in ferroelectrics near the Curie temperature [61]. The amplitude and the relaxation rate are related [60–62]. These considerations also hold true for liquid crystals [60,61,63]. Figures 12a and 12b show the observed dielectric response of poly-*r*-benzyl-L-glutamate (PBLG) and poly-*r*-methyl-L-glutamate (PMLG), respectively [42]. The loss peaks in both cases are broad with values of n and m in conformity with the cluster model [41]. Table 12 gives the values of shape indices n and m for PBLG in different states, from which it may be observed that as the local order decreases in solution, the value of n decreases, and that of m increases [41,63]. These examples cover some typical cluster structures with different values of m and n [41].

It is suggested that the quantum-mechanical cluster model provides explanations for the relaxation dynamics in materials that show non-Debye susceptibility behavior over a wide frequency range. The cluster model shows that the free energy of a cluster is held constant and its entropy

Figure 12. Master curves for the dielectric response of oriented films of (a) PBLG and (b) PMLG. The theoretical spectral shape in the plots has been determined with the values (a) $m = 0.28$, $n = 0.87$; (b) $m = 0.24$, $n = 0.92$. Plot (a) is scaled at 333 K; (b), at 299 K. In both, the small magnitude of the dispersion has limited the accuracy with which the real part of the susceptibility could be determined for the higher frequency values [42].

evolves at the expense of its internal energy (i.e., enthalpy), resulting in a power-law relaxation process.

5. APPLICATION OF DIELECTRIC SPECTROSCOPY IN DETECTING AGING IN INSULATING POLYMERS

5.1. Dielectric Aging and Treeing

Polymers experience aging when subjected to a mechanical or electric stress over an extended period of time. The aging produces irreversible deterioration of physical, chemical, and dielectric and other electrical properties, which may eventually lead to electrical breakdown of an

Table 12. Spectral Shape Indices Observed in Dielectric Response of PBLG in Different Physical States

insulating polymer. It must be stressed that physical and chemical aging may occur independently without the application of an external electric field. However, the aging process may be accelerated by the field in conjunction with other factors.

The mechanisms for electrical breakdown have been extensively reviewed [64]. The chemical aging models have also been reviewed [65] and will not be discussed in detail here. The present section provides in brief the results of a study of aging of polyethylene under an AC field in humid environment by dielectric spectroscopy.

Dielectric aging in a dry environment at moderate to high electric field appears to begin mostly at imperfections in materials where the local field tends to be enhanced. At such locations, treelike electrical channels may form and propagate due to the occurrence of partial discharges. Space charges play a significant role in the initiation and growth of electrical trees [66]. Water trees in polymeric insulators with AC fields in humid environments may arise from microphase separation in partially oxidized polymers as a result of field-induced electrochemical processes [67]. It has been shown that water trees in cross-linked polyethylene consist of tracks of hydrophilic carboxylate salts in the amorphous phase of the polymer [68–70]. The dielectric aging and the water tree growth incorporate electrochemical processes following the electrophysical process of water and ion diffusion in the polymer [68]. It has been suggested that the electrochemical degradation of polyolefins associated with aging and water treeing involve five fundamental steps: (1) electrolysis of water, in which oxygen and hydrogen peroxide radicals are formed, as both are oxidizing agents; (2) initiation of degradation; (3) catalysis of degradation by metal ions; (4) chain scission, resulting in the formation of ketones and carboxylate ions; and (5) conversion of ketones to carboxylate ions [71]. Electric-field-driven oxidation has also been proposed by other workers [64,72–74].

The electrooxidation occurs in the local field direction, and water tree tracks are formed by chain scission in the amorphous regions of the polymer. The track region is hydrophilic. As a result, water molecules in the polymer matrix condense to form liquid water in the track, which then transports ions to provide further oxidation at the tip of the track. Thus a track propagates itself in a similar manner to that of a self-propagating electrical tree or a gas breakdown channel, although at a different rate [71].

It may thus be expected that aging and its progress due to the electrooxidation of a polymer in a humid environment may be detected by a study of its dielectric behavior over a wide frequency range.

5.2. Evidence of Aging in Frequency Response

Figure 13 shows the frequency response of the real and the imaginary parts [$\chi'(\omega)$ and $\chi''(\omega)$, respectively] of the complex susceptibility $\chi(\omega)$ of unaged and crosslinked polyethylene (XLPE) cable samples and samples AC-aged (6 kV/mm, 50 Hz) for up to 6000 h in water at room temperature [36,75]. It may be observed from the fitted response that there are three relaxation processes: (1) a high-frequency (HF) loss peak at $\sim 5 \times 10^5$ Hz, (2) a

Figure 13. Dielectric behavior of XLPE cable samples, unaged and AC-aged ($6 \times 10^6 \text{ V m}^{-1}$, 50 Hz, room temperature, water) up to 6000 h [36].

medium-frequency (MF) loss peak at ~ 1 Hz, and (3) a low-frequency (LF) loss peak at $\sim 10^{-4}$ Hz. It is suggested that the HF loss peak is due to bound water containing ions. It has been stated that in principle there are two relaxations in water: the fluctuations in polarization and the dissociation of water into ions. The latter relaxation occurs in the gigahertz range, whereas the former one may be observed at $\sim 10^5$ Hz. For example, for a solution of MgSO_4 in water at 20°C [76], the following chemical reactions of the electrolyte may occur, each possessing its own relaxation characteristic:

The first process is slower than the second, for which the relaxation peak occurs at $\sim 2 \times 10^5$ Hz, which is in agreement with the location of the HF peak in Fig. 13 [45,76]. The second chemical reaction is more rapid and is outside the experimental range of Fig. 13. The HF peak (Fig. 13) is observed to be fairly independent of the aging time. It has also been shown that the diffusion coefficient of water vapor in polyethylene is $\approx 1.4 \times 10^{-6} \text{ m}^2/\text{s}$ and is independent of electrical stress [77,78]. Furthermore, polar impurities in polyethylene have been alleged to attract water [70], which will be bound in the polymer. In view of these observations, the origin of the observed HF peak (Fig. 13) may be attributed to the ions in bound water, as stated before [28,29,36].

XLPE cable samples contain crosslinking byproducts (such as cumyl alcohol and acetophenone, as well as antioxidants), which may diffuse out of the cable with the progress of time. In addition, antioxidants react chemically with the oxidation products in the sample. The MF loss peak at ~ 1 Hz appears to increase slightly (Fig. 13) with continued aging. It also becomes broader, overlapping with the LF peak. It is suggested that the MF peak may

originate from the presence of the polar moieties discussed above [28,29,36].

The LF loss peak (Fig. 13), occurring at 10^{-4} Hz, changes significantly with aging. It may be noticed that the magnitude of this peak at first rises sharply, up to an aging time of 1000 h. Subsequently it decreases progressively, although its magnitude is still greater after 6000 h of aging than that of the unaged sample. Furthermore, the LF loss peak becomes broader with increasing aging time.

The LF loss peak amplitude increases initially because of the formation of free radicals. It may be argued that a competitive process involving the production of polar moieties due to electrochemical reactions and injected space charges establishes itself with increasing aging time. Eventually, the space charge component becomes dominant as the polymer becomes more conductive. The relaxation loss behavior thus shows the presence of intracluster interaction in the MF-HF region and of intercluster charge motion in the low-frequency region; the latter phenomenon becomes dominant with continued aging [29,36].

Figure 14 [28,36,75] shows a possible electrical equivalent circuit for the unaged and electrically aged XLPE samples in a humid environment. The dielectric relaxation behavior of the unaged XLPE cable sample of Fig. 13 may be represented by a parallel-connected network of (1) three series-connected frequency-dependent resistances R_1 , R_2 , and R_3 and (2) three dissipative capacitances C_1 , C_2 , and C_3 , giving three dipolar peaks in the LF, MF, and HF regions, respectively. The QDC response in the LF region with progressive aging has been taken into account by removing the resistance R_3 from the circuit. The observed broadening of the MF peak with aging will cause R_2 to diminish with aging, although it will still have a nonzero value. The values of R_1 and C_1 for the HF peak should not change significantly, as the HF peak remains unaffected by field aging. Figure 14 also incorporates the very high-frequency capacitance C_∞ and G_0 in parallel. The latter parameter represents any DC conduction mechanism in the dielectric [75].

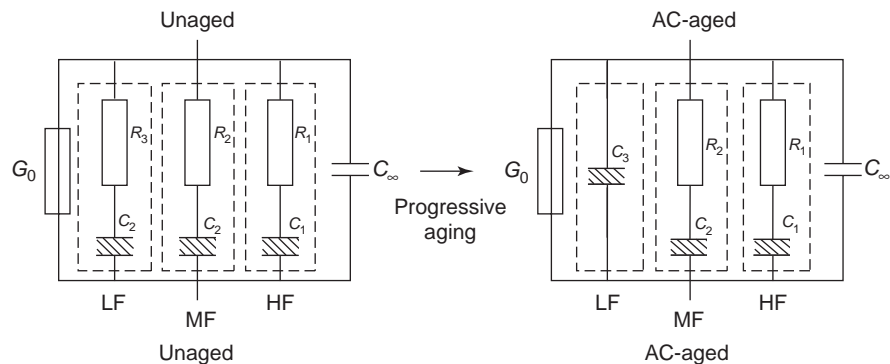

Figure 14. Analog equivalent circuits of unaged and AC-aged XLPE cable samples [28,36,75].

It is thus suggested that the dielectric spectroscopy, particularly in the LF range, may be a convenient tool in identifying aging [79]. Furthermore, the Debye relaxation model [3] and the intracuster and intercluster manybody interaction model [41,42] may provide explanations for the relaxation behavior observed at a molecular level.

DIELECTRIC RESONATOR ANTENNAS

H. K. NG
K. W. LEUNG
City University of Hong Kong
Kowloon, Hong Kong SAR

1. INTRODUCTION

1.1. Background

Traditionally, a dielectric resonator (DR) was used as an oscillator or a filter [1], which was treated as a source of energy storage rather than as an antenna. The DR was first proposed as an effective radiator in 1983 by Long et al. [2]. They demonstrated the radiation capability of the DR with different shapes [3,4]. Henceforward, DRs were widely accepted as efficient antennas.

Researchers look for a compact, low-loss, and low-cost antenna. A DR is simple in construction; it consists of dielectric material and, therefore, has no metallic loss. This is a prominent feature especially for operation in the millimeter-wave region, where the radiation efficiency of conventional metallic antennas is usually limited by metallic loss. In addition, the wavelength inside the DR is smaller than that in free space by a factor of $1/\sqrt{\epsilon_r}$, where ϵ_r is the dielectric constant of the DR. Therefore, by increasing ϵ_r , it is possible to obtain a smaller antenna.

For many years, researchers have studied different DR shapes, such as cylindrical [2,5], rectangular [3], hemispherical [4], triangular [6,7], spherical cap [8], and cylindrical ring [9,10]. Various shapes of the dielectric resonator antenna (DRA) are shown in Fig. 1. In general, in fundamental mode a DRA radiates like a magnetic dipole, a functions that is independent of antenna shape. Although DRAs are well suited for high-frequency applications, only a few of them have been examined through limited theoretical work.

Early studies of the DRA concentrated on linear polarization (LP) [11–16]. Figure 2 shows the coaxial-probe-fed DRA, which was widely used for excitation of LP DRAs. However, it introduces ohmic loss and large probe self-reactance at high frequencies. Furthermore, a hole must be drilled in the superhard DR to accommodate the probe. This inadvertently creates undesirable airgaps [17] between the probe and the DR, causing measured results to

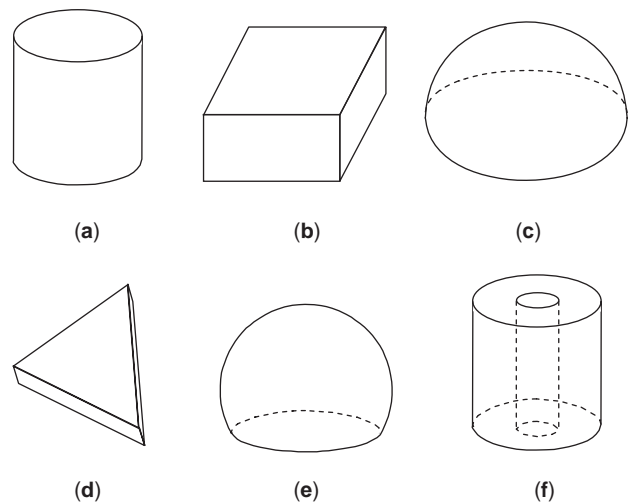

Figure 1. Various DRA configurations: (a) cylindrical; (b) rectangular; (c) hemispherical; (d) triangular; (e) spherical cap; (f) cylindrical ring.

deviate from the theoretical design. More recently, an LP DRA has been investigated using a new excitation scheme [18]: the conformal strip excitation (Fig. 3). The strip is simply cut from an adhesive conducting tape and then mounted on the DRA surface. Since the strip does not penetrate inside the DRA, the strip length can be adjusted very easily. This greatly facilitates postmanufacture trimmings of the antenna. Moreover, using this excitation method, the undesirable airgap between the feeding probe and the DRA [19] can be avoided. This article focuses on the proposed conformal-strip-fed DRA. We will introduce an angular displacement for the strip to have one more degree of freedom for matching the impedance.

The circularly polarized (CP) DRA [20–24] has been a very attractive topic because, it allows a more flexible orientation between the transmitting and receiving antennas than does the LP system. In addition, CP fields are less sensitive to the propagation effect than are LP fields, and the CP system is therefore widely used in satellite communications. A simple and straightforward CP DRA design utilizes a quadrature feed [5,25,26], but this substantially increases the size and complexity of the feed network. Petosa et al. [27] shifted the complexity from the feed network to the DRA, but the cross-shaped DRA may

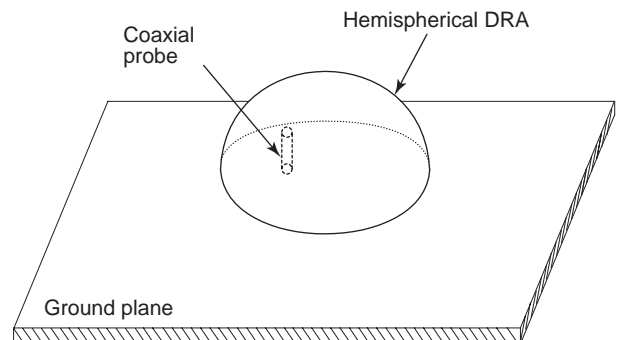

Figure 2. Configuration of coaxial-probe-fed DRA.

Figure 3. Configuration of conformal-strip-fed DRA.

not be available in the commercial market. To avoid these problems, a parasitic patch has been applied to the conformal-strip-fed DRA [20,24]. The use of a parasitic patch on the DRA was first considered by Li et al. [28] and later by Chen et al. [29]. In their work, the parasitic patch was placed on top of a DRA, mainly to tune the operating frequency instead of exciting CP fields. More recently, the use of a parasitic patch for the excitation of CP fields has been extended to aperture-coupled sources [30,31]. In this article, we will also demonstrate a CP DRA with a parasitic patch.

1.2. Methodology

In the analyses, the mode-matching method is used to find the various Green's functions, from which the integral equations for the conformal strip and parasitic patch currents are formulated. The equations are then solved using the method of moments (MoM).

To speed the numerical computation, the impedance integrals are evaluated either using newly obtained recurrence formulas or by direct analytical integration. It is well known that evaluating self-impedance integrals numerically is difficult because of the singularity problem of Green's functions. Around the singular points, excessive modal terms of the DRA Green's functions are required for accurate calculation of the functions. However, the amplitudes of high-order Hankel functions are so large that they are difficult to handle numerically. In addition, the integrands will fluctuate very sharply around these points and therefore very dense sampling points will be required to evaluate the integrals accurately, leading to considerable programming effort and computation time. The singularity problem was previously solved using the recurrence approach [18]. Since low-order integrals can be evaluated analytically, all the impedance integrals can be calculated without the need for any numerical integration. The same approach will be used in this article. The recurrence formulas [18] can be used only for a constant latitude current around the equatorial plane. Although they can be generalized for pulse-mode basis functions at any latitude angles, new recurrence formulas for piecewise sinusoidal (PWS) basis functions are discussed in this article instead to accelerate the MoM convergence rate.

2. CONFORMAL-STRIP-EXCITED DRA

2.1. Introduction

The conformal strip described in Ref. 18 was placed along a meridian plane of the hemispherical DRA. Virtually, the strip length is the only strip parameter used for tuning the impedance (the width of a slender strip has a relatively small effect on the input impedance). We extend the previous theory [18] to include an arbitrary angular strip displacement θ_0 . The strip begins at the base of the hemisphere and then bends back, as shown in Fig. 4. By doing so, we can desirably obtain one more degree of freedom in designing the DRA. The effect of strip displacement on input impedance was investigated, and it was found that impedance matching can easily be achieved by varying this parameter. The far fields of the new configuration were also studied. Measurements were carried out to verify the calculations, and reasonable agreement between theory and experiment was found.

2.2. Theory

To simplify the formulation, the coordinate system shown in Fig. 4 is used. With this coordinate system, the unknown strip current can be expanded using sinusoidal functions and, thus, the related MoM integrals can be evaluated in closed form. A hemispherical DRA of radius a and dielectric constant ϵ_r is excited by a conformal strip of length l and width W . The conformal strip has angular displacement θ_0 from the z axis.

2.2.1. Green's Functions. Nevels and his collaborators [33,34] have presented the modal Green's function as the sum of particular and homogeneous solutions. The potentials associated with the source in unbounded regions correspond to the particular part, whereas the boundary discontinuities are taken into account by the homogeneous part. As both the excitation strip and the parasitic element are on the DR surface in the present problem, it is unnecessary to use the previous approach. In the following formulation, the fields are assumed to vary harmonically as $e^{j\omega t}$. The field and source points are denoted by $\vec{r}(r, \theta, \phi)$ and $\vec{r}'(r', \theta', \phi')$, respectively. The Green functions ($r=r'=a$) of \hat{E}_ϕ due to a $\hat{\phi}$ -directed point current is

Figure 4. Configuration of the conformal-strip-excited hemispherical DRA with an angular strip displacement θ_0 .

found as follows

$$G_{J_\phi}^{E_\phi} = \frac{j\eta_0}{2\pi ar} \sum_{n=0}^{\infty} \frac{2n+1}{n(n+1)} \sum_{m=1}^n m \frac{(n-m)!}{(n+m)!} \sin m(\phi - \phi') \cdot \left\{ \frac{1}{\Delta_n^{\text{TE}}} \frac{d}{d\theta'} P_n^m(\cos \theta') \frac{P_n^m(\cos \theta)}{\sin \theta} \Phi_n - \frac{1}{\Delta_n^{\text{TM}}} \frac{P_n^m(\cos \theta')}{\sin \theta'} \frac{d}{d\theta} P_n^m(\cos \theta) \Psi_n \right\} \quad (1a)$$

$$G_{J_\phi}^{E_\phi} = \frac{j\eta_0}{2\pi ar} \sum_{n=0}^{\infty} \frac{2n+1}{n(n+1)} \sum_{m=1}^n \frac{(n-m)!}{(n+m)!} \cos m(\phi - \phi') \cdot \left\{ \frac{1}{\Delta_n^{\text{TE}}} \frac{d}{d\theta'} P_n^m(\cos \theta') \frac{d}{d\theta} P_n^m(\cos \theta) \Phi_n - \frac{m^2}{\Delta_n^{\text{TM}}} \frac{P_n^m(\cos \theta')}{\sin \theta'} \frac{P_n^m(\cos \theta)}{\sin \theta} \Psi_n \right\} \quad (1b)$$

where

$$\Phi_n = \begin{cases} \hat{H}_n^{(2)}(k_0 a) \hat{J}_n(kr) & r < a \\ \hat{J}_n(ka) \hat{H}_n^{(2)}(k_0 r) & r > a \end{cases} \quad (1c)$$

$$\Psi_n = \begin{cases} \hat{H}_n^{(2)}(k_0 a) \hat{J}'_n(kr) & r < a \\ \hat{J}'_n(ka) \hat{H}_n^{(2)'}(k_0 r) & r > a \end{cases} \quad (1d)$$

It should be mentioned that the functions Φ_n and Ψ_n have different forms for the E field inside ($r < a$) and outside ($r > a$) the DR. All other symbols were defined in Refs. 35 and 36.

2.2.2. MoM. Enforcing the boundary condition that the total tangential electric fields should vanish on the strip surface, we have

$$E^s + E^i = 0 \quad (2)$$

where E^s and E^i are defined as the scattered and impressed fields due to the current density $J_{\phi s}$ and the excitation source, respectively. Using a delta gap source model, the impressed field can be written as $(V_0/a)\delta(\phi)$. Then Eq. (2) can be rewritten as

$$\frac{-1}{W} \iint_{S_0} G_{J_\phi}^{E_\phi} J_{\phi s}(\phi) dS' = \frac{V_0}{a} \delta(\phi) \quad (3)$$

where S_0 is the strip surface. Let $I(\phi) = J_{\phi s} W$ be the strip current, which is expanded as follows using the MoM

$$I(\phi) = \sum_{q=1}^N I_q f_q(\phi) \quad (4)$$

where I_q are unknown expansion coefficients to be determined, and $f_q(\phi)$ are PWS basis functions given by

$$f_q(\phi) = \begin{cases} [\sin k_e(h - a|\phi - \phi_q|)] / \sin k_e h & a|\phi - \phi_q| < h \\ 0 & \text{elsewhere} \end{cases} \quad (5)$$

where $h = 2l/(N+1)$, $\phi_q = (-l + qh)/a$, and $k_e = \sqrt{(\epsilon_r + 1)/2} k_0$ are the PWS-mode half-length, the center-point of the q th expansion mode, and the effective wave-number at the DRA-air interface, respectively. The expansion coefficients are found via the matrix equation $[Z_{pq}][I_q] = [f_p(0)]$, where Z_{pq} are given by

$$Z_{pq} = \frac{-ja^2 \eta_0}{4\pi W^2} \sum_{n=1}^{\infty} \frac{2n+1}{n(n+1)} \left\{ \frac{\hat{J}_n(ka) \hat{H}_n^{(2)}(k_0 a)}{\Delta_n^{\text{TE}}} \times \sum_{m=0}^n \frac{2}{\Delta_m} \cdot \frac{(n-m)!}{(n+m)!} [\Theta_1(n, m)]^2 \Phi(p, q, m) \right. \quad (6)$$

$$\left. - \frac{\hat{J}'_n(ka) \hat{H}_n^{(2)'}(k_0 a)}{\Delta_n^{\text{TM}}} \sum_{m=1}^n 2m^2$$

$$\cdot \frac{(n-m)!}{(n+m)!} [\Theta_2(n, m)]^2 \Phi(p, q, m) \right\}$$

$$\Theta_1(n, m) = \int_{\theta_0 - W/(2a)}^{\theta_0 + W/(2a)} \frac{dP_n^m(\cos \theta)}{d\theta} \sin \theta d\theta \quad (7)$$

$$\Theta_2(n, m) = \int_{\theta_0 - W/(2a)}^{\theta_0 + W/(2a)} P_n^m(\cos \theta) d\theta \quad (8)$$

$$\Phi(p, q, m) = \left[\frac{2k_e a (\cos k_e h - \cos m \phi_h)}{(m - k_e a)(m + k_e a) \sin k_e h} \right]^2 \quad (9)$$

$$\times \cos m(\phi_p - \phi_q)$$

where

$$\phi_h = \frac{h}{a \sin \theta_0} \quad (10)$$

Since recurrence formulas exist for the integrals Θ_1 and Θ_2 , the integrals can be calculated very easily and quickly. Consequently, the solution (3) is a regular modal series that can be implemented very straightforwardly. As the solution can be calculated without need for any numerical integration, it is computationally very efficient. After the strip current is obtained, the input impedance can be readily calculated from

$$Z_{\text{in}} = \frac{1}{2 \sum_{q=1}^N I_q f_q(0)} \quad (11)$$

Figure 5. Measured and calculated input impedances for the configuration $a = 12.5$ mm, $\epsilon_r = 9.5$, $l = 12.0$ mm, $W = 1.2$ mm, and $\theta_0 = 80^\circ$. (From Leung and Ng [32], © 2001 John Wiley & Sons, Inc.)

where the factor of 2 accounts for the image effect of the ground plane. From the strip current the radiation can be found easily.

2.3. Results and Discussion

To verify the theory, a hemispherical DRA of $a = 12.5$ mm and $\epsilon_r = 9.5$ was measured using an HP8510C network analyzer. A conformal strip of length $l = 12.0$ mm and width $W = 1.2$ mm was cut from an adhesive conducting tape. For the calculation part, two basis functions and 60 modal terms were used. Figure 5 shows the measured and calculated input impedances for $\theta_0 = 80^\circ$, and reasonable agreement between theory and experiment is observed. The measured and calculated resonant frequencies are 3.52 and 3.58 GHz, respectively, with error 1.7%. The results are consistent with the source-free value of 3.68 GHz [36].

Figure 6 displays the calculated input impedance for $\theta_0 = 60^\circ, 70^\circ$, and 80° . It is observed that the impedance increases with θ_0 , showing that θ_0 can be used as a new parameter to match the impedance.

The measured and calculated far fields at 3.56 GHz for $l = 12.0$ mm, $W = 1.2$ mm, and $\theta_0 = 80^\circ$ are shown in Fig. 7, where reasonable agreement between theory and experiment is observed. The fields are of a broadside mode, as expected. It is found that the copolarized field is stronger than the cross-polarized field by more than 16 dB in the

Figure 6. Calculated input impedances for $\theta_0 = 60^\circ, 70^\circ$, and 80° , with $a = 12.5$ mm, $\epsilon_r = 9.5$, $l = 12.0$ mm, $W = 1.2$ mm. (From Leung and Ng [32], © 2001 John Wiley & Sons, Inc.)

broadside direction ($\theta_0 = 0^\circ$), which is sufficient for many practical applications. Note that the H -plane cross-polarized field is not symmetric about the center, due to the angular displacement of the excitation strip.

3. CIRCULARLY POLARIZED DRA EXCITED BY A CONFORMAL STRIP WITH A PARASITIC PATCH

3.1. Introduction

Thus far, the work on CP DRAs has been mainly experimental. The first theoretical work was carried out by Esselle [21], who used the finite-difference time-domain (FDTD) method to study the CP rectangular DRA. The FDTD method can handle a large class of problems, but since it is purely numerical, a very long computation time is required. Moreover, no physical insights into the problem can be obtained through the numerical formulation. In this section, a CP DRA excitation method that employs a single parasitic patch is presented [24]. The conformal-strip-excited hemispherical DRA [18] is used for the demonstration. Nevertheless, the CP technique can be used with other excitation methods and DRAs.

3.2. Theory

The configuration of the DRA is shown in Fig. 8, where a hemispherical DRA of radius a and dielectric constant ϵ_r is

Figure 7. Measured and calculated co- and cross-polarized field patterns at $f = 3.5$ GHz, with $a = 12.5$ mm, $\epsilon_r = 9.5$, $l = 12.0$ mm, $W = 1.2$ mm. (From Leung and Ng [32], © 2001 John Wiley & Sons, Inc.)

Figure 8. Configuration of conformal-strip-excited DRA with a parasitic patch. (From Leung and Ng [24], 2003 © IEEE.)

fed by the conformal strip of length l_1 and width W_1 . The parasitic patch of length l_2 and width W_2 is displaced at ϕ_0 from the excitation strip. Since the patch current involves both θ and ϕ components, in this case, integrals of associated Legendre functions will inevitably encountered. Therefore, a convectional coordinate system is used in this section.

Image theory is used to remove the ground plane. The equivalent imaged configuration, shown in Fig. 9, is a spherical DRA with the strip and patch lengths doubled: $L_1 = 2l_1$ and $L_2 = 2l_2$.

3.2.1. Green's Functions. Since the excitation strip is assumed to be slender, it has only a longitudinal current. For the parasitic patch, however, the length-to-width ratio is arbitrary. Therefore, both the latitude and azimuthal currents have to be considered. The current distributions are shown in Fig. 9. In the formulation, the superscripts A

and B refer to the excitation strip and the parasitic patch, respectively. The $\hat{\theta}$ -directed current J_θ^A flows on the surface of the excitation strip. For the parasitic patch, the $\hat{\theta}$ - and $\hat{\phi}$ -directed patch currents are defined as J_θ^B and J_ϕ^B , respectively.

The $\hat{\theta}$ - and $\hat{\phi}$ -directed E -field Green's functions due to a $\hat{\phi}$ -directed point current J_ϕ have been obtained in (1a) and (1b). Now, two more Green's functions in (12a) and (12b) are found that are due to a $\hat{\theta}$ -directed point current J_θ :

$$G_{J_\theta}^{E_\theta} = \frac{j\eta_0}{2\pi ar} \sum_{n=0}^{\infty} \frac{2n+1}{n(n+1)} \sum_{m=0}^n \frac{(n-m)!}{(n+m)!} \cos m(\phi - \phi') \cdot \left\{ \frac{m^2}{\Delta_n^{TE}} \frac{P_n^m(\cos \theta')}{\sin \theta'} \frac{P_n^m(\cos \theta)}{\sin \theta} \Phi_n - \frac{1}{\Delta_n^{TM} \Delta_m} \frac{d}{d\theta'} P_n^m(\cos \theta') \frac{d}{d\theta} P_n^m(\cos \theta) \Psi_n \right\} \quad (12a)$$

$$G_{J_\theta}^{E_\phi} = \frac{j\eta_0}{2\pi ar} \sum_{n=0}^{\infty} \frac{2n+1}{n(n+1)} \sum_{m=1}^n m \frac{(n-m)!}{(n+m)!} \sin m(\phi - \phi') \cdot \left\{ \frac{1}{\Delta_n^{TE}} \frac{P_n^m(\cos \theta')}{\sin \theta'} \frac{d}{d\theta} P_n^m(\cos \theta) \Phi_n - \frac{1}{\Delta_n^{TM}} \frac{d}{d\theta'} P_n^m(\cos \theta') \frac{P_n^m(\cos \theta)}{\sin \theta} \Psi_n \right\} \quad (12b)$$

3.2.2. MoM. With the Green's functions presented above, the strip and patch currents can be solved by using the MoM. Enforcing the boundary condition that the total E field should vanish on the conducting excitation strip, we have

$${}^A E_{J_\theta}^0 + {}^B E_{J_\theta}^0 + {}^B E_{J_\phi}^0 + E^i = 0 \quad (13)$$

Figure 9. Equivalent geometry of the DRA configuration.

where E^i is the impressed E field on the excitation strip. Equation (13) can be rewritten in terms of Green's functions,

$$\iint_{S_A} G_{J_0}^{E_0} J_0^A dS' + \iint_{S_B} G_{J_0}^{E_0} J_0^B dS' + \iint_{S_B} G_{J_\phi}^{E_0} J_\phi^B dS' + E^i = 0 \quad (14)$$

where S_A and S_B are the surfaces of the excitation strip and parasitic patch, respectively. For simplicity, the delta gap source is used again to model the excitation, $E^i = (V_0/\alpha)\delta(\theta)$, where V_0 is the excitation voltage and is set to unity for convenience. Let $I_\theta^A = J_\theta^A W_1$ be the excitation strip current and $I_\theta^B = J_\theta^B W_2$, $I_\phi^B = J_\phi^B L_2$; then (14) becomes

$$\begin{aligned} & \frac{-1}{W_1} \iint_{S_A} G_{J_0}^{E_0} I_\theta^A dS' + \frac{-1}{W_2} \iint_{S_B} G_{J_0}^{E_0} I_\theta^B dS' \\ & + \frac{-1}{L_2} \iint_{S_B} G_{J_\phi}^{E_0} I_\phi^B dS' = \frac{1}{\alpha} \delta(\theta) \end{aligned} \quad (15)$$

The next step is to expand the currents using the MoM as follows

$$I_\theta^A(\theta) = \sum_{p_1=1}^{N_1} I_{p_1}^{0A} f_{p_1}^{0A}(\theta) \quad (16)$$

$$I_\theta^B(\theta) = \sum_{p_2=1}^{N_2} I_{p_2}^{0B} f_{p_2}^{0B}(\theta) \quad (17)$$

$$I_\phi^B(\phi) = \sum_{p_3=1}^{N_3} I_{p_3}^{\phi B} f_{p_3}^{\phi B}(\phi) \quad (18)$$

where $f_{p_1}^{0A}(\theta)$, $f_{p_2}^{0B}(\theta)$, and $f_{p_3}^{\phi B}(\phi)$ are PWS basis functions given by

$$f_{p_1}^{0A}(\theta) = \begin{cases} \frac{\sin(\theta_h^A - |\theta - \theta_{p_1}^A|)}{\sin \theta_h^A}, & a|\theta - \theta_{p_1}^A| < h_1 \\ 0 & \text{elsewhere} \end{cases} \quad (19)$$

$$f_{p_2}^{0B}(\theta) = \begin{cases} \frac{\sin(\theta_h^B - |\theta - \theta_{p_2}^B|)}{\sin \theta_h^B}, & a|\theta - \theta_{p_2}^B| < h_2 \\ 0 & \text{elsewhere} \end{cases} \quad (20)$$

$$f_{p_3}^{\phi B}(\phi) = \begin{cases} \frac{\sin k_e(h_3 - a|\phi - \phi_{p_3}^B|)}{\sin k_0 h_3}, & a|\phi - \phi_{p_3}^B| < h_3 \\ 0 & \text{elsewhere} \end{cases} \quad (21)$$

in which

$$\theta_h^A = \frac{h_1}{a}, \quad \theta_{p_1}^A = \frac{\pi}{2} - \frac{L_1}{2a} + p_1 \theta_h^A, \quad h_1 = \frac{L_1}{N_1 + 1} \quad (22)$$

$$\theta_h^B = \frac{h_2}{a}, \quad \theta_{p_2}^B = \frac{\pi}{2} - \frac{L_2}{2a} + p_2 \theta_h^B, \quad h_2 = \frac{L_2}{N_2 + 1} \quad (23)$$

$$\phi_h^B = \frac{h_3}{a}, \quad \phi_{p_3}^B = \phi_0 - \frac{W_2}{2a} + p_3 \phi_h^B, \quad h_3 = \frac{W_2}{N_3 + 1} \quad (24)$$

and $k_e = \sqrt{(\epsilon_r + 1)/2} k_0$ is the effective wavenumber at the DRA-air interface. By employing the Galerkin procedure, we multiply both sides of (15) by $f_{q_1}^{0A}(\theta)$ ($1 \leq q_1 \leq N_1$) and integrate the result over the strip surface, yielding

$$\begin{aligned} & \frac{-1}{W_1^2} \sum_{p_1=1}^{N_1} I_{p_1}^{0A} \iint_{S=S_A} \iint_{S'=S_A} f_{q_1}^{0A}(\theta) G_{J_0}^{E_0} f_{p_1}^{0A}(\theta') dS' dS \\ & + \frac{-1}{W_1 W_2} \sum_{l=1}^{N_2} I_{p_2}^{0B} \iint_{S=S_A} \iint_{S'=S_B} f_{q_1}^{0A}(\theta) G_{J_0}^{E_0} f_{p_2}^{0B}(\theta') dS' dS \\ & + \frac{-1}{W_1 L_2} \sum_{v=1}^{N_3} I_{p_3}^{\phi B} \iint_{S=S_A} \iint_{S'=S_B} f_{q_1}^{0A}(\theta) G_{J_\phi}^{E_0} f_{p_3}^{\phi B}(\theta') dS' dS \\ & = \int_{\pi/2-L_1/a}^{\pi/2+L_1/a} f_{q_1}^{0A}(\theta) \delta(\theta) d(\theta) \end{aligned} \quad (25)$$

Similarly, two more integral equations can be obtained by enforcing the following boundary conditions on the parasitic patch:

$${}^A \mathbf{E}_{J_0}^\phi + {}^B \mathbf{E}_{J_0}^\phi + {}^B \mathbf{E}_{J_\phi}^\phi = 0 \quad (26a)$$

$${}^A \mathbf{E}_{J_0}^0 + {}^B \mathbf{E}_{J_0}^0 + {}^B \mathbf{E}_{J_\phi}^0 = 0 \quad (26b)$$

Applying the Galerkin procedure again, we multiply the two equations by $f_{q_2}^{0B}(\theta)$ ($1 \leq q_2 \leq N_2$) and $f_{q_3}^{\phi B}(\phi)$ ($1 \leq q_3 \leq N_3$), respectively. Totally, there are three sets of equations with three sets of unknowns, which can be solved via the following matrix equation

$$\begin{bmatrix} [Z_{\theta\theta}^{AA'}(p_1, q_1)]_{N_1 \times N_1} & [Z_{\theta\theta}^{AB'}(p_1, q_2)]_{N_1 \times N_2} & [Z_{\theta\phi}^{AB'}(p_1, q_3)]_{N_1 \times N_3} \\ [Z_{\theta\theta}^{BA'}(p_2, q_1)]_{N_2 \times N_1} & [Z_{\theta\theta}^{BB'}(p_2, q_2)]_{N_2 \times N_2} & [Z_{\theta\phi}^{BB'}(p_2, q_3)]_{N_2 \times N_3} \\ [Z_{\phi\theta}^{BA'}(p_3, q_1)]_{N_3 \times N_1} & [Z_{\phi\theta}^{BB'}(p_3, q_2)]_{N_3 \times N_2} & [Z_{\phi\phi}^{BB'}(p_3, q_3)]_{N_3 \times N_3} \end{bmatrix} \cdot \begin{bmatrix} [I_{p_1}^{0A}]_{N_1 \times 1} \\ [I_{p_2}^{0B}]_{N_2 \times 1} \\ [I_{p_3}^{\phi B}]_{N_3 \times 1} \end{bmatrix} = \begin{bmatrix} [V_{q_1}^A]_{N_1 \times 1} \\ [0]_{N_2 \times 1} \\ [0]_{N_3 \times 1} \end{bmatrix} \quad (27)$$

where, for $X, Y = A$ or B and $\alpha, \beta = \theta$ or ϕ , we obtain

$$Z_{\alpha\beta}^{XY'}(p, q) = \frac{-1}{\Gamma_\alpha^X \Gamma_\beta^Y} \iint_{S=S_X} \iint_{S'=S_Y} f_p^{\alpha X}(\alpha) G_{\beta}^{E_z} f_{q'}^{\beta Y}(\beta') dS' dS \quad (28)$$

$$V_{q_1}^A = \int_{\pi/2-L_1/a}^{\pi/2+L_1/a} f_{q_1}^{\theta A}(\theta) \delta(\theta) d\theta \quad (29)$$

with $\Gamma_\theta^{A,B} = W_{1,2}$ and $\Gamma_\phi^B = L_2$. For the voltage matrix $[V_{q_1}^A]$, the center element is equal to unity but all the other elements are zero. After the current vector $[I_{p_1}^{\theta A}]$ is obtained from (27), the input impedance can be calculated from $Z_{in} = \gamma / \sum_{p_1=1}^{N_1} I_{p_1}^{\theta A} f_{p_1}^{\theta A}(0)$, where $\gamma = 1$ for the equivalent spherical structure and $\frac{1}{2}$ for the original hemispherical structure. The other two current vectors $[I_{p_2}^{\phi B}]$, $[I_{p_3}^{\phi B}]$, together with $[I_{p_1}^{\theta A}]$, will be used to calculate the radiation fields of the antenna. To this end, the key step is to evaluate the various impedance elements $Z_{\alpha\beta}^{XY'}$, which will be discussed next.

3.2.3. Evaluation of Z Matrix. Numerical evaluation of $Z_{\alpha\beta}^{XY'}$ will be very difficult when $X = Y$, since the field and source points may coincide in this case, causing the singular problem to occur. Using the previous approach [18], all $Z_{\alpha\beta}^{XY'}$ can be calculated without the need for any numerical integration. Thus, the computation time and programming effort are greatly reduced. To begin with, the Green's functions (1) and (12) are substituted into (29) to get nine different expressions:

$$\begin{aligned} Z_{\theta\theta}^{AA'}(p_1, q_1) &= -\frac{ja^2\eta_0}{2\pi W_1^2} \sum_{n=1}^{\infty} \\ &\cdot \left\{ \sum_{m=0}^n \rho_{TE}(n, m) \cdot m^2 \cdot \Theta_1^A(p_1, n, m) \right. \\ &\Theta_1^A(q_1, n, m) \cdot \Phi_1(m, \phi_A, \phi_A) \\ &- \sum_{m=0}^n \frac{\rho_{TM}(n, m)}{\Delta_m} \cdot \Theta_2^A(p_1, n, m) \\ &\left. \Theta_2^A(q_1, n, m) \cdot \Phi_1(m, \phi_A, \phi_A) \right\} \end{aligned} \quad (30)$$

$$\begin{aligned} Z_{\theta\phi}^{AB'}(p_1, q_2) &= -\frac{ja^2\eta_0}{2\pi W_1 W_2} \sum_{n=1}^{\infty} \\ &\cdot \left\{ \sum_{m=0}^n \rho_{TE}(n, m) \cdot m^2 \cdot \Theta_1^A(p_1, n, m) \right. \\ &\Theta_1^B(q_2, n, m) \cdot \Phi_1(m, \phi_A, \phi_B) \\ &- \sum_{m=0}^n \frac{\rho_{TM}(n, m)}{\Delta_m} \cdot \Theta_2^A(p_1, n, m) \\ &\left. \Theta_2^B(q_2, n, m) \Phi_1(m, \phi_A, \phi_B) \right\} \end{aligned} \quad (31)$$

$$\begin{aligned} Z_{\phi\phi}^{AB'}(p_1, q_3) &= -\frac{ja^2\eta_0}{2\pi W_1 L_2} \sum_{n=1}^{\infty} \\ &\cdot \left\{ \sum_{m=0}^n \rho_{TE}(n, m) \cdot m \cdot \Theta_1^A(p_1, n, m) \right. \\ &\Theta_4^B(n, m) \cdot \Phi_2(q_3, m, \phi_A, \phi_B) \\ &- \sum_{m=0}^n \rho_{TM}(n, m) \cdot m \cdot \Theta_2^A(p_1, n, m) \\ &\left. \Theta_3^B(n, m) \cdot \Phi_2(q_3, m, \phi_A, \phi_B) \right\} \end{aligned} \quad (32)$$

$$\begin{aligned} Z_{\phi\theta}^{BA'}(p_2, q_1) &= -\frac{ja^2\eta_0}{2\pi W_1 W_2} \sum_{n=1}^{\infty} \\ &\cdot \left\{ \sum_{m=0}^n \rho_{TE}(n, m) \cdot m^2 \cdot \Theta_1^B(p_2, n, m) \right. \\ &\Theta_1^A(q_1, n, m) \cdot \Phi_1(m, \phi_B, \phi_A) \\ &- \sum_{m=0}^n \frac{\rho_{TM}(n, m)}{\Delta_m} \Theta_2^B(p_2, n, m) \\ &\left. \Theta_2^A(q_1, n, m) \cdot \Phi_1(m, \phi_B, \phi_A) \right\} \end{aligned} \quad (33)$$

$$\begin{aligned} Z_{\theta\theta}^{BB'}(p_2, q_2) &= -\frac{ja^2\eta_0}{2\pi W_2^2} \sum_{n=1}^{\infty} \\ &\cdot \left\{ \sum_{m=0}^n \rho_{TE}(n, m) \cdot m^2 \cdot \Theta_1^B(p_2, n, m) \right. \\ &\Theta_1^B(q_2, n, m) \cdot \Phi_1(m, \phi_B, \phi_B) \\ &- \sum_{m=0}^n \frac{\rho_{TM}(n, m)}{\Delta_m} \Theta_2^B(p_2, n, m) \\ &\left. \Theta_2^B(q_2, n, m) \cdot \Phi_1(m, \phi_B, \phi_B) \right\} \end{aligned} \quad (34)$$

$$\begin{aligned} Z_{\phi\phi}^{BB'}(p_2, q_3) &= -\frac{ja^2\eta_0}{2\pi W_2 L_2} \sum_{n=1}^{\infty} \\ &\cdot \left\{ \sum_{m=0}^n \rho_{TE}(n, m) \cdot m \cdot \Theta_1^B(p_2, n, m) \right. \\ &\Theta_4^B(n, m) \cdot \Phi_2(q_3, m, \phi_B, \phi_B) \\ &- \sum_{m=0}^n \rho_{TM}(n, m) \cdot m \cdot \Theta_2^B(p_2, n, m) \\ &\left. \Theta_3^B(n, m) \cdot \Phi_2(q_3, m, \phi_B, \phi_B) \right\} \end{aligned} \quad (35)$$

$$\begin{aligned}
Z_{\phi\theta}^{BA'}(p_3, q_1) = & -\frac{ja^2\eta_0}{2\pi W_1 L_2} \sum_{n=1}^{\infty} \\
& \cdot \left\{ \sum_{m=0}^n \rho_{TE}(n, m) \cdot m \cdot \Theta_4^B(n, m) \right. \\
& \Theta_1^A(q_3, n, m) \cdot \Phi_2(p_1, m, \phi_B, \phi_A) \\
& - \sum_{m=0}^n \rho_{TM}(n, m) \cdot m \cdot \Theta_3^B(n, m) \\
& \left. \Theta_2^A(q_3, n, m) \cdot \Phi_2(p_1, m, \phi_B, \phi_A) \right\}
\end{aligned} \quad (36)$$

$$\begin{aligned}
Z_{\phi\theta}^{BB'}(p_3, q_2) = & -\frac{ja^2\eta_0}{2\pi W_2 L_2} \sum_{n=1}^{\infty} \\
& \cdot \left\{ \sum_{m=0}^n \rho_{TE}(n, m) \cdot m \cdot \Theta_4^B(n, m) \right. \\
& \Theta_1^B(q_2, n, m) \Phi_2(p_3, m, \phi_B, \phi_B) \\
& - \sum_{m=0}^n \rho_{TM}(n, m) \cdot m \cdot \Theta_3^B(n, m) \\
& \left. \Theta_2^B(q_2, n, m) \cdot \Phi_2(p_3, m, \phi_B, \phi_B) \right\}
\end{aligned} \quad (37)$$

$$\begin{aligned}
Z_{\phi\phi}^{BB'}(p_3, q_3) = & -\frac{ja^2\eta_0}{2\pi L_2^2} \sum_{n=1}^{\infty} \\
& \cdot \left\{ \sum_{m=0}^n \frac{\rho_{TE}(n, m)}{\Delta_m} \Theta_4^B(n, m) \right. \\
& \Theta_4^B(n, m) \cdot \Phi_3(p_3, q_3, m, \phi_B, \phi_B) \\
& - \sum_{m=0}^n \rho_{TM}(n, m) \cdot m^2 \cdot \Theta_3^B(n, m) \\
& \left. \Theta_3^B(n, m) \cdot \Phi_3(p_3, q_3, m, \phi_B, \phi_B) \right\}
\end{aligned} \quad (38)$$

where

$$\begin{aligned}
\rho_{TE}(n, m) = & \frac{2n+1}{n(n+1)} \cdot \frac{\hat{J}_n(ka)\hat{H}_n^{(2)}(k_0a)}{\Delta_n^{TE}} \\
& \cdot \frac{(n-m)!}{(n+m)!}
\end{aligned} \quad (39)$$

$$\begin{aligned}
\rho_{TM}(n, m) = & \frac{2n+1}{n(n+1)} \cdot \frac{\hat{J}_n(ka)\hat{H}_n^{(2)'}(k_0a)}{\Delta_n^{TM}} \\
& \cdot \frac{(n-m)!}{(n+m)!}
\end{aligned} \quad (40)$$

$$\begin{aligned}
\Phi_1(m, \phi_X, \phi_Y) \\
= \int_{\phi_{X1}}^{\phi_{X2}} \int_{\phi_{Y1}}^{\phi_{Y2}} \cos m(\phi - \phi') d\phi' d\phi
\end{aligned} \quad (41)$$

$$\begin{aligned}
\Phi_2(p, m, \phi_X, \phi_Y) \\
= \int_{\phi_{X1}}^{\phi_{X2}} \int_{\phi_{Y1}}^{\phi_{Y2}} \sin m(\phi - \phi') f_p^{\phi_Y}(\phi) d\phi' d\phi
\end{aligned} \quad (42)$$

$$\begin{aligned}
\Phi_3(p, q, m, \phi_B) \\
= \int_{\phi_{B1}}^{\phi_{B2}} \int_{\phi_{B1}}^{\phi_{B2}} f_p^{\phi_B}(\phi) \cos m(\phi - \phi') \\
f_q^{\phi_B}(\phi') d\phi' d\phi
\end{aligned} \quad (43)$$

$$\begin{aligned}
\Theta_1^X(p, n, m) \\
= \int_{\theta_p^X - \theta_h^X}^{\theta_p^X + \theta_h^X} P_n^m(\cos \theta) f_p^{\theta X}(\theta) d\theta
\end{aligned} \quad (44)$$

$$\begin{aligned}
\Theta_2^X(p, n, m) \\
= \int_{\theta_p^X - \theta_h^X}^{\theta_p^X + \theta_h^X} \frac{dP_n^m(\cos \theta)}{d\theta} \sin \theta f_p^{\theta X}(\theta) d\theta
\end{aligned} \quad (45)$$

$$\Theta_3^B(n, m) = \int_{\pi/2 - l_2/a}^{\pi/2 + l_2/a} P_n^m(\cos \theta) d\theta \quad (46)$$

$$\Theta_4^B(n, m) = \int_{\pi/2 - l_2/a}^{\pi/2 + l_2/a} \frac{dP_n^m(\cos \theta)}{d\theta} \sin \theta d\theta \quad (47)$$

and

$$\begin{aligned}
\phi_{A1} = -W_1/2a, \quad \phi_{A2} = W_1/2a, \quad \phi_{B1} = \phi_0 - W_2/2a, \\
\text{and } \phi_{B2} = \phi_0 + W_2/2a
\end{aligned} \quad (48)$$

The integrals will be evaluated by either using the recurrence technique or analytical integration. This will be discussed in the following paragraphs.

3.2.3.1. $\Theta_1^X(p, n, m)$ and $\Theta_2^X(p, n, m)$. To evaluate $\Theta_1^X(p, n, m)$ and $\Theta_2^X(p, n, m)$ ($X=A$ or B) analytically, the absolute sign of the PWS functions $f_p^{\theta A}(\theta)$ (19) and $f_p^{\theta B}(\theta)$ (20) is first removed by breaking each integral into two parts. After several mathematical manipulations, the

following results are obtained

$$\begin{aligned} \Theta_1^X(p, n, m) = & \frac{1}{\sin \theta_h^X} [\sin(\theta_h^X - \theta_p^X) I_1(n, m) \\ & + \cos(\theta_h^X - \theta_p^X) I_1'(n, m) \\ & + \sin(\theta_h^X + \theta_p^X) I_2(n, m) \\ & - \cos(\theta_h^X + \theta_p^X) I_2'(n, m)] \end{aligned} \quad (49)$$

$$\begin{aligned} \Theta_2^X(p, n, m) = & \frac{1}{\sin \theta_h^X} [\sin(\theta_h^X - \theta_p^X) I_3(n, m) \\ & + \cos(\theta_h^X - \theta_p^X) I_3'(n, m) \\ & + \sin(\theta_h^X + \theta_p^X) I_4(n, m) \\ & - \cos(\theta_h^X + \theta_p^X) I_4'(n, m)] \end{aligned} \quad (50)$$

where

$$\begin{aligned} I_{1,2}(n, m) = & \left[x \sqrt{1 - x^2} P_n^m(x) \right]_{x_1}^{x_2} + K(m, n) - \frac{2}{2n + 1} \\ & \cdot \left\{ \frac{1}{2n + 3} K(n + 2, m + 2) \right. \\ & - \left(\frac{1}{2n + 3} + \frac{1}{2n - 1} \right) K(n, m + 2) \\ & \left. + \frac{1}{2n - 1} K(n - 2, m + 2) \right\} \end{aligned} \quad (51)$$

$$\begin{aligned} I_{1,2}'(n, m) = & \frac{-n(n - m + 1)}{(2n + 1)(2n + 3)} K(n + 2, m + 1) \\ & + \left\{ \frac{(n + 1)(n + m)}{(2n + 1)(2n - 1)} + \frac{n(n - m + 1)}{(2n + 1)(2n + 3)} \right\} \\ & \cdot K(n, m + 1) - \frac{(n + 1)(n + m)}{(2n + 1)(2n - 1)} K(n - 2, m + 1) \end{aligned} \quad (52)$$

$$\begin{aligned} I_{3,4}(n, m) = & \frac{-(n - m + 1)}{2n + 1} K(n + 1, m) \\ & - \frac{m + n}{2n + 1} K(n - 1, m) \end{aligned} \quad (53)$$

$$\begin{aligned} I_{3,4}'(n, m) = & \frac{-1}{2n + 1} \{ K(n + 1, m + 1) \\ & - K(n - 1, m + 1) \} \end{aligned} \quad (54)$$

in which

$$K(n, m) = \int_{x_1}^{x_2} \frac{P_n^m(x)}{\sqrt{1 - x^2}} dx \quad (55)$$

with $[f(x)]_{x_1}^{x_2} = f(x_2) - f(x_1)$, $x_1 = \cos(\theta_p^X - \theta_h^X)$, $x_2 = \cos \theta_p^X$ for $I_{1,3}, I_{1,3}'$ and $x_1 = \cos \theta_p^X$, $x_2 = \cos(\theta_p^X + \theta_h^X)$ for $I_{2,4}, I_{2,4}'$. For $K(n, m)$, the recurrence formulas with arbitrary x_1, x_2

have been obtained [37] as follows

$$\begin{aligned} K(n + 1, m) = & \frac{-(2n + 1)}{(n + 1)(n - m + 1)} \left[\sqrt{1 - x} P_{n+1}^m(x) \right]_{x_1}^{x_2} \\ & + n(n + m) K(n - 1, m) \end{aligned} \quad (56)$$

$$\begin{aligned} K(n, m + 1) = & -2[P_n^{m+1}(x)]_{x_1}^{x_2} \\ & + (n + m)(n - m + 1) K(n, m - 1) \end{aligned} \quad (57)$$

with initial values given by

$$\begin{aligned} K(0, 0) = & [\sin^{-1}(x)]_{x_1}^{x_2}, \quad K(1, 0) = -[1 - x^2]_{x_1}^{x_2}, \\ K(n, 1) = & [P_n(x)]_{x_1}^{x_2} \end{aligned} \quad (58)$$

3.2.3.2. $\Theta_3^B(n, m)$ and $\Theta_4^B(n, m)$. The integrals $\Theta_3^B(n, m)$ and $\Theta_4^B(n, m)$ were studied in [18, Eqs. (11) and (12)], and the results are given by

$$\begin{aligned} \Theta_3^B(n + 1, m) = & \frac{1}{(n + 1)(n - m + 1)} \\ & \left\{ -(2n + 1)[1 - (-1)^{n+m}] \right. \\ & \left. \sqrt{1 - x_b^2} P_n^m(x_b) + n(n + m) \Theta_3^B(n - 1, m) \right\} \end{aligned} \quad (59)$$

$$\begin{aligned} \Theta_3^B(n, m + 2) = & -2[1 - (-1)^{n+m}] P_n^{m+1}(x_b) \\ & + (n + m + 1)(n - m) \Theta_3^B(n, m) \end{aligned} \quad (60)$$

where

$$x_b = \cos\left(\frac{\pi}{2} - \frac{l_2}{a}\right) = \sin \frac{l_2}{a} \quad (61)$$

and the initial values are

$$\Theta_3^B(n, 0) = \Theta_3^B(n, 1) = [(-1)^n - 1] P_n(x_b) \quad (62)$$

The integral $\Theta_3^B(n, m)$ can be expressed in terms of $\Theta_4^B(n, m)$, which is given by

$$\begin{aligned} \Theta_4^B(n, m) = & [(-1)^{n+m} - 1] \sqrt{1 - x_b^2} P_n^m(x_b) \\ & - \frac{1}{2n + 1} [(n + m) \Theta_3^B(n - 1, m) \\ & - (m - n - 1) \Theta_3^B(n + 1, m)] \end{aligned} \quad (63)$$

3.2.3.3. $\Phi_2(p, m, \phi_X, \phi_Y)$. The integrals $\Phi_2(p, m, \phi_X, \phi_Y)$ are zero when $m = 0$. When $m \neq 0$, the integration can be

performed analytically. The result is given by

$$\Phi_2 = \frac{-2k_e a}{\sin k_e h} \cdot \frac{[\cos m(\phi_{X2} - \phi_p) - \cos m(\phi_{X1} - \phi_p)](\cos k_e h - \cos m\phi_h^B)}{(m - k_e a)(m + k_e a)} \quad (64)$$

The last integral $\Phi_3(p, q, m, \phi_B)$ is given by (9). Now all the integrals can be evaluated analytically. Note that $Z_{\alpha\beta}^{XY}$ are simply regular series that can be implemented easily in a straightforward manner.

3.2.4. Evaluation of Radiation Field Patterns. The far field of the antenna comprises radiation from the excitation strip current I_θ^A and parasitic patch current components I_θ^B, I_ϕ^B . The electric far field is given by

$$\begin{aligned} E_{\theta,\phi}(r, \theta, \phi) &= \frac{j\eta_0 a}{2\pi W_1} \cdot \frac{e^{-jk_0 r}}{r} \sum_{p_1=1}^{N_1} I_{p_1}^{\theta A} \cdot \mathbf{E}_{\theta\theta,\theta\phi}^{A'}(p_1, \theta, \phi) \\ &+ \frac{j\eta_0 a}{2\pi W_2} \cdot \frac{e^{-jk_0 r}}{r} \sum_{p_2=1}^{N_2} I_{p_2}^{\theta B} \cdot \mathbf{E}_{\theta\theta,\theta\phi}^{B'}(p_2, \theta, \phi) \\ &- \frac{j\eta_0 a}{2\pi L_2} \cdot \frac{e^{-jk_0 r}}{r} \sum_{p_3=1}^{N_3} I_{p_3}^{\phi B} \cdot \mathbf{E}_{\theta\phi,\phi\phi}^{B'}(p_3, \theta, \phi) \end{aligned} \quad (65)$$

in which

$$\begin{aligned} E_{\theta\theta}^{X'}(p, \theta, \phi) &= \sum_{n=1}^{\infty} j^n \frac{2n+1}{n(n+1)} \\ &\times \left\{ \frac{j\hat{J}_n(ka)}{\Delta_n^{\text{TE}}} \sum_{m=0}^n m^2 \frac{(n-m)!}{(n+m)!} \frac{P_n^m(\cos \theta)}{\sin \theta} \right. \\ &\Theta_1^X(p, n, m) \Phi_4(m, \phi) \\ &- \frac{\hat{J}_n'(ka)}{\Delta_n^{\text{TM}}} \sum_{m=0}^n \frac{1}{\Delta_m} \frac{(n-m)!}{(n+m)!} \frac{dP_n^m(\cos \theta)}{d\theta} \\ &\left. \Theta_1^X(p, n, m) \Phi_4(m, \phi) \right\} \end{aligned} \quad (66)$$

$$\begin{aligned} E_{\theta\phi}^{X'}(p, \theta, \phi) &= \sum_{n=1}^{\infty} j^n \frac{2n+1}{n(n+1)} \\ &\times \left\{ \frac{j\hat{J}_n(ka)}{\Delta_n^{\text{TE}}} \sum_{m=0}^n m \frac{(n-m)!}{(n+m)!} \frac{dP_n^m(\cos \theta)}{d\theta} \right. \\ &\Theta_2^X(p, n, m) \Phi_5(m, \phi) \\ &- \frac{\hat{J}_n'(ka)}{\Delta_n^{\text{TM}}} \sum_{m=0}^n m \frac{(n-m)!}{(n+m)!} \frac{P_n^m(\cos \theta)}{\sin \theta} \\ &\left. \Theta_5^X(p, n, m) \Phi_5(m, \phi) \right\} \end{aligned} \quad (67)$$

$$\begin{aligned} E_{\phi\theta}^{B'}(p, \theta, \phi) &= \sum_{n=1}^{\infty} j^n \frac{2n+1}{n(n+1)} \\ &\times \left\{ \frac{j\hat{J}_n(ka)}{\Delta_n^{\text{TM}}} \sum_{m=0}^n m \frac{(n-m)!}{(n+m)!} \frac{dP_n^m(\cos \theta)}{d\theta} \right. \\ &\Theta_3^B(n, m) \Phi_6(p, m, \phi) \\ &- \frac{\hat{J}_n'(ka)}{\Delta_n^{\text{TE}}} \sum_{m=0}^n m \frac{(n-m)!}{(n+m)!} \frac{P_n^m(\cos \theta)}{\sin \theta} \\ &\left. \Theta_3^B(n, m) \Phi_6(p, m, \phi) \right\} \end{aligned} \quad (68)$$

$$\begin{aligned} E_{\phi\phi}^{B'}(p, \theta, \phi) &= \sum_{n=1}^{\infty} j^n \frac{2n+1}{n(n+1)} \\ &\times \left\{ \frac{j\hat{J}_n(ka)}{\Delta_n^{\text{TM}}} \sum_{m=0}^n m^2 \frac{(n-m)!}{(n+m)!} \frac{P_n^m(\cos \theta)}{\sin \theta} \right. \\ &\Theta_4^B(n, m) \Phi_7(p, m, \phi) \\ &- \frac{\hat{J}_n'(ka)}{\Delta_n^{\text{TE}}} \sum_{m=0}^n \frac{1}{\Delta_m} \frac{(n-m)!}{(n+m)!} \frac{dP_n^m(\cos \theta)}{d\theta} \\ &\left. \Theta_4^B(n, m) \Phi_7(p, m, \phi) \right\} \end{aligned} \quad (69)$$

where, for $X=A$ or B

$$\Phi_4^X(m, \phi) = \int_{\phi_{X1, X1}}^{\phi_{X2, X2}} \sin m(\phi - \phi') d\phi' \quad (70)$$

$$\Phi_5^X(m, \phi) = \int_{\phi_{X1, X1}}^{\phi_{X2, X2}} \cos m(\phi - \phi') d\phi' \quad (71)$$

$$\Phi_6^B(p, m, \phi) = \int_{\phi_{B1}}^{\phi_{B2}} \sin m(\phi - \phi') f_p^{\phi B}(\phi') d\phi' \quad (72)$$

$$\Phi_7^B(p, m, \phi) = \int_{\phi_{B1}}^{\phi_{B2}} \cos m(\phi - \phi') f_p^{\phi B}(\phi') d\phi' \quad (73)$$

The integrals $\Phi_4^X(m, \phi)$ (70) and $\Phi_5^X(m, \phi)$ (71) can easily be evaluated in a single step. For $\Phi_6(p, m, \phi)$ and $\Phi_7(p, m, \phi)$, the results were obtained previously [38, p. 302] and are summarized here:

$$\Phi_4^X(m, \phi) = \begin{cases} \frac{1}{m} [\cos m(\phi - \phi_{X2}) - \cos m(\phi - \phi_{X1})] & m \neq 0 \\ 0 & m = 0 \end{cases} \quad (74)$$

$$\Phi_5^X(m, \phi) = \begin{cases} -\frac{1}{m} [\sin m(\phi - \phi_{X2}) - \sin m(\phi - \phi_{X1})] & m \neq 0 \\ 0 & m = 0 \end{cases} \quad (75)$$

Figure 10. The range of PWS-mode half-angle $\theta_h^{A,B}$ for stable calculations of $\Theta_1^X(p, n, m)$ and $\Theta_2^X(p, n, m)$, with $n=60$ and $m=60$. (From Leung [37], © 2001 IEEE.)

$$\Phi_6^B(p, m, \phi) = \frac{2k_e a}{\sin k_e h} \cdot \frac{\sin m(\phi - \phi_p)(\cos k_e h - \cos m\phi_h^B)}{(m - k_e a)(m + k_e a)} \quad (76)$$

$$\Phi_7^B(p, m, \phi) = \frac{2k_e a}{\sin k_e h} \cdot \frac{\cos m(\phi - \phi_p)(\cos k_e h - \cos m\phi_h^B)}{(m - k_e a)(m + k_e a)} \quad (77)$$

It should be mentioned that, by using $\vec{H} = (1/\eta_0)\hat{r} \times \vec{E}$, the magnetic far fields can be found easily.

3.3. Results and Discussion

3.3.1. Convergence Check. The convergence checks for the modal solution and MoM were done. In the following calculations, 60 modal terms and $N_1=N_2=5$, $N_3=3$ were used.

The numerical stability of the integrals $\Theta_{1,2}^X(p, n, m)$ ($X=A$ or B) that utilize the new recurrence formulas has also been studied. Although these results are analytically exact, their numerical accuracy may be unsatisfactory because of the finite precision of the computer. It was found that the stability of the results decreased with increasing order and degree of $P_n^m(x)$, and therefore the worst cases of $\Theta_{1,2}^X(p, 60, 60)$ are considered, where p is a dummy parameter in the stability check. The usable range for the PWS half-mode angles $\theta_h^{A,B}$ as a function of the PWS center angles $\theta_p^{A,B}$ is shown in Fig. 10. Only the range $0^\circ \leq \theta_p^{A,B} \leq 90^\circ$ is shown because the results are symmetric for $90^\circ \leq \theta_p^{A,B} \leq 180^\circ$. Since $0^\circ \leq \theta \leq 180^\circ$ for the adopted coordinate system, only the region $\theta_h^{A,B} \leq \theta_p^{A,B}$ (below the straight line $\theta_h^{A,B} = \theta_p^{A,B}$) should be considered for $0^\circ \leq \theta_p^{A,B} \leq 90^\circ$. It is seen that Θ_2^X has a slightly smaller stable region than does Θ_1^X and, hence, the overall stable region is limited by Θ_1^X . The shaded area in the figure shows the overall stable region, outside which the results will become unstable. Note that care has to be taken for $\theta_p^{A,B} < 46^\circ$, as the half-mode angles $\theta_h^{A,B}$ in this case should

Figure 11. Phase difference between far-field E_θ and E_ϕ as a function of parasitic patch location, with $|E_\theta| = |E_\phi|$, $\epsilon_r=9.5$, $a=12.5$ mm, $l_1=14$ mm, $W_1=1.2$ mm, and $W_2=2$ mm. (From Leung and Ng [24], 2003 © IEEE.)

not be too small or unstable results will be obtained. In this article, all results are calculated within the stable region, and thus the accuracy is ensured. For $\Theta_3^B(n, m)$ (46) and $\Theta_4^B(n, m)$ (47), the recurrence results [18] are very stable and can therefore be used directly.

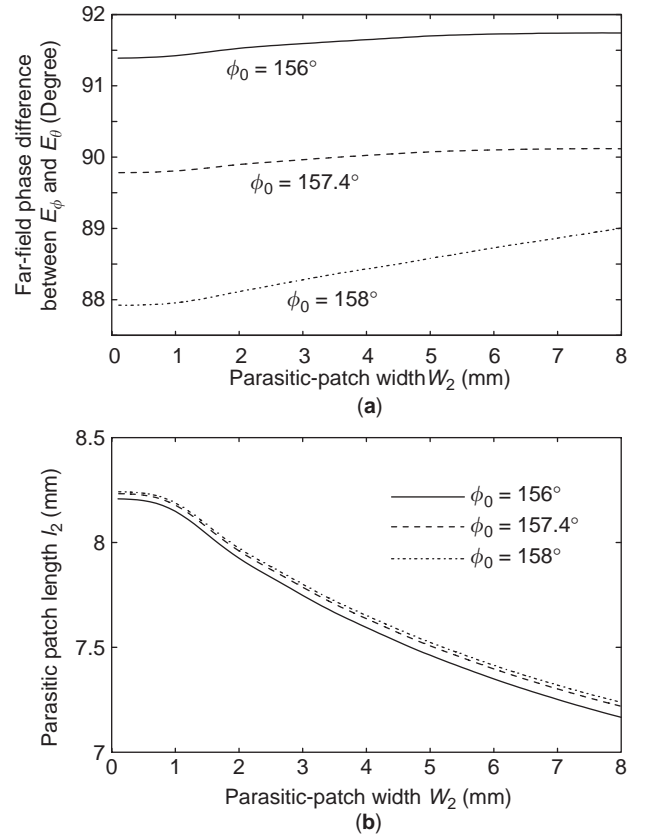

Figure 12. (a) Far-field phase difference as a function of parasitic patch width, with $|E_\theta| = |E_\phi|$, $\epsilon_r=9.5$, $a=12.5$ mm, $l_1=14$ mm, $W_1=1.2$ mm; (b) parasitic patch length as a function of parasitic patch width, with $|E_\theta| = |E_\phi|$, $\epsilon_r=9.5$, $a=12.5$ mm, $l_1=14$ mm, and $W_1=1.2$ mm. (From Leung and Ng [24], 2003 © IEEE.)

3.3.2. Circularly Polarized DRA. It is well known that the far fields E_θ and E_ϕ have to be equal in amplitude but different in phase by 90° for ideal CP fields. The angular positions of the patch ϕ_0 , patch length l_2 , and patch width W_2 are tuned to meet these two requirements. The roles of the parasitic patch and excitation strip will be discussed.

3.3.2.1. Effects of Parasitic Patch. To demonstrate the results, a DR of dielectric constant $\epsilon_r=9.5$ and radius $a=12.5$ mm is used. The excitation strip has length $l_1=14$ mm and width $W_1=1.2$ mm. Figure 11 shows the far-field phase difference between E_θ and E_ϕ as a function of the parasitic patch position ϕ_0 with $|E_\theta|=|E_\phi|$. The condition $|E_\theta|=|E_\phi|$ is maintained in the curve by adjusting the length l_2 of the parasitic patch. With reference to the figure, the 90° phase difference is obtained when $\phi_0=157.4^\circ$. The corresponding patch length l_2 is also given in the figure, where it is found that l_2 should be equal to 7.96 mm in order to excite CP fields.

The effect of the patch width W_2 on the phase difference is shown in Fig. 12(a) for different ϕ_0 values. It is found that the phase difference only increases slightly with W_2 . Again, the condition $|E_\theta|=|E_\phi|$ is maintained by adjusting

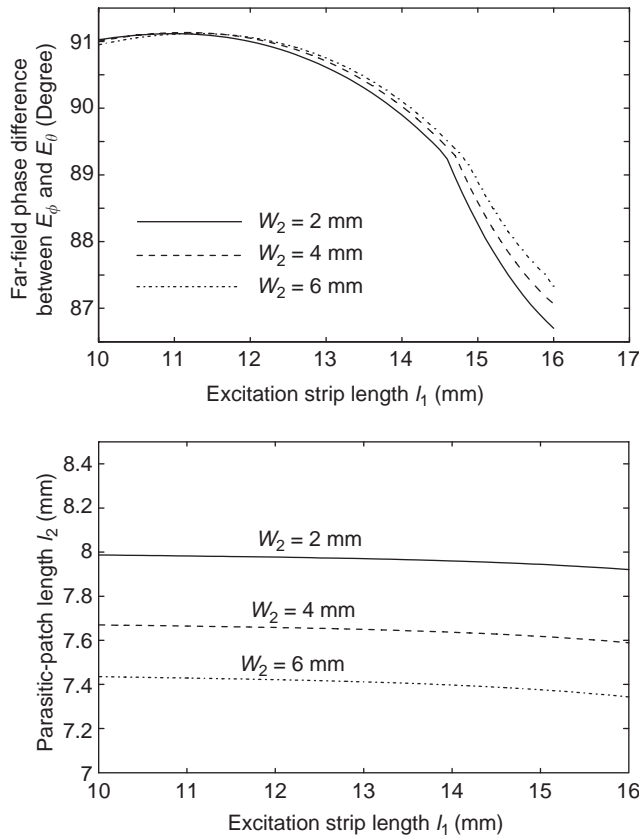

Figure 13. (a) Far-field phase difference as a function of excitation strip length, with $|E_\theta|=|E_\phi|$, $\epsilon_r=9.5$, $a=12.5$ mm, $W_1=1.2$ mm, and $\phi_0=157.4^\circ$; (b) parasitic patch length as a function of excitation strip length, with $|E_\theta|=|E_\phi|$, $\epsilon_r=9.5$, $a=12.5$ mm, $W_1=1.2$ mm and $\phi_0=157.4^\circ$. (From Leung and Ng [24], 2003 © IEEE.)

l_2 , shown in Fig. 12(b). It is seen that in order to keep $|E_\theta|=|E_\phi|$, l_2 should decrease when W_2 increases. Note that the length-to-width ratio (l_2/W_2) is almost the same for different ϕ_0 . From the results, it can be deferred that the patch location is more important than the patch width in the CP design.

3.3.2.2. Effects of the Excitation Strip. The effect of the conformal strip length l_1 on the phase difference for different W_2 is shown in Fig. 13(a). The corresponding patch length l_2 for keeping $|E_\theta|=|E_\phi|$ is shown in Fig. 13(b). It can be observed from Fig. 13(a) that by increasing l_1 by 60% (from 10 to 16 mm) the phase angle is reduced by only 4.2% (from 91° to 87.2°) for $W_2=4$ mm. This shows that the strip length l_1 has only a small effect on CP operation. Moreover, with reference to Fig. 13(b), the patch length l_2 remains almost unchanged as l_1 varies, meaning that virtually no adjustments of the parasitic patch dimensions are required to maintain CP operation. These are very favorable results, as this suggests that once the antenna generates CP fields, the length of the excitation strip can be varied alone in order to change the

Figure 14. Calculated input impedance as a function of frequency with 0-dB AR at $f=3.56$ GHz: $\epsilon_r=9.5$, $a=12.5$ mm, $W_1=1.2$ mm, and (—) $l_1=10$ mm, $l_2=7.89$ mm, $W_2=2.73$ mm, $\phi_0=158.5^\circ$; (---) $l_1=12$ mm, $l_2=7.88$ mm, $W_2=2.73$ mm, $\phi_0=158.5^\circ$; (- - - -) $l_1=14$ mm, $l_2=7.91$ mm, $W_2=2.26$ mm, $\phi_0=157.4^\circ$: (a) input resistance; (b) input reactance. (From Leung and Ng [24], 2003 © IEEE.)

input impedance, without significantly disturbing CP operation. This greatly facilitates the impedance tuning of the CP antenna. It is noted from Fig. 13(b) that the wider the patch width W_2 is, the smaller the patch length l_2 is required.

Figure 14 shows the calculated input impedance for $l_1 = 10, 12, 14$ mm. For each l_1 , the parameters of the parasitic patch are adjusted to give the 0-dB AR at $f = 3.56$ GHz. With reference to the figure, the input impedance can be altered by changing l_1 and, thus, the impedance matching can be achieved for practical designs. The parameters of the parasitic patch for each case are shown in the figure caption. Note that the patch sizes and locations for different l_1 are almost the same, which is consistent with the discussion above. Since it is futile to change the strip and patch parameters iteratively, the design process is very simple.

3.3.3. Measured and Calculated Results. To verify the theory, an experiment was carried out using a hemispherical DR of dielectric constant $\epsilon_r = 9.5$ and radius $a = 12.5$ mm. The excitation strip has length $l_1 = 14$ mm and width $W_1 = 1.2$ mm, whereas the parasitic patch has length $l_2 = 7.9$ mm, width $W_2 = 2.2$ mm, and angular position $\phi_0 = 157.4^\circ$. Both the excitation strip and parasitic patch were cut from a conducting adhesive tape. Measurements were done with an HP8510C network analyzer, and the reference place was set at the coaxial aperture by using the port extension. To reduce possible errors introduced by airgaps between the ground plane and DR, the DR was first put on the adhesive side of a conducting tape [18]. Figure 15 shows the measured and calculated input impedance for the DRA. The measured and calculated resonant frequencies (zero reactance) are 3.25 and 3.27 GHz with only 0.62% error. The return loss (minimum $|S_{11}|$) was also studied. It was found that the measured and calculated matching frequencies ($|S_{11}| < -20$ dB) are operated at 3.42 and 3.43 GHz, respectively, which are higher than the

Figure 15. Measured and calculated input impedance for the DRA, with $\epsilon_r = 9.5$, $a = 12.5$ mm, $l_1 = 14$ mm, $l_2 = 7.9$ mm, $W_1 = 1.2$ mm, $W_2 = 2.2$ mm, and $\phi_0 = 157.4^\circ$. (From Leung and Ng [24], 2003 © IEEE.)

zero-reactance values. A similar phenomenon was observed in Ref. 36.

Figure 16 shows the measured and calculated ARs as a function of frequency. Again, reasonable agreement between theory and experiment is obtained. The ripple in the measured result is caused mainly by the finite ground-plane diffraction. It is found that the calculated 3-dB AR bandwidth is 2.4%, which is typical for a singly fed DRA.

The measured and calculated $x-z$ and $y-z$ plane radiation patterns are shown in Figs. 17a and 17b, respectively. Again, reasonable agreement between theory and experiment is obtained. As expected, the radiation fields are of a broadside mode. It is observed that the antenna is operated in a right-hand CP mode, with more than 27 dB difference between the right-hand and left-hand fields in the broadside direction ($\theta = 0^\circ$). It should be mentioned that the antenna can be operated in a left-hand CP mode by symmetrically displacing the parasitic patch on the opposite side, that is, by changing ϕ_0 from 157.4° to 202.6° .

Figure 16. Measured and calculated ARs as a function of frequency in the broadside direction, with $\epsilon_r = 9.5$, $a = 12.5$ mm, $l_1 = 14$ mm, $l_2 = 7.9$ mm, $W_1 = 1.2$ mm, $W_2 = 2.2$ mm, and $\phi_0 = 157.4^\circ$. (From Leung and Ng [24], 2003 © IEEE.)

Figure 17. Measured and calculated right-hand and left-hand field patterns at $f = 3.52$ GHz, with $\epsilon_r = 9.5$, $a = 12.5$ mm, $l_1 = 14$ mm, $l_2 = 7.9$ mm, $W_1 = 1.2$ mm, $W_2 = 2.2$ mm, and $\phi_0 = 157.4^\circ$: (a) x - y plane; (b) y - z plane. (From Leung and Ng [24], 2003 © IEEE.)

4. CONCLUSION

Conformal-strip-excited LP and CP hemispherical DRAs has been studied theoretically and experimentally. In the analysis, the MoM has been applied to find the strip currents. To reduce computation time and complexity, the integrals associated with the associated Legendre functions have been evaluated by virtue of recurrence formulas. Linearly Polarized DRA has been introduced as an angular strip displacement to facilitate impedance matching. By adding a parasitic patch on the sidewall of the DRA, a CP DRA can be excited. The parasitic patch has been displaced at 157.4° from the excitation strip to give the optimum AR around the design frequency. It has been found that the AR and input impedance of the antenna are controlled predominantly by the parasitic patch and excitation strip, respectively. Because each part can be designed independently, the design of the CP DRA is quite an easy task.

DIELECTRIC RESONATOR FILTERS

S. BILA

Because microwave filtering is an important function required to keep a number of different systems in working order, the specifications of a filter are varied. We can, however, try to classify some of them as presented in Table 1. The constraints are electrical, mechanical, thermal, and commercial.

The objective in this article is to show the advantages of the dielectric resonator (DR) technique to satisfy some of these functions, along with its disadvantages, in comparison with some other well-known solutions.

DRs are suitable for bandpass filtering. DR filters are classified as three-dimensional (3D) devices, in opposition to two-dimensional (2D) planar ones.

The main advantages of 2D solutions are their relative bycompact dimensions, their easier integration in circuit or module environment, and their well-known design and manufacturing procedures. They are, however, limited in their applications to the processing of low power, sizable relative bandwidth signal, in relation to the poor unloaded quality factor of localized microwave elements or planar resonators. Some solutions are proposed to restrict losses, such as applying supraconductors or active-element techniques, but they remain inadequate to replace 3D devices, in particular for high-power requirements.

In the class of 3D devices, designers have first chosen waveguides or metallic empty cavities to satisfy their very narrow bandwidth filtering requirements. However, since the mid-1980s, high-dielectric-constant materials, having low loss tangent and good thermal stability, have become available. The DR solution has been preferred for a number of applications, in particular spatial ones. This technique allows us to reduce significantly the cavities and waveguide device sizes, for equivalent electrical and increased thermal performances. Some average ratios can be given for dual-mode resonators (DR compared with cavity):

1 : 4 in volume
 1 : 2 in mass

Moreover, the DR shape and the mode in which it is excited can be chosen to give a response to particular requirements, as we will see later in this article. A number of DR shapes and filter topologies have, however, been proposed. Our work here is limited to the presentation of the most popular ones.

In this article, we present some characteristic parameters of DR filters, which are generally introduced

Because microwave filtering is an important function required to keep a number of different systems in working order, the specifications of a filter are varied. We can, however, try to classify some of them as presented in Table 1. The constraints are electrical, mechanical, thermal, and commercial.

The objective in this article is to show the advantages of the dielectric resonator (DR) technique to satisfy some of these functions, along with its disadvantages, in comparison with some other well-known solutions.

DRs are suitable for bandpass filtering. DR filters are classified as three-dimensional (3D) devices, in opposition to two-dimensional (2D) planar ones.

The main advantages of 2D solutions are their relative bycompact dimensions, their easier integration in circuit or module environment, and their well-known design and manufacturing procedures. They are, however, limited in their applications to the processing of low power, sizable relative bandwidth signal, in relation to the poor unloaded quality factor of localized microwave elements or planar resonators. Some solutions are proposed to restrict losses, such as applying supraconductors or active-element techniques, but they remain inadequate to replace 3D devices, in particular for high-power requirements.

In the class of 3D devices, designers have first chosen waveguides or metallic empty cavities to satisfy their very narrow bandwidth filtering requirements. However, since the mid-1980s, high-dielectric-constant materials, having low loss tangent and good thermal stability, have become available. The DR solution has been preferred for a number of applications, in particular spatial ones. This technique allows us to reduce significantly the cavities and waveguide device sizes, for equivalent electrical and increased thermal performances. Some average ratios can be given for dual-mode resonators (DR compared with cavity):

1 : 4 in volume
 1 : 2 in mass

Moreover, the DR shape and the mode in which it is excited can be chosen to give a response to particular requirements, as we will see later in this article. A number of DR shapes and filter topologies have, however, been proposed. Our work here is limited to the presentation of the most popular ones.

In this article, we present some characteristic parameters of DR filters, which are generally introduced

Table 1. Microwave Filter Specifications

Electrical	Mechanical	Thermal	Commercial
Central frequency	Mass and volume	Temperature range of use	Components and materials costs
Passband width	Vibration resistance	Maximum dissipated power	Machining cost
Passband ripple	Machining tolerances	Sensitivity of electrical response to temperature variations	Design cost
Out-of-band selectivity and rejection	Manufacturing difficulties		Delay for design and realization of filter
Response isolation			
Insertion losses			
SWR			
Group delay			
Power capabilities			

during the synthesis procedure. These definitions are helpful in explaining the choices of filter designers, in particular the DR shapes and arrangements in multipole devices.

In Section 1, the class of devices loaded by cylindrical DRs is investigated. This is a common shape for the DR. It can be excited on a symmetric mode (TE_{0n} or TM_{0m}) or on a first hybrid mode (HEM_{11}). Different DR arrangements in the filter are presented and discussed.

For particular applications in microwave filtering, we can fit the DR shape or the DR mode. For high-power applications, it is important to put the high-dielectric-constant material in contact with a metallic enclosure, to improve the thermal dissipation. DRs of a quarter-cut cylinder, a cylindrical rod, or a dielectric plate shielded in a metallic cavity are investigated. Solutions are also given to optimize the isolation of the filter response on the frequency axis, or to apply DR to the millimeter wave filtering. These particular applications are included in Section 2.

Approaches developed to design DR filters are discussed in Section 4. A four-pole DR filter synthesis is proposed as an example.

1. ELECTRICAL CHARACTERISTIC PARAMETERS OF A DR FILTER

Applying conventional methods, the design of microwave filters starts with the selection of an ideal transfer function that fulfills the electrical objectives of the specifications. The synthesis of this ideal transfer function leads to an equivalent lumped-element circuit. This circuit is characterized by a coupling matrix that depends on the lumped-element values. A number of studies have been devoted to this task [1,2]. Different circuit topologies can be chosen. However, for the DR filters presented in this article, the equivalent circuit is close to the one presented in Fig. 1 (canonical symmetric design). Nevertheless, if another solution is chosen, the same characteristic parameters may have to be computed.

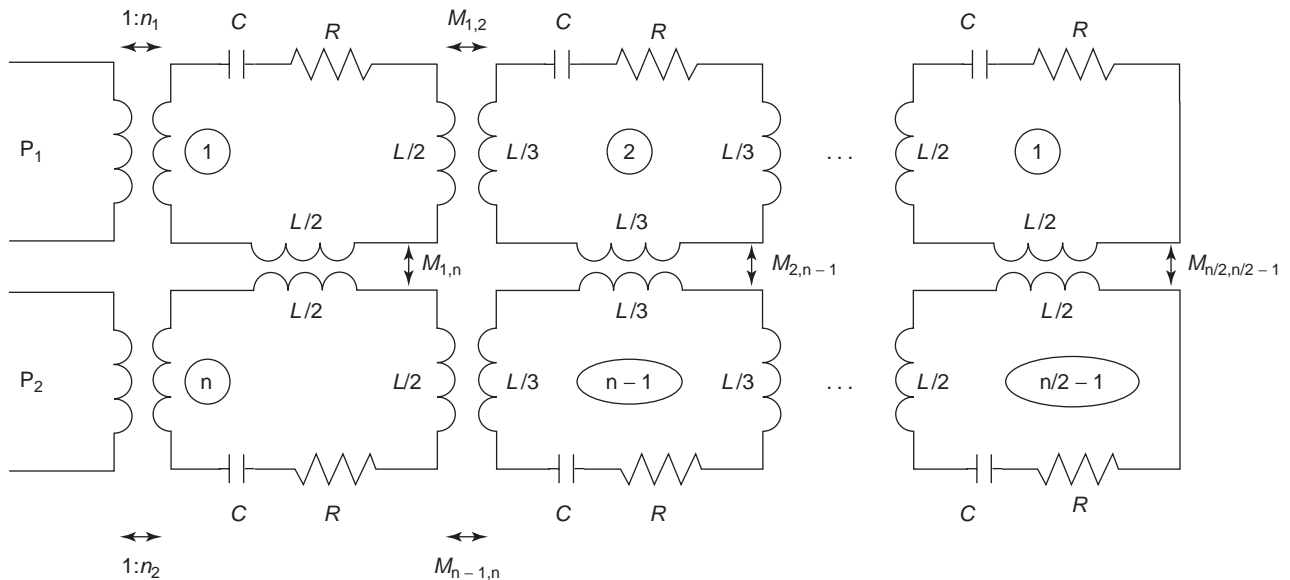

Figure 1. Equivalent circuit of a symmetric n -pole filter.

From the circuit presented Fig. 1, we define the following:

- The central frequency of the filter:

$$f_0 = \frac{1}{2\pi\sqrt{LC}} \quad (1)$$

- The unloaded quality factor of each resonator:

$$Q_0 = \frac{L\omega_0}{R}, \quad \omega_0 = 2\pi f_0 \quad (2)$$

- The input and output coupling coefficients. In the electrical scheme, the coupling levels between the excitation access (P_1 and P_2) and the first and last resonators (1 and n) are characterized, respectively, by the ratios $1/n_1$ and $1/n_2$. It is however generally preferred to define external quality factors Q_{ei} [1] at port i , ($i \in \{1, 2\}$), by

$$Q_{ei} = \frac{2\pi L f_0}{R_{ei}} \quad \text{with} \quad (3)$$

$$R_{ei} = R_0 n_i^2 \quad (4)$$

as the external loading resistance at port P_i . Coupling coefficients α_i are also defined at port i by

$$\alpha_i = \frac{Q_0}{Q_{ei}} \quad (5)$$

- The coupling coefficient between resonators. The resonators are intercoupled, longitudinally and crosswise, in the general case. We define a coupling coefficient K_{ij} between resonators i and j by

$$K_{ij} = \frac{M_{ij}}{L} \quad (6)$$

The crosswise coupling coefficients (except $K_{n/2,n/2-1}$) may cancel to obtain conventional Butterworth or Chebyshev responses. Some of them are different from zero and can be negative for elliptic bandpass function realizations, including transmission zeros in the out-of-band part of the transmission response.

These parameters help the designer perform the third synthesis step, the computation of the device dimensions. The topology of the filter, in particular the DR arrangement, is easily directly deduced from the equivalent-circuit one, which, in fact, justifies this approach. In Section

3, we explain how the dimensions of the filter are computed from knowledge of the parameters f_0 , M_{ij} , and Q_{ei} .

2. FILTERS COMPOSED OF CYLINDRICAL DRs

Cylindrical DRs are more often used to realize multipole filters. We discuss this class of solutions here. The DR is generally shielded in a metallic box, to avoid radiation losses. It can then be excited on transverse electric TE_{0n} modes, transverse magnetic TM_{0m} modes, or hybrid HEM_{nm} modes. The natures of the transmission lines or waveguides used to couple the filter, the nature of the DRs arrangement in the device, and the nature of the electrical, mechanical, and thermal characteristics of the filter depend on the choice of the DR mode. Table 2 compares the performance levels of the TE_{01} , TM_{01} , and HEM_{11} modes. The dimensions are optimized to obtain a resonant frequency equal to 4 GHz. We notice that the DR acting on the TE_{01} mode is the less bulky one. Even if the electrical performances are comparable, the TM_{01} mode is more radiative in the cavity, which increases the metallic losses on the enclosure. The HEM_{11} mode is in fact very interesting for reduction of filter size. The filter performance of each particular TE, TM, or hybrid mode is discussed below.

2.1. Monomode Filter

The DRs are excited on the symmetric TM_{01} or TE_{01} modes. An n -pole “monomode” filter is then composed of n DRs. The dimensions of each DR and of the metallic enclosure are generally chosen to optimize, at the filter center frequency, the dielectric and metallic losses and the device sizes, as well as to avoid spurious responses around the filter bandpass.

Different topologies of the TE_{01} mode, have been reported in the literature. The DRs can be placed side by side on the same plane. To obtain good isolation on this mode, the ratio between diameter and height of each DR is generally chosen to be 2. Then the radial radiation of each DR is small and the DRs can be coupled directly; a metallic iris does not have to be placed systematically between the DRs to limit the filter size.

Two examples of realization are presented in Figs. 2 and 3. Different techniques can be employed to couple the filter. Propagative rectangular waveguides can be connected to both ends of a waveguide section above cutoff, which contains the DR. The TE_{01} mode of the DRs is excited if their axis are positioned along the wide dimension of the monomode waveguide (Fig. 2). The distances between the first (and respectively last) DR and the junctions between

Table 2. Comparison between TE_{01} , TM_{01} , HEM_{11} , and DR^a Mode Performance Levels

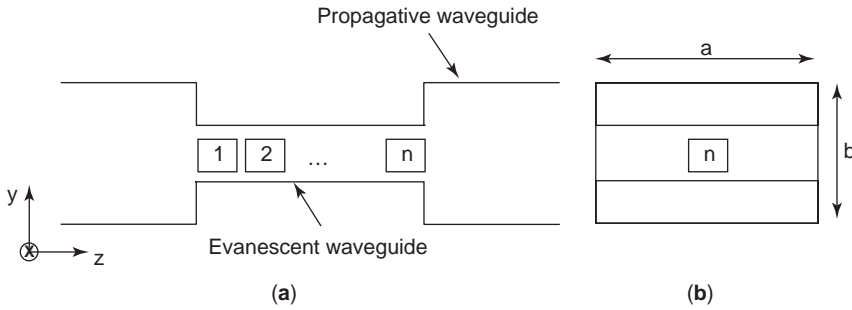

Figure 2. DRs excited on a TE_{01} mode through rectangular waveguides.

the waveguide sections enable us to tune the level of the input (respectively output) coupling coefficient. This technique is suitable for high-power applications.

To improve the integration of the filter in its environment, we must couple the first and last DRs to microstrip lines (Fig. 3). Nevertheless, the metallic losses of such a structure increases, as the DR must be placed near the metallic strip and ground plane to obtain the required coupling levels. The evolution of the coupling coefficient as a function of the distance between the line and the DR is given in Ref. 3.

Dielectric resonators might also be coupled through coaxial probes [4] or loops [5]. Particular attention to the positioning of the excitation systems around the DR enable us to obtain a good isolation of the bandpass response on the frequency axis.

From the devices shown in Figs. 2a and 2b [4–6], we obtain narrow-bandpass Chebyshev or Butterworth responses. Stopband filters can also be realized easily using these DR coupling techniques, coupling the DR to a propagative waveguide or a transmission line [7].

Coupling the DRs side by side enables us to maintain them easily, such as on a dielectric substrate, whose material is chosen to improve the temperature stability of the filter. Moreover, some tuning elements can be integrated around the DRs; some metallic or dielectric screws are generally placed along the DRs axis to tune the filter resonant frequency, as well as between the DRs to adjust the coupling coefficients.

On the TE_{01} , TM_{01} , and TM_{02} modes, DRs have also been mounted axially on a cylindrical dielectric rod. To

obtain an elliptic response on these symmetric modes, in the same device we can combine axial and side-by-side mounting configurations. A two-stage device is constructed. The transversal coupling M_{ij} can then be achieved, as it has been done for empty metallic cavities. A negative coupling is obtained by setting some upper and lower cavity axis; the resulting transmission zeros placed around the passband response increase the filter selectivity [8].

Different techniques, including those mentioned previously, have been developed for the mounting of DRs in their enclosure; for instance, the DRs can be glued on a dielectric support. This technique may, however, be critical because of the generation of parasitic gaps between the glued materials and the poor glue loss tangent. A mounting based on a differential dilatation phenomenon between each DR and its environment is more suitable for obtaining high electrical performance. The capability of the filter to withstand vibration is fundamental for space applications. Some test measurements are given, for example, in Ref. 9.

2.2. Dual-Mode Filters

Dual-mode filters [10] are now widely used because they offer equivalent electrical performance levels, smaller size, and less mass than do classical fundamental TE or TM-mode filters. A metallic screw, or another perturbation is placed around the DR to break the rotational symmetry. Then, on the first or second hybrid mode, the two polarizations sections are imposed, and their frequencies differ in relation to the perturbation dimension. Figure 4 presents a two-pole dual-mode filter, composed of only one DR. Two monomode DRs would be coupled to obtain the same electrical response. The DR is excited through coaxial probes. Two tuning screws are generally added in the excitation probe axis to tune the central resonant frequency.

The coupling screw is placed at an angle of 45° from the excitation axis. In this case, the symmetry of the structure suffices to fix the direction of the two polarizations. The electromagnetic environment of each mode differs; thus the resonant frequencies f_1 and f_2 of the two polarizations differ. The power combining is constructive between f_1 and f_2 at the output access, which explains the bandpass response obtained from this device. Some transmission zeros are also observed, due to the combination of opposite phases between the two polarizations, and between these phases and a higher-order mode of the DR [11].

Figure 3. DR lines excited on a TE_{01} mode through microstrip lines.

Figure 4. Dual-mode DR excited by two coaxial probes.

For n -pole elliptic realization, with $n > 2$ and n as an odd number, we need to couple parallel modes in adjacent DRs (longitudinal coupling) and to avoid extra coupling between orthogonal modes of different DRs. Three screws are placed around each DR as shown in Fig. 4, and adjacent DRs are generally iris-coupled. Two orthogonal rectangular apertures machined in a metallic plate enable us to impose the required coupling level between each set of parallel polarizations. To obtain a negative sign on some crosswise coupling coefficients, the different screws are not positioned at the same angle with the excitations in the different cavities. This technique is well known for metallic cavity realizations [12]. An example of four-pole topology is presented in Fig. 5, where the DRs are coupled to input-output coaxial probes.

The excitation can also take the form of rectangular waveguides, coupled to the input-output cavities through

Figure 5. Example of four-pole dual-mode DR filter.

rectangular irises, for power applications. These irises are then generally placed in a plane perpendicular to the DR axis.

Adjacent DRs can also be coupled directly, rather than iris coupled [13]. Then realizations of small coupling levels may require large separation between adjacent DRs, and may consequently require significant sizes. However, the introduction of evanescent waveguide sections between DRs enable us to reduce the device dimensions [14]. The drawbacks of this method are the filter spurious characteristics and the dependent coupling level between the mode sets of adjacent DRs. In the same way as monomode realizations, dual-mode DRs can be mounted in a planar relationship to one another. Each DR is again enclosed in a metallic cavity. The DR intercouplings are controlled independently by a metallic iris that contains two rectangular noncrossing apertures placed in an appropriate manner [15]. This solution is interesting for its flexibility in the arrangement of the DR cavities.

More than two modes have also been coupled in the same DR cavity, to conserve weight and size in comparison with the previous solutions. The two polarizations of the HEM_{11} modes and the TM_{01} mode have been simultaneously excited in a planar DR-mounted cavity. Two of these three-pole modules have been coupled through an iris composed of two separate T-shaped apertures [16].

3. PARTICULAR APPLICATIONS OF DRS IN MICROWAVE FILTERING

3.1. DR for High-Power Applications

The dual-mode devices we have presented above are interesting for their high electrical performance levels and limited sizes. But even if the filter dissipated power is small, the resulting thermal dissipation remains critical for certain applications, such as space applications, because the thermal conductivity of most dielectric material is poor.

A solution consists of positioning the high permittivity resonators in contact with the metallic enclosure, to improve the thermal dissipation efficiency, and then to improve the power-handling capability of the filter.

We can first take advantage of the electromagnetic field symmetry of a cylindrical DR. It can be divided into two or more parts, without modifying the resonant frequency and field repartition of some modes, if the physical metallic walls are placed in planes in which electrical wall conditions are naturally verified [17,18]. In this way a cylindrical DR excited on a TE_{01} mode can be split, for example, into four parts. If each of the cut planes are in contact with a metallic wall (Fig. 6), all quarter-cut DRs will resonate at the same frequency.

The improvement of the power-handling capability is not the sole purpose of this technique. A number of cylindrical DR modes do not satisfy the electrical wall condition in the planes where they are imposed on the quarter-cut DR. They are then suppressed in the “image” DR. Hence the out-of-band rejection performances of the filter is improved, suppressing spurious responses.

Figure 6. Equivalent cylindrical (a) and quarter-cut (b) DRs excited on a TE_{01} mode (— electric field lines).

This technique also provides very compact structures, reducing the size not only of the DR but also of the metallic enclosure. This is an important advantage, particularly for 900-MHz–3-GHz applications. Nevertheless, the metallic losses on the metallic plane in contact with the DR increase dramatically, resulting in a poor unloaded

Figure 8. TM dual-mode resonator.

quality factor Q_0 of the DR. We can note, however, that the image resonator might be preferred to coaxial dielectric field resonators, considering the sizes and losses at the same frequency. Figure 7 presents a possible arrangement of the DRs to realize an elliptic five-pole function [17].

Different techniques have been proposed to increase the unloaded quality factor of the split DR. TM dual-mode DRs have been developed for use in the L and C frequency bands for mobile communication applications. A cross is formed as shown in Fig. 8, by two parallelepipedic DRs excited on a TM_{01} mode [19]. The tuning element required to couple the two degenerated modes is not a metallic screw, but a perturbation directly machined near the center of the cross. An unloaded quality factor equal to 9000 has been obtained at 1.9 GHz, for a dielectric loss tangent equal to 5×10^{-5} [20]. A high-permittivity dielectric plate has also been placed in a metallic enclosure to provide a good compromise between the unloaded quality factor level and the thermal dissipation capability [21]. The corners of a thin parallelepipedic plate have been cut to provide a good contact between the resonator and a cylindrical metallic cavity (Fig. 9).

The dimensions are optimized to limit the metallic and dielectric losses on the first TE mode that has degenerated. It has been shown that the electrical performance of this resonator is not far from that of the cylindrical

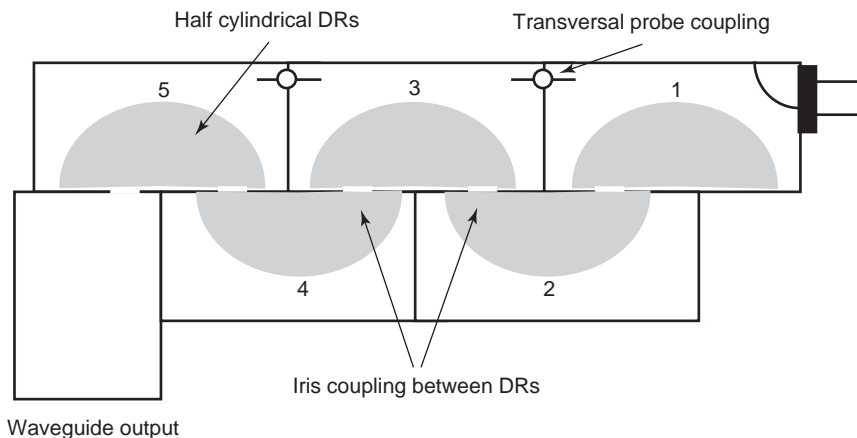

Figure 7. Five-pole elliptic filter using the split-DR technique.

Figure 9. High-permittivity dielectric plate resonator technique.

dual-mode one, and this solution is more suitable for power applications. Metallic screws are generally placed around the dielectric plate to couple the first TE polarizations. Slots are then machined in the plate, both to couple these polarizations and to optimize the out-of-band rejection of the filter. Superimposed cavities are coupled through metallic cross irises. The topology of an eight-pole autocorrected quasielliptic filter is presented in Fig. 10. The transmission and reflection responses, along with the group delay of the filter, are presented in Fig. 11.

Some other studies have been performed to optimize the DR shape to increase the unloaded quality factor of the resonators, in particular by choosing adequate forms of the DR dielectric support in contact with the metallic enclosure [22].

3.2. Filter Configurations for Optimization of Out-of-Band Rejection

Conventional DR filters have relative poor stopband rejection performance, due to the excitation of higher-order mode resonances. A lowpass filter, placed at the output of the bandpass DR filter, might solve this problem, but the bulk and the electrical performance of the cascaded filter suffer from this solution. Different filter configurations have, however, been proposed to increase the out-of-band rejection.

We have already underlined that the quarter-cut DR, or the TM_{01} DR, which are of interest for power applications, are also efficient techniques for elimination of some of the spurious responses.

Coupling structures have been designed to suppress the excitation of some modes. A single-mode TE_{01} filter realization is, for example, presented in Ref. 23. The diameter: height ratio of the DR is generally chosen to optimize the mode isolation. A hole can be machined in the cylindrical DR, along its axis [24,25], and the DR shape can be matched [26] to increase this isolation. A more sophisticated solution consists of mixing DRs excited on different modes in a same filter. To obtain part of the ring DR isolation, and part of the compactness of dual-mode devices, TE_{01} ring DRs and a HEM_{11} dual-mode DR have been coupled to realize six-pole elliptic filters, combining four DRs. DRs can be mounted axially [27] or side by side [28] in their metallic enclosures. As an example, the center frequency of the realized filter is equal to 1.23 GHz; its passband is 20 MHz, and the out-of-band rejection is better than -40 dB in the 1–1.9 GHz frequency band [27].

3.3. DR for High-Frequency Applications

When the frequency increases, the dimensions of cylindrical DRs excited on the first TE_{01} , TM_{01} , and HEM_{11} modes become too small. The limit of conventional DR applications can be set around 20 GHz. To solve the manufacturing problem, spherical DRs have been proposed. But the critical mechanical stability of the devices, along with the spurious modes around the bandpass limits their applications.

Figure 10. Dielectric plate eight-pole connected elliptic filter.

Figure 11. (a,b) Transmission and reflection coefficient variations as a function of the frequency; (c) group delay variation in filter passband.

We can, however, use cylindrical DRs on whispering gallery modes [29]. For important azimuthal variation number, the DR can be used easily up to 100 GHz. Moreover, the field is very effectively stored in with the DR, and the unloaded quality factor, which thus depends only on the material loss tangent, is important. Examples of filter realizations are given in Ref. 30.

4. THEORETICAL DESIGN OF MICROWAVE DR FILTERS

4.1. Introduction

DRs are used for the realization of narrowband filters up to 0.01% relative bandwidth. The electrical responses of such devices are then very sensitive to their geometric and

physical characteristics, and particular attention must be paid to their design.

The purpose of the theoretical design can be not only to optimize the filter performances but also to reduce the cost of the product. If the design is not efficient, the time required for the tuning can be important; different devices are manufactured, and even in the phase when the dimensions are known, an experimenter must spend time and effort to tune each filter.

However, DR structures are difficult to analyze, because their geometries are very complex. We have seen that the filter topologies are diverse; DRs can be intercoupled or coupled through a metallic iris; they may be excited by coaxial probes, metallic waveguides, and microstrip lines; their shapes are not systematically

cylindrical; and they can be maintained in their metallic enclosures through a wide variety of systems. Moreover, the structures are very compact, and if we can define different segments in its composition, strong couplings are generated between the DRs through high-order modes. Thus the classical approach that is applied in the circuit software, namely, the segmentation method, is not efficient here; we cannot characterize each segment independently from the others, and we cannot connect the different contributions to obtain the device response.

Analytical-approach models were initially developed to assist designers. These methods are described in Ref. 31. Since the late 1980s, rigorous analyses have been performed, first on some parts of the DR filter. Examples include application of modal methods [32,33], the finite-element method [34], or the method of lines [35] to characterize axisymmetric dielectric-loaded metallic cavities, computing the resonant frequencies of these devices. Some other studies have been performed on the design of three-dimensional resonator, which is nonsymmetrical in structure. The resonant frequency of a DR shielded in a parallelepipedic enclosure has been computed applying the modal method [36] and the finite-element method [37,38]. From these computations we can easily deduce the coupling coefficient between two DRs for symmetric structures. The coupling coefficient between a DR and a waveguide or a transmission line has been computed by

applying the finite-element method [39,40]. Now, with the evolution of computer capabilities, a number of research teams are interested in the electromagnetic optimization of DR devices applying numerical simulation. A number of articles deal with the rigorous design of multipole filters. In this section we will describe a solution for the rigorous design of a multipole DR filter using the finite-element method [40].

4.2. Method for Optimized Design of a DR Filter

The procedure generally applied to determine the geometric dimensions of a multipole filter is deduced from the lumped-element synthesis presented in Section 1. To explain this approach, we have chosen here to design a dual-mode four-pole DR filter because this design groups together some problems found in a large variety of DR filter topologies. In the dual-mode DR presented in Section 1, the metallic screws are replaced by slots directly machined in the DR. The four-pole filter, shown in Fig. 12, consists of a metallic cavity, two input/output coaxial probes, and two slotted DRs coupled through metallic cross irises. Because the experimental filter will not be tuned, the synthesis procedure has to be performed rigorously. To compute the filter dimensions that satisfy given electrical characteristics, we develop the approach presented in Fig. 13.

Metallic cavities :	Dielectric resonators :	Crossed iris :
$H_C = 14.1 \text{ mm}$	$H_{DR} = 3.4 \text{ mm}$	$L_{14} = 5.20 \text{ mm}$
$R_C = 15.5 \text{ mm}$	$R_{DR} = 7.6 \text{ mm}$	$L_{23} = 7.70 \text{ mm}$
	$\epsilon_{DR} = 37$	$w = 1.00 \text{ mm}$
		$t = 1.00 \text{ mm}$
Tuning notches :	Coupling notches :	Notch-DR distances :
$D_{DR1} = 0.62 \text{ mm}$	$D_{12} = 0.93 \text{ mm}$	$d_{DR1} = 1.10 \text{ mm}$
$D_{DR2} = 0.62 \text{ mm}$	$D_{34} = 0.93 \text{ mm}$	$d_{DR2} = 1.10 \text{ mm}$
$w = 1.00 \text{ mm}$	$w = 1.00 \text{ mm}$	

Figure 12. Four-pole slotted DR filter.

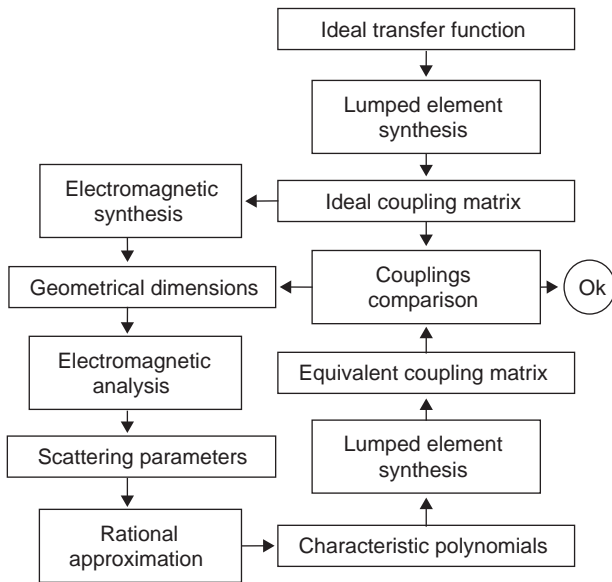

Figure 13. Design method of multipole filter.

In the first stage, an equivalent lumped-element circuit is synthesized from the ideal transfer function. The synthesis leads to a coupling matrix that characterizes the ideal equivalent circuit. This objective coupling matrix gives all the information about the ideal electrical characteristic parameters of the filter.

Applying the 3D finite-element method [40], we can then compute the initial dimensions of the structure with respect to the previous electrical parameters. An electromagnetic synthesis allows us to determine the following:

1. The DR and metallic cavity dimensions required to satisfy the center frequency f value.
2. The probe depth penetration, computed to obtain the required input/output coupling coefficient levels.
3. The dimension of the cross iris to obtain the required coupling coefficient between the parallel polarizations of the two DRs. The theoretical synthesis method is generally interrupted here for classical applications. Screws are then placed around the filter to couple the polarizations and to account for the resonant frequencies of the filter. Then a set of irises are manufactured, and each experimental device has to be tuned. Choosing the slotted DR solution, we can continue with the synthesis computations.
4. The coupling notch dimensions, which impose the coupling coefficient between the two polarizations of each DR.
5. The dimensions of a second notch, which are introduced to compensate for the influence of the probes and the iris on the resonant frequency of the excited polarization.

Then, all the dimensions of the device presented in Fig. 12 are known, but only approximately because of the segmentation approach applied in these initial steps, which does not account for the indirect dependence between the different elements.

In the third stage, an electromagnetic optimization loop is performed applying the following procedure:

1. The 3D finite-element method is applied in order to compute the scattering parameters between the access ports of the whole structure.
2. The scattering parameters are approximated as rational functions in the frequency domain.
3. From the approximated rational functions, an equivalent circuit, namely, a coupling matrix, of the simulated filter is synthesized.
4. By comparing the extracted coupling matrix and the ideal one, the filter dimensions are corrected according to the dimension sensitivities from the electromagnetic synthesis.

The loop is performed as long as the electrical objective is not attained.

This procedure is detailed in Refs. 40 and 41. The ideal transfer function and the electromagnetic response at the

Figure 14. Comparison of ideal and electromagnetic results.

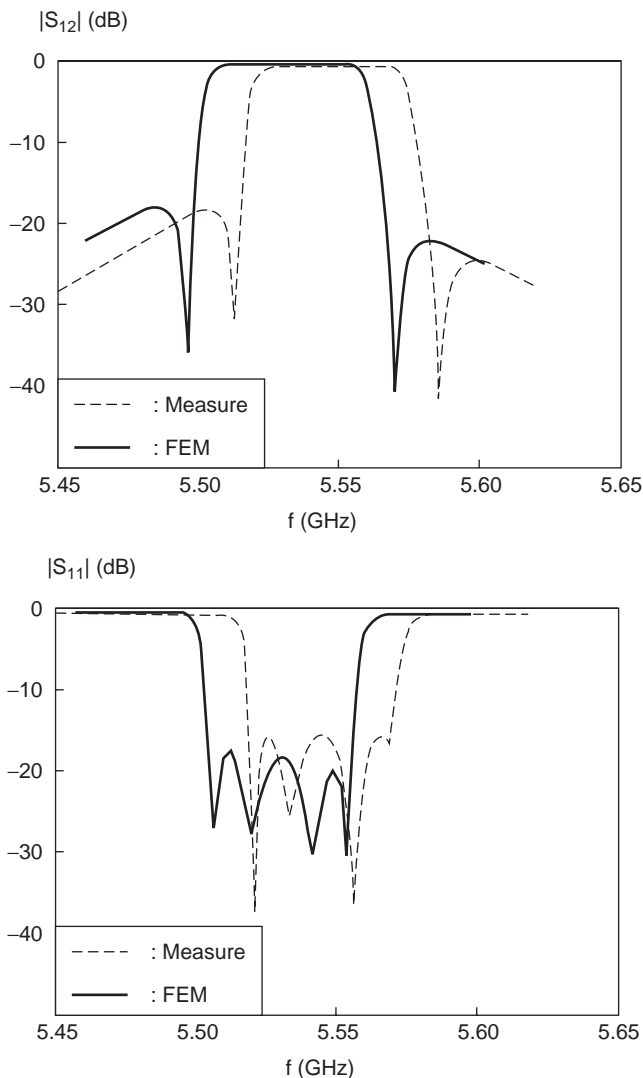

Figure 15. Comparison of theoretical and measured results.

end of the optimization are compared in Fig. 14. We can note the good convergence of the electromagnetic model response with a return loss of > 30 dB in the passband. In Ref. 40, the filter is designed with a slightly different filtering pattern. The electromagnetic response along with the experimental results are presented in Fig. 15. The filter is realized and measured without tuning elements. The difference between the computed and measured center frequencies is less than 0.2%, and the difference between the bandwidths is less than 5%. The theoretical and experimental standing-wave ratios are in good agreement.

5. CONCLUSION

DRs are currently placed in a number of devices, especially in microwave filters. The topologies of these filters are diverse, and they are a function of the system in which they are placed. Their main applications are found in the treatment of power signals and very narrow bandwidth filtering.

In this article, we have described different topologies proposed in recent years (as of 2004). A number of research teams are still working to increase the performance of DR filters, and to widen their domain of applications. Some of the topics under consideration are the following:

- The realization of filters in the millimeter wavelength band
- The work performed to decrease the volume and weight of DR devices
- The realization of DR filters without mechanical tuning for mass production
- The design of reconfigurable DR filters for multifrequency band applications
- The development of advanced synthesis techniques for simplified design of DR filters [42], for example, with a minimum number of elements

DIELECTRIC RESONATOR OSCILLATORS

Oscillators producing energy at microwave frequencies are an essential component in most microwave communication systems, such as communication links, radar, and frequency synthesizers. There are significant commercial pressures to improve the performance of oscillators with respect to giving them lower noise characteristics, higher DC-to-RF efficiency, better temperature and frequency stability, and so on. The dielectric resonator when coupled with two/three-terminal active devices provides a vehicle for producing high-quality fixed-frequency or narrowband

tunable oscillators. Low-loss temperature-stable dielectric materials with high-quality Q factors mean that miniature resonators can be formed that have physical compatibility with microwave integrated circuits [1]. A dielectric resonator (DR) can be used to form the stabilizing element in an oscillator. Dielectric resonator oscillators (DROs) are characterized by the following properties: high-frequency stability, high efficiency, and low manufacturing cost. They also can be made to provide good temperature stability.

Two- and three-terminal active devices exhibit phase noise characteristics at microwave frequencies. Oscillators constructed using these devices can have their phase noise behavior improved by the addition of a DR element.

For a three-terminal device the dielectric resonator for first-order feedback topologies [2] can occupy one of several positions within the circuit, as illustrated in Fig. 1.

In Fig. 1a the DR is mounted in order to provide parallel feedback to the three-terminal active device. Here the coupling action is between device ports [3].

In Fig. 1b the DR is located so that energy produced as a result of negative resistance obtained at the device port is reflected back with correct phasing into the active device by the DR, which presents a high impedance at the device port. The DR acts as a bandstop filter, and in this way an oscillation is set up. This configuration has good phase noise characteristics. However, it is sensitive to load variation and tends to mode-jump in the presence of two resonant circuits [4]. The configuration in Fig. 1c generally provides superior performance compared to the other two methods and is compatible with the off-chip bonding processes required for stabilizing monolithic microwave integrated circuit (MMIC) oscillators. Here the DR acts as a very high- Q resonator element for the series feedback oscillator, giving good frequency stability and low phase noise. In a field-effect transistor (FET) realization, where the DR is coupled to the gate circuit and the feedback is a common source, the operating point is very insensitive to load variation, due to intrinsic isolation between the input and output provided by the low gate-to-drain capacitance of the active device. A varactor diode can be added for tuning purposes. Higher-order feedback implementations [5], for example, shunt feedback DRO configurations such as those given in Fig. 2, are also possible [6]. Multiple DR and push-push frequency doubling oscillator configurations are also possible [7].

In Fig. 2 the DR behaves as a high- Q filter in the positive feedback path. In Fig. 2a part of the output signal is coupled back to the input port. By adjusting lengths l_1 and l_2 , the Barkhausen oscillation condition can be satisfied. In Fig. 2b the DR is coupled between two ports and the

Figure 1. Typical DRO topologies.

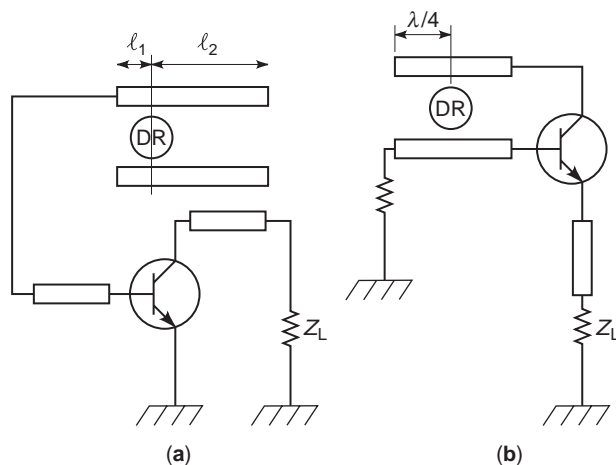

Figure 2. Shunt feedback topologies.

output is taken from the third. Here the position of the DR is adjusted in order to maximize the negative resistance at the output port of the active device.

In the shunt feedback configurations the two coupling coefficients in the parallel feedback case cannot be adjusted separately. Also, since the coupling is to an open-circuit line, these types of circuits tend to be very sensitive to the lateral position of the DR.

The selection of the active device for oscillator applications depends on the frequency of operation. Below 12 GHz, bipolar junction transistors (BJTs) and HBT find application due to their superior flicker $1/f$ and noise levels [8]. A 4-GHz, 21-dBm series feedback bipolar transistor DR oscillator with a phase noise spectral density of -130 dBc/Hz at 10 kHz from the carrier was reported [9]. Values of -89 dBc/Hz at 10 kHz offset have been reported at 21.4 GHz for a reflection type DRO producing 10 dBm output power [10]. Stabilized Gunn oscillators operating at 35 GHz [11] and HBT DROs at 25 GHz have also been reported [12].

It is significant to note that generally as frequency increases, output power can be maintained only at the expense of increased phase noise, since the DR must be coupled more tightly to the circuit.

The key elements to be optimized with respect to oscillator performance are

- Output power
- Startup stability
- Phase noise
- DC-RF efficiency
- Tuning range
- Sensitivity to DR placement
- Frequency pushing/pulling

For a very high-frequency operation into the millimeter-wave region, or for very high Q -factor operation in the centimeter wavelength region, DRs operated in whispering gallery mode [13] are employed [14–16]. Here the important dimension is the circumference rather than the diameter of the DR. This leads to more practical-sized DRs for higher-frequency circuits.

1. DIELECTRIC RESONATORS

A dielectric resonator (DR) is a high-dielectric-constant ceramic material formed into a regular geometric shape, usually a solid or hollow cylindrical or cuboid shape. The material usually has a relative dielectric constant of around 30–40 (but can be as high as 92) and exhibits low-loss characteristics. The high permittivity of the material means that energy can be stored within the DR. The DR can resonate in various modes that are governed by the dimensions, geometry, and electrical properties of the DR itself and by the physical environment in which it is to operate. The development of temperature-stable high-dielectric-constant dielectric materials means that it is now possible to construct resonators that exhibit minimum change in resonant frequency with temperature.

The most commonly used DR shape is a solid cylinder. Here the most common mode of operation is denoted the $TE_{01\delta}$ or dipole mode (Fig. 3).

For a dielectric constant of 40, only 5% of the electric field and 40% of the magnetic field exist outside the DR. This energy decays rapidly as the distance from the DR surface increases [17]. The resonant frequency of an isolated cylindrical DR is given approximately by Gisson [18] as

$$f_{\text{GHz}} = \frac{34}{a\sqrt{\epsilon_r}} \left[\frac{a}{\ell} + 3.45 \right] \quad (1)$$

where a, ℓ are in millimeters and $0.5 < a/\ell < 2$, while $30 < \epsilon_r < 50$.

For operation in fundamental mode the dimensions of the DR are approximately one guide wavelength: $\lambda g = \lambda_0 / \sqrt{\epsilon_r}$.

The lowest frequency of operation is limited by tolerable DR size; typically this is 1 GHz, while the highest frequency, about 100 GHz, is governed by internal losses and minimum resonator dimensions [19]. In order to avoid spurious modes, the length of the DR is usually restricted to lie between $0.175a \leq \ell \leq 0.225a$.

2. DIELECTRIC RESONATOR MATERIAL PROPERTIES

The Q factor and temperature stability provided by dielectric resonators are invariably impaired by imperfect material parameters. The material from which the resonator is constructed will have losses produced by its finite

Figure 3. Cylindrical dielectric resonator $T_{01\delta}$ mode.

conductivity and also by polarization-induced damping under radiofrequency (RF) excitation conditions [20].

If dielectric loss within the resonator is denoted Q_d , then

$$Q_d = \frac{W}{W_d \tan \delta} \quad (2)$$

where $\tan \delta$ is the loss tangent of the resonator material, W is the total energy stored in the cavity, and W_d is the energy stored in the dielectric resonator. Q_d is often quoted as

$$Q_d = \frac{C}{f} \quad (3)$$

where C is a constant quoted by the resonator manufacturer.

Sometimes the loss tangent is given as

$$\tan \delta = A + Bf \quad (4)$$

where A and B are constants quoted by the manufacturer.

A more complete description of the losses in the resonator yields the total dissipated power in the resonator P_{tot} to be

$$P_{\text{tot}} = P_d + P_c + P_r + P_{\text{ext}} \quad (5)$$

where

P_d = power dissipated in the dielectric material

P_c = power dissipated in the surrounding enclosed metal

P_r = radiation loss

P_{ext} = power coupled to the external circuit

From this, Q factors for each term can be related to

Dielectric loss

$$Q_d = \frac{\omega W_e}{P_d} \quad (6)$$

Conductor loss

$$Q_c = \frac{\omega W_e}{P_c} \quad (7)$$

Radiation loss

$$Q_r = \frac{\omega W_e}{P_r} \quad (8)$$

External Q factor

$$Q_{\text{ext}} = \frac{\omega W_e}{P_{\text{ext}}} \quad (9)$$

where W_e is the total electric energy stored in the cavity defined by the shield enclosing the dielectric resonator.

The total loaded Q factor for the enclosed DR is

$$\frac{1}{Q_L} = \frac{1}{Q_d} + \frac{1}{Q_c} + \frac{1}{Q_r} + \frac{1}{Q_{ext}} \quad (10)$$

while the unloaded Q factor is

$$\frac{1}{Q_u} = \frac{1}{Q_d} + \frac{1}{Q_c} + \frac{1}{Q_r} \quad (11)$$

Techniques for measuring these quantities have been suggested in Refs. 21–23.

Temperature-dependent effects that cause a change in the DRs stabilizing function within an oscillator also need to be quantified.

The *linear coefficient of expansion* for a material is defined as the change in length of a rod of the material $\Delta\ell$, divided by its length L such that

$$\frac{\Delta\ell}{L} = \alpha T \quad (12)$$

where α (ppm/°C) is the linear expansion coefficient. As a DR puck expands or contracts, its resonant frequency will vary such that

$$\frac{\Delta f}{f_o} = -\alpha \Delta T \quad (13)$$

The negative sign indicates that as the DR puck becomes longer, its resonant frequency decreases.

With a DR, its relative permittivity ϵ_r is also a function of temperature. This variation is expressed very approximately as

$$\frac{\Delta\epsilon_r}{\epsilon_r} = \tau_E \Delta T \quad (14)$$

where τ_E is the temperature coefficient of the dielectric resonator (ppm/°C).

By combining these relationships together, we obtain an approximate equation for the temperature stability of a DR:

$$\frac{\Delta f}{f} = \frac{\partial f}{\partial L} \frac{\Delta L}{f} + \frac{\partial f}{\partial \epsilon_r} \frac{\Delta \epsilon_r}{f} \quad (15)$$

By denoting the temperature coefficient of the resonant frequency of the DR as τ_{DR} , we obtain

$$\tau_{DR} = -\alpha - \frac{T \tau_E}{2} \quad (16)$$

This equation implies that by making τ have twice the magnitude of α and giving it an opposite sense of operation, τ_E can be reduced to zero; that is, the DR can be temperature-compensated. Note, however, that since the DR will expand as temperature is increased, τ must always be negative for temperature compensation to occur.

Now consider the effect that these temperature changes have on the stability of a DRO. If an unstabilized oscillator

has a negative frequency drift with temperature, then a DR with a positive temperature coefficient is required so that temperature–frequency stabilization can be achieved. The frequency stability τ_f of a DRO has been modeled in Ref. 24 as

$$\tau_f = \tau_{DR} + \left(\frac{k+2}{4Q_u}\right) \frac{\partial\phi}{\partial\tau} \quad (17)$$

where $\partial\phi/\partial\tau$ is the temperature-induced phase variation of the active-circuit one-port measurement

$$\tau_{DR} = \frac{1}{f_o} \frac{df_o}{dT}$$

The second term just stated indicates that for a free-running oscillator the frequency drift is amplified by an amount proportional to the coupling coefficient of the DR.

By arranging Eq. (17), it is possible to find the desired value for τ_{DR} that yields zero τ_f

$$\tau_{DR} = -\left(\frac{k+2}{4Q_u}\right) \frac{\partial\phi}{\partial\tau} \quad (18)$$

Here $\partial\phi/\partial\tau$ and τ_{DR} are unknown. The in situ value for τ_{DR} when placed in its operating configuration can be found using a load-pull technique.

Alternatively if $\partial\phi/\partial\tau$ is assumed to be constant for a small change in coupling coefficient k , then Eq. (17) can be used to form two simultaneous equations from which the in situ τ_{DR} can be obtained directly. This second method should be used with caution since $\partial\phi/\partial\tau$ is nonlinear.

From this discussion it is clear that judicious selection of τ_{DR} and coupling coefficient can be used to compensate for temperature-induced DRO frequency drift [24].

3. QUALITY FACTOR

Quality or Q factor relates energy stored to average power loss. In a DR-based circuit, this is of critical importance since it is a measure of the resonator bandwidth, which is inversely proportional to the Q factor. Temperature stability and AM/FM noise performance of dielectric resonator oscillator circuits also depend on the Q factor:

$$Q = \omega_0 \frac{\text{energy stored}}{\text{average power loss}} \quad (19)$$

$$\omega_0 = \text{resonant frequency rad/s}$$

A second equation for quality factor that relates to group delay through a resonant circuit is useful for oscillator work [25]. This is the loaded quality factor Q_L :

$$Q_L = \omega_0 \frac{\tau}{2} = -\frac{\omega_0}{720} \frac{d\phi}{df} \quad (20)$$

Here, τ = group delay(s) and ϕ = phase of the open-loop voltage transfer function (degrees). The loaded Q is used in oscillator design to express the width of the phase slope

and resonance curve, including the effects of external components. As a consequence, Q_L is dominated by components external to the DR that have their own Q factor, called, Q_{ext} .

The unloaded Q factor Q_u is used when the Q of the resonant circuit is determined only by dissipation losses in the resonator. These various Q factors are related as follows:

$$\frac{1}{Q_L} = \frac{1}{Q_u} + \frac{1}{Q_{\text{ext}}} \quad (21)$$

For oscillator design Q_L can be used in the determination of single-sideband noise prediction.

4. LUMPED-ELEMENT COUPLING MODELS

By assuming that the aspect ratio of the DR and the frequency of operation have been selected such that only a single mode is excited then an isolated DR can be represented as a series resonant circuit with equivalent-circuit components R_r , C_r , and L_r [26].

Figure 4 shows a DR coupled to a short section of microstrip line, at reference plane pp^1 , which is represented by R_1 , C_1 , and L_1 . When the resonator is excited in $TE_{01\delta}$ mode, the coupling can be represented by a mutual inductance term L_m , which is proportional to the separation distance d , between the microstrip line and the DR (Fig. 4) [27].

If the microstrip line is assumed to have zero loss in the coupling region, R_1 can be neglected. By neglecting the microstrip-line capacitance, the resulting simplified equivalent circuit can be expressed close to resonance as a parallel resonant circuit (Fig. 5) where [28]

$$R = \frac{\omega^2 L_m^2}{R_r}$$

$$C = \frac{L_r}{\omega^2 L_m^2}$$

$$L = \omega^2 L_m^2 C_r$$

Figure 4. Equivalent circuit of DR coupled to microstrip line.

Figure 5. Simplified model of DR coupled to microstrip line.

The general expression for a parallel resonant circuit is

$$Z = \frac{R}{1 + j2Q_0\delta} \quad (22)$$

Hence

$$Q_u = \frac{\omega_0 L_r}{R_r} = \omega_0 R C \quad (23)$$

$$\omega_0^2 = \frac{1}{L_r C_r} = \frac{1}{LC} \quad (24)$$

$$\delta = \frac{\omega - \omega_0}{\omega} \quad (25)$$

Thus the equivalent circuit impedance (Fig. 4) can be written as

$$Z_T = j\omega L_1 + \frac{R}{1 + j2Q_u\delta} \quad (26)$$

These results are valid close to the fundamental resonance $TE_{01\delta}$ mode of the DR where δ^2 tends to zero. Outside this frequency range other DR modes exist, which can be modeled by a Foster-type equivalent circuit consisting of a series cascade of parallel tuned circuits [29]. With this approach characterization of the i th resonant circuit requires the i th resonant frequency, unloaded Q factor, and effective coupled resistance to be determined. In addition, when the resonant frequencies of several modes occur in close proximity the individual modal performances cannot be easily established because of mode interaction [30,31]. It is useful to note that $TE_{01\delta}$ mode can be well separated from other modes by correct selection of DR and enclosure dimensions.

When integrating the DR into an oscillator by means of a microstrip connecting line, the parallel tuned circuit in Fig. 5 becomes externally loaded as shown in Fig. 6.

Here the DR is loaded by the internal impedance of the generator and the load. If Z_g and Z_L are assumed to be real with line lengths ℓ_1 and ℓ_2 reduced to zero at resonance, the parallel structure reduces to R . From Eq. (27) the value of R depends on the amount of coupling between the DR and the line. A coupling coefficient term observed at the input port is defined as the ratio of the resonator coupled resistance k at the resonator frequency to the resistance external to the resonator [32]

$$k = \frac{R}{R_{\text{ex}}} \quad (27)$$

Figure 6. Oscillator DR coupling.

or

$$k = \frac{Q_u}{Q_e} \tag{28}$$

for a DR coupled to a matched line $R_g = R_L = Z_0$, here

$$k = \frac{R}{2Z_0} \tag{29}$$

for a DR coupled to a short-circuited load $R_L = 0$, here

$$k = \frac{R}{Z_0} \tag{30}$$

When a reactive termination loads the resonant circuit, this presents itself in series with the parallel equivalent circuit. This will cause an imperfect match and will also cause an additional reactive load to appear in series with the equivalent circuit [33].

If x_1 is the normalized reactance appearing in series with the parallel resonant circuit, then the definition for the coupling coefficient observed at the input port becomes

$$k = \frac{R}{Z_N(1+x_1^2)} \tag{31}$$

and for a short circuit

$$k = \frac{R}{Z_0(1+x_1^2)} \tag{32}$$

here

$$x_1 = \frac{\omega L_1}{Z_N} \tag{33}$$

where Z_N is the total impedance loading the DR.

Also under these conditions the resonant frequency shifts to a new frequency f_L where

$$f_L = f_0 \left[1 + \frac{x_1 k}{2Q_u} \right] \tag{34}$$

and

$$Q_u = Q_L(1+k) \tag{35}$$

When coupled to a matched microstrip line, x_1 is usually much less than one.

When the microstrip-line lengths l_1, l_2 are not equal to zero, then the DR is coupled to the generator and load terminations Z_L, Z_g via microstrip-line segments l_1, l_2 (Fig. 6).

For a matched line Eq. (28) is valid. For a short-circuit load and assuming lossless line

$$k = \frac{R}{Z_0(1 + \tan^2(\beta l_2))} \tag{36}$$

Here maximum coupling occurs at

$$l_2 = \frac{n\lambda_g}{4}, \quad n = 0, 2, 4 \tag{37}$$

while minimum coupling occurs at

$$l_2 = \frac{m\lambda_g}{4}, \quad m = 1, 3, 5 \tag{38}$$

where λ_g = effective wavelength of the microstrip line.

The same result occurs when considering the impedance presented at the input port under similar conditions.

Terminating the line in an arbitrary reactance shifts the maxima and minima of the magnetic field along the line. Since the $TE_{01\delta}$ mode couples to the magnetic field, line coupling will be maximized at peaks in the magnetic field standing wave and minimized at troughs. Coupling to the maximum point on the standing wave will present the coupling coefficient given by Eq. (29) at $n = 0, 2, 4$, and so on. The maximum coupling coefficient is reported experimentally to consistently occur at a distance $d = 0.7a$, where a is the radius of the DR puck [33].

5. MEASUREMENT OF DR COUPLING COEFFICIENT

The most convenient method for experimentally estimating coupling coefficient k involves a measurement of loaded quality factor Q_L , which is related to k as

$$Q_L = \frac{Q_u}{1+k} \tag{39}$$

However, Q_u is not normally known and has to be determined by the losses at ω_0 . From Ginzton [34] and Khanna

[35], Q_L can be established from the phase of the input impedance locus obtained by a one-port measurement made on the DR

$$Q_L = \frac{f_0}{f_4 - f_3} \quad (40)$$

where f_0 is the center frequency, f_3 is the frequency at which the phase is lagging that at f_0 by 45° , and f_4 is the frequency at which the phase is leading that at f_0 by 45° . The results obtained by this method are typically 10% greater than those obtained by the method of deembedded S parameters shown next.

By assuming zero radiation loss at the DR microstrip junction, it can be shown from scattering parameter theory that for a matched system

$$k = \frac{1 - [S_{11}]^2 - [S_{21}]^2}{2[S_{21}]^2} \quad (41)$$

A number of useful computer source codes for computing the resonant frequency and unloaded Q factor for shielded DRs are given in Ref. 36.

6. DIELECTRIC RESONATOR COUPLED TO A MICROSTRIP LINE

The most frequently used method of integrating a DR into a microwave integrated circuit is to couple it to a microstrip line. Here the problem is confined to the $TE_{01\delta}$ mode of a cylindrical DR (Fig. 1). Here the suffixes refer to the standing-wave pattern in the azimuthal, radial, and axial directions, respectively, for the fundamental TE mode $\delta = 1$.

A typical coupling configuration is shown in Fig. 7. An approximate representation of the H -field lines is given in order to illustrate the inductive nature of the coupling between a DR in $TE_{01\delta}$ mode and the quasi-TEM mode of microstrip line.

Here the magnetic field lines match each other principally on the radial direction of the DR field directly under the microstrip line. The coupling between the DR and the line is inversely proportional to the separation and, between them, is defined by a mutual inductance coupling coefficient term k . With this type of coupling a proportion

of energy is radiated away from the DR. Therefore the effect of losses in the microstrip substrate, signal line, and enclosure act to perturb the electromagnetic field and alter the Q factor of the DR [37,38]. For oscillator design an equivalent circuit model for the line DR coupled arrangement is required. The DR may be fixed to the line using a low-loss adhesive [39,40]. If the adhesive has a slow setting time, then reworking of the DR position for tuning can be made.

7. DIELECTRIC RESONATOR TUNING

For optimum phase noise designs the oscillator center frequency should be equal to that of the dielectric resonator. For many circuits it is useful to have a DR tuning facility. One way of achieving this is to use mechanical tuning (Fig. 8).

Here a metal [41], dielectric [42], or DR [43] plunger is inserted in either the topwall or the sidewall of the structure. The presence of the tuning element causes a localized distortion of the electromagnetic fields. With a metal plunger, the additional losses in the plunger lower the Q_u of the resonator as the coupling between DR and plunger becomes tighter, that is, as L is reduced. For a metal plunger as L is reduced, the frequency of operation is increased, while the reverse is true for a dielectric plunger. Generally a DRO used with the metal plunger tuning arrangement also produces a reduced output power as L decreases. With this arrangement, about a 3% tuning range can be made.

With a second DR replacing the plunger topcap in Fig. 8, the resultant change in Q_u is smaller than for the metal tuner case. This arrangement yields about an 8% tuning range.

Electronic tuning of the DR is also possible using a varactor diode as the tuning element. This can be mounted internally to the DR [44] or more usually as the termination on a line coupled to the DR (Fig. 1). A large tuning range requires tight coupling between the DR and the varactor, which inevitably leads to a reduction in Q_u .

If Q_u is the unloaded Q of the varactor, then [45]

$$Q_{ur} = \frac{Q_u}{2} \left(\frac{f_0}{\Delta f} \right) \quad (42)$$

Figure 7. DR coupled to microstrip line, physical and electrical equivalent.

Figure 8. Mechanical DR tuning arrangement.

where Q_{ur} is the unloaded Q of the varactor tuned DR and Δf is the change in resonance frequency. According to Ref. 45, an approximately 0.5% tuning bandwidth can be obtained with this arrangement.

Other techniques such as optical tuning [46], magnetic tuning [47], and segmented disk tuning also exist [48].

8. OSCILLATOR BASIC THEORY

8.1. Negative Resistance

In order for microwave oscillation to begin, a means to overcome the resistive losses in the circuit has to be provided. These losses include undesired stray and parasitic resistances, and also the load into which the oscillator must operate (usually 50Ω). To do this, the concept of *negative resistance* is introduced. To illustrate the concept, consider the simple equivalent circuit of Fig. 9. If the amount of negative resistance exactly cancels the sum of the positive resistances, then the circuit will have a resonant or oscillation frequency where the inductive reactance is equal to the capacitive reactance; that is

$$2\pi fL = \frac{1}{2\pi fC} \tag{43}$$

where f = resonant frequency, L = inductance, and C = capacitance. This condition is known as the *steady-state oscillation condition*. In order for oscillation to build up, an excess of negative resistance is required. Then, any small perturbation in the circuit, such as electrical noise, will kickstart a resonance. As oscillation builds, the amount of negative resistance decreases until the steady-state condition is met. A negative resistor can be formed from an unstable active device with suitable feedback applied. Consider a transistor with feedback such that the magnitude of the input reflection coefficient (S_{11})

Figure 9. Simple equivalent circuit of a microwave oscillator.

Figure 10. Negative-resistance oscillator schematic showing port definitions.

is greater than one. This means that when an AC signal is incident on the port, more energy is reflected than is actually incident. This can be regarded as a negative resistance.

8.2. Oscillator Equation

The one-port negative-resistance oscillator schematic is illustrated in Fig. 10. The oscillator can be considered as a two-port negative-resistance circuit and a one-port resonator. The resulting oscillator then operates into a one-port load. The large-signal steady-state oscillation condition is given by

$$\Gamma_r \cdot S'_{11} = 1 \tag{44}$$

where Γ_r is the reflection coefficient of the resonator and S'_{11} is the large-signal input reflection coefficient of the negative-resistance circuit, when terminated in the load. The reflection coefficients stated immediately above are complex numbers, and so the equation can be expanded into its magnitude and angle parts:

$$|\Gamma_r| \cdot |S'_{11}| = 1 \tag{45}$$

$$\text{Ang}(\Gamma_r) + \text{Ang}(S'_{11}) = 0 \tag{46}$$

If the equations are now expanded into impedance forms, then we obtain

$$R + R_n = 0 \tag{47}$$

$$X_L + X_C = 0 \tag{48}$$

where R is the sum of positive resistances, R_n is the negative resistance, X_L is the inductive reactance, and X_C is the capacitive reactance. Equation (48) simply expands to Eq. (43) and determines the resonant frequency.

We have already stated that before steady-state oscillation can be achieved, there must be an excess negative resistance to enable resonance to start. At the buildup of

oscillation, Eqs. (47) and (48) can be approximated to

$$r + r_n < 0 \tag{49}$$

$$x_L + x_C = 0 \tag{50}$$

where the resistances and reactances are now small-signal values. In terms of reflection coefficients, the small-signal approximation to the oscillation condition becomes

$$|\Gamma_r| \cdot |S'_{11}| > 1 \tag{51}$$

$$\text{Ang}(\Gamma_r) + \text{Ang}(S'_{11}) = 0 \tag{52}$$

where the reflection coefficients are now the more easily measurable small-signal values. It should be noted here that Γ_r depends on the value of characteristic impedance Z_0 used to calculate it. Hence it is possible with this approach to find a startup condition in terms of Γ in one port but not in another for a given Z_0 .

8.3. Oscillator Graphical Analysis

The solving of the small-signal *oscillation condition* is illustrated graphically in Fig. 11 with reference to Fig. 10. Here the Z (complex) represents the overall impedance of the closed-loop oscillator, including the load. The frequency at which the imaginary part goes through zero (i.e., resonance) is clear, and at this frequency there is an excess negative resistance.

8.4. N-Port Oscillation Condition

It can be shown that the condition for oscillation is also present at the output port of the previously discussed negative-resistance circuit. This means that we could also solve

$$\Gamma_L \cdot S'_{22} = 1 \tag{53}$$

where Γ_L is the reflection coefficient of the load and S'_{22} is the large-signal output reflection coefficient of the negative resistance circuit, when terminated in the resonator. This condition can be shown to hold at all ports of an N -port oscillator [49].

Figure 11. Graphical oscillator solution showing one-port oscillation condition.

8.5. Oscillator Figures of Merit

8.5.1. Frequency Pulling. As the reflection coefficient of the load Γ_L forms a vital part of Eq. (53) and influences the input reflection coefficient S'_{11} in Eq. (44), it is obvious that any change in its phase will affect the oscillation frequency. The change in oscillation frequency due to a change in the load reflection coefficient is known as *frequency pulling*. This is usually determined by first measuring the frequency of an oscillator into a load of known reflection coefficient (often -12 dB). The phase of the load is then varied from 0 to 360° by means of a phase shifter or sliding load. The maximum deviation from the nominal frequency is the pulling figure. Pulling can be greatly reduced by isolating the oscillator’s output from the load. This is usually achieved by use of a buffer amplifier with high reverse isolation.

8.5.2. Frequency Pushing. The basic function of the DRO is to convert DC energy to RF. The scattering parameters of the active device are dependent on the applied bias voltages and currents. Even regulated power supply voltages can experience fluctuations which lead to minute changes in output frequency. The change in oscillation frequency with respect to DC supply voltage is known as *frequency pushing*. The parameter is measured by first noting the nominal oscillator frequency. The applied DC supply voltage is then varied (by one volt, for example) and the frequency deviation measured. Frequency pushing is then expressed in units of frequency per volt. In practical circuits pushing is minimized by using well-regulated supply voltages.

8.6. Oscillator Stability

An oscillator is said to be stable if the output frequency (and power) do not vary with temperature and time. Dielectric resonators are good for producing stable oscillators because of their high Q factors. Dielectric resonators may be used in oscillators in two distinct ways:

1. As a high- Q passive element coupled to a free-running oscillator. Here the DR is not used as the oscillator’s main resonator, but is “locked” to this resonance. Such an oscillator is known as a *dielectrically stabilized oscillator* (DSO).
2. As a circuit element in the oscillator, whereby the DR actually determines the oscillation frequency.

It is known that free-running oscillators generally have a negative temperature coefficient. Thus the oscillator’s frequency falls as temperature is increased. The temperature coefficient of a DR can be made positive by careful choice of material composition. Thus the DR can be made to compensate for free-running oscillator drift. The temperature stability of a complete DRO is dependent on [50]

- The coupling coefficient between the DR and the rest of the circuit
- The Q of the oscillator

- The rate of change of the active device's reflection coefficient phase with temperature

Typical variations in oscillator frequency with temperature in DROs are of the order of 4 ppm/°C. This value can be reduced, to values as low as 1 ppm/°C, by several techniques, including

- *Phase Locking.* A high-frequency voltage-controllable DRO is phase-locked to a low-frequency crystal oscillator of superior phase noise and stability; this improves long-term frequency stability.
- *Digital Compensation.* Here the performance of an oscillator with temperature is measured and the information stored in programmable read-only memory. A temperature sensor circuit is then used, in conjunction with a lookup table, to apply a correction voltage to the oscillator in order to hold it at constant frequency.
- By stabilizing the DRO in a temperature-controlled localized oven [51].

The primary properties of a dielectric resonator oscillator, that is, frequency and output power, can be measured using the test setup illustrated in Fig. 12. The frequency of oscillation is measured on a high-frequency spectrum analyzer, or RF counter. The power can also be read from the analyzer display, but is often more accurately determined using a separate RF power meter.

Frequency pushing can now be determined by observing the shift in oscillation frequency as the supply voltage is varied. Pulling is measured by replacing the power meter with a tunable load of known return loss (usually 12 dB). The phase of this load is then varied through 360°, and the resulting maximum excursion from the nominal frequency are noted.

Phase noise can be measured on the analyzer display at suitable offset frequencies. A correction has to be made for the filter (resolution) bandwidth of the measuring instrument. More accurate phase noise measurement (especially close to the carrier) requires a dedicated phase noise testset.

The abovementioned oscillator parameters are usually determined over a range of temperatures. This enables the variation of the frequency and output power with temperature to be determined.

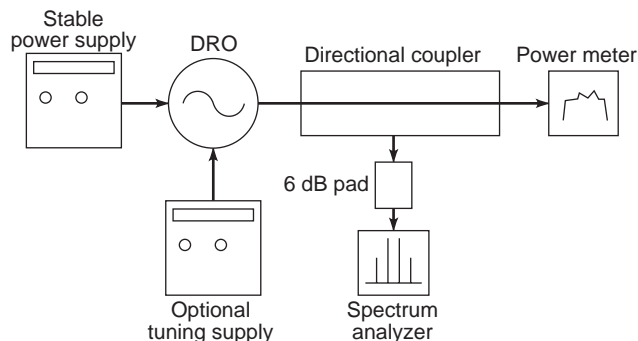

Figure 12. Typical DRO test setup for measuring power output and frequency spectrum.

9. OSCILLATOR PHASE NOISE

The phase noise of an oscillator is an important quantity. Ultimately phase noise limits adjacent-channel selectivity in a receiver. The output signal from a physical oscillator is not monochromatic. In a real oscillator, noise sidebands arise since the frequency of the signal can vary with time as a result of phase noise created by phase modulation of the signal [52]. The usual method for characterizing the noise is to determine the single-sideband (SSB) phase noise power spectral density at a given frequency offset from the carrier (dBc/Hz). A frequency offset figure of 10 kHz is often quoted.

The phase noise comes from the various noise sources available in the circuit as well as the active-device intrinsic noise sources. These noise sources induce phase noise by nonlinear device mechanisms causing upconversion of the baseband noise to the oscillator frequency. Noise sources that are due to white noise generally contribute $1/f^2$ to the spectrum of the phase noise, while $1/f$ noise adds $1/f^3$ to the phase noise spectrum. Individual noise sources are to a first approximation considered uncorrelated. In practice, up/downconversion can occur, leading to correlated amplitude-modulated (AM) and frequency-modulated (FM) noise effects. The $1/f$ noise acts to alter the frequency of the oscillation.

When designing a DRO with low phase noise, the unloaded Q factor of the resonator should be as high as possible. The $1/f$ noise of the active device should be as low as possible. JFETs, then bipolar transistors and HBTs, have the lowest $1/f$ noise with GaAs FETs having the worst $1/f$ performance. Also the center frequency of oscillation of the DR is usually equal to that of the oscillator. Here the DR acts to select the frequency of oscillation. Under these conditions the center frequency of the DR will have a maximum rate of change of phase with respect to frequency; that is, the resonator will have its highest Q . Noise power density is split between AM and PM noise by equal amounts. In addition, AM noise is usually much more dominant than PM noise at offset frequencies far removed from the carrier [53]. Close to the carrier PM noise is the dominant factor. Methods for simulating oscillator phase noise are given in Refs. 54 and 55.

Leeson's Eq. (52) and Eq. (54) describe the expected single-sideband (SSB) phase noise power density at a frequency f_m offset from the carrier for an oscillator using a single resonator; here

$$L_{\text{pm}} \approx 10 \log_{10} \left[\frac{NRkT}{A} \frac{1}{8Q_L^2} \left(\frac{f_0}{f_m} \right)^2 \right] \text{dBc/Hz} \quad (54)$$

where NR is the device noise ratio, A = oscillator output power, Q_L = loaded Q , f_0 = oscillator center frequency (Hz), and f_m = carrier offset (Hz).

Equation (54) shows that the oscillator SSB phase noise is affected by the loaded Q squared, namely, 6 dB improvement per Q_L doubling, hence the incentive for using a DR with as high a Q as possible. Leeson's equation shows that the SSB phase noise reduces at 6 dB/octave over the range it applies. This range is for f_m greater than frequency f_1 ,

the $1/f$ flicker noise corner frequency, and less than below the frequency f_2 , where $f_2 = f_0/2Q_L$. Above f_2 the oscillator upconverted white noise dominates. To correctly apply this equation, the $1/f$ noise for the device must be known a priori. In addition, the device noise ratio at its operating power level (assumed to be in the linear range of operation) and loaded Q for the circuit are also required. A detailed discussion of low-noise oscillator design and measurement methods can be found in Ref. 56.

10. DESIGN EXAMPLE—10.8-GHz DRO

Consider the schematic of Fig. 13. The circuit consists of a common-source MESFET-based negative-resistance circuit (NRC), with series capacitive feedback. The DR is coupled to the gate via a $50\text{-}\Omega$ -terminated microstrip transmission line. The substrate for the transmission line is chosen to be $254\text{-}\mu\text{m}$ -thick alumina ($\epsilon_r = 9.9$). The width of the line is $238\text{ }\mu\text{m}$, which corresponds to a characteristic impedance of $50\text{ }\Omega$.

The first step is to choose a suitable DR size. As a practical example, consider the Murata TE_{01 δ} DRD series [57]. The most suitable dimensions for a 10.8-GHz circuit are a diameter of 6.5 mm and a thickness of 2.9 mm. It can be shown that this puck will resonate at approximately 10.34 GHz when enclosed in a well-spaced metallic environment. In a practical circuit the resonator will operate at a higher frequency, due to the presence of the thin substrate. The shift in frequency can be approximated by the

analytical formula in Ref. 50. Final tuning to 10.89 Hz by use of a metal tuning screw can then be achieved.

Step 2 involves choice of a suitable transistor and bias condition. For this example a GMMT 0.5- μm -gate-length/300- μm -gate-width GaAs MESFET is used. When biased at $+5\text{ V } V_{ds}$ and $I_{ds} = 50\% I_{dss}$, the transistor exhibits some 12 dB of available gain at this frequency. This is more than adequate for this type of oscillator design.

Next the two-port NRC is designed. To do this, the series capacitive feedback is varied until the magnitude of the input reflection coefficient (S_{11}) is greater than one, indicating negative resistance. In practice a value greater than 1.2 should be used. This is generally enough to ensure sufficient excess negative resistance to kickstart an oscillation. For this transistor a value of 0.24 pF results in $|S_{11}|$ being of the order of 1.4 at 11 GHz, as illustrated in Fig. 14.

Next the complete oscillator is simulated to solve the small-signal approximation to the complex condition for oscillation, that is, $\Gamma \cdot S_{11} > 1$. A model for the coupled DR can be developed using the mutually coupled parallel LCR model and coupling factor k , as discussed previously. In practice the equivalent circuit is merely an RF open circuit at resonance. Therefore the circuit can be simplified to the circuit shown in Fig. 15. To complete the oscillator design, the transmission-line length l_1 , at which point the center of the DR is placed, is calculated. For this example a value of 4.427 mm is determined. The resulting oscillation frequency, in terms of real and imaginary parts of the overall impedance, is shown in Fig. 16. The angle goes through zero at 10.8 GHz, with the resulting magnitude

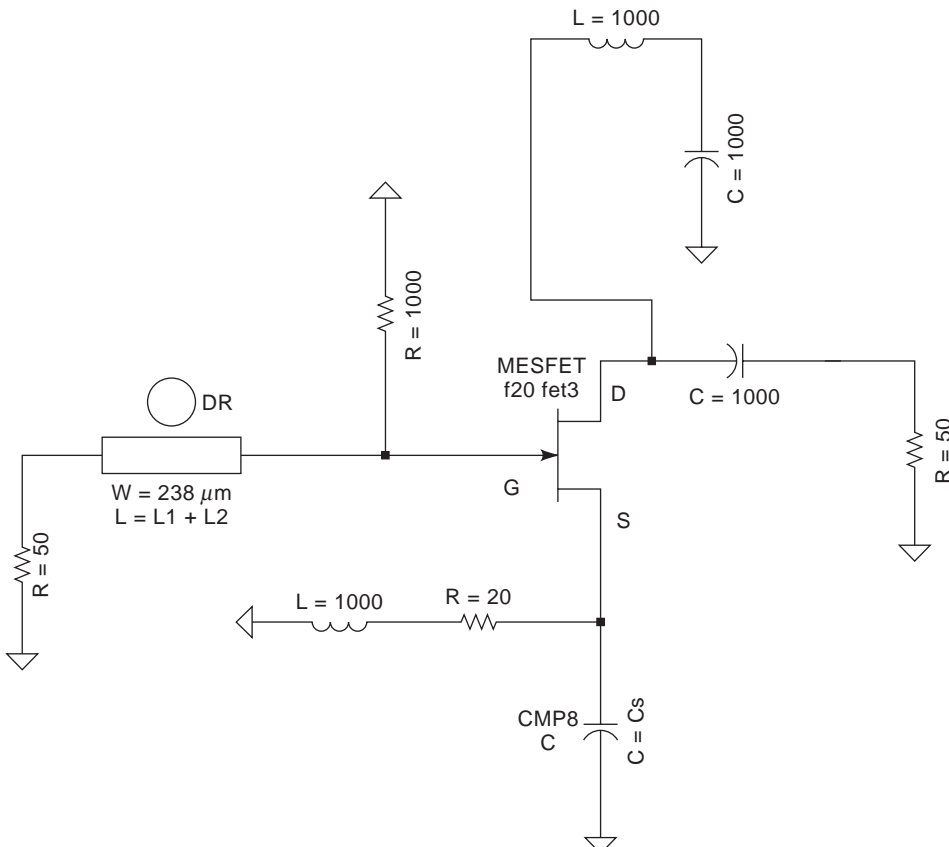

Figure 13. Circuit schematic for 10.8-GHz DRO example design ($\epsilon_r = 10.0$, $h = 254\text{ }\mu\text{m}$).

Figure 14. One-port input reflection plot.

Figure 16. One-port oscillation condition.

simultaneously exceeding 1.2. A large-signal simulation can be performed using a harmonic balance technique to predict output power and other important oscillator parameters. For this example +11 dBm output power was predicted, with a DC-to-RF conversion efficiency of approximately 13%. In addition the phase noise was predicted as -80 dBc/Hz at 10 kHz offset. This is achieved by including important noise parameter values in the non-linear device model.

In practice the circuit is now fabricated by using an arbitrary length for l_2 , and suitably terminating the line in the characteristic impedance, 50 Ω. The circuit is biased as required and the DR placed on the alumina in approximately the correct position. The puck is then moved around until oscillation of suitable magnitude, Q factor, and phase noise is obtained. The resonator is then fixed into position, and mechanically tuned to the exact required frequency.

Figure 15. Simplified equivalent circuit for 10.8 GHz DRO example design.

Electronic tuning of the circuit to enable phase locking to a crystal reference is possible. To achieve this, a $\lambda/4$ length of transmission line incorporating a tuning varactor is also coupled to the resonator. Tuning the varactor capacitance changes the phase of the coupled line, resulting in pulling of the DR frequency.

11. DRO CAD TECHNIQUES

The practical realization of dielectric resonator oscillators DROs can be assisted by the use of linear and nonlinear CAD tools. Linear scattering parameters can be used to represent the active device and feedback network [3,58–61]. Important DRO performance features such as output power, efficiency, steady state stability and tuning range, have been simulated [62–64].

Series feedback DROs have been designed using S-parameter methods whereby a topology is selected to yield maximum negative resistance at one port while maintaining small-signal startup conditions [50,65]. When parallel feedback topology is used, a more complex design procedure is required [66]. Here, when the DR is coupled between two of the device terminals, the reflection coefficient at the third terminal Γ_3 is expressed in terms of the DR and active device scattering parameters. The position of the DR and hence the coupling coefficient are optimized to maximize Γ_3 and a matching circuit designed to maximize the startup condition [61].

Small-signal techniques do not necessarily lead to maximum power oscillators, nor do they ensure stability of operation. Nonlinear large signal techniques are needed to do this. Broadly two classes exist here: time domain [67] and harmonic balance [68]. The former method uses numerical integration of state space equations describing the active device and the embedding circuit. All circuit elements must be represented in the time variable as voltage-dependent current equations. There are no constraints on the harmonic content; hence highly nonlinear circuits can be examined. The time-domain approach is well suited to oscillator simulation because oscillation startup, transient, and steady response can all be obtained on a single analysis run. However, each timestep must be small enough to ensure numerical convergence of the integration routine. This is a severe limitation when high- Q resonators such as DRs are used [69].

With the harmonic balance approach, nonlinear circuit elements are analyzed in the time domain and transformed into the frequency domain, where they are represented by a finite number of harmonic currents. Linear elements are solved directly in the frequency domain. Where linear and nonlinear components are joined, current continuity forms the boundary condition for the harmonic balance algorithm. With this approach the high- Q circuits are solved by numerically efficient algorithms directly in the frequency domain. However, in order to simulate circuits with strong nonlinearities, many harmonics are needed for accurate representation of the nonlinear waveforms, thus increasing computational time. In addition, the harmonic balance approach yields only steady-state information about the oscillator's behavior.

In a DRO the DR dampens higher harmonics; thus the harmonic balance approach is attractive here [63]. In Ref. 63 the device topology was fixed a priori and the circuit element values were numerically optimized to satisfy a prescribed set of electrical specifications. An alternative approach is to synthesize from the maximum added power condition the general device terminations [70]. This approach has been adapted for DRO synthesis [71,72]. Most commercially available industrial circuit simulators for microwave use such as a Hewlett-Packard model [73] will handle time-domain and harmonic balance simulation with embedded large-signal active-device models.

1. INTRODUCTION

The widespread use of the dielectric resonator (DR) in microwave engineering is due to four main attributes: price, performance, size, and versatility. The price of a DR is low, particularly when manufactured in large quantities. As a resonant element in microwave circuits they give very high performance in terms of Q factor and temperature

stability. The DR is smaller and lighter than conventional air-filled cavity resonators, enabling significant miniaturization; the reduction in size being proportional to $\sqrt{\epsilon_r}$, where ϵ_r is the relative permittivity of the DR material. DRs are also extremely versatile components, finding important applications over a wide range of frequency bands in microwave filters, oscillators, and antennas in both microwave integrated circuit (MIC) and monolithic microwave integrated circuit (MMIC) environments. They are also used in measurement techniques for determining the relative permittivity and loss tangent of dielectric materials and the surface resistance of superconductors.

The most common shape for the DR is a cylinder with its diameter greater than its length, where the $TE_{01\delta}$ (transverse electric) mode is dominant. This mode is similar to a magnetic dipole that is aligned with the axis of the cylinder, with the azimuthal E fields forming concentric circles about the axis. Other DR shapes that also find use are dielectric ring resonators, spheres, and parallelepipeds. The resonator is usually placed in a cylindrical or rectangular cavity, or on top of a substrate within a cavity as shown in Fig. 1. The use of the substrate allows external coupling of the DR mode to a nearby microstrip line, while the cavity enclosure prevents radiation losses and shields the resonator from external fields. The air-dielectric interfaces of the DR form the walls of a cavity that support resonant modes, similar to the configuration for a conventional cavity resonator. However, in a DR evanescent fields exist in the air region outside the dielectric material, due to imperfect confinement of the field by the DR walls. For large dielectric constants the DR walls can be approximated as perfect magnetic conductors (PMC), or open circuits, that require the magnetic field tangential to the wall to be zero. The accuracy of this approximation improves as the dielectric constant increases in value.

Richtmeyer pioneered the concept of the “dielectric resonator” in 1939 showing that suitably shaped dielectric objects such as spheres and circular rings could act as high-frequency resonators [1]. This seminal work received little further attention until 1962, when Okaya and Barash described theory and experimental results on rectangular DRs made from TiO_2 (rutile) and $SrTiO_3$ (strontium titanate) [2]. They introduced an approximate second-order analysis of the modes in rectangular DRs that gave reasonably accurate results when compared with measurements, and observed the poor temperature stability of the available high-dielectric-constant materials. In 1968 Cohn published a second-order analysis of the cylindrical DR operating in the $TE_{01\delta}$ mode and equations for DR interresonator coupling [3], which enabled high- Q bandpass filters to be designed using high-purity TiO_2 ($\epsilon_r \approx 100$) [4]. Unfortunately the high sensitivity of TiO_2 to changes in temperature made these DR filters impractical, but led Cohn to throw down a challenge to material scientists to develop high-dielectric-constant materials with improved temperature sensitivity.

This challenge was met when Raytheon developed the first barium tetratitanate ceramics that were both low loss and temperature stable [5], which were further improved on by researchers at Bell Laboratories [6]. At around the same time it was shown that a dielectric resonator placed

Figure 1. (a) Configuration of a cylindrical dielectric resonator loaded in a cavity; (b) dielectric resonator on a substrate coupled to a microstrip line.

between two parallel conducting plates could be used to accurately measure complex permittivity and permeability [7]. The next advance was the development of ceramic materials with adjustable temperature coefficients [8], enabling the value of temperature coefficient to be chosen to minimize or cancel out the material thermal expansion, leading to DR components with high temperature stability. These breakthroughs in material science technology paved the way for a large number of new temperature-stable filter and oscillator circuits based on DRs [9].

The first dual-mode axial-mounted DR-loaded cavity filter, introduced in 1982 [10], used hybrid-mode DRs and was able to match the performance of conventional dual-mode waveguide filters. Dual-mode filters have the advantage of reduced size and weight over monomode devices. Because of these advantages, the filter became popular for space applications. Dual-mode filters in planar cavities [11] and triple-mode filters were introduced soon after [12]. Advances in the mode-matching technique also led to the precise design of $TE_{01\delta}$ [13], $TM_{01\delta}$ [14], and $EH_{11\delta}$ mode filters [15,16].

In recent years, more emphasis has been placed on techniques for improving the spurious performance of DRs and DR filters, to overcome limitations imposed by the crowded mode spectrum of DRs. Several methods have arisen to achieve this goal. The simplest method involves optimization of the DR dimensions [17]. Mode suppression devices also can provide a small improvement. In $TE_{01\delta}$ -mode DR filters the use of resonant irises [18] or quarter-cut resonators [19] has shown a good suppression of higher-order modes. Quarter-cut resonators can also give extremely good heat dissipation and are suitable for use in high-power filters.

More effective methods involve using “composite” resonators [20,21], exciting combinations of different modes of the same type of resonator [22,23], or mixing two completely different types of resonators, for example, combine and $TE_{01\delta}$ DRs [24–26], or conductor- and dielectric-loaded resonators [27]. Since the higher-order modes of the different resonators occur at different frequencies, the spurious performance is enhanced considerably. Improved performance can also be achieved with filters containing rectangular DRs [28], dielectric combines [29], conductor-loaded DRs [30], and sandwiched conductor DRs [31]. The development of the hybrid dielectric/high-temperature superconductor (HTS) resonator is a further innovation that has the benefit of extremely low losses and reduced size [32]. Another advance was the introduction of a resonator

that uses slots in the DR for tuning and coupling dual-mode DR filters, thus replacing the tuning and coupling screws traditionally used [33]. Filters constructed using slotted DRs have the advantage that they require very little tuning. An excellent reference on the topic of DRs, DR filters, and DR oscillators is the book edited by Kajfez and Guillon [34].

2. ANALYSIS OF DIELECTRIC RESONATORS

As mentioned previously, early analysis methods for DRs modeled the resonator walls as perfect magnetic conductor (PMC) surfaces [2]. Cohn [3] improved on this approach by setting only the curved DR surfaces to be PMC walls, with the flat surfaces modeled as air–dielectric interfaces, allowing fields to leak out into an infinite circular waveguide with magnetic walls. Kobayashi derived analytical solutions for dielectric rod resonators short-circuited at both ends [35,36]. Regions not accounted for in the PMC wall model were gradually included through the use of perturbation and variational techniques and can be described as approximate techniques [37–51]. The resonant frequencies calculated using perturbational techniques or variational methods are more accurate than the simple PMC wall models, but are usually limited to the axially symmetric modes. The approximate methods have limitations since in some of the regions they may not satisfy Maxwell’s equations or exact boundary conditions. To increase the accuracy of prediction and for applicability to more general structures, rigorous analysis and numerical methods are required.

The finite-difference frequency-domain (FDFD) method is one numerical technique that has been successfully applied to rotationally symmetric DRs [52–55]. This technique discretizes the fields inside the DR and then, by imposing boundary conditions, formulates a matrix eigenvalue problem that is solved to obtain the resonant frequency, field distribution, and unloaded Q for any given mode. The powerful finite-element method (FEM) has also been applied to DRs [56–59]. In this method the solution region is discretized into subregions or elements. Governing equations are then derived, assembled over the elements of the solution region and the resulting system of equations solved. FEM is a versatile method as it can handle complex geometries and inhomogeneous media much better than can the finite-difference method owing to the use of highly flexible adaptive meshing schemes.

Early FEM formulation solutions were plagued by the appearance of nonphysical “spurious” modes, but by using “mixed” elements these modes may be eliminated [59]. Integral equation (IE) formulations [60,61] and the method of moments (MoM) have also been applied to DRs, to accurately compute resonant frequencies, unloaded Q , and field distributions. IE formulations and MoM use Green’s functions and hence are ideally suited to modeling resonators in open regions; their use can become quite complicated for cavity-type applications.

Mode matching combines analytical solutions and computational models for closed-region problems, and has been extensively applied to analyze DRs in cylindrical and rectangular cavities [62–74]. This technique divides the DR into subregions and may be classified as either radial or longitudinal mode-matching, depending on the way the subregions of the DR are divided and matched. The fields in each subregion are expressed as a linear combination of the appropriate eigenmode fields of an infinite waveguide with unknown coefficients. Fields of the adjacent regions are then “matched” to satisfy boundary conditions, from which an infinite system of linear equations is obtained in terms of the unknown coefficients. The zeros of the determinant of the system yield the resonant frequencies of the DR. The number of modes used in the generation of the system must be increased until relative convergence is achieved. Solution of the resonant frequencies also gives the modal field distributions, and hence the unloaded Q may be calculated for any given mode. Because of the appearance of complex modes in the longitudinal mode-matching technique [70] as well as computational difficulties, the radial mode-matching technique has emerged as the more popular method. Radial mode matching has been successfully applied to analyze DRs in rectangular cavities by using a Bessel–Fourier series to match the fields between two different coordinate systems at a fictitious boundary [72]. Resonant frequencies of uniaxial anisotropic DRs [73] and generalized multilayer anisotropic DRs [74] have also been analyzed using radial mode matching. For the multilayer anisotropic DRs, whispering gallery modes and unloaded Q were also calculated. Although mode matching is very accurate and computationally efficient, it is limited in the number of inhomogeneous regions and resonator shapes it can model. The problem size may also be limited when using FEM and MoM by the excessive time it takes to fill and solve a matrix, as the number of unknowns increases.

The finite-difference time-domain (FDTD) method [75] has been widely used to solve a broad range of electromagnetic problems. In this method Maxwell’s time-dependent curl equations are solved directly. The time-domain fields are calculated using explicit update equations. This approach has several advantages over the frequency-domain methods mentioned previously. Broadband results may be obtained from a single simulation, arbitrary structures may be analyzed, and the problem size is not limited by the size of the matrix to be inverted, a limitation encountered in frequency-domain methods. Frequency-domain parameters may be obtained by Fourier-transforming time-domain values obtained from the FDTD algorithm. Nonlinear materials and devices may

also be modeled. FDTD has been applied to dielectric resonators using the 2D rotationally symmetric (RS) FDTD algorithm coupled with the discrete Fourier transform (DFT) [76,77]. To improve computational efficiency as well as computing Q values, digital filtering coupled with Prony’s method [78] or the matrix–pencil technique [79] has been used instead of the DFT. Computational efficiency has also been improved by using digital filtering and the MUSIC (multiple signal classification) algorithm [80], and the Pade interpolation method [81]. These techniques reduce the number of timesteps required to obtain accurate resonant frequencies from time-domain samples. A nonorthogonal FDTD method has also been used to model DRs [82]. An effective dielectric constant was used with a 3D rectangular FDTD algorithm [83] to increase the accuracy in modeling the curved surfaces of a DR for hybrid modes in rectangular enclosures. A locally conformal FDTD method has also been used to model both open and closed DRs [84]. Resonant frequencies for selected higher-order modes have been calculated using FDTD [85,86], as have unloaded Q using perturbation techniques [87,88].

3. MODES AND MODE CHARTS

The modes of a cylindrical DR of the type shown in Fig. 1a may be classified as transverse electric (TE), transverse magnetic (TM), or hybrid electromagnetic (HEM). Three subscripts are used to differentiate between the different modes of a given classification. The first subscript is an integer m denoting the azimuthal field variation of the mode, while the second integer n refers to the number of radial variations. Usually, the third subscript p of a resonator mode refers to the integer number of half-wavelength variations in the axial or z direction. However, the imperfect walls of the DR leads to a field variation smaller than half a wavelength and so is denoted by [34]

$$p = l + \delta \quad \text{for } l = 0, 1, 2, 3, \dots \quad (1)$$

A further property of cylindrical DRs is the circular symmetry of the TE and TM modes, that is, $m = 0$ for all TE and TM modes. The hybrid modes are further classified into EH and HE modes according to the function P , defined as the ratio of the H_z to E_z field components of the hybrid mode [89]. For $|P| < 1$, the mode is classified as HE and is TM-like in its characteristics. When $|P| > 1$, the mode is classified as EH and is TE-like. The modes that exist in the cylindrical DR and their appropriate subscripts are summarized in Table 1.

A number of authors have used different notations in the literature to designate hybrid modes. Notations such as HE_{mnp} [60] or simply HE_{mn} [64] have been used but do not differentiate between the TE-like and TM-like nature of the hybrid modes. This distinction is important when determining the appropriate method for (1) external coupling to the mode, (2) interresonator coupling, and (3) spurious mode suppression. The HE/EH notation also includes more information about the field distribution of the mode.

Table 1. Mode Classifications for Cylindrical DRs

Mode	Mode Classification	m	n	p
TE_{0np}	Transverse electric (TE)	$m = 0$	$n = 1, 2, 3, \dots$	$p = \delta, 1 + \delta, 2 + \delta, 3 + \delta, \dots$
TM_{0np}	Transverse magnetic (TM)	$m = 0$	$n = 1, 2, 3, \dots$	$p = \delta, 1 + \delta, 2 + \delta, 3 + \delta, \dots$
EH_{mnp}	Hybrid (TE-like)	$m = 1, 2, 3, \dots$	$n = 1, 2, 3, \dots$	$p = \delta, 1 + \delta, 2 + \delta, 3 + \delta, \dots$
HE_{mnp}	Hybrid (TM-like)	$m = 1, 2, 3, \dots$	$n = 1, 2, 3, \dots$	$p = \delta, 1 + \delta, 2 + \delta, 3 + \delta, \dots$

To understand the nature of the modes more clearly, the field distributions of several lower-order modes have been calculated for the generic structure of Fig. 2 using the FDTD method. This figure shows the parameters used to characterize the DR. These parameters were set to $D_x = 0$, $d/D = 2.0$, $L/D = 0.4$, $M = L$, $\epsilon_r = 38.0$, and $\epsilon_3 = 1$ for the field calculations. The results of these calculations are plotted for $TE_{01\delta}$, $TM_{01\delta}$, $EH_{11\delta}$, and $HE_{11\delta}$ modes in Fig. 3a and the $EH_{21\delta}$, $HE_{21\delta}$, $EH_{31\delta}$, and $HE_{31\delta}$ modes in Fig. 3b. Each plot represents the transverse fields of the resonator taken as a slice through the center of the DR. It should be noted that the field patterns within the dielectric material for the HE_{mnp} and EH_{mnp} modes have a strong resemblance to the respective TM_{mnp} and TE_{mnp} modes in a PMC wall cylindrical resonator. This is further confirmation of the TM-like nature of the HE modes and TE-like characteristics of the EH modes.

Each mode of the cylindrical DR can be characterized by either an electric (P) or magnetic dipole (M) moment. These dipole moments are shown for some of the lower-order modes in Fig. 4. For a given mode, a comparison between the dipole moment and the field plot of Fig. 3 confirms that the E field (or H field) does indeed align with the electric (or magnetic) dipole moment. This dipole moment characterization is useful for determining the best way to externally couple energy to a particular mode. It is usually best to couple to electric dipole modes via the E field using an electric field probe. For magnetic dipole modes, it is best to couple through the H field using a loop-type probe that intercepts the magnetic field lines. These recommendations serve as a rough guide for coupling to the modes of the DR, but are not the only methods possible.

Mode charts for the resonator configuration of Fig. 2 have been calculated using the commercial software CST Microwave Studio [90], and are presented in Figs. 5–8. Mode charts are important for determining the spurious performance of a DR, enabling the frequency spacing between adjacent modes to be analyzed. This knowledge allows the dimensions of the DR and cavity to be designed to give optimal spurious separation. The charts also show the effect that the proximity of the cavity to the DR has on the resonant frequency of each mode. This information is useful for determining the appropriate location of tuning elements in the cavity. Figure 5 shows the effect of the cavity height on several lower-order modes. Over the range plotted almost all the mode resonant frequencies decrease as the cavity height increases; only the TM_{0np} modes increase in frequency. For $M/D > 0.7$, the cavity height has little or no effect on the modes, and the resonant frequencies approach a constant value.

A plot of normalized frequency versus DR aspect ratio (D/L) is given in Fig. 6. This shows that the $TE_{01\delta}$ mode is dominant (lowest in frequency) for $D/L > 1$, while the $HE_{11\delta}$ mode is dominant for $D/L < 1$. In practice D/L is typically set to approximately 2.5, so that the $TE_{01\delta}$ mode is dominant and there is good separation between the $TE_{01\delta}$ and $HE_{11\delta}$ modes. Figure 7 is a mode chart for the ratio between the cavity diameter and DR diameter (d/D). Similar to the configuration shown in Fig. 5, once the cavity diameter is greater than a certain value, this ratio no longer influences the resonant frequency of the modes, and they converge to a constant value. Kobayashi showed that by using a dielectric ring resonator, a DR with a concentric hole in its center, the mode separation is improved [17]. This property is illustrated in the mode chart of Fig. 8. It shows that increasing the diameter of the hole (D_x) has little effect on the $TE_{01\delta}$ mode, while the higher-order modes tend to increase in frequency.

4. SIMPLIFIED ANALYSIS OF THE $TE_{01\delta}$ MODE

This section examines a simplified method for calculating the resonant frequency of a $TE_{01\delta}$ mode in a DR. It is more accurate than the magnetic wall models and provides intuition into the nature of the fields in and around the DR. Although the accuracy is less than that of variational [46] and mode-matching solutions [62], the formulation has the advantage of low complexity. This method was first presented by Itoh and Rudokas in 1977 [41] and was expanded on by Kajfez [34].

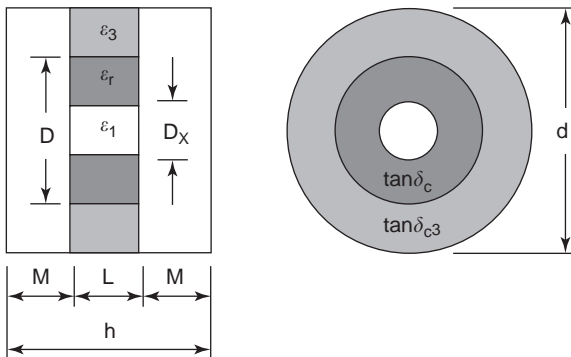

Figure 2. Configuration of a dielectric ring resonator (DRR) in a cylindrical cavity. The DRR is supported in the cavity by a low dielectric constant material (ϵ_3). (From Kobayashi and Miura [17], © 1984 IEEE.)

The configuration under analysis is shown in Fig. 9 and consists of a cylindrical DR with radius a and height L , separated by M_1 and M_2 from the lower and upper ground planes, respectively. This structure is analyzed using a cylindrical coordinate system (r, ϕ, z) and is divided into six regions as shown in the figure. At resonance most of the energy of the DR is stored in region 1, while the fields decay exponentially in regions 2–4. Regions 5 and 6 are ignored since very little energy is stored there. This approximation introduces a small error, but greatly simplifies the solution of the equations that define the structure. Since the $TE_{01\delta}$ mode is circularly symmetric, only the E_ϕ , H_r , and H_z fields exist. To satisfy the boundary conditions and ensure the continuity of the tangential fields, E_ϕ in each region is

$$E_{\phi 1} = A_1 J_1(k_{r1}r) \cos(\beta z - \theta) \quad (2)$$

$$E_{\phi 2} = A_2 J_1(k_{r1}r) \sinh(\alpha_2(z + M_1)) \quad (3)$$

$$E_{\phi 3} = A_3 J_1(k_{r1}r) \sinh(\alpha_3(z - L - M_2)) \quad (4)$$

$$E_{\phi 4} = A_4 K_1(k_{r4}r) \cos(\beta z - \theta) \quad (5)$$

where

$$A_2 = A_1 \frac{\cos(\theta)}{\sinh(\alpha_2 M_1)}, \quad A_3 = A_1 \frac{\cos(\beta L - \theta)}{\sinh(\alpha_3 M_2)},$$

$$A_4 = A_1 \frac{J_1(k_{r1}a)}{K_1(k_{r4}a)}$$

and

$$\beta^2 = k_0^2 \epsilon_{r1} - k_{r1}^2 = k_0^2 \epsilon_{r4} + k_{r4}^2, \quad \alpha_2^2 = k_{r1}^2 - k_0^2 \epsilon_{r2}, \quad (6)$$

$$\alpha_3^2 = k_{r1}^2 - k_0^2 \epsilon_{r3}$$

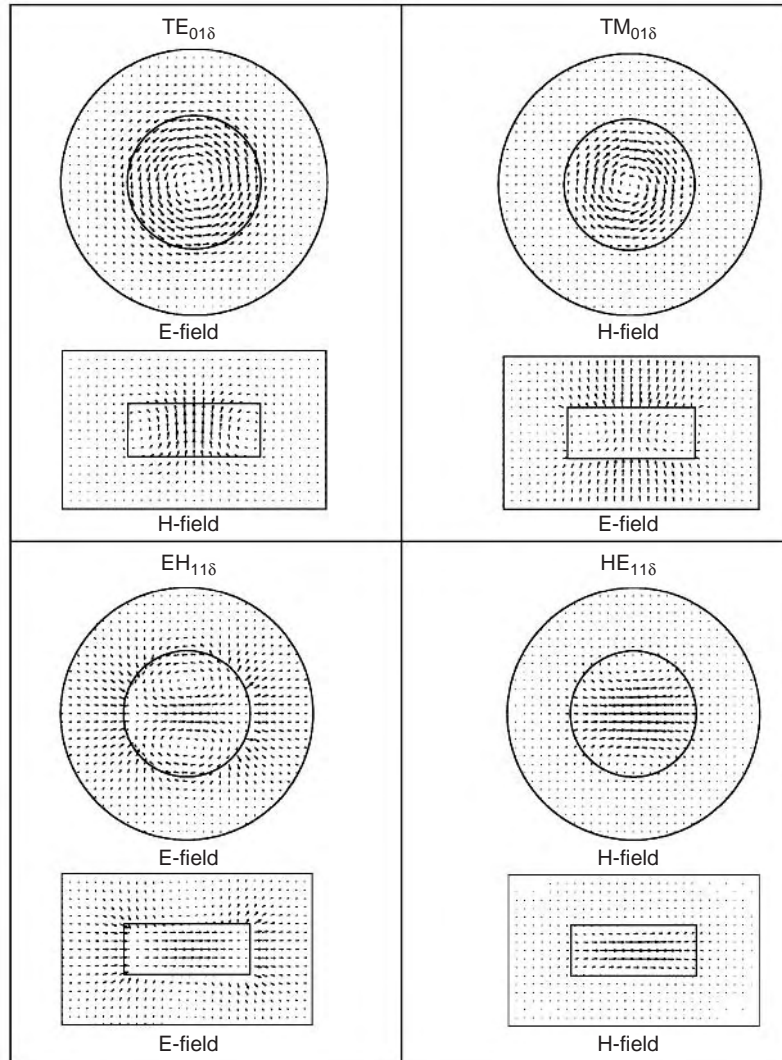

Figure 3. Field distributions for the (a) $TE_{01\delta}$, $TM_{01\delta}$, $EH_{11\delta}$, and $HE_{11\delta}$ modes and (b) $EH_{21\delta}$, $HE_{21\delta}$, $EH_{31\delta}$, and $HE_{31\delta}$ modes.

(b) Figure 3. (Continued).

In Eqs. (2)–(5) and those that follow $J_n(k_r r)$ is the Bessel function of the first kind, order n , while $K_n(k_r r)$ is the modified Bessel function of the second kind, order n .

From Maxwell's equations H_r is derived from E_ϕ as follows

$$H_{r1} = \frac{j\beta}{\omega\mu_0} A_1 J_1(k_{r1}r) \sin(\beta z - \theta) \quad (7)$$

$$H_{r2} = -\frac{j\alpha_2}{\omega\mu_0} A_2 J_1(k_{r1}r) \cosh(\alpha_2(z + M_1)) \quad (8)$$

$$H_{r3} = -\frac{j\alpha_3}{\omega\mu_0} A_3 J_1(k_{r1}r) \cosh(\alpha_3(z - L - M_2)) \quad (9)$$

$$H_{r4} = \frac{j\beta}{\omega\mu_0} A_4 K_1(k_{r4}r) \sin(\beta z - \theta) \quad (10)$$

while H_z is obtained in a similar manner:

$$H_{z1} = \frac{jk_{r1}}{\omega\mu_0} A_1 J_0(k_{r1}r) \cos(\beta z - \theta) \quad (11)$$

$$H_{z2} = \frac{jk_{r1}}{\omega\mu_0} A_2 J_0(k_{r1}r) \sinh(\alpha_2(z + M_1)) \quad (12)$$

$$H_{z3} = \frac{jk_{r1}}{\omega\mu_0} A_3 J_0(k_{r1}r) \sinh(\alpha_3(z - L - M_2)) \quad (13)$$

$$H_{z4} = -\frac{jk_{r4}}{\omega\mu_0} A_4 K_0(k_{r4}r) \cos(\beta z - \theta) \quad (14)$$

Figure 4. Magnetic (M) and electric (P) dipole moments for several modes of the cylindrical DR. (From Kobayashi and Miura [17], © 1984 IEEE.)

Applying continuity conditions to H_{z1} and H_{z4} at $r = a$ gives the first eigenvalue equation

$$\frac{J_1(k_{r1}a)}{k_{r1}J_0(k_{r1}a)} = -\frac{K_1(k_{r4}a)}{k_{r4}K_0(k_{r4}a)} \quad (15)$$

where

$$k_{r4}^2 = k_0^2(\epsilon_{r1} - \epsilon_{r4}) - k_{r1}^2 \quad (16)$$

The continuity conditions for H_{r1} and H_{r2} at $z = 0$ give

$$\tan(\theta) = \frac{\alpha_2}{\beta} \coth(\alpha_2 M_1) \quad (17)$$

while the continuity conditions for H_{r1} and H_{r3} at $z = L$ give

$$\tan(\beta L - \theta) = \frac{\alpha_3}{\beta} \coth(\alpha_3 M_2) \quad (18)$$

Figure 5. Mode chart of normalized frequency versus M/D (with $D/L=2.5$, $d/D=2$, $D_x=0$).

Figure 6. Mode chart of normalized frequency versus $(D/L)^2$ (with $d/D=2$, $M/D=0.4$, $D_x=0$).

Figure 7. Mode chart of normalized frequency versus d/D (with $D/L=2.5$, $M/D=0.4$, $D_x=0$).

Figure 8. Mode chart of normalized frequency versus D_x/D (with $D/L=2.5$, $d/D=2$, $M/D=0.4$).

Combining Eqs. (17) and (18) by eliminating θ yields the second eigenvalue equation

$$\beta L = \tan^{-1} \left(\frac{\alpha_2}{\beta} \coth(\alpha_2 M_1) \right) + \tan^{-1} \left(\frac{\alpha_3}{\beta} \coth(\alpha_3 M_2) \right) + p\pi, \quad (19)$$

$p = 0, 1, 2, 3, \dots$

For the $TE_{01\delta}$ mode $p=0$. Solving the coupled Eqs. (6), (15), and (19) gives k_0 , from which the resonant frequency is calculated

$$f_0 = \frac{k_0 c}{2\pi} \quad (20)$$

where c is the speed of light in a vacuum, or 2.99792458×10^8 m/s. In practice, Eqs. (6), (15), and (19) are solved numerically using a zero-finding computer program or subroutine such as Broyden's method. Several example configurations from the literature as well as their computed and measured resonant frequencies are given in Table 2. These results show that when M_1 and M_2 are

Figure 9. Configuration of the DR used in the simplified analysis of a $TE_{01\delta}$ mode. (From Itoh and Rudokas [41], © 1977 IEEE.)

Table 2. Comparison of Simplified Method with Measured Values for TE_{01δ} Mode

ϵ_{r1}	ϵ_{r2}	ϵ_{r3}	ϵ_{r4}	a (mm)	L (mm)	M_1 (mm)	M_2 (mm)	f_0 (GHz) Measured	f_0 (GHz) Computed
36.2	1.0	1.0	1.0	3.015	4.16	3.41	3.41	7.94 [46]	8.311 (+4.7%)
34.19	9.6	1.0	1.0	7.49	7.48	0.7	0.72	4.348 [34]	4.355 (+0.2%)
63.7	1.0	1.0	1.0	14.29	11.25	0.0	0.0	2.131 [7]	2.131 (0%)

large, which corresponds to an open DR, the accuracy of the method worsens. The accuracy increases as the PEC walls get closer to the resonator. When $M_1 = M_2 = 0$, the analysis is exact. This leads to the conclusion that the method is best suited to DRs placed on thin substrates with the PEC cavity enclosure close to the topface of the DR, such as would be seen in an MIC or MMIC environment. It also works well for DRs sandwiched between two PEC plates, a configuration typically used to measure relative permittivity and loss tangent of dielectric materials [7].

5. Q FACTOR

The quality factor is an important figure of merit for assessing the performance of a DR, or any microwave resonator. It characterizes both the dielectric and conductor losses for closed resonators, as well as radiation losses for open resonators. In this section, only closed resonators are considered. Filter insertion loss is inversely proportional to the resonator unloaded Q . Design objectives require a low insertion loss, which in turn necessitates high- Q resonators. Narrow bandwidth filters also require high- Q resonators, particularly in today's crowded electromagnetic spectrum where communications receivers need high cochannel and spurious signal rejection.

General Q calculations will be described for the structure shown in Fig. 2. It consists of a cylindrical cavity made out of metal, a high-permittivity dielectric ring resonator, and its dielectric supporting structure. The unloaded quality factor Q_u of a resonator is defined as [91]

$$Q_u = \omega_0 \frac{\text{stored energy}}{\text{average power dissipated}} \quad (21)$$

$$= \omega_0 \frac{W}{P_c + P_d + P_{\text{sup}}}$$

where ω_0 is the resonant frequency of the DR; W is the stored energy; and P_c , P_d , and P_{sup} are the power dissipated due to losses in the conductor, dielectric resonator, and dielectric support, respectively. The unloaded Q may be expressed in terms of the individual Q factors of the conductor Q_c , the dielectric resonator Q_d , and dielectric support Q_{sup} as follows:

$$\frac{1}{Q_u} = \frac{1}{Q_c} + \frac{1}{Q_d} + \frac{1}{Q_{\text{sup}}} \quad (22)$$

The stored energy, W may be written as [92]

$$W = W_e + W_m \quad (23)$$

where W_e and W_m denote the energies stored in the electric and magnetic fields, respectively. The stored electric energy is defined as

$$W_e = \frac{1}{4} \int_V \epsilon |\mathbf{E}|^2 dV \quad (24)$$

and the stored magnetic energy is

$$W_m = \frac{1}{4} \int_V \mu |\mathbf{H}|^2 dV \quad (25)$$

However, at resonance, the stored magnetic energy equals the stored electric energy, or $W_e = W_m$; hence

$$W = 2W_e = 2W_m = \frac{1}{2} \int_V \epsilon |\mathbf{E}|^2 dV = \frac{1}{2} \int_V \mu |\mathbf{H}|^2 dV \quad (26)$$

So, from Eq. (26) it is clear that the stored energy may be calculated from either the electric field or the magnetic field.

The conductor power dissipation is calculated from the tangential magnetic fields at the surface of the conducting enclosure as

$$P_c = \frac{1}{2} \oint_S R_S |\mathbf{H}_{\text{tan}}|^2 dS \quad (27)$$

where R_S is the surface resistance of the conductor, \mathbf{H}_{tan} is the magnetic field tangential to the enclosure walls, and S denotes the surface area of the enclosure walls. Introducing the skin depth, $\delta = 1/\sqrt{\pi f_0 \mu \bar{\sigma} \sigma_0}$, where f_0 is the resonant frequency, σ_0 is the conductivity of the enclosure, and $\bar{\sigma}$ is a relative conductivity, which accounts for the surface roughness of the conductor, the power dissipation due to the conducting walls may be redefined as

$$P_c = \omega_0 \frac{\delta}{4} \oint_S \mu |\mathbf{H}_{\text{tan}}|^2 dS \quad (28)$$

Then from Eqs. (26) and (28) we can now define the conductor Q as [85]

$$Q_c = \omega_0 \frac{W}{P_c} = \frac{2}{\delta} \frac{\int_V \mu |\mathbf{H}|^2 dV}{\oint_S \mu |\mathbf{H}_{\text{tan}}|^2 dS} \quad (29)$$

To model both damping and ohmic losses within the dielectric resonator material, a complex permittivity

is introduced:

$$\varepsilon_c = \varepsilon - j \frac{\sigma}{\omega} \quad (30)$$

The loss tangent is the ratio between the imaginary and real parts of the complex permittivity and is a measure of the power loss in the dielectric. The loss tangent is defined as

$$\tan \delta_c = \frac{\sigma}{\omega \varepsilon} \quad (31)$$

Rearranging Eq. (31), we can obtain the effective conductivity to account for the losses in the dielectric resonator:

$$\sigma_{\text{eff}} = 2\pi f_0 \varepsilon_r \varepsilon_0 \tan \delta_c \quad (32)$$

Then the dielectric resonator power dissipation may be calculated as

$$P_d = \frac{1}{2} \int_{V'} \sigma_{\text{eff}} |\mathbf{E}|^2 dV' \quad (33)$$

where V' denotes the volume of the dielectric resonator only. From Eqs. (26) and (33) the dielectric resonator Q is [85]

$$Q_d = \omega_0 \frac{W}{P_d} = \omega_0 \frac{\int_V \varepsilon |\mathbf{E}|^2 dV}{\int_{V'} \sigma_{\text{eff}} |\mathbf{E}|^2 dV'} \quad (34)$$

where V is the volume of the entire resonator and ε is a function of position for inhomogeneous resonators. Using a similar approach we may define the Q factor for the dielectric support

$$Q_{\text{sup}} = \omega_0 \frac{W}{P_{\text{sup}}} = \omega_0 \frac{\int_V \varepsilon |\mathbf{E}|^2 dV}{\int_{V''} \sigma_{\text{eff}_3} |\mathbf{E}|^2 dV''} \quad (35)$$

where σ_{eff_3} is the effective conductivity of the dielectric support and V'' is the volume of the dielectric support only. The effective conductivity of the dielectric support may be found using Eq. (32).

Q factors as a function of M/D for the resonator configuration of Fig. 2 have been calculated using the commercial software CST Microwave Studio [90], and are presented in Figs. 10–13 for the $\text{TE}_{01\delta}$, $\text{EH}_{11\delta}$, $\text{HE}_{11\delta}$, and $\text{TM}_{01\delta}$ modes. The metallic walls of the cavity are modeled as copper, with $\sigma = 5.8 \times 10^7 \text{ S/m}$, while the loss tangent of the dielectric material is set to $\tan \delta = 5 \times 10^{-5}$. Each of these figures show the effect of the cavity height on Q_c , Q_d , and Q_u . In general, as the cavity height increases so does the value of Q_c , which leads to a greater value of Q_u . This is to be expected since the fields outside the DR walls are evanescent, so increasing the height of the cavity reduces the size of the tangential fields induced on the metallic walls. In practice, the cavity size cannot be increased indefinitely to increase the Q factor, because the overall volume of the cavity needs to be kept small. For filter applications, the cavity size cannot be made too large

Figure 10. Q factor versus M/D for the $\text{TE}_{01\delta}$ mode (with $\varepsilon_r = 38$, $\varepsilon_3 = 1$, $D/L = 2.5$, $d/D = 2$, $D_x = 0$).

Figure 11. Q factor versus M/D for the $\text{EH}_{11\delta}$ mode (with $\varepsilon_r = 38$, $\varepsilon_3 = 1$, $D/L = 2.5$, $d/D = 2$, $D_x = 0$).

Figure 12. Q factor versus M/D for the $\text{HE}_{11\delta}$ mode (with $\varepsilon_r = 38$, $\varepsilon_3 = 1$, $D/L = 2.5$, $d/D = 2$, $D_x = 0$).

Figure 13. Q factor versus M/D for the $TM_{01\delta}$ mode (with $\epsilon_r = 38$, $\epsilon_3 = 1$, $D/L = 2.5$, $d/D = 2$, $D_x = 0$).

because substantial field strength is required on the cavity walls to generate interresonator coupling. Cavity design should take into consideration Q_u , cavity volume, and spurious performance; it usually requires a compromise between these parameters and is further influenced by the intended DR application.

6. MATERIAL PARAMETERS

An important parameter for evaluating the temperature stability of a dielectric resonator is the temperature coefficient of resonant frequency τ_f . This parameter takes into account the thermal linear expansion of the DR material and its enclosure, as well as the variation in the relative permittivity ϵ_r of the DR material as a function of temperature. The temperature coefficient is expressed as the ratio of the change in frequency to the original frequency divided by the change in temperature:

$$\tau_f = \frac{\Delta f_0}{f_0 \Delta T} \quad (36)$$

Units of the temperature coefficient are parts per million per degree Celsius (ppm/°C). The temperature coefficient for the structure in Fig. 2, which includes the effect of the dielectric support, is [13]

$$\tau_f = A_r \tau_r + A_3 \tau_3 + (A_D + A_x + A_L) \tau_x + A_C \tau_C \quad (37)$$

where

$$\begin{aligned} \tau_r &= \frac{\Delta \epsilon_r}{\epsilon_r \Delta T}, & \tau_3 &= \frac{\Delta \epsilon_3}{\epsilon_3 \Delta T}, \\ \tau_x &= \frac{\Delta D}{D \Delta T} = \frac{\Delta D_x}{D_x \Delta T} = \frac{\Delta L}{L \Delta T}, & (38) \\ \tau_C &= \frac{\Delta d}{d \Delta T} \end{aligned}$$

and

$$\begin{aligned} A_r &= \frac{\epsilon_r}{f_0} \frac{\Delta f_0}{\Delta \epsilon_r}, & A_3 &= \frac{\epsilon_3}{f_0} \frac{\Delta f_0}{\Delta \epsilon_3}, & A_D &= \frac{D}{f_0} \frac{\Delta f_0}{\Delta D}, \\ A_x &= \frac{D_x}{f_0} \frac{\Delta f_0}{\Delta D_x}, & A_L &= \frac{L}{f_0} \frac{\Delta f_0}{\Delta L}, & A_C &= \frac{d}{f_0} \frac{\Delta f_0}{\Delta d} \end{aligned} \quad (39)$$

In Eq. (38) τ_r and τ_3 represent the temperature coefficients of the dielectric constants of the resonator and support, while τ_x and τ_C are the coefficients of thermal linear expansion for the dielectric material and conductor enclosure, respectively. The constants A_r , A_3 , A_D , A_x , A_L , and A_C can be determined accurately by calculating the small resonant frequency shifts Δf_0 caused by the small changes $\Delta \epsilon_r$, $\Delta \epsilon_3$, ΔD , ΔD_x , ΔL , or Δd , respectively. In practice, temperature compensation of the dielectric resonator configuration can be obtained by choosing τ_r to cancel out τ_x and τ_C . Manufacturers usually supply materials with a range of τ_r values to choose from. Some typical values of dielectric constant, loss tangent, temperature coefficient, and thermal expansion for DR materials from two different manufacturers are given in Tables 3 and 4.

7. EXTERNAL AND INTERRESONATOR COUPLING

For a DR to be useful in a microwave circuit, it must be coupled to an external transmission line, another resonator, or both. One of the simplest ways to externally couple the $TE_{01\delta}$ mode in an MIC environment is to place it next to a microstrip line, as shown in Fig. 1b. Since the $TE_{01\delta}$ mode behaves like a magnetic dipole, its magnetic field loops link with the transverse field of the microstrip line. The coupling structure and field lines of the DR and microstrip are illustrated in Fig. 14a [93]. By simply changing the distance d between the DR and microstrip line, the coupling value is varied. The equivalent circuit of the coupling structure is a parallel resonant circuit placed in series with the microstrip line [94], as shown in Fig. 14b.

Table 3. Typical Parameters of DR Materials Available from Trans-Tech

Series	Dielectric Constant	Q (1/tan δ)	Available τ_f (ppm/°C)	τ_x (ppm/°C)	Composition
2900	29–30.7	> 50,000 at 2 GHz	4/2/0/–2	> 10	BaZnTa oxide
3500	34.5–36.5	> 35,000 at 2 GHz	6/3/0/–3	10	BaZnCoNb
4300	43	> 9500 at 4.3 GHz	6/3/0/–3/–6	6.5	Zrtitanium-based
4500	44.7–46.2	> 9500 at 4.3 GHz	6/3/0/–3/–6	6.5	Zrtitanium-based
8300	35–36.5	> 9500 at 4.3 GHz	9/6/3/0/–3	10	Titanate-based
8700	29.5–31	> 10,000 at 10 GHz	4/2/0	10	BaZnTa oxide

Table 4. Typical Parameters of Resomics DR Materials Available from Murata

Material Code	Dielectric Constant	Q ($1/\tan \delta$)	Available τ_f (ppm/ $^{\circ}$ C)	τ_z (ppm/ $^{\circ}$ C)
U	36–40	>6000 at 7 GHz	–4–10	6–7
M	37–40	>7000 at 7 GHz	0–6	6–7
V	33–36	>10,000 at 10 GHz	0–8	12–13
R	29–31	>12,000 at 10 GHz	0–6	10.7
B	27–29	>15,000 at 10 GHz	0–6	11
E	24–25	>20,000 at 10 GHz	0–6	10.7
F	23–24	35,000 at 10 GHz	0–4	11

The external coupling, characterized by the external coupling factor Q_e , may be calculated using a magnetic field flux method. This procedure relates Q_e to the energy stored in the resonator and the magnetic flux linking the microstrip and DR together [93]

$$Q_e = 4 \frac{Z_c}{\omega_0 \mu_0^2} \frac{W}{\left\{ \int \int_S \mathbf{H} \cdot d\mathbf{S} \right\}^2} \quad (40)$$

where

$$W = \frac{1}{4} \epsilon_0 \epsilon_i \int_{V_i} |\mathbf{E}_i|^2 dV_i \quad (41)$$

In these equations, Z_c is the characteristic impedance of the microstrip, \mathbf{H} is the magnetic field vector, S is the cross section of the microstrip substrate, \mathbf{E}_i is the electric field

vector in medium i , ϵ_i is the relative permittivity of medium i , and V_i is the volume of medium i . Details of an analytical expression for Q_e that gives good agreement with measured results are presented in Ref. 93.

The analysis of interresonator coupling coefficients between two DRs in a waveguide will now be examined. A typical coupling structure for this situation is shown in Fig. 15. It consists of two identical DRRs placed coaxially within a cutoff circular waveguide of diameter d . The spacing between the two DRRs is $2M$, and the spacing to the PEC walls enclosing the cylindrical waveguide at each end is M_1 . This structure supports many different modes, but for this analysis we are only interested in the modes that couple magnetically through a dominant TE evanescent mode in the cutoff waveguide such as the $TE_{01\delta}$ and $EH_{11\delta}$ modes. The derivation of the coupling coefficient presented follows the approach of Zaki and Chen [95]. The equivalent circuit for a magnetically coupled mode near resonance, shown in Fig. 16a, consists of two series-resonant circuits coupled by a mutual inductance M . Defining the coupling coefficient k in terms of the equivalent-circuit parameters gives

$$k = \frac{M}{L} \quad (42)$$

Since this analysis will exploit the structural symmetry of the configuration given in Fig. 15, we define an equivalent circuit with a symmetry plane as shown in Fig. 16b. Replacing the symmetry plane with a PEC yields a single resonant circuit. The resonant frequency of the circuit f_e may be related to its equivalent-circuit parameters to obtain

$$f_e = \frac{1}{2\pi\sqrt{(L-M)C}} \quad (43)$$

Repeating the procedure for the PMC wall yields a circuit with a resonant frequency f_m that may be given in terms of the equivalent-circuit parameters as

$$f_m = \frac{1}{2\pi\sqrt{(L+M)C}} \quad (44)$$

Solving Eqs. (42)–(44) for the coupling coefficient k yields

$$k = \frac{M}{L} = \frac{f_e^2 - f_m^2}{f_e^2 + f_m^2} \quad (45)$$

Figure 14. (a) Configuration of $TE_{01\delta}$ mode DR coupled to a microstrip line (from Guillon et al. [93], © 1981 IEEE); (b) equivalent circuit of the coupled DR (from Khanna and Garault [94], © 1983 IEEE).

Figure 15. Configuration of coupled dielectric ring resonators (DRRs) showing the position of the structurally symmetric plane. (From Kobayashi and Minegishi [13], © 1987 IEEE.)

Figure 16. Equivalent circuit of two magnetically coupled resonators: (a) in conventional form; (b) including a structural symmetry plane. (From Zaki and Chen [95], © 1987 IEEE.)

The computation of inter-resonator coupling has been reduced to the problem of calculating the resonant frequencies of two different structures that have a PEC or PMC wall at the plane of structural symmetry. A similar equation may be derived for electric coupling, only the signs of the numerator values are reversed [14]. A more general equation for both electric and magnetic coupling is

$$k = \frac{|f_e^2 - f_m^2|}{f_e^2 + f_m^2} \tag{46}$$

The resonant frequencies f_e and f_m may be calculated using an approximate analysis method, mode matching, or numerical techniques such as FDTD, FEM, or FIT. Each method has been used in the literature to accurately calculate DR interresonator coupling coefficients. This technique may also be used to calculate interresonator coupling through a slot in a conducting wall, as long as the configuration has a structural symmetry plane similar to that shown in Fig. 15. Measured and computed coupling coefficients for two $EH_{11\delta}$ DRRs coupled via a slot are compared in Fig. 17 [96]. The inset of the figure shows the configuration of the coupling structure.

Figure 17. Measured and calculated slot coupling coefficients of an $EH_{11\delta}$ DRR for a slot width of 1.6 mm and a slot thickness of 1 mm (dimensions $d = 37.4$ mm, $D = 21$ mm, $D_x = 8.4$ mm, $L = M = 7.4$ mm, $\epsilon_r = 35$, $f_0 = 4.030$ GHz). Inset shows configuration of the structure. (From Weily et al. [96]; this material is used by permission of John Wiley and Sons, Inc. Copyright © 2001 by John Wiley and Sons, Inc.)

DIGITAL MICROWAVE RECEIVERS

JOHANN F. LUY
TH. MUELLER
DaimlerChrysler Research
Ulm, Germany

1. INTRODUCTION

The general tasks of a receiver are amplification, channel selection, and demodulation of a signal. The kind of channel selection may be used to distinguish between analog and digital receiver architectures. In a superheterodyne receiver (Fig. 1), the problem of image frequency suppres-

Figure 1. Analog receiver: superheterodyne principle.

sion can be solved quite well by proper selection of the IF frequencies and bandpass filters. Channel selection is determined by the analog filters, and reconfiguration by software is not supported.

Quadrature direct-conversion architecture is obtained if the RF and first IF mixer stages are dropped and the RF signal is fed directly to the analog in-phase and quadrature downconversion mixers (Fig. 2). The reduced complexity of this zero-IF receiver is the advantage of this concept. The disadvantages are the problems with static and dynamic offsets and corresponding errors in amplitude and phase of the received signals.

The simplified principle of a digital receiver is shown in Fig. 3, where the analog signal passes an antialiasing filter (AAF) and a sample-and-hold (S/H) unit. The sampled values of the signal are then converted into the digital domain by an analog-to-digital converter (ADC) and fed into an accumulator (ACCW) for further digital signal processing. Digital signal processing of the received signal provides high flexibility and opens new possibilities regarding diversity techniques. By broadband sampling of the FM band between 87 and 108 MHz, it has been shown that coherent superposition of different channels containing the same information can lead to significantly improved signal quality [1]. Channel diversity and MIMO signal processing techniques become possible with digital front ends [2].

2. RF AND IF SAMPLING ARCHITECTURE

By sampling the radio frequency (RF) or intermediate frequency (IF), the number of input stages and therefore the hardware effort can be reduced. The architectures of both receiver types are shown in Fig. 4. The performance of the ADC with respect to bandwidth and resolution [3] is decisive for the choice of the receiver architecture. The ADC performs a quantization in time and in value of the input RF or IF signal.

Figure 2. Analog receiver: direct-conversion architecture.

Figure 3. Digital receiver illustrating the bandpass-limited sampling concept.

The sampling process with the sampling frequency f_S can be understood in frequency domain by folding the input signal with a series of diracs with distance f_S (see Fig. 5). The input signal at frequency f_{IF} is shifted by the sampling process to $f_{IF} - kf_S$, where k is an integer value. A filter has to select a frequency band so that only the desired signal is sampled and all the other frequency components are suppressed to avoid aliasing [4]. The requirements on the slope of the filter are minimal if the input frequency is an odd multiple of $f_S/4$ because the distance to the next possible interferer becomes maximal. The complex downconversion is usually realized in the digital domain. This enables the use of high-order modulation schemes, and ensures exact gain and phase matching in in-phase and quadrature branches. Especially for a fixed IF frequency, the digital downconversion can be realized by multiplying the sampled signal with $+1s$ and $-1s$ (see Fig. 4b).

By choosing a high sampling rate, the achievable signal-to-noise ratio in the desired channel can be calculated by the formula

$$\text{SNR}_{\text{CH}} = \text{SNR}_{\text{ADC}} + 10 \log_{10} \left(\frac{f_S}{2B_{\text{CH}}} \right)$$

with the channel bandwidth B_{CH} , the sampling frequency f_S , and the signal-to-noise ratio of the ADC SNR_{ADC} in decibels. It can be seen that with increasing sampling rate the SNR also increases. The state of the art is about 72 dB SNR_{ADC} at a sampling rate of 105 MHz [5].

The highest flexibility can be reached with broadband RF sampling receivers [6]. Here all channels are available in parallel, and the channel bandwidth and demodulation are defined by digital signal processing so that the radio is fully software-defined. In contrast to IF sampling receivers, the dynamic range that has to be handled by the ADC becomes critical. To calculate the necessary dynamic range, we have to accumulate the power of all interferers and noise in the digitized frequency band. As an example, the specification of GSM¹ defines a maximum interferer power of -23 dBm, whereas noise and interferers in the desired channel with a bandwidth of 200 kHz have to keep below -112 dBm. If we perform IF sampling, the IF filter will be able to suppress most of the interferers so that the interfering power will be below -43 dBm.

The second important factor when defining receivers is intermodulation. The state of the art is about 90 dB spurious-free dynamic range [5]. To compare this with traditional downconverting architectures, we should remember

¹European Telecommunication Standard, ETS 300-577, FTS 300 577, *Radio Transmission and Reception*, Dec. 1999, European Telecommunication Standards Institute, Valbonne, France.

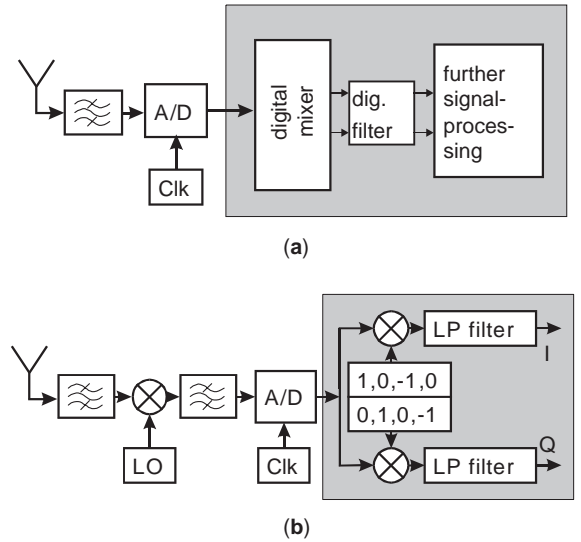

Figure 4. (a) RF sampling receiver; (b) IF sampling receiver.

that the spurious-free dynamic range (SFDR) of an amplifier or mixer can be calculated out of the third-order interception point ICP3_{out} and the output noise power N_{out} :

$$\text{SFDR} = \frac{2}{3}(\text{ICP3}_{\text{out}} - N_{\text{out}}).$$

A standard monolithic integrated mixer [7] will show an SFDR of about 82 dB referring to a channel bandwidth of 200 kHz.

The selection of the sampling frequency also depends on the technical feasibility of the antialiasing filter. Choosing a frequency plan where the input signal with bandwidth B is centered on f_{SIG} an odd multiple of $f_S/4$, a filter margin on each side of $f_S/2 - B$ is allowed to reach the specified suppression of interferers. In practice [8], bandwidth B should be maintained below $f_S/4$, which corresponds to a minimum oversampling ratio of 2.

An important issue for the implementation of RF or IF sampling ADCs is sampling jitter [9]. The sources of sampling jitter are mainly the clock generator phase noise and the aperture jitter of the sampling unit. The slope of the input signal will transform the error $\Delta\tau$ of the sampling time in an amplitude error Δy as shown in Fig. 6:

$$\Delta y = \Delta\tau \cdot \left. \frac{\partial y}{\partial t} \right|_{t_s}$$

In broadband sampling receivers the input signal consists of the desired signal and a couple of interferers. The slope of the signal can be calculated by the sum of the slopes of each partial signal, weighted with its amplitude. If one signal is dominant, it will define the slope of the input signal. If the signal amplitude is much lower than the amplitude of the interferer, then the slope of the input signal will be defined by the interferer. If the sampled signal is independent of the sampling frequency, then we have to look on the statistical properties of the input signal.

Figure 5. General six-port architecture.

For a sinusoidal input signal y with amplitude A_{sin} , we obtain the variance of the slope

$$\begin{aligned} \text{Var}\left(\frac{\partial y}{\partial t}\right) &= \int p_{\text{slope}}(y)y^2 dy \\ &= 2A_{\text{sin}}^2 f^2 \pi^2 \end{aligned}$$

Finally we can calculate the achievable signal to noise ratio in decibels when sampling a sinusoid signal with a nonideal sampling circuit:

$$\begin{aligned} \text{SNR}_{\text{dB}} &= 10 \log\left(\frac{P_{\text{SIG}}}{P_{\text{noise}}}\right) \\ &= 10 \log\left(\frac{\frac{1}{2}A_{\text{sin}}^2}{2A_{\text{sin}}^2 f^2 \pi^2 \Delta\tau^2}\right) \\ &= -20 \log(2f\pi\Delta\tau) \end{aligned}$$

3. SIX-PORT ARCHITECTURE

The six-port direct-conversion technique is another promising approach toward software configurable receivers at millimeter-wave carrier frequencies. The crucial advantage over the sampling architecture is its simple construction requiring only the reference oscillator as an active RF component, making this technology particularly attractive for future low-cost and broadband RF front ends operating at millimeter-wave frequencies.

The six-port technology traces back to the 1970s, when it was developed as an alternative network analyzer [10]. By means of a six-port reflectometer, it is possible to mea-

sure the complex reflection coefficient of a device under test (DUT). Furthermore, by the application of 2 six-ports—one on each side of the unknown DUT—it is possible to determine the complete set of the S-parameters [11]. Starting in the mid-1990s the six-port principle was investigated for use as a direct-conversion receiver [12,13]. Complete receivers were realized, and signals that were modulated by quadrature phase shift keying (QPSK) and quadrature amplitude modulation (QAM) schemes have since been received and demodulated successfully. Sony has verified the concept for a multicarrier system based on HIPERLAN/2 (High-Performance Local Area Network/2) and UMTS-FDD (Universal Mobile Telecommunication System–Frequency-division duplex) standards [14,15], and Nokia has found the six-port direct-conversion technique in a receiver a viable concept for mobile terminals [16]. Other applications include anticollision radars [17], very accurate short-range distance measurement [18], and direction finding systems [19].

The functional principle of six-port devices is based on the measurement of four independent output powers corresponding to the complex ratio between two superposed electromagnetic waves under different phase angles. While in reflectometers used for the measurement of the complex reflection coefficient, a leakage from the LO port to the test port of the DUT is essential, six-port circuits for receivers require a very large isolation of the LO and the RF ports. Carrier recovery (Fig. 7) is a possible approach to avoid the need for an independent LO in a six-port direct digital receiver [22].

To describe this principle, the six-port in Fig. 8 is considered together with two input signals, one from a local oscillator (LO)

$$a_{\text{LO}}(t) = |a_{0,\text{LO}}| \cdot e^{j(2\pi f_{\text{LO}}t + \phi_{\text{LO}})}$$

and the other from the RF port

$$a_{\text{RF}}(t) = |a_{0,\text{RF}}| \cdot e^{j(2\pi f_{\text{RF}}t + \phi_{\text{RF}})}$$

which is the RF signal to be detected, that is, measured by the six-port receiver.

Ideally, the six-port circuit represents a nondissipative network and the frequencies of the RF and LO signal are identical. For example, at port 3, the RF signal is attenuated twice by 3 dB and 90° phase-shifted. This signal is added to the LO signal, which is also attenuated twice by 3 dB although it does not receive a phase shift. For zero phase shift between the LO and the RF signal and the same amplitudes at the input ports, this leads to a resulting amplitude of $\sqrt{2}/2$ for the superposed wave to be detected at port 3. During a 360° phase shift of the RF signal, the amplitudes resulting at the output ports are sine functions.

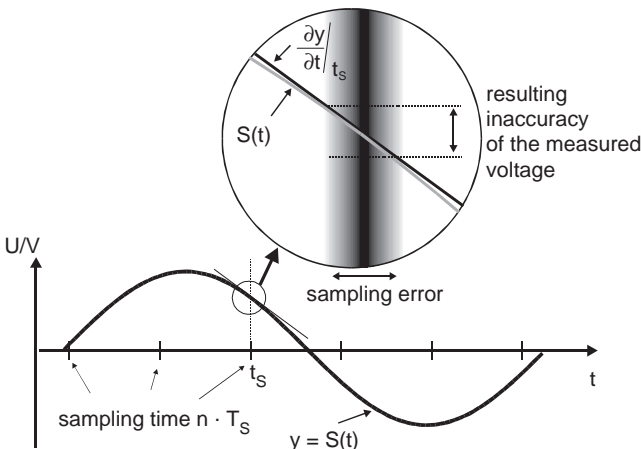

Figure 6. Transformation of sampling error in amplitude error.

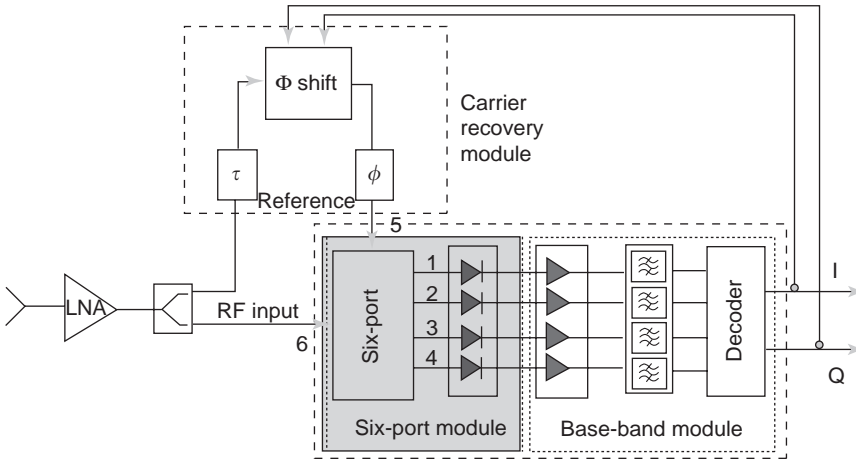

Figure 7. Architecture of hardware six-port direct digital receiver with carrier recovery from QPSK signal (from Ref. 22).

At each output port (ports 3–6) the signal passes through detector circuits. A diode is used to rectify the signal, and a subsequent lowpass filter (LPF) outputs the amplitude of the signal, which is amplified and A/D-converted. It becomes clear that the diode is the most critical block in this receiver chain that has to be operated in its quadratic region where the output voltage depends linearly on the power to be detected. However, minor deviations from the square law can be compensated in the digital domain by suitable calibration methods.

From at least three linearly independent output powers, the complex ratio between the two input signals

$$\Gamma(t) = \left| \frac{a(t)_{0,RF}}{a(t)_{0,LO}} \right| \cdot e^{j(2\pi \Delta f t + \Delta\phi)}$$

can be determined. Furthermore, it can be shown that if the leakage from the LO signal to the RF port is neglected, the following linear relationship exists between the I and Q components of the RF waveform and the power ratios P_i/P_3 ($i = 3 \dots 6$):

$$I(t) = \sum_{i=3}^6 A_i \frac{P_i(t)}{P_3(t)}$$

$$Q(t) = \sum_{i=3}^6 B_i \frac{P_i(t)}{P_3(t)}$$

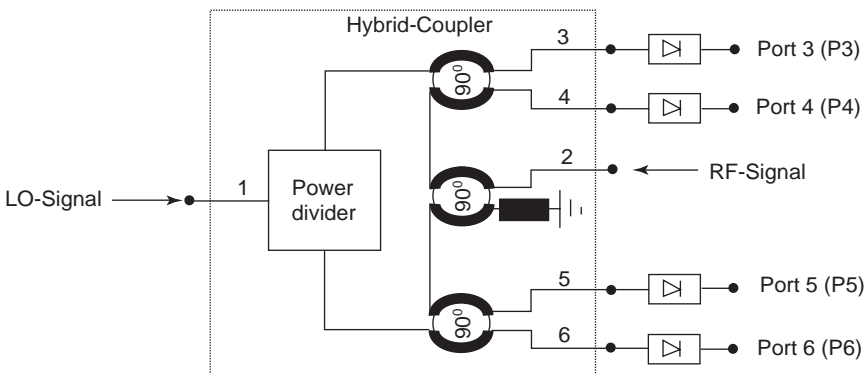

Figure 8. Sampling process in the frequency domain.

where A and B are calibration coefficients to be determined by a suitable method. In the case of QPSK modulation, this can be done by solving eight equations from four known different states. As real six-ports are dependent on the operating frequency, a calibration has to be done for each frequency. Simulation and measurement results for QPSK modulation from 2 to 20 GHz using the same circuit and the described calibration method confirm the broadband operation of the six-port technology [20].

Apart from the described simple method, the so-called dual-tone calibration method is often used [21]. This method has to be applied if there is a relevant leakage from the LO to the RF port as, for example, in reflection coefficient measurements or radar applications.

The advantages and disadvantages of the six-port technology, when compared to conventional heterodyne or zero-IF (ZIF) architectures, strongly depend on the application of interest. First to mention are the additional output paths, which require more LNAs, filters, and ADCs. In real communication standard environments, a DC offset is caused by second-order nonlinearities, which are also present in ZIF receivers and require an additional compensation circuit in each path. In comparison to heterodyne receivers, an image rejection filter and one LO can be saved in a six-port architecture. It should also be mentioned that three output ports in suitable five-port architecture are in principle sufficient to explicitly determine the amplitude and phase. The additional sixth port serves a way as a cyclic redundancy check and extends the

operation bandwidth. This can reduce the hardware effort further with respect to cost of accuracy and bandwidth.

However, the main advantage of the six-port technology is its broadband capability and the possibility for software configuration and calibration. The six-port technology also becomes very attractive when extremely high carrier frequencies at millimeter wavelengths are used. The trend toward higher data rates will make use of new bands: 17, 24, and 60 GHz have been considered. The intrinsic broadband property makes it in principle possible to design RF front-ends operation over more than three decades of bandwidth. Additionally, the same hardware can in general be used for different standards simply by loading suitable baseband processing algorithms. When these software algorithms also become available in the future, extremely broadband six-port RF front-ends might be the technology of choice for SDR platforms. This can help support a certain quality of service (QoS) as different bands and standards can be probed and selected to transmit information in harsh side conditions.

The six-port technique is very well suited for accurately measuring the phase difference of two waves. This makes the principle very attractive for determining the angle of an incident wavefront, which is essential for multiple-input/single-output (MISO) and multiple-input/multiple-output (MIMO) systems. In a simple approach as described in Ref. 19, the LO is replaced by a second antenna and can lead to accurate results in the case where a plane wave at a fixed frequency has to be detected. Modifications including an optimization of the number of input antennas and output ports as well as frequency selection mechanisms are considered and might offer smart six-port-based antennas for digital beamforming, MISO, MIMO, and space diversity compatibility.

4. HIGH-Q MILLIMETER-WAVE FILTERS WITH INTEGRATION CAPABILITY

Important issues in digital microwave receivers are the design and the realization of high-Q filters for planar

integration. Several approaches are known from the literature (Fig. 9):

- Dielectric resonators attain the highest possible Q values but have poor integration capability.
- Use of multiple wafers that are glued or bonded may lead to unloaded Q values up to several hundred. Integration capability depends on the possible use of multiple wafers.
- Use of a single wafer with planar filters usually results in unloaded Q-values that are quite low. If the substrate is 3D-structured, unloaded Q values up to 400 are feasible at center frequencies around 20 GHz.

Three-dimensional structuring of silicon substrates can help provide enough “volume” to obtain high quality factors. In order to avoid multiple wafer bonding or gluing techniques, a tilted waveguide resonator concept is applied with feeding structures of an inductive type. The concept of a microelectromechanical system antialiasing filter (MEMS AAF) is illustrated in Fig. 10. In one realization scheme the silicon material itself is used as dielectric fill material whereas the cavity surrounding is realized by subsequent placing of metallized via holes [23]. Q values of 100 are possible at center frequencies of 22 GHz if high-resistivity silicon is used as the dielectric fill material for the resonator.

An air-filled cavity concept leads to still higher Q values: ≤400 are obtained from a microstrip-coupled resonator operated in a H_{101} resonance. Figure 11 gives an impression from the layout and the realization of a 22.4-GHz microstrip-coupled filter [24].

5. APPLICATIONS: SOFTWARE-DEFINED MULTIPLE-STANDARD TUNER PLATFORM

The number of different audio and video standards is actually increasing. Beside analog audio and video, we have to cope with different digital audio standards such as DAB [Digital Audio Broadcasting (European standard)], IBOC

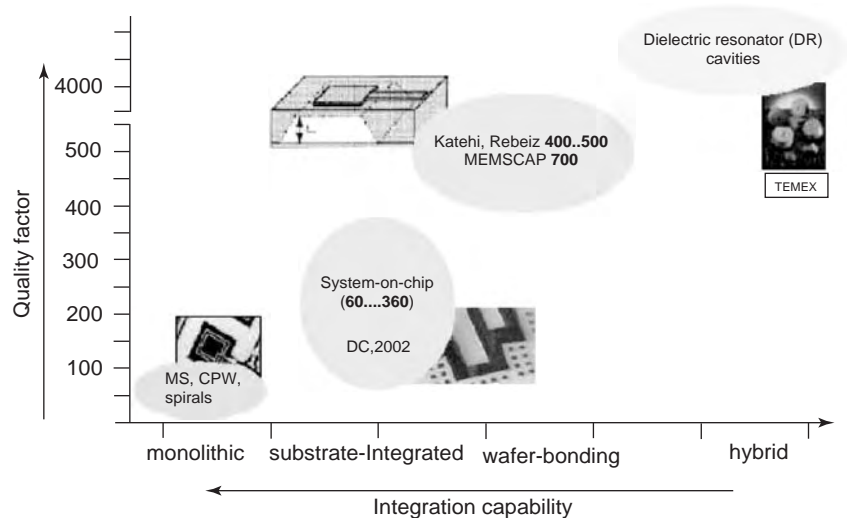

Figure 9. Quality factor versus integration capability of several filter techniques.

Figure 10. Concept of inductively coupled 90° tilted resonator (a) and part of realized version with metallized via holes (b) in high resistivity silicon.

[in-band/on-channel (radio)], DRM [Digital Radio Mondial (international consortium)]. Sirius Satellite Radio, and XM Satellite Radio, beside the new digital video standards such as DVB-T (Digital Video Terrestrial Broadcasting). A realization by parallel implementation of all standards is no longer practical because of size, weight, and power consumption [25]. Therefore a fully software reconfigurable receiver has to handle these standards and be capable of making updates during the receiver lifetime. The principal block diagram is shown in Fig. 12. Two receiver paths are realized to enable antenna diversity for all frequency ranges.

Figure 11. Microstrip-coupled resonator. The length of each side is 9.45 mm.

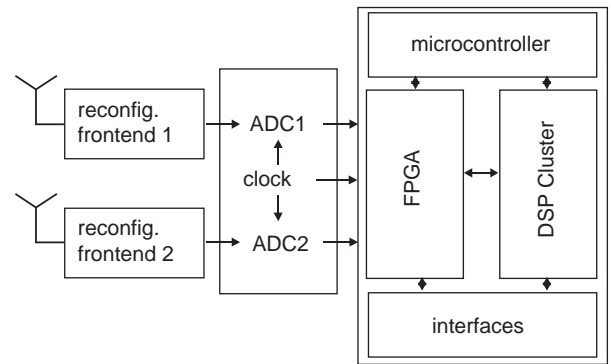

Figure 12. Block diagram of a reconfigurable receiver for automotive applications.

Two independent frontends amplify the signal and realize, if necessary, the downconversion on an IF frequency. In a first realization step the front end is able to handle the FM frequency range from 88 to 108 MHz and the DVB-T frequency range between 470 and 861 MHz. It is possible to extend it to AM/DRM (0.1–10 MHz), DAB (174–230 MHz), and the satellite based digital audio broadcasting services Sirius/XM Sat Radio at 2.3 GHz.

The sampling clock is about 76.8 MHz, so the FM spectrum can be sampled directly and channel selection is performed in the digital domain. Because of limited signal processing power for DVB-T and FM, two different sampling rates are used. For FM the signal is directly sampled so that the wanted signal between 88 and 108 MHz appears at 11.2–31.2 MHz after sampling. The DVB-T signal is mixed down to an IF frequency of 155 MHz and sampled after IF filtering with a sample rate of 48 MHz. The signal will finally appear at 11 MHz.

Direct sampling of the FM signal requires that the ADC be able to handle the whole dynamics of the FM band. Slow fading of the input signal is adapted by digital programmable amplifiers, whereas fast fading must be handled in digital domain.

The main task of the input stages is to suppress out-of-band interferers that may appear in the wanted signal band after sampling. A four-stage filter based on low-cost printed LC resonators is built up and realizes a suppression higher than 80 dB of out-of-band interferers. For FM the highest signal levels can be expected in the wanted signal band so that the filtering fulfills the requirements.

The requirement for the ADC is a signal-to-noise ratio of about 90 dB related to a signal bandwidth of 400 kHz and a spurious-free dynamic range (SFDR) of 95 dB. Particularly regarding the SFDR, care has to be taken when designing the ADC driver stages.

For DVB-T reception, an analog downconverter stage is implemented to achieve a fixed intermediate frequency of 155 MHz. To avoid IF disturbance by the image frequency, an adjustable analog input filter is used. It is based on LC resonators with varactor diodes and can be controlled over a digital to analog converter by the microcontroller. A suppression of more than 80 dB of the image frequency 310 MHz above the used channel is realized. The frequency response is depicted in Fig. 5. After downconversion the

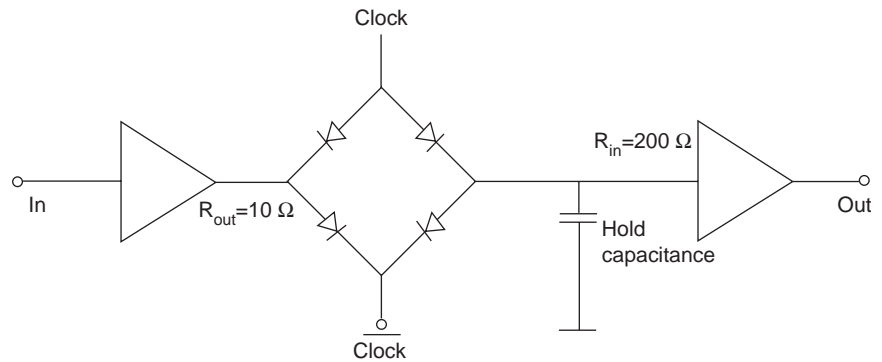

Figure 13. High-frequency sample-and-hold circuit.

amplification can be directly set by the digital signal processing unit to achieve an optimum amplitude at the input of the analog to digital converter.

By using an IF bandwidth of about 10 MHz, all standards in this frequency range can be handled, so it is only a question of digital signal processing to process them.

Because DVB-T uses an 8-channel OFDM modulation scheme, the influence of phase noise of the local oscillator is critical [26,27]. At 100 kHz offset a phase noise of -110 dBc is achieved, which conforms to simulations sufficient for DVB-T.

The complex downconversion and channel filtering is realized in a FPGA (field-programmable gated array). Further signal processing tasks, including demodulation, channel estimation, interleaving, and decoding, are implemented partly in the FPGA and in an array of DSPs.

6. A MILLIMETER-WAVE SAMPLING HEAD

The basic components of a millimeter-wave sampling head are shown in Fig. 13 [28]. The analog RF input signal passes the high- Q MEMS AAF and is then converted to a low impedance level ($<10 \Omega$). The impedance transformer and amplifiers can be realized in commercial SiGe technology for operation frequencies up to 24 GHz [29]. As a switch stage, a silicon millimeter wave integrated circuit (SIMMWIC) Schottky diode quadruple bridge is used [30]. The Schottky diodes have a cutoff frequency of 1.5 THz. The impedance transformer II is again realized in SiGe technology and has to provide a high input impedance level.

7. CONCLUSIONS

Two kinds of digital receivers are discussed in this article: the direct bandpass-limited sampling receiver and the six-port configuration. The sampling architecture poses the highest requirements for the analog-to-digital converter. Bandpass limitation can be used to relax these requirements or to trade against higher resolution of the converter. The bandpass filter makes this approach basically a narrowband solution. The six-port digital receiver is based on a scalar measurement technique that uses multiple detection channels at different points during the

period of a signal, which consists of the signal to be received and a reference signal of the same frequency. As this is an additive rather than a multiplicative mixing process, the system dynamics of a six-port receiver are inferior to, for example, those of a heterodyne or direct conversion receiver. The six-port receiver, however, is basically broadband-capable and does not have to cope with image rejection problems.

Direct narrowband sampling of millimeter-wave signals becomes feasible with silicon-based high-speed integration technologies and high- Q MEMS approaches. If a sampling and clock frequency of 10.66 GHz is applied to a carrier frequency of 24 GHz and a signal with 250 MHz bandwidth is used a resolution of 3 bits is obtained if noise shaping is not applied.

This article presents an overview of digital radiocommunications with emphasis on wireless personal communications. Digital radio consists of two main processes: speech coding (and video coding for future systems) and modulation. In speech coding, the continuous analog voice signal is converted into a discrete digital form. In communication systems that provide digital voice services, it is necessary to encode the analog speech into a digital stream for transmission over the channel and at the receiver, to reconstruct the signal with acceptable fidelity. Modulation, on the other hand, is the process of impressing the discrete digital signal onto a radio signal, by varying some parameter or parameters in combination (usually the amplitude, frequency, or phase) of the radio signal. Digital transmission systems exist in a wide variety of forms, mainly determined by the nature of the channel over which the system operates. A process which is common to many digital transmission systems is regeneration. Typically, the received signal at the input of a repeater (receiver) arrives attenuated and dispersed by the channel and corrupted by noise. The first operation of the receiving repeater, therefore, is to preamplify and shape the weakened signal to a level and form from which a reliable threshold detection may be performed. In a wireless channel, the transmitted signal also undergoes multipath fading and shadowing due to obstructions in the transmission path. To combat the effect of multipath fading, the receiver may employ diversity reception, channel coding, and equalization.

The main objective of wireless personal communication is to allow the user access to the capabilities of the global network at any time and without regards to location and mobility. There has been a tremendous growth in the number of subscribers to wireless services in the last decade. As a result, it became very difficult to operate and maintain the quality of the original first-generation analog cellular systems. As the number of subscribers increases in these systems, call quality diminishes. To handle the increasing traffic, the cellular concept in which identical frequencies at noninterfering distances are reused, was adopted giving rise to more interference in the system. Digital radio, used extensively in second-generation and the evolving third-generation systems, considerably improves the quality of the cellular system and enhances the services available to the mobile subscribers. Some advantages of digital cellular radio include [1,2]:

1. More efficient use of the limited radiofrequency (RF) spectrum to improve system capacity
2. Improving the voice quality beyond what is possible with analog cellular systems, especially maintaining voice quality in heavy traffic conditions and use of voice activity detection to save power and increase throughput

3. Providing support for a wider array of services and features
4. Simplifying the task of frequency planning, operating, and maintaining the cellular system
5. Providing a smooth transition from the analog systems to digital radio systems.

Cordless and cellular telephony have gained widespread user acceptance. Cordless telephones are low-power, low-range phones that enable the user to move around the home or office and still place and receive phone calls. The handsets typically operate within 100 m of the user's base station, which is connected to the public switched telephone network (PSTN). Cordless telephony has evolved from being a simple home appliance to sophisticated systems in applications for universal low-power cordless and telepoint systems aimed at pedestrians, and cordless private branch exchange (PBX). Digital cordless telephone systems (such as CT2, DECT, PHS) are optimized for low-complexity equipment and high-quality speech in a quasistatic (with respect to user mobility) environment. They can support higher data rates and more sophisticated applications.

On the other hand, digital cellular radio, originally targeted at vehicular users in urban areas, was developed to maximize bandwidth efficiency and frequency reuse in a macro-cellular, high-speed fading environment. The first-generation cellular systems are analog systems based mostly on frequency-division multiple access (FDMA) and have very limited capacity and poor to average speech quality. The second-generation cellular systems (e.g., IS-54, GSM, IS-95) are all-digital systems and use more efficient multiple access techniques to share the available spectrum among the users. Although personal communications services (PCS) may be regarded as a third-generation system, its implementation uses modified versions of the cellular protocols used in the second-generation systems. While the first-generation analog and second-generation digital systems are designed to support voice communication with limited data communication capabilities, third-generation systems will focus on providing a wide variety of services which include wireless extensions of integrated services digital network (ISDN) and broadband asynchronous transfer mode (ATM). These systems will concentrate on service quality, system capacity, and terminal and personal mobility issues. They will use a variety of cell structures ranging from the conventional macrocells to microcells for urban areas, picocells for indoor applications, and supercells for satellite-based systems.

1. DIGITAL CELLULAR RADIO

1.1. The Cellular Concept

The continuous increase in the demand for telecommunications services and systems has resulted in spectral congestion. Thus the original one cell system with a high-power transmitter to provide good coverage in a wide service area has quickly become limited in capacity. The cellular concept in which the geographic service area

Figure 1. Frequency reuse.

is divided into small regions (called *cells*), each of which is served by a low-power transmitter (base station), has provided a solution to the spectral congestion problem. Adjacent cells are assigned different frequency channels so that the frequencies can be reused throughout the coverage area, leading to a considerable improvement in system capacity. Figure 1 shows a seven-cell frequency reuse pattern. Although frequency reuse increases system capacity, it also increases the amount of adjacent-channel and co-channel interference present in the system. Therefore, for the efficient utilization of the radio spectrum, the frequency allocation scheme must be optimized to increase capacity and minimize interference. As the traffic grows in the coverage area, new cells and channels can be added to the system. The hexagonal cell structure is usually employed in the design of a cellular system; however, in practice the actual cell coverage area (footprint) is irregular and depends on the terrain and multipath characteristics of the radio channel [3]. As such, there may be some regions within the coverage region where there is exceptionally high likelihood of deep signal fades (called *blindspots*) due to shadowing, tunnels, and other obstructions in the signal path. Blindspots can be overcome by using repeaters that receive the signals selectively in one direction, amplify them, and then retransmit exact replicas of the signals in the required direction. Three types of repeaters may be identified, namely: broadband repeaters, frequency-band-selective repeaters, and channel-selective repeaters [4]. Signal degradation at the cell boundaries is handled by handoff operation.

1.2. Handoff

Handoff encompasses a set of functions that are supported between a mobile user and the cellular network that allows the user to move from one cell to another or one radio channel to another, within or between cells, while a call is in progress. When a mobile user is engaged in a call, it will frequently move out of the coverage area of the base station with which it is communicating, and unless the call is passed to another base station, the call will be lost. Thus, the system continuously monitors the quality of the

signals received from the active mobile users. When the signal falls below a preset threshold the system checks whether another base station can receive the mobile user at a better signal level, and if so, the mobile user is commanded by a control signal to switch to the new frequency (corresponding to the new base station). Although the process of measuring the signal quality, channel allocation, and handoff may take a few seconds, there should not be any noticeable break in conversation of the mobile user. Effective and reliable handoff is essential in controlling cochannel interference, especially for microcellular systems.

1.3. The Cellular Network

The structure of all cellular networks is essentially similar. Being complete telephone networks, they have dedicated exchanges within the interconnected system with base stations connected to the exchanges. In practice, however, there are different ways of planning the network depending on the capacity requirement, implementation cost, and capabilities of the chosen manufacturer's equipment. As shown in Fig. 2, a typical cellular system consists of mobile stations, base stations, and a mobile switching center (MSC). Each mobile unit contains a transceiver, antenna, and control circuitry and may be handheld or mounted in a vehicle. The communication between the mobile station and the base station is defined by a standard *air interface*. Each cell in the coverage area is served with one or more base stations that are connected to the MSC. The MSC, in turn, coordinates the activities of the

base stations and connects them via microwave or fiber links to the public switched telephone network (PSTN) which forms the global telecommunications network that connects wireline telephone switching centers (called central offices) to MSCs throughout the world.

1.4. Multiple-Access Schemes

Multiple-access techniques are utilized to accommodate multiple users in the available channels. The multiple access scheme controls the allocation of the channel capacity to the users. The allocation scheme is chosen to maximize the spectral efficiency and minimize transmission delay in the system. Other desirable properties of the multiple-access scheme include fairness of the allocation process, stability of the system, robustness with respect to equipment failure and changing conditions of other users in the system, and flexibility in allowing the integration of voice and data traffic. In addition, in a wireless mobile communication environment, the hidden terminal problem and near-far effect, the effects of multipath fading and shadowing, as well as the effects of cochannel and adjacent channel interference must also be considered. The commonly used multiple-access schemes in cellular systems are frequency-division multiple access (FDMA), time-division multiple access (TDMA), and code-division multiple access (CDMA). In FDMA, the available bandwidth is divided into channels that are assigned to the users on demand and each user uses the channel for the entire duration of the transmission. Frequency guardbands are provided at the edges of the band to minimize crosstalk. Although FDMA has relatively low complexity, requires few overhead bits (for synchronization and framing), and usually does not require equalization since the effect of intersymbol interference (ISI) is minimal, it is wasteful because only a fixed number of users (channels) can be supported and when a channel is not being used it remains idle. Furthermore, FDMA requires very tight filtering to minimize adjacent channel interference and intermodulation. In TDMA systems, the usage of each frequency channel is partitioned into multiple time slots, and each user is assigned a specific frequency-timeslot combination. Thus, in a given cell only a single mobile user uses the entire frequency at any given time. Although TDMA has the disadvantages of requiring synchronization (as well as overhead for guard timeslots) and equalization and can also be wasteful, it permits the use of flexible bit rates and may be used for bursty transmission to save power. Another major advantage of TDMA (over FDMA) arises from the fact that by transmitting and receiving in different time slots it may be possible to eliminate the duplexer circuitry in the mobile unit, replacing it with a fast-switching circuit that turns the transmitter and the receiver on and off at the appropriate times, thus prolonging the battery life of the handsets. Also, TDMA-based systems tend to be more flexible and more open to technological change. Thus, with improvements in speech coding algorithms, a TDMA channel is more easily reconfigurable to accept new techniques supporting higher, lower, or variable bit rates, without disrupting the frequency plan of the cellular network. With CDMA (which uses direct-sequence

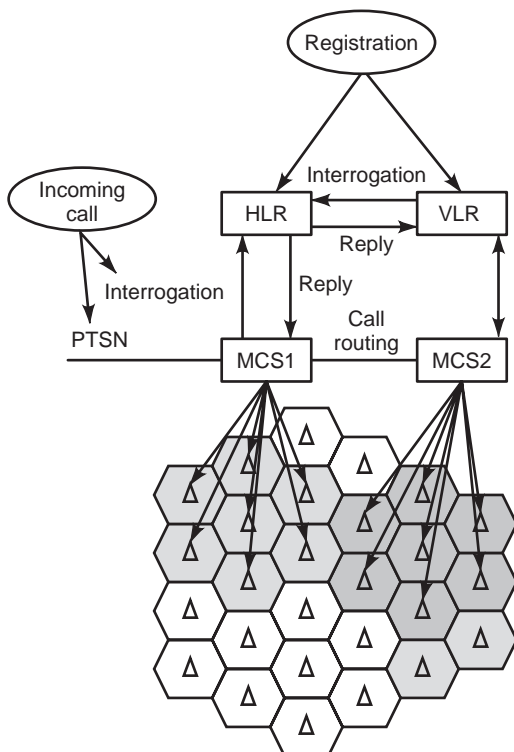

Figure 2. The cellular network.

spreading), a frequency channel is shared simultaneously by multiple users in a given cell, and the signals are distinguished by spreading them with different codes. CDMA has the advantage of offering multipath immunity and interference rejection and provides a graceful performance degradation as the number of users in the system increases. However, CDMA is susceptible to the near-far problem and requires power control [3]. Figure 3 illustrates the three commonly used multiple access schemes in cellular networks.

In general, digital systems can support more users per base station per megahertz of spectrum, allowing wireless system operators to provide service in high-density areas more economically. The use of TDMA or CDMA digital architecture provides the additional advantage of sharing the radio hardware in the base station among the multiple users. It offers flexibility for mixing voice/data communication and the support of new services. A potential for further capacity increases is also possible with the use of reduced-rate speech coders. Furthermore, reduced RF transmit power (increasing battery life of handsets) and the use of encryption for communication privacy, are possible. It offers a more natural integration with the evolving digital wireline network and reduced system complexity (mobile-assisted handoffs, fewer radio transceivers, etc.). While the second-generation cellular systems are based on digital transmission, some of them are designed to coexist with their analog counterparts, while all the evolving third-generation cellular and PCS systems use digital transmission.

In wireless communications systems, it is usually desirable for the subscriber to simultaneously send information to the base station while receiving information from the base station. The process whereby the subscriber can transmit and receive information simultaneously is known as *duplexing*. The two most commonly used duplexing techniques are frequency-division duplexing (FDD) and time-division duplexing (TDD). In FDD, the forward link (base-to-mobile station) and the reverse link (mobile-to-base station) transmissions are done simultaneously on different frequency channels. In this case, a

device called a *duplexer* is used inside each subscriber unit and base station to allow the simultaneous signal transmission and reception on the duplex channel pair. In TDD systems, the same frequency band is used in both the forward and the reverse links but it is required that the transmissions in different directions occur in different time slots.

A performance measure that is commonly used to characterize a digital radio system is the spectral efficiency. The spectral efficiency of a digital radio system E_s is defined as [5]

$$E_s = \frac{\eta_c}{WCA_c} \text{ (erlangs/MHz/km}^2\text{)} \quad (1)$$

where η_c is the carried traffic per channel in erlang, W is the channel bandwidth in MHz, A_c is the cell area in km^2 , and C is the cluster size (number of cells in a reuse cluster).

1.5. Speech Coding

In wireless systems that provide digital voice services, there is the need to encode the analog speech signal into a digital stream for transmission over the channel (air interface). At the receiver, the signal is reconstructed with acceptable fidelity. There are several major parameters to consider in choosing a speech coding scheme for wireless application. These include the transmitted bit rate (kbps), the delivered speech quality, robustness to transmission errors, and complexity of implementation of the chosen scheme. Available speech coding techniques may be classified into three main categories: waveform coding, model-based coding, and hybrid techniques. Waveform coding techniques are usually the simplest to implement and their implementation may be done in either the time domain or the frequency domain. At the transmitter, the analog speech is sampled, quantized, and encoded into digital stream for transmission. At the receiver, a decoder reconstructs the original speech signal. The coder-decoder combination is commonly referred to as a *codec*. Waveform

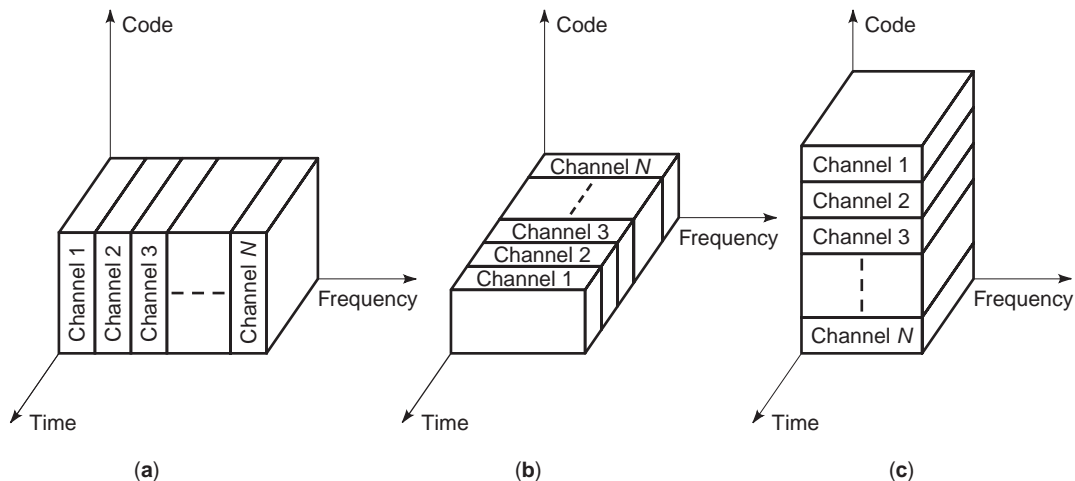

Figure 3. Multiple-access techniques: (a) FDMA; (b) TDMA; (c) CDMA.

speech coding techniques implemented in the time domain include pulse-code modulation (PCM), differential PCM (DPCM), delta modulation (DM), and adaptive predictive coding (APC). One form of delta modulation known as digitally variable slope delta modulation (DVSDM) is used in the second-generation UK cordless telephone system (CT2) because of its implementational simplicity and low cost, but to some extent sacrificing voice quality. When waveform coding is implemented in frequency-domain, the speech signal is filtered into contiguous, nonoverlapping sub-bands encoded independently using time-domain techniques. Examples include subband coding (SBC) and adaptive transform coding (ATC) schemes. In model-based speech coding techniques, signal processing algorithms are used to extract and transmit certain parameters from the analog speech waveform that correspond to the actual time-varying parameters of the speech production mechanism in the human vocal tract (modeled as an electric filter). Thus the algorithms, which are usually called *vocoders*, attempt to describe the speech production mechanism in terms of a few independent parameters used as the information-bearing signals. At the receiver, the received parameters are decoded and used to control a speech synthesizer that is an algorithmic representation of the speech generation model, thereby approximating the original speech signal. Vocoders are medium complexity systems and operate at low bit rates. Their poor speech quality may be attributed to the oversimplified source models used and the assumption that the source and the filter are independent. The poor and synthetic quality of speech vocoders has led to the speech coding approach known as *residual excitation*. In this approach, the speech is synthesized, but a small part is transmitted as a coded waveform part and another as a vocoded part; hence the name *hybrid*. The penalty is the higher bit rate of transmission required, but now a very much improved speech quality is realized. Examples of model-based speech coding schemes that are often used in wireless applications include linear predictive coder (LPC) which usually requires some form of error correction coding when used in wireless channels, long term predictors that include multipulse excitation (MPE-LPT) and regular pulse excitation (RPE-LPT), code-excited linear predictive (CELP) coder and quadrature code-excited linear predictive (QCELP) speech coding schemes, and residual-excited linear predictive coding (RELPC). Table 1 summarizes the

speech coding specification for some cordless and cellular systems [3].

1.6. Modulation Techniques

Many modern mobile communications systems use digital modulation techniques as they offer the advantages of greater noise immunity and robustness to channel impairments, easier multiplexing and integration of different types of information (e.g., voice, data, and video), and greater security over their analog counterparts. Digital modulation also allows the use of source coding, error control coding, encryption, and equalization to improve the performance of the overall system. New advances in very-large-scale integration (VLSI) and digital signal processing (DSP) technology have also improved the effectiveness of the digital modulation schemes used in wireless communications systems. The choice of a digital modulation scheme for use in a wireless environment is influenced by several factors. A desirable modulation scheme provides low bit error rates at low received signal-to-noise ratios, occupies a minimum bandwidth, performs well in a multipath fading environment, and is easy and cost-effective to implement. Since the existing modulation techniques do not simultaneously possess all of these qualities, tradeoffs are often made in a modulation scheme for a particular wireless application. The performance of a digital modulation scheme is usually measured in terms of power efficiency and bandwidth efficiency. *Power efficiency* describes the ability of the modulation scheme to preserve the fidelity of the digital message at low power levels. It is usually expressed as the amount of power (usually given as the ratio of the signal energy per bit to noise power spectral density, E_b/N_0) required at the input of the receiver to achieve a specified probability of error. *Bandwidth efficiency* describes the ability of the modulation scheme to accommodate data within a limited bandwidth. It is defined as the ratio of the throughput data rate per hertz in a given bandwidth and directly reflects how effectively the allocated bandwidth is utilized. While power and bandwidth considerations are very important, other factors must also be considered in choosing a modulation scheme for a wireless application. For example, cellular systems are usually interference-limited and the performance of the modulation scheme in an interference environment is also important. The sensitivity of the receiver to timing

Table 1. Speech Coder Used in Various Digital Radio Systems

Standard	Service Type	Speech Coder Type Used	Bit Rate (kbps)
GSM	Cellular	RPE-LTP	13
CD-900	Cellular	SBC	16
USDC (IS-54)	Cellular	VSELP	8
IS-95	Cellular	CELP	1.2, 2.4, 4.8, 9.6
IS-95 PCS	PCS	CELP	14.4
PDC	Cellular	VSELP	4.5, 6.7, 11.2
CT2	Cordless	ADPCM	32
DECT	Cordless	ADPCM	32
PHS	Cordless	ADPCM	32
DCS-1800	PCS	RPE-LTP	13
PACS	PCS	ADPCM	32

jitters caused by the time-varying channel is an important consideration. For personal communications systems that serve a large number of subscribers in the service area, a modulation scheme that allows a simple yet efficient detector is desirable in order to minimize the cost and complexity of the subscriber receiver unit. Digital modulation schemes may be classified as linear or nonlinear.

In a linear modulation scheme, the transmitted signal may be expressed as

$$\begin{aligned} \phi(t) &= \text{Re}\{A f(t) \exp(j\omega_c t)\} \\ &= A[f_a(t) \cos(\omega_c t) - f_b(t) \sin(\omega_c t)] \end{aligned} \tag{2}$$

where A is the amplitude, $\omega_c = 2\pi f_c$ is the angular carrier frequency, f_c is the carrier frequency, and $f(t) = f_a(t) + j f_b(t)$ is the complex envelope representation of the modulating signal. Linear modulation techniques have good bandwidth efficiency and are attractive for wireless communication systems where there is increasing demand to accommodate more and more subscribers within a limited bandwidth. However, linear modulation schemes are usually transmitted using RF amplifiers, which have poor power efficiency. The use of power efficient amplifiers leads to the regeneration of filtered sidelobes causing severe adjacent-channel interference. A number of techniques have been developed to handle this problem in practice. Examples of linear modulation schemes that are commonly used in practical mobile applications include binary phase shift keying (BPSK), quadrature phase shift keying (QPSK), offset QPSK, and $\pi/4$ QPSK. Coherent detection uses the carrier frequency and phase information to provide optimum detection. It is well known that when coherent detection is used at the receiver the bit error rate performance of BPSK in an additive white Gaussian noise (AWGN) channel is given by

$$P_{E,BPSK}(\gamma) = Q(\sqrt{2\gamma_b}) \tag{3}$$

where

$$Q(t) = \frac{1}{\sqrt{2\pi}} \int_t^\infty \exp(-x^2/2) dx$$

$\gamma_b = \gamma^2(E_b/N_0)$ and γ is the random attenuation factor due to channel fading. The average bit error rate is then obtained by averaging Eq. (3) over the probability density function of γ^2 , $p(\gamma)$:

$$\int_0^\infty P_{E,BPSK}(\gamma) p(\gamma) d\gamma \tag{4}$$

In a Rayleigh fading environment, we have

$$p(\gamma) = \frac{1}{\gamma} e^{-\gamma/\bar{\gamma}} \tag{5}$$

and the average bit error rate can be shown to be given by

$$\bar{P}_{E,BPSK} = \frac{1}{2} \left(1 - \sqrt{\frac{\bar{\gamma}}{1+\bar{\gamma}}} \right) \tag{6}$$

where $\bar{\gamma} = E(\gamma_b) = (E_b/N_0)E(\gamma^2)$ is the average signal-to-noise ratio. In practice, the carrier phase information may not be known precisely or may be random (due to channel fluctuations). In such cases, differentially coherent detection may be employed. The probability of error for differential PSK in AWGN is

$$P_{E,DPSK} = \frac{1}{2} \exp(-\gamma_b) \tag{7}$$

while the average bit error rate can be shown to be given by

$$\bar{P}_{E,DPSK} = \frac{1}{2(1+\bar{\gamma})} \tag{8}$$

The bit error rate performance of QPSK is similar to that of BPSK. However, QPSK comprises two orthogonal BPSK signals and thus has the advantage of providing twice the spectral efficiency of BPSK with the same energy. As such, twice as much data can be transmitted in the same bandwidth. QPSK ideally has a constant amplitude property but occasional π -radian phase shifts momentarily cause the signal envelope of filtered QPSK to pass through zero. This causes serious problems when QPSK is used in mobile/satellite applications with nonlinear amplification because of interference from the sidelobes. OQPSK is a modified version of QPSK in which π -radian phase shifts do not occur. Although OQPSK has the same signal constellation and, therefore, same bit error performance as QPSK, it is not susceptible to adjacent channel interference caused by the regeneration of sidelobes. In $\pi/4$ QPSK the maximum phase transition of 135° is a compromise between the 180° phase transition of QPSK and 90° for OQPSK. Noncoherent detection can be used to demodulate a $\pi/4$ QPSK signal and can provide better performance in a multipath fading environment than OQPSK. Thus $\pi/4$ QPSK has the same performance (bit error rate and spectral efficiency) as QPSK but has less amplitude fluctuation. $\pi/4$ QPSK has been adopted in the North American digital standard (IS-54), the Japanese digital cellular and the Trans European Trunked Radio [3].

Nonlinear modulation techniques have constant envelope so that power efficient class C amplifiers can be used without introducing degradation in the spectrum occupied by the transmitted signal, but they usually occupy larger bandwidths than do linear modulation schemes. Examples of constant-envelope modulation schemes that are frequently used in mobile communication applications are frequency shift keying (FSK), minimum shift keying (MSK), and Gaussian minimum shift keying (GMSK). In binary FSK, the transmitted signal of bit duration T_b may be expressed as

$$f_k(t) = \sqrt{\frac{2E_b}{T_b}} \cos \omega_k t, \quad 0 \leq t \leq T_b \tag{9}$$

when the binary digit $k(k=0, 1)$ is transmitted, where $\omega_0 - \omega_1 = 2n\pi/T_b$ and n is an integer. The average probability of error of the optimum coherent detector in a Rayleigh fading channel corrupted by AWGN can be shown to be given by

$$\bar{P}_{E,\text{CFSK}} = \frac{1}{2} \left(1 - \sqrt{\frac{\bar{\gamma}}{2 + \bar{\gamma}}} \right) \quad (10)$$

while it is

$$P_{E,\text{NCFSK}} = \frac{1}{2 + \bar{\gamma}} \quad (11)$$

for a noncoherent detector. The phase information in FSK signal is not properly utilized at the receiver except for synchronization. MSK is a special case of *continuous phase* FSK (CPFSK) in which the peak frequency deviation is half the bit rate. Thus, MSK may be regarded as a special case of OQPSK with the rectangular pulseshaping replaced by half-sinusoidal pulse shaping. Thus, like OQPSK, MSK has a constant envelope but the phase transitions are continuous. Also, an MSK signal (like an FSK signal) can be demodulated coherently or noncoherently. Finally, GMSK may be regarded as a special case of MSK in which the sinusoidal weighting function is replaced by a Gaussian shaped pulse. GMSK also has constant envelope and excellent spectral efficiency. The average bit error rate of coherently demodulated MSK (and GMSK) in Rayleigh fading channel may be shown to be given by [3]

$$P_{E,\text{MSK}} = \frac{1}{2} \left(1 - \sqrt{\frac{\eta\bar{\gamma}}{1 + \eta\bar{\gamma}}} \right) \quad (12)$$

where η is a constant that depends on the product of the demodulator 3 dB bandwidth and the symbol duration (BT) and is given by

$$\eta \cong \begin{cases} 0.68, & \text{for GMSK (BT} = 0.25) \\ 0.85, & \text{for MSK (BT} = \infty) \end{cases} \quad (13)$$

GMSK has been adopted for use in GSM, DECT, and U.S. cellular packet data (CDPD).

2. CHANNEL PROPAGATION

The performance of a wireless communications system is limited by the nature of the mobile radio channel. The transmission path between the transmitter and the receiver usually varies as a result of obstructions from buildings, mountains, and foliage and also as a result of variations in the atmosphere. Thus, electromagnetic wave propagation is usually influenced by the mechanisms of reflection, refraction, and scattering. Multiple reflections cause the transmitted signal to travel along different paths of varying lengths and attenuations, and the interactions of these waves at the receiver location causes multipath fading. Notwithstanding the multipath

fading, the long-term average strength of the received signal decreases as the separation between the transmitter and the receiver increases.

2.1. Channel Propagation Models

Propagation models to characterize the mobile channel can usually be classified into two groups, depending on whether they focus on predicting the average received signal strength (*large-scale* models) or the variability of the received signal (*small-scale* models) at a given distance from the transmitter. Large-scale propagation models based on measurements of actual channels indicate that the mobile radio channel may be characterized by the fourth-power loss model [6]:

$$P_r = \frac{P_t V}{d^\alpha} \quad (14)$$

where P_r is the average received power, P_t is the average transmitted power, d is the distance between the mobile and the base station, α is the exponent of power attenuation ($\alpha \approx 4$, for macrocells), and V is a random variable whose decibel value can be modeled by a zero-mean Gaussian variable (i.e., V is *lognormal*) with standard deviation in the range of 6–12 dB. The propagation in an urban microcellular channel with a line-of-sight (LoS) may be characterized by the following dual-slope path loss model [6]

$$P_r = \frac{P_t V}{d^{\alpha_1} \left(1 + \frac{d}{d_0} \right)^{\alpha_2}} \quad (15)$$

where α_1 and α_2 are the attenuation exponents, and $d_0 = 4h_t h_r / \lambda$, where λ is the transmission wavelength and h_t and h_r are the transmitting and receiving antenna heights, respectively. The decibel standard deviation of the lognormal random variable V is now on the order of 3 dB. Measurements in several urban environments indicate that for small transmitting and receiving antenna heights ($h_t = h_r \approx 3.7$ m), $\alpha_1 \approx 2.2$ and $\alpha_2 \approx 3.3$. For medium antenna heights (about 8.5 m), $\alpha_1 \approx 2.2$ and $\alpha_2 \approx 3.4$ and for large antenna heights, $\alpha_1 \approx 2.1$ and $\alpha_2 \approx 4.2$ [3].

On the other hand, small-scale multipath propagation causes rapid fluctuations in signal strength (fading) over small distances or time intervals. Small-scale propagation is also influenced by Doppler shifts caused by relative motion between the transmitter and the receiver, and by the time dispersion caused by the multipath propagation delays. Time dispersion due to multipath propagation causes the transmitted signal to undergo either *flat* or *frequency-selective* fading. The Rayleigh and Rice probability density functions are commonly used to model envelope fluctuations in a flat-fading channel when there is no direct transmission path between the transmitter and the receiver and when a LoS component is present, respectively. The Nakagami m distribution is a more general model that has been shown to provide a better match to envelope measurements in different mobile radio environments than the Rayleigh and Rice distributions. The Rayleigh

distribution is a special case of the Nakagami distribution, while the Rice distribution can be approximated by the Nakagami distribution for a large range of mean signal-to-noise ratio values.

2.2. Combating Multipath Fading

Two major causes of performance degradation in wireless systems are multipath fading and shadowing. There are three ways to combat the effects of fading in these systems: diversity reception, channel coding, and equalization. Diversity reception techniques are used extensively on multipath fading radio channels to reduce the effect of fading on system performance, including both fixed and mobile terminals. In diversity reception, several replicas of the transmitted signal, each carrying the same information and undergoing independent fading, are combined at the receiver. The diversity may be obtained in time, frequency, or space. There are several ways that the receiver may combine the received diversity signals for optimum performance. Three of the commonly used linear combining schemes are maximal-ratio combining (MRC), equal-gain combining (EGC), and selection diversity combining (SDC). *Microscopic diversity* reduces the effect of instantaneous short-term (or small-scale) fading by combining several uncorrelated signals received at the radio port using any of the combining methods. *Macroscopic diversity* mitigates the effect of long-term (or large-scale) shadowing by using several geographically distributed base stations to serve each cell. The base station with the largest average local mean signal power is usually selected [5,7]. Figure 4 shows the diversity gain obtained by using MRC microscopic diversity reception in detecting BPSK signals in a Rayleigh fading channel. We observe from the figure that with a coherent detector at the receiver, in order to obtain an error rate of 10^{-3} , the receiver requires a signal-to-noise ratio (SNR) of 24 dB when there is no diversity ($L=1$), but only 11 dB with dual-branch diversity ($L=2$) and 4 dB with fourth-order ($L=4$) diversity. The

Figure 4. Average bit error rate for a BPSK system with L -branch microscopic MRC diversity in a Rayleigh fading channel.

Figure 5. Average bit error rate for a BPSK system with macroscopic selection diversity (and dual-branch microscopic MRC diversity) in a shadowed Rayleigh fading channel.

performance of DPSK is about 3 dB inferior to that of coherent PSK. In Fig. 5, the effect of macroscopic selection diversity is shown, with the lognormal shadowing assumed to have a decibel standard deviation of 6 dB. At a bit error rate of 10^{-3} and with dual order microscopic diversity, macroscopic diversity of order 3 ($N=3$) provides about 5 dB improvement over the system with no macroscopic diversity ($N=1$).

In channel coding schemes, extra bits (with no message) are added to the information bitstream before being transmitted over the channel. At the receiver, the added redundant bits are used to detect/correct errors that may have occurred in the bitstream. Channel error control techniques used in wireless channels may be classified into three groups, namely: error detection coding (the most commonly used error detection scheme is the cyclic redundancy check (CRC) codes because they are very easy to implement using shift registers), forward error correction (FEC) coding (using block or convolutional codes), and automatic repeat request (ARQ) transmission protocols. The amount of diversity gain introduced by channel coding depends on the minimum distance of the code. The addition (and interleaving) of redundant bits into the data bitstreams in the channel coding process gives rise to time or frequency diversity and improves the resistance of the system to multipath fading.

The time-variant multipath channel after exhibits bursty error characteristics. By the process of interleaving, the bursty channel can be transformed into a channel having independent errors by spreading the coded data over several timeslots. Interleaving is used extensively in the second-generation digital cellular systems.

A very serious problem in high-data-rate transmission systems is intersymbol interference (ISI) caused by frequency-selective multipath fading. In this case, increasing the transmission power worsens the problem because the interference power increases. Signal processing techniques (known as equalization) may be used to minimize

the effect of ISI. In wireless applications, *adaptive* equalization is used since the mobile channel is random and time-varying. The operation of an equalizer usually involves the transmission of a known, fixed-length training sequence to set the parameters of the equalizer at the receiver. New algorithms, called "blind equalization," which do not require training sequences, are currently under research. During data transmission, the adaptive equalizer uses recursive algorithms to evaluate the channel and estimate the filter coefficients that are used to compensate for the channel distortions. Adaptive equalizers can be classified as linear or nonlinear depending on how the equalizer output is used for subsequent control (feedback) of the equalizer.

3. WIRELESS TRANSCEIVER STRUCTURE

The complexity of radiocommunication systems is increasing significantly with the application of more sophisticated multiple access and digital modulation techniques that are necessary in order to accommodate the tremendous growth in the number of subscribers of wireless communication services. Advances in wireless technology and new applications for wireless systems and services have given rise to a variety of portable voice, data, and messaging systems. The development of low-rate digital speech coding techniques and the continuous increase in the device density of integrated circuits have led to completely digital second-generation cellular systems. Also, the evolving third-generation cordless, cellular, and PCS systems are all expected to be fully digital. Digital signal processing (DSP) techniques traditionally used for speech and channel codecs are presently being used extensively for advanced digital communications transceiver design. In addition to speech and channel codecs, these techniques are also being used for detection and demodulation, equalization, frequency synthesis, and channel filtering.

3.1. Radio Receiver Principles

A considerable amount of computing resources are necessary to achieve the performance desired for personal communication systems and the required power needed to drive the constituent units of the system may be prohibitive for portable applications. Thus, the key requirements for wireless portable terminals are performance, cost, power consumption, and size. Low power consumption may be achieved through technology and system-level tradeoffs. The receiver power is consumed by the RF components, baseband DSP, digital application-specific integrated circuits (ASICs), and mixed signal devices. At the system level, power consumption may be optimized by proper choice of system operations such as time-division multiplexing and voice-activity detection. For example, many digital processors feature powerdown modes that allow turning off peripheral and certain computational units. One drawback of such method, however, is that it does not always allow for fast rampups. In a wireless environment, the receiver may have to process very low desired signal levels in the presence of large levels of

unwanted signals. Therefore, the architecture used in the receiver front end must satisfy requirements such as sensitivity, dynamic range, selectivity, and manufacturability. Radio receiver principles that may be used include the superheterodyne principle, digital receivers with DSP techniques, and direct-conversion receivers [8].

In a direct-conversion receiver, the received RF signal is filtered in a duplexer, and passed through a low-noise amplifier followed by a bandpass filter. The output of the filter is then split and, along with two local oscillators in phase quadrature at the carrier frequency, are fed to a quadrature mixer. The outputs of the quadrature mixer are then passed through a lowpass filter followed by analog-digital (A/D) conversion to produce the in-phase (I) and quadrature (Q) samples. Since the receiver processes the full RF spectrum at baseband, this architecture requires high dynamic range, high sensitivity, low noise, as well as proper amplitude and phase balancing between the I and Q branches. The main advantage of the direct-conversion architecture is its simplicity as it has a low component count. It also has a wide tuning range and high selectivity. However, a number of challenges are present in its realization. For example, a high-gain low-noise mixer is necessary to combat the $1/f$ amplifier noise at baseband as well as a technique to cancel the associated large DC-offset. The direct-conversion receiver architecture is used in a number of cellular and wireless products. For example, a radio receiver that incorporates direct-conversion into an integrated circuit in a way that avoids the need for discrete intermediate frequency filters and is particularly suitable for use in wireless devices has been proposed [9]. Also, FSK paging receivers at 450 MHz and 930 MHz as well as some 900 MHz wireless LAN products are available.

3.2. Miniaturization

Wireless personal communication devices such as pagers and cellular and cordless telephones are becoming more compact and more light weight as a result of improvements in device-mounting technology and development of different kinds of devices. By using advanced very large-scale integration (VLSI) technology, the implementation of complex algorithms is economically feasible. The use of complementary metal-oxide semiconductor (CMOS) device scaling technology has facilitated the employment of denser and faster memory chips as well as digital microprocessors. Rapid advances in solid-state integrated circuit technology have fueled the growth of commercial wireless communication systems with the desire to produce high-performance, low-power, small-size, low-cost, and high-efficiency devices. The increasing use of integrated circuits in radio designs has resulted in significant improvements in the reliability and performance of the digital receivers. Rapid advances in packaging technology resulting in compact designs of wireless terminals as well as considerable drops in manufacturing costs resulting from improved procedures in assembly and testing have also increased the deployment of these devices.

3.3. Design Tools

The lifecycles of many cellular and cordless products are very short. As such, in order to compete successfully, companies must turn system concepts into silicon VLSI very rapidly. High-quality computer-aided design tools are therefore very important for efficient design, simulation, and realization of the systems. The design methodology used in these tools must be chosen to allow different levels of abstraction at different points in the timescale. The algorithms used in these design tools are usually comprehensively specified with block diagrams that are specified hierarchically, with each block representing a signal processing operation. The blocks are usually parameterized so that automatic evaluation of the different simulations can be done based on the block diagrams. Depending on the digital communication system involved, multirate and variable-rate processing may be supported. Two simulation approaches that are available in practical design tools are the data-flow-oriented approach (e.g., COSSAP from Synopsys) and the time-driven approach (e.g., SPW from Candence) [10]. In addition to the algorithmic simulations, the architecture of the digital communication system also needs to be simulated. The simulation of the architecture may be software-based or hardware-based.

4. OVERVIEW OF DIGITAL RADIO SYSTEMS

4.1. Digital Cellular Systems

Digitization allows the use of TDMA and CDMA over FDMA as multiple-access alternatives. The North American Digital Cellular systems have evolved into two *Interim Standards*, one based on TDMA (IS-54) and the other based on CDMA (IS-95). The Global System for Mobile communication (GSM) as well as the Japanese Pacific Digital Cellular (PDC) system (which is very similar to the IS-54 system) are also based on TDMA while the Broadband-CDMA (IS-665) system is a specialized CDMA system [3,5,11].

4.1.1. North American Digital Cellular Systems. The development of a digital cellular standard in North America came as a result of tremendous increase in the demand for cellular services. The capacity of the first-generation analog advanced mobile phone system (AMPS) was limited, and there was no new spectrum available to meet the increased demand. Therefore, the objective of the second-generation systems was not only to increase the capacity of the existing spectrum but also to provide additional services. The Cellular Telecommunications Industry Association (CTIA) which consists mainly of cellular service providers and the Telecommunication Industry Association (TIA) consisting of equipment manufacturers established a technical committee to develop a digital standard. Finally, in 1989, the industry adopted the dual-mode transmission standard, which is referred to as the Electronics Industry Association Interim Standard 54.

4.1.2. TDMA System (IS-54). This is an all-digital second-generation cellular system that was designed to

coexist with and eventually replace the first-generation analog cellular system. On the forward link, the spectrum allocation for IS-54 is 824–849 MHz while on the reverse link it is 869–894 MHz. The modulation scheme used is differential quadrature phase shift keying (DQPSK) with $\pi/4$ radians phase shift between successive symbols, to reduce amplitude fluctuations in the signal envelope. However, as it is a linear modulation scheme, it has poor power efficiency resulting in larger size and weight of the handset. Each TDMA frame has 6 timeslots of 324 bits each, with a framelength of 40 ms, giving a bit rate of 48.6 kbps. Since the channel spacing is 30 kHz, the resulting bandwidth efficiency of 1.62 bps/Hz is relatively high. The speech coder is VSELP operating at 7.95 kbps and produces a speech frame every 20 ms (or 159 bits every second). Of these, the leading 77 bits of each frame are protected with error control coding and the remaining 82 bits are unprotected, resulting in 260 channel bits per frame. Thus the full-rate coder results in a transmitted data rate of 13 kbps.

4.1.3. CDMA System (IS-95). This system is based on direct-sequence CDMA (DSSSS) and was proposed by Qualcomm in 1989 and adopted in 1993. IS-95 was also designed to be compatible with the AMPS. The spectrum allocation for IS-95 on the forward link is 824–849 MHz, while it is 869–894 MHz on the reverse link. With an allowable bandwidth of 1.25 MHz, it uses a direct-sequence spread-spectrum signal with chip rate 1.228 Mbps. The speech coder used is QCELP with variable rates (ranging from 1200 to 9600 bps) determined by the accompanying voice activity detector. Block interleaving with duration 20 ms provides time diversity while the wide bandwidth allows for frequency diversity and multipath (rake) diversity, making the system robust to multipath fading. Different modulation and spreading techniques are employed on the forward and reverse links. On the forward link, BPSK modulation is used with QPSK spreading. For a single user, either form of modulation yields the same performance, but in a multiple-access environment the use of QPSK spreading randomizes the phase of the desired user relative to the other users in the system giving rise to much less phase degradation for the desired user. Although the 64×64 Hadamard matrix used may allow 64 users in a cell, only 61 Walsh codes are available since the remaining codes are reserved for the pilot, synchronization, and paging channels. Also, on the forward channel, many user signals are multiplexed and transmitted to multiple users, allowing a common pilot signal to be inserted for all the users. Therefore, coherent demodulation is possible on the forward link. On the reverse link, on the other hand, since the users operate asynchronously and are power controlled, no pilot signal is transmitted by the mobile users. Therefore, noncoherent M -ary ($M=64$) orthogonal modulation/demodulation, which is power efficient, is employed on the reverse link.

IS-95 is modified in the following ways in order to support higher data rates for better speech quality at PCS

frequencies:

1. On the reverse link, the convolutional code rate is changed from $\frac{1}{3}$ to $\frac{1}{2}$.
2. On the forward link, the convolutional code rate is changed from $\frac{1}{2}$ to $\frac{3}{4}$.
3. The standard QCELP speech coder is replaced by QCELP13, which also has variable rate and is designed to provide improvements in spectral quantization, voice activity detection, and pitch prediction. It operates in several modes (which includes QCELP).
4. The data rate is changed from (1200, 2400, 4800, 9600 bps) to (1800, 3600, 7200, 14400 bps).

4.1.4. Broadband CDMA System (IS-665). The wideband CDMA standard supports several bandwidths (5, 10, or 15 MHz) at PCS frequencies. The forward link is similar to that of IS-95 with a few exceptions. There is a pilot signal, a synchronization signal, and up to seven paging signals and several traffic signals are supported as options. Also, unlike IS-95, where the chip rate is 1.228 Mbps, in IS-665, several chip rates (of 4.096, 8.192, and 12.288 Mbps) may be used. On the reverse link, the mobile users transmit pilot signals to the base station. Therefore, coherent detection (of the QPSK modulated signal) is possible. Both the CDMA (IS-95) and the Broadband CDMA (IS-665) systems are synchronized by the Global Position Satellite (GPS) time. The speech coding scheme used is ADPCM.

4.1.5. European Digital Cellular—GSM (DCS 1800). The GSM standard was developed as a joint initiative by members of the Conference of European Posts and Telecommunications Administration (CEPT) with the initial objective of building a unified pan-European network, giving the subscribers a uniform service and easy roaming throughout all of Europe. The GSM technical standard makes full use of currently available technology, incorporating features such as low bit rate speech, convolutional channel coding with bit interleaving, and frequency hopping. Services supported by GSM may be classified into three types: telephone services, data services, and supplementary ISDN services. The spectrum allocation for GSM at 900 MHz is categorized into the *standard* or the *extended* GSM band while the allocation for GSM at 1800 MHz is referred to as *Digital Cellular System 1800* (DCS 1800) band. The frequency assignments for these bands are as follows: for forward link, 935–960 MHz standard GSM, 925–960 MHz extended GSM, and 1805–1880 MHz DCS 1800; for reverse link, 890–915 MHz standard GSM, 880–915 MHz extended GSM, and 1710–1785 MHz DCS 1800.

With a spacing of 200 kHz, the standard GSM has 124 channels, the extended GSM has 174 channels, and DCS 1800 has 374 channels. Each GSM channel supports eight simultaneous users using TDMA of framelength 4.615 ms. The modulation is GMSK with $BT = 0.3$ and slow frequency-hopping every frame at 217 hops per second is used to provide additional protection against frequency-selective fading and cochannel interference. Interleaving is also used to minimize the effect of deep fades. The speech coder

is a regular pulse-excited linear predictive coder (RPE-LPC) with long-term prediction with voice detection capability (voice activity detection factor of 40%) and provides a net bit rate of 13 kbps. It operates in discontinuous transmission mode to prolong battery life. Presently, GSM networks have been deployed in over 60 countries in Europe, the Middle East, Asia, and Africa. In North America, GSM is deployed as PCS 1900.

4.1.6. Japanese Personal Digital Cellular. Established in 1991, the Japanese Personal Digital Cellular (PDC) system is very similar to the North American IS-54 system in terms of their operational characteristics and in the requirement that they replace an existing analog cellular system. The frequency allocation for the PDC represents the main difference between the two systems. PDC has two small frequency bands in the 800/900 and the 1400 MHz band. On the forward link, the frequency assignments are 810–826 MHz and 1477–1501 MHz, while on the reverse link, they are 940–956 MHz and 1429–1453 MHz. With a channel spacing of 25 kHz to be compatible with the existing analog system, PDC uses TDMA to multiplex three slots for three users in a 20-ms frame onto a carrier. The modulation is $\pi/4$ DQPSK with a channel data rate of 422 kbps, and the VSELP voice coder uses error correction coding. Mobile-assisted handoff facilitates the use of small cells, and with the use of space diversity, reduces the required carrier-to-interference ratio. The system provides high quality services, high security, and long handset battery life.

4.2. Digital Cordless Telephony

Cordless telephones are low-power, low-range, full-duplex communication systems that use radio to extend the handset to a dedicated base station with a specific telephone number that is connected to the public switched telephone network. Cordless telephone systems provide the user with limited mobility and it is seldom possible to maintain a call if the user travels outside the coverage range of the base unit. In the first-generation cordless telephone systems, the handset typically operates with localized mobility within a very limited range (on the order of 10 m) of the base unit and is used in the home or in the office. They use analog frequency modulation and operate mainly as extension telephone to a transceiver connected to the public wired network. Because of its analog nature and limited operating range, it has limited traffic-carrying capacity, which in turn limits the full development potential of these systems. Second-generation cordless telephone systems are based on digital transmission format and provide wider coverage ranges, offer good speech quality, provide better security, are more resistant to interference and noise, and use compact handsets with built-in antenna [2].

4.2.1. Cordless Telephone—CT2. This is a second-generation cordless telephone standard introduced in Great Britain in 1989 and designed for residential and office use. It is also used to provide *telepoint services*. Telepoint is a service that is provided to cordless handset owners from

cordless base stations located in public places, such as railway stations and shopping centers. This is a basic public communication service for the less migratory, more localized sector of the traveling market and does not compete directly with the wide roaming mobile cellular network. Thus, the handset purchased for residential or office use can also be used to access the telepoint service while the user is in transit between the home and the office. In CT2, speech waveforms are coded using ADPCM with a bit rate of 32 kbps. Two-way full-duplex conversation is achieved using time-division duplexing (TDD). The modulation used is Gaussian filtered FSK with bandwidth-bit period product $BT = 0.3$. A Canadian enhancement of CT2 is called CT2+ and provides additional mobility management functions.

4.2.2. Digital European Cordless Telecommunication (DECT). DECT is a pan-European standard for cordless telephone that was designed to provide cost-effective communication to high user densities in picocells. Intended applications of DECT include residential cordless telephony, telepoint services, and cordless PBX. Although DECT is functionally closer to a cellular system than a standard cordless telephone system, the interface of DECT to the PSTN or ISDN network remains the same as for a corded telephone. DECT uses TDMA with TDD and the base station can support multiple handsets simultaneously with a single transceiver. The modulation and speech coding techniques used in DECT are similar to those in CT2.

4.2.3. Personal Handyphone System (PHS). PHS is a Japanese air interface standard with the design objective of providing service not only for home and office use but also for public access capability. PHS uses TDMA and TDD, with each TDMA frame of 5 ms duration. The speech coding used is ADPCM with data rate of 32 kbps in conjunction with CRC error detection (with no error correction) and the modulation used is $\pi/4$ DQPSK. Since PHS uses dynamic channel assignment the base stations can allocate channels based on the signal strength seen at both the base station and the portable, and handoffs are supported only at walking speeds as the system is designed for microcell/indoor PCS use.

4.2.4. Personal Access Communication Systems (PACS). PACS is a third-generation personal communications system designed to support voice, data, and video images for low-speed portable applications in microcell/indoor environments. The PACS interface provides wireless connectivity to a local exchange carrier (LEC) and it uses TDMA, with frequency-division duplexing (FDD). The modulation used is $\pi/4$ QPSK, with coherent demodulation, which provides substantially better performance than do other digital cordless telephone systems with discriminator-based receivers. Two-branch polarization diversity with feedback at both the base station, and the handset gives an improvement that approaches a four-branch diversity reception system. The subscriber unit uses adaptive power

control to minimize battery drains during transmission and to reduce cochannel interference on the reverse link.

4.3. Paging Systems

A traditional paging system is a one-way, wireless communication device that sends brief messages (usually a numeric message, an alphanumeric message, or a voice message) to notify a subscriber of the need to call a particular telephone number or to receive further instruction from another location. There are two types of paging systems: the radio common carrier (or a *subscriber* system) and the *private* paging systems. The subscriber paging system is a licensed, public paging company providing paging services to the public and the coverage area may be local, statewide, nationwide, or international. The private paging system involves a customer-owned transmission system and paging receivers for private paging use. When multiple transmitters broadcast a page (known as *simulcast*), the subscribers can roam from the home area to anywhere the paging system is networked. The traditional definition of paging has evolved from the one-way communication device to a two-way device that sends and receives data with services including customized response functions, connection to online information services, e-mail messaging, etc. A number of signaling standards for paging systems have also evolved. Examples include POCSAG, which is a one-way paging system; ERMES, which is the European paging system; Motorola's FLEX family of paging products; and AT&T's P-act, which is a narrowband PCS paging system [12].

5. PERSONAL COMMUNICATION SERVICES

Wireless personal communication services (PCS) is a concept that extends wireless communications beyond the limitations of the current cellular system to provide users with the ability to communicate with anyone, anywhere, and at any time. A number of characteristics are generally associated with PCS in order to provide reliable service on demand anywhere, any time. The handsets must be portable and easy to use with a long battery life, each user must have a single personalized number that can be reached anywhere, and the system must provide an individualized feature profile that follows the user and provides service at any location. PCS must support various user mobility patterns and provide wide user roaming ability to provide for universal accessibility. Consequently, different cell sizes must be used depending on the type of application and user density. In general, four types of cells can be distinguished for PCS: the picocell (for low-power indoor applications), the microcell (for low-power indoor or outdoor pedestrian applications in high-population-density areas), the macrocell (for high-power vehicular applications), and supermacro cells (for use with satellite systems). Radio systems for PCS must have a variety of operating power levels, and the users should be able to use the service in diverse environments with a wide variation in the radio propagation properties. The system must allow easy integration of the wireless system with the

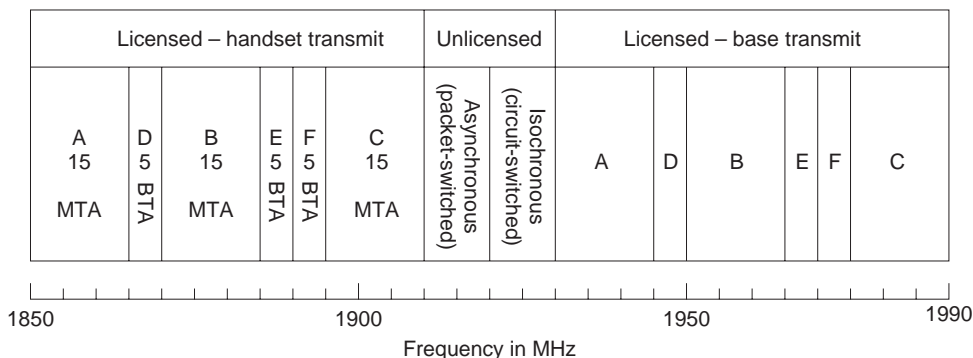

Figure 6. The US PCS frequency plan.

wireline system and ubiquitous deployment of the radio systems.

The services that can be offered by PCS and cellular are identical, except that the operating frequencies are different. The subscriber is indifferent to the frequency band as long as the services are not affected. Thus, the main forces that influence the PCS and the cellular industries are similar. Some of these forces are the regulators, PCS operators, equipment vendors, subscribers, and competing products. The service area in the United States and its territories are divided into 51 major trading areas (MTAs) and 493 basic trading areas (BTAs) according to the Rand McNally 1992 *Commercial Atlas and Marketing Guide*, 123rd ed. Based on FCC regulation, each area in the United States can be served by at least six PCS operators, in addition to the existing two cellular operator and one specialized mobile radio (SMR) service operators [12].

One of the most important defining elements of PCS is the FCC's allocation of 120 MHz of spectrum around the 1200 MHz frequency band for licensed operation and another 20 MHz for unlicensed operation, resulting in a total of 140 MHz for PCS. This is about three times the 50 MHz spectrum currently used by the cellular system, indicating the resolve to make PCS more widely available. Figure 6 shows the frequency allocation for PCS.

No specific technology has been mandated by the FCC for the PCS market. As such, a number of competing technologies have been chosen by the major PCS carriers. Presently, seven PCS standards can be identified. These include GSM (PCS 1900), a derivative of the GSM/DCS 1800 standard; CDMA, a modification of IS-95; DAMPS; PACS, air interface for pedestrian applications; CDMA/TDMA, a composite hybrid that uses TDMA within cells and CDMA between cells; DECT-based TDMA; and broadband CDMA [12]. Of these, the four most widely deployed systems at the present time are GSM, CDMA, TDMA, and PACS.

DIODES

KONSTANTINOS MISIAKOS
 NCSR "Demokritos"
 Athens, Greece

The word *diode* originates from the Greek word Δίοδος, meaning passage or way through. In electronics terminology, in fact, diode refers to a two-terminal device that allows current to flow in one direction while it blocks the flow of current in the opposite direction. Such devices usually employ semiconductor junctions or metal-semiconductor junctions. There are also diodes made of vacuum tubes or metal—purely ionic crystal contacts. This article deals with semiconductor p-n-junction diodes because they are the most widely used in practice because of their versatility, reproducibility, stability, and compatibility with integrated circuit technology. Additionally, an

insight into the operation of the p-n-junction diode is the basis for understanding the device physics of other semiconductor devices, the majority of which use the p-n-junction as the building block. The semiconductor of our choice will be silicon because almost all diodes, discrete or integrated, are made of this element. Extensions to other semiconductors will be made to generalize theoretical results or to set limits to the validity of certain equations.

Figure 1a shows the electrical symbol of a diode. The arrow-type symbol indicates the conduction direction. For a diode to conduct an appreciable electric current, the voltage on the left side of the symbol must be a little higher than the voltage on the right side. If this polarity is reversed, the current drops to negligible values even for a large bias. The two previous polarity modes are known as *forward bias* and *reverse bias*, respectively. In Fig. 1b the very basic material structure of a diode is shown. The starting material is a high-purity silicon crystal, the properties of which are properly modified by selectively introducing dopants (elements) from either the third or the fifth column of the periodic table. The third-column elements, when introduced into the silicon lattice, behave as acceptors: they trap electrons from the valence band, thereby creating positively charged holes in the valence band and negatively charged immobile acceptor ions. The acceptor-doped part of the diode is called the p side. On the other hand, fifth-column elements behave as donors; they give up their fifth electron, creating a population of conduction band electrons and positively charged immobile donor ions. The donor-doped part of the device is the n side. The introduction of acceptor and donor dopants into silicon creates the two polarity sides of the diode, as shown in Fig. 1a. Schematically speaking, when applying a forward bias, the higher voltage on the p side makes the electron and hole gases move into each other. Thus, an electric current is created through electron-hole pair recombination. On the contrary, a lower voltage on the p side moves the charge carriers away, thus preventing recombination and eliminating the current. In terms of dopants, the previous account of how the p-n diode is formed also holds for germanium diodes, which also is a fourth-column elemental semiconductor. For compound semiconductors (e.g., GaAs, InP, CdTe), the chemical origin of donor and acceptor dopants is more complex in relation to the semiconductor elements themselves.

In Fig. 2 the current-voltage (I - V) characteristic of an ideal diode as well as a realistic one is shown. The ideal

Figure 1. Electrical symbol of a diode (a) and illustration of a semiconductor p-n junction (b). In (b) the large circles with the minus and the plus signs are the acceptor and the donor ions, whereas the small circles are the holes (empty) and the electrons (dark).

Figure 2. The current-voltage characteristics of an ideal diode (curve 1) and a realistic one (curve 2).

diode would behave as a perfect switch when forward-biased; unlimited current flows without any voltage drop across the device. The same ideal diode would allow no current in the reverse direction, no matter what the magnitude of the reverse bias is. Now, a realistic semiconductor diode would exhibit a resistance to current flow in the forward direction, whereas in reverse bias a small current would always be present due to leakage mechanisms. The disagreement between the ideal and the actual electrical behavior is not restricted only to the static I - V characteristics shown in Fig. 2. It extends to the transient response obtained when applying a time-dependent terminal excitation. The response of a realistic diode cannot follow at exactly the same speed as the terminal excitation of an ideal diode would. When designing a diode to be used as a switching device, care is taken to bring the device electrical characteristics as close to the ideal ones as possible. This is done by choosing both the geometric features and the fabrication process steps in a way to suppress the parasitic components of the diode. As a result of the semiconductor electronic band structure as well as technological constraints, material limitations impose certain basic restrictions on the device performance and create the subsequent deviation from the ideal performance. In the following sections, these restrictions will be investigated, and the deviation from the ideal performance will be analyzed in terms of the basic device physics, material constants, and geometry considerations.

Before considering the device physics of the diode, we will briefly discuss the steps in the basic fabrication process employed when making a silicon diode. These steps determine its basic geometric and technological characteristics, which in turn determine the device electrical behavior. Today, almost all silicon diodes are made through the standard planar process of the silicon integrated circuit technology. A silicon wafer is first oxidized at temperatures in the vicinity of 1000°C . Such oxidation creates a silicon dioxide (SiO_2) cover layer with a thickness on the order of a micrometer. This layer is used as a mask for the subsequent technological steps. The SiO_2 film is then patterned by lithographic techniques and through etching, which allows windows of exposed silicon to be opened. Then, either by diffusion or by ion implantation, dopants are introduced into the exposed areas. The dopants are of a type opposite to the one already existing in the original wafer. In this way, p-n junctions are created in the exposed areas. In the rest of the wafer, the SiO_2 layer stops the ions

and prevents diffusion into the silicon bulk. On the back surface, another diffusion or implantation of the same dopants as in the bulk is usually applied for reasons that will become clear in the next sections. At the end, metal contacts are evaporated on the front and the back. Lithography, again, on the frontside defines the contacts of the individual diodes. The metal contacts are required for the diodes to interact with the external world in terms of terminal excitation (voltage or current) and terminal response (current or voltage, respectively). Similar methods are used for germanium diodes, whereas the compound semiconductor devices are usually made by epitaxial growth on proper substrates and by in situ doping.

1. FUNDAMENTALS OF P-N JUNCTIONS

The basic p-n-junction device physics was proposed by Shockley [1]. He derived the current-voltage characteristics, considering the electron and hole current continuity equations and the relationship between the carrier quasi-Fermi levels and the externally applied potentials. Here, we rederive the general current-voltage relation of a p-n junction based on Shockley's classic work [1] and its later extension [2].

1.1. Basic Equations and Assumptions

To formulate the electron-hole transport in a semiconductor device mathematically, we can always start by expressing the carrier densities and currents in terms of the carrier quasi-Fermi potentials under uniform temperature conditions:

$$J_n = -e\mu_n n \nabla F_n \quad (1a)$$

$$J_p = e\mu_p p E + eD_p \nabla n \quad (1b)$$

$$n = n_i \exp\left(\frac{-eF_n - E_i}{kT}\right) \quad (1c)$$

$$J_p = -e\mu_p p \nabla F_p \quad (2a)$$

$$J_p = e\mu_p p E - eD_p \nabla p \quad (2b)$$

$$p = n_i \exp\left[\frac{-(-eF_p) + E_i}{kT}\right] \quad (2c)$$

In Eqs. (1a) and (2a), J_n and J_p are the electric current densities of electrons and holes, respectively. Equations (1b) and (2b) express the currents in terms of drift and diffusion, where μ_n , D_n , n and n_p , D_p , p are the mobilities, diffusivities, and volume densities of electrons and holes, respectively. Finally, F_n and F_p are the electron and hole quasi-Fermi potentials, E_i is the intrinsic energy level, and E the electric field density. Figure 3 shows the energy band diagram of a p-n junction under forward bias and illustrates the space dependence of the quasi-Fermi potentials, of the bottom of the conduction band E_c , and of the top of the valence band E_v . Equations (1c) and (2c) hold provided that the differences $E_c - (eF_n)$ and $(eF_p) - E_v$ are positive and at least several times the thermal energy kT . Equations (1a) and (2a) are borrowed from thermodynamics and hold provided that the bias is such that perturbations from equilibrium are small. "Small" here implies that the energy distribution of electrons and holes in the conduction and the valence band, respectively, continue (within a good approximation) to follow the Boltzmann statistics. Additionally, we assume that the mean free paths of the carriers are negligible compared to the physical dimensions of the device. Finally, Eqs. (1) and (2) hold provided quantum-mechanical tunneling of carriers across potential barriers is not important. Such a constraint is relaxed in the last section of nonconventional transport diodes.

Figure 3. The band diagram of a forward-biased p-n junction. Boundaries C_1 and C_2 are the ohmic contacts, whereas C_j is the base-injecting boundary.

The second set of equations to be considered is the electron and hole continuity equations:

$$\frac{\partial n}{\partial t} = \frac{1}{e} \nabla \cdot \mathbf{J}_n - U(n,p) + G \quad (3)$$

$$\frac{\partial p}{\partial t} = \frac{1}{e} \nabla \cdot \mathbf{J}_p - U(n,p) + G \quad (4)$$

where U is the electron–hole net recombination rate either by band-to-band transitions or through traps, whereas G is the band-to-band generation rate resulting from ionizing radiation or impact ionization processes. For the sake of simplicity, we assume that U and G are the same for both carriers. Equations (3) and (4) are more general than the previous ones because they do the “bookkeeping” by equating the increase in the rate of carrier density to minus the carrier losses resulting from carrier out-fluxing ($\nabla \mathbf{J}_p/e$ and $-\nabla \mathbf{J}_n/e$) and recombination.

Next is the Poisson equation, which relates the electric field to the charge density caused by both mobile and immobile charges:

$$\nabla \cdot \mathbf{E} = \frac{e}{\varepsilon} [-n + p + N_D - N_A] \quad (5)$$

where ε is the semiconductor dielectric constant and N_D and N_A are the donor and acceptor densities, respectively. The charge density resulting from donors and acceptors is not carrier density dependent, unless the temperature drops to the cryogenic region.

The final equation to be considered is the one that equates the electric field to the gradient of the electrostatic potential:

$$\mathbf{E} = \frac{1}{e} \nabla E_c = \frac{1}{e} \nabla E_v = \frac{1}{e} \nabla E_i \quad (6)$$

Equation (6) implies that the electrostatic potential is determined by conduction and the valence band edges because the carriers there have only potential energy. The last equation assumes that the separation in the energy scale of the three levels (E_c , E_v , and E_i) is space-independent. So, in Eq. (6), as well as in Eqs. (1b,c) and (2b,c), we neglect band distortion resulting from heavy doping or other effects (e.g., mechanical strain). This is discussed in a later section on heavy doping effects.

1.1.1. Boundary Conditions. Equations (1)–(6) form a system of six relations with six unknown variables: F_n , F_p , E_i , J_n , J_p , and E . They apply, within the range of their validity, to any semiconductor device. In this sense, any semiconductor device understanding, design, operation, and performance is based on this set of six equations. What distinguishes a device of a particular kind is its boundary conditions, as well as the doping and trap density and type.

1.1.2. Ohmic Contacts. For a diode, a two-terminal device, the boundary conditions necessarily include two ohmic contacts that will supply the charge to be trans-

ported through the device. The voltage across and the current through the two ohmic contacts are, interchangeably, the excitation or the response of the device. The ohmic contacts are realized by depositing metals (e.g., Ti or Al) on heavily doped regions of the semiconductor. An ideal ohmic contact should, by definition, establish thermodynamic equilibrium between the metal and the semiconductor at all the contact points. In analytical terms, this is expressed by equating the carrier quasi-Fermi potentials to the metal Fermi potential

$$F_n(C_1) = F_p(C_1) = V_1 \quad (7a)$$

$$F_n(C_2) = F_p(C_2) = V_2 \quad (7b)$$

where V_1 and V_2 are the voltages of the metal contacts ($V_1 - V_2$ is the terminal voltage), whereas C_1 and C_2 are the contact areas of the first and the second ohmic contact, respectively. The pinning of the Fermi potentials at the externally applied voltages is illustrated in Fig. 3. If $V_1 = V_2$ and G in Eqs. (3) and (4) were zero, the device would be in equilibrium. Then the solution of the previous system of six equations would be zero currents and equal and flat Fermi potentials throughout the diode. When an external voltage is applied, the splitting of the Fermi potential values between the two ohmic contacts drives the device out of equilibrium. Such a boundary value split enforces a separation of the electron and hole quasi-Fermi potentials through the device, as shown in Fig. 3. The separation of the two potentials implies that the nonequilibrium conditions mainly refer to the interaction between electrons and holes. At any point, excluding ohmic contacts, electrons are out of equilibrium with respect to holes because the relaxation time of interband transitions (recombination and generation mechanisms) required to bring them into equilibrium are too slow (milliseconds or microseconds for germanium and silicon and nanoseconds for most compound semiconductors). On the contrary, the intra-band transitions resulting from scattering have short relaxation times (picoseconds) so that electrons or holes are nearly in equilibrium within their band. This is required for the carrier Fermi potentials to have a meaning, as mentioned in the discussion following Eqs. (1) and (2).

1.1.3. Semiconductor–Insulator Interfaces. The surface that bounds the device includes, in addition to the ohmic contact, the semiconductor–vacuum or semiconductor–insulator interface. The exposed semiconductor surface is usually covered by an insulating film (SiO_2 in silicon) to reduce recombination. If we assume that there is no injection in the insulator, then at the interface the boundary conditions for Eqs. (3) and (4) are

$$\frac{\partial n_s}{\partial t} = -\frac{1}{e} J_n^n - U_s \quad (8)$$

$$\frac{\partial p_s}{\partial t} = -\frac{1}{e} J_p^n - U_s \quad (9)$$

where the subscript “s” refers to surface densities and the superscript “n” refers to the normal component looking

into the insulator. The boundary conditions for Eq. (5) are dictated by the laws of electrostatics. The discontinuity of the normal component of the dielectric displacement vector must be equal to the surface charge density, whereas the tangential component of the electric field must be continuous.

Because the boundary conditions have been set, the system of six equations [Eqs. (1)–(6)] can be solved, in principle. As it turns out, the solution of such a nonlinear system of coupled equations can be found only numerically even for one-dimensional p-n junctions with uniform acceptor and donor densities. To derive analytical approximations, we need to make certain assumptions regarding the physical makeup of the device and the degree of bias. These analytical expressions help predict the device response under reasonable bias, whereas the appreciation of their validity range provides an insight into the diode device physics.

2. DOPING CARRIER PROFILES IN EQUILIBRIUM AND THE QUASINEUTRAL APPROXIMATION

As mentioned earlier, a p-n-junction diode consists of an acceptor-doped p region in contact with a donor-doped n region. The two-dimensional area where the donor and acceptor densities are equal is called the *metallurgical junction*. Let's assume, for the moment, equilibrium conditions. In such a case, the currents are zero and the quasi-Fermi potentials are equal and spatially independent, $F_n = F_p = F$. Therefore, from Eqs. (1c) and (2c), $pn = n_i^2$, where n_i is the intrinsic carrier density. Now, the six equations reduce to the Poisson equation, which, with the help of Eqs. (1c), (2c), and (6), takes the form

$$\nabla^2[E_i - (-eE)] = \frac{e^2}{\epsilon} \left[-n_i \exp\left(\frac{(-eF) - E_i}{kT}\right) + n_i \exp\left(\frac{E_i - (-eF)}{kT}\right) + N_D + N_A \right] \quad (10)$$

The last equation is known as the *Boltzmann–Poisson* equation. Approximate analytical solutions are possible when the donor and acceptor densities are uniform in the n and p regions, respectively. In this case, the field is zero, and the bands are flat everywhere except at and near the metallurgical junction. The finite field region around the metallurgical junction is called the *space charge region*, whereas the zero-field regions are called *quasineutral regions*, for reasons to be explained shortly. In the n and p quasineutral regions, electrons and holes are the majority carriers, respectively. The majority-carrier densities are equal to the respective doping densities. With reference to the metallurgical junction, the space charge region extends W_A and W_D within the p and the n regions. At zero bias, and in one dimension, an approximate solution of

Eq. (10) gives

$$W_A = \sqrt{\frac{2\epsilon}{e} V_{bi} \frac{N_D}{N_A(N_A + N_D)}} \quad (11a)$$

$$W_D = \sqrt{\frac{2\epsilon}{e} V_{bi} \frac{N_A}{N_D(N_A + N_D)}} \quad (11b)$$

$$V_{bi} = \frac{kT}{e} \ln\left(\frac{N_A N_D}{n_i^2}\right) \quad (11c)$$

In Eq. (11c) V_{bi} is the zero bias electrical potential difference, or barrier, between the p and the n sides reflected in the level differences of the flat bands of each side. Such a barrier prevents majority carriers from diffusing into the other side. These approximations result by assuming that the electron and hole densities are zero in the space-charge region. This is the depletion approximation, which reduces Eq. (10) to a linear second-order differential equation with constant terms and coefficients.

The zero-field condition for the rest of the n and p sides, outside the space charge region, apparently justifies the term quasi-neutral regions. This term also applies when the n and p regions have gradually changing dopant profiles in the sense that the net space charge is much less than the majority-carrier charge. Here, by gradually changing we mean that the doping profile $N(x)$ in the quasineutral region must be such that [3]

$$\frac{ekT}{e^2} \left| \nabla^2 \left[\ln \frac{N(x)}{n_i} \right] \right| \ll N(x) \quad (12)$$

In such regions, the zero-bias majority-carrier density continues to be nearly the same as the net dopant density, but the electric field is not zero as in the uniform doping case.

3. FORWARD AND REVERSE BIAS CONDITIONS

The quasineutrality condition of the n and p regions is preserved even under bias, but now the boundaries with the space charge region move appropriately to accommodate the new boundary conditions. This neutrality condition can be expressed as

$$n \approx p + N_D - N_A \quad (13)$$

Under a small forward bias, the applied voltage changes the electric field preferentially at the space charge region, because it is the region with the fewest carriers, has the highest resistance, and is in series with more conductive n and p regions. The equilibrium barrier height V_{bi} lowers under forward bias, and the majority electrons overcoming the repulsive field diffuse from the n side to the p side, whereas the holes are doing the opposite. The carrier quasi-Fermi potentials are no longer equal, as shown in Fig. 3. The diffusion process, through the space charge region and inside the quasineutral regions, increases dramatically

the minority-carrier population on either side and gives rise to an appreciable electric current.

For forward voltages, the degree of bias defines three injection-level regimes distinguished by how the minority-carrier density compares to the majority one in the quasineutral regions. These regimes are the low-level, the moderate-level, and the high-level injection condition. In the low-level injection regime, the minority-carrier density is well below the majority-carrier density, and the electric field in the quasineutral regions is practically unaffected by the bias. As a result, the applied voltage drops across the space charge region and reduces the barrier height from V_{bi} to $V_b = V_{bi} - V$. Provided the depletion approximation still holds, Eq. (11) still applies and V_{bi} is replaced by V_b . In low-level injection, the majority-carrier density is the same as at zero bias, as Eq. (13) points out, and is nearly equal to the net doping density. In the high-level injection regime, the minority-carrier injection is so intense that the injected carriers have densities far exceeding the dopant densities. Now, both carrier densities are about the same, $n = p$, to preserve neutrality in the quasineutral region. In other words, there is no real distinction between minority and majority carriers in terms of concentrations, but we obtain an electron-hole plasma having densities well above those of the dopant densities instead. In the moderate injection, the minority-carrier density approaches the order of magnitude of the majority-carrier density causing the majority-carrier density to start to increase, as Eq. (13) implies.

Under reverse bias, the built-in barrier increases in the space charge region, the repulsive forces on the majority carriers coming from the quasineutral regions increase, and injection of minority carriers is not possible. The space charge region is now totally depleted from both carriers, and a small leakage current exists as a result of thermal generation of electron-hole pairs in the depletion region.

3.1. Recombination Currents in the Steady State

Here, we will introduce the base and emitter terms as well as a general expression for the terminal current as the sum of recombination components. Between the two quasineutral regions, the emitter is the one that is heavily doped, usually by diffusion or implantation, whereas the base is more lightly doped and occupies most of the substrate on which the device is made, at least in silicon. The heavy doping of the emitter excludes the possibility of moderate- or high-level injection conditions in this region. At forward bias, majority carriers from the emitter diffuse as minority carriers to the base where they recombine. Simultaneously, recombination occurs in the emitter, because minority carriers are backinjected from the base, as well as in the space charge region. At steady state, $\partial n/\partial t = \partial p/\partial t = 0$, and in the dark $G = 0$. Now, the continuity equations [Eqs. (3) and (4)] become after volume integration:

$$I_D = I_e + I_b + I_{SCR} \quad (14)$$

where I_D is the terminal current and I_e , I_b , and I_{SCR} are the net recombination currents in the emitter, the base, and the space charge region, respectively. Equation (14)

expresses the total current as the sum of the recombination currents in the three regions of the device. Therefore, excess carrier recombination along with diffusion are the two basic transport mechanisms that determine the diode current at a given bias. The carrier recombination occurs either at the ohmic contacts, at the surface, or in the bulk. The minority carriers that arrive at the ohmic contact are supposed to recombine simultaneously there, to preserve the boundary condition, Eq. (7). The bulk recombination occurs either through traps or through band-to-band transitions. In terms of trap-mediated recombination, the Shockley-Read-Hall mechanism [4,5] is the most common:

$$U_{SRH} = \frac{(pn - n_i^2)N_t}{\frac{1}{\sigma_p v_{th}} \left[n + n_i \exp\left(\frac{E_t - E_i}{kT}\right) \right]} + \frac{1}{\sigma_n v_{th}} \left[p + n_i \exp\left(-\frac{E_t - E_i}{kT}\right) \right] \quad (15)$$

In Eq. (15), N_t is the trap density, σ_n and σ_p are the electron and hole capture cross sections, respectively, E_t is the trap energy level in the gap, and v_{th} is the carrier thermal velocity. The band-to-band recombination is discussed in Section 6.

4. APPROXIMATE ANALYTICAL EXPRESSIONS IN THE STEADY STATE

As mentioned previously, the set of Eqs. (1)–(6) has no analytical solution in the general case. Approximate closed-form expressions, though, are possible when low-level injection conditions dominate in the quasineutral base region. Without loss of generality, we assume that we are dealing with a p-n diode with a heavily doped p emitter and an n base. The steady-state situation results when a terminal bias, say, a terminal voltage V , is steadily applied on the terminals, and we wait long enough for the initial transient to disappear. The steady-state version of the continuity equations [Eqs. (3) and (4)] is simplified because the time derivatives are set equal to zero. First, we will derive the expressions for the base current, and then extensions will be made for the recombination current in the emitter and the space charge regions. If low-level injection conditions prevail in the base, then, to a good approximation, the original system of equations [Eqs. (1)–(6)] reduces to the minority-carrier equations [Eqs. (2) and (4)], which are now decoupled from Eq. (5) (the Poisson equation). This decoupling results because, as mentioned earlier, at low-level injection the electric field is practically bias-independent. Any small field variations would affect only the drift current of the majority carriers because of their high density; the minority carriers would not be influenced. That is why we focus on the minority-carrier transport to exploit the Poisson equation decoupling. Another reason for focusing on the minority carriers is the fact that the recombination in low-level injection, where $p \ll n$, can always be written as a linear function of their

density:

$$U = (p - p_0)/\tau \quad (16)$$

In Eq. (16), p_0 is the equilibrium carrier density, whereas the variable τ , the minority-carrier lifetime, is the inverse of the derivative of the recombination rate with respect to the minority-carrier density. In the case of Shockley–Read–Hall recombination, $\tau = 1/\sigma_p v_{\text{th}} N_t$. Therefore, from Eqs. (2b), (4), and (16), we end up with

$$-\nabla \cdot (\mathbf{E} \mu_p p' - D_p \nabla p') - p'/\tau + G = 0 \quad (17)$$

where $p' = p - p_0$ is the excess minority-carrier density. Because of the field independence on p' , Eq. (17) is linear and becomes homogenous if $G = 0$. In the latter case, the solution is proportional to $p'(C_j)$, the excess minority-carrier density at the injecting boundary (Fig. 3).

4.1. Forward Bias and Low-Level Injection

Under forward bias, a basic assumption will be made. This assumption allows the coupling of the minority-carrier density to the externally applied terminal voltage; the Fermi levels are flat in the regions where the carriers are a majority and also in the space charge region. Under this condition and from Eqs. (1c), (2c), and (7), we obtain

$$p(C_j)n(C_j) = n_i^2 \exp(eV/kT) \quad (18)$$

$$p'(C_j) = \frac{n_i^2 [eV/kT - 1]}{N_D(C_j)} \quad (19)$$

Equation (18) holds under any injection level, provided that the flat Fermi potential assumption holds, whereas Eq. (19) for the excess minority-carrier density holds only in low-level injection. The proportionality of the solution with respect to $p'(C_j)$ forces all carrier densities and currents to become proportional to the term $\exp(eV/kT) - 1$. Here, we note that the surface recombination is also a linear function of the excess minority-carrier density when $p \ll n$. More analytically, Eq. (9) becomes

$$J_p^n = eS_p p' \quad (20)$$

where S_p is the surface recombination velocity. Therefore, the total base recombination current in Eq. (14) is proportional to the term $\exp(eV/kT) - 1$. The same is true for the quasineutral emitter recombination. Thus, Eq. (14) becomes

$$I_D = (I_{0e} + I_{0b})[\exp(eV/kT) - 1] + I_{\text{SCR}} \quad (21)$$

where the preexponential factors I_{0b} and I_{0e} are the base and emitter saturation currents, respectively. Equation (19) points out that the saturation currents are proportional to n_i^2 .

The space charge region recombination is a current component that is hard to express in analytical terms. This difficulty arises because in this region the field

depends on the bias and there is no such entity as a minority carrier. Consequently, the linearity conditions that allowed us to derive Eq. (21) no longer hold. To derive an approximate expression for the bias dependence of I_{SCR} , certain simplifications must be made throughout the space charge region regarding the integral of Eq. (15). These simplifications result in a bias dependence of the form $\exp(eV/nkT) - 1$, where n , the ideality or slope factor, takes values from 1 to 2 [2]. The specific value depends on the trap position in the energy gap, the doping profiles, and the cross section for hole capture relative to the cross section for electron capture. This range for n holds provided that the capture coefficients do not depend on the electric field. Now the preexponential factor I'_{SCR} is proportional to n_i . Finally, the expression for the forward current of a diode in the base of which low-level injection conditions prevail becomes

$$I_D = (I_{0e} + I_{0b})[\exp(eV/kT) - 1] + I'_{\text{SCR}}[\exp(eV/nkT) - 1] \quad (22)$$

For voltages higher than $3nkT/e$, the unity can be dropped from Eqs. (21) and (22). Because of a better slope factor, the emitter and base recombination will dominate the diode current for voltages above a certain level. Below this level, the space charge region recombination must also be considered.

Such trends are seen in Fig. 4. Curve 1 is the $I-V$ characteristic of a diode with a base doping of

Figure 4. The experimental $I-V$ characteristics of two different diodes. Diode 1 has a base thickness of $250 \mu\text{m}$, a base-doping density of $5.5 \times 10^{14} \text{cm}^{-3}$, and an area of $2.9 \times 2.9 \text{mm}^2$. Diode 2 has a base thickness of $300 \mu\text{m}$, a base-doping density of $4.5 \times 10^{11} \text{cm}^{-3}$, and an area of $5 \times 5 \text{mm}^2$. The base in both devices is of n type. Plot 3 is the $I-V$ characteristic of diode 2 at 78K . The other plots are at 300K . Curve 1 ($-V$) is the reverse bias characteristic, with reversed sign, of diode 1 (top axis). The straight lines in curves 1, 2, and 3 are the exponential $\exp(eV/nkT) - 1$ fits to the experimental points. The slope factor n is also shown.

$5.5 \times 10^{14} \text{ cm}^{-3}$ and has an ideality factor of 1 in the bias range from 0.2 up to 0.4 V. For lower voltages, the space charge region recombination slightly increases the ideality factor and makes the measured current deviate from the $\exp(eV/kT) - 1$ dependence. The ideality factor also increases for voltages above 0.4 V because of high-injection effects, which are discussed in the next subsection. The device of curve 2 has a very light doping density in the base, $4.5 \times 10^{11} \text{ cm}^{-3}$ and is driven in high injection at even smaller bias. As discussed in the next subsection, curve 2 exhibits unity slope factor even at very low voltages.

Curve 3 shows what happens if the temperature is reduced to 78 K. The sharp reduction of the intrinsic carrier density due to its $\cong \exp(-E_g/2kT)$ dependence requires much higher voltages to reach the same current as at 300 K. In fact, to reach a current density of 10 mA/cm^2 , a voltage in excess of 1 V is required. The reduction of n_i reduces the recombination in the base and the emitter is much faster than in the space charge region because the proportionality constants are n_i^2 and n_i , respectively. Therefore, at low temperatures, the bias regions with higher than 1 ideality factor are expected to be wider. This is evidenced in curve 3 of Fig. 4, where the ideality factor is 3.5 for voltages below 950 mV. The increase of the ideality factor above 2 is a result of the Poole-Frenkel effect, which reduces the effective energy separation of the traps from the bands [6]. The influence of small values of n_i on the ideality factor is evident not only when the temperature drops but also when the bandgap increases. In several compound semiconductor devices, their large bandgap, compared to 1.1 eV of silicon, results in an intrinsic carrier density, which is several orders of magnitude smaller than the 10^{10} cm^{-3} value for silicon at 300 K [7,8]. Consequently, their $I - V$ characteristics show slope factors substantially larger than 1 for the entire range of bias. On the contrary, germanium diodes have slope factors of 1 even at reduced temperatures because of the smaller gap, 0.66 eV, of the semiconductor.

4.1.1. The One-Dimensional Case. Equation (22) holds for any three-dimensional geometry and doping profiles because no assumption, except for low-level injection, was made so far regarding doping profiles and device topology. If, however, we want to express in closed form the saturation values of the emitter and base recombination currents, then one-dimensional devices with uniform doping profiles must be considered. In such a case, the one-dimensional, homogenous, and constant-coefficient version of Eq. (17) becomes

$$\frac{d^2 p'}{dx^2} = \frac{p'}{L_p^2} \quad (23)$$

where $L_p = \sqrt{D_p \tau}$ is the minority-carrier diffusion length. The first boundary condition for Eq. (23) is Eq. (19) applied at the injecting boundary. The other one refers to the ohmic contact. If it is an ideal ohmic contact deposited directly on the uniformly doped base, then the second boundary condition becomes, from Eq. (7), $p'(l) = 0$. Here,

l is the base length and the coordinate origin is at the injecting boundary, as shown in Fig. 3. In many cases, between the ohmic contact and the uniformly doped base, a thin and heavily doped region intervenes.

This region has a thickness on the order of a micrometer and a doping of the same type as the rest of the base. The purpose of such a layer, called the "backsurface field," is to provide a better ohmic contact and to isolate the contact from the lightly doped base so that carrier recombination-generation is reduced [9]. Such a backsurface field terminates the lightly doped base of diode 2 in Fig. 4 making it a p-i-n diode, where "i" stands for intrinsic. Therefore, in the presence of this contact layer, the base ends at a "low/high" n-n⁺ junction. In terms of minority-carrier recombination, this interface is characterized by an effective recombination velocity S_{pe} , experienced by the minority carriers at the low side of the junction. The expression for S_{pe} is

$$S_{pe} = \frac{I_{0c} N_D}{en_i^2 S} \quad (24)$$

where I_{0c} is the saturation value of the recombination current in the backsurface field and S is the device cross section. Equation (24) can be derived from Eq. (20), by applying Eq. (19) at the n-n⁺ junction and by equating the minority current at the low/high junction to the recombination in the heavily doped region.

Under the previous boundary conditions, the solution of Eq. (23) yields for the base saturation current:

$$I_{0b} = S \frac{en_i^2 D_p}{N_D L_p} \frac{1 + \frac{D_p}{S_{pe} L_p} \tanh(\ell/L_p)}{\tanh(\ell/L_p) + \frac{D_p}{S_{pe} L_p}} \quad (25)$$

Equation (25) shows that, in terms of the one-dimensional geometry, the quantity that matters is the ratio ℓ/L_p . Values of this ratio much less than one define the short base, whereas values above 3 define the long base. In the long-base case, Eq. (25) becomes $I_{0b} = Sen_i^2 D_p / (N_D L_p)$. Similar equations hold for a uniform emitter, too, but now the heavy-doping effects could modify the value of n_i^2 , as will be discussed in Section 6. If the base doping is very light, as in a p-i-n diode, then the increased value of I_{0b} will make the base recombination dominate the current components in Eq. (22). Accordingly, the influence of space charge region recombination current on the slope factor will be suppressed even for voltages as low as a few kT/e , as shown in Fig. 4, curve 2. Also, by extrapolating the $\exp(eV/kT)$ fit of curve 2 at zero voltage, a base recombination current of 0.7 nA is obtained. This corresponds to a 300 K saturation current density of 2.8 nA/cm^2 compared to emitter saturation current densities on the order of pA/cm^2 . On the other hand, diode 1, with a base doping density three orders of magnitude higher than that in diode 2, exhibits a saturation current of 24 pA/cm^2 . This saturation current comes mainly from the base recombination as a result of its relatively light doping density and the absence of a backsurface field, which gives S_{pe} very high values.

Equation (25) applies to uniformly doped regions. If the doping is nonuniform, closed-form expressions are not possible, in the general case. This is the case because the one-dimensional version of Eq. (17) is still an ordinary differential equation with nonconstant coefficients. However, analytical approximations based on iterative techniques can be derived [10].

4.1.2. Diffusion in Three Dimensions. Equation (23) holds provided the cross-sectional dimensions of the diode are much larger than the diffusion length. Otherwise, lateral diffusion of minority carriers in the base becomes important. In such a case, the three-dimensional version of Eq. (23) takes the form

$$\nabla_{p'}^2 = \frac{p'}{L_p^2} \quad (26)$$

The last equation can be solved very accurately by semi-analytical techniques based on the two-dimensional Fourier transform [11]. Simulation results are as shown in Fig. 5. As illustrated, in the case of a point contact diode having emitter dimensions of $0.1 L_p$, the base recombination is expected to increase by a factor of 25 as a result of the lateral carrier diffusion.

4.2. High-Level Injection

So far, our analytical approaches were based on the low-level injection assumption. In high-level injection, where

Figure 5. Three-dimensional diffusion base saturation current of a planar p-n junction with a square emitter having a sidelength L . The top surface of the base is supposed to have zero recombination velocity. The current is normalized with respect to the one-dimensional diffusion current $I_{0b} = en_i^2 L^2 D_p / N_D L_p$. In curve 2, $S_{pe} = 0$ and $l = L_p/2$. In curve 2, l is assumed to be infinite. In curve 3, $S_{pe} = D_p/L_p$ and $l = L_p/2$, whereas in curve 4, S_{pe} is assumed to be infinite and $l = L_p/2$.

$n = p$, an equation similar to Eq. (23) can be derived where now the hole diffusion length is replaced by the ambipolar diffusion length [12]. The boundary conditions, however, are not linear and depend on the electric field, which, now, is a function of bias. If the quasi-Fermi potentials are flat in the quasineutral base, then the electron-hole plasma density p is space independent and equals $n_i \exp(eV/2kT)$, as can be derived from Eq. (18). In such a case, by integrating the recombination current in the emitter, the base, and the backsurface field, we obtain

$$I_D = (I_{0e} + I_{0c}) \exp(eV/kT) + (eSl/\tau') \exp(eV/2kT)n_i \quad (27)$$

In Eq. (27), τ' is the high-injection lifetime defined as the ratio of the recombination rate divided by the plasma density. The flat Fermi level condition can easily be satisfied in p-i-n diodes where the light base doping density makes the high-level injection possible even at a bias of 0.4 V. In Fig. 4, curve 2 shows the $\exp(eV/2kT)$ dependence, or slope factor of 2, for voltages of about 0.4 V, which drive the p-i-n device to high-level injection. For even higher voltages, the emitter and backsurface field recombination in Eq. (27) starts dominating the current, and the slope factor drops again. For higher base doping densities, as in curve 1 of diode 1, the required voltage for high-level injection conditions could exceed 0.5 V at 300 K. Now, the heavily doped region recombination in Eq. (27) competes with the bulk recombination, and the slope factor of 2 does not appear. The bent of both curves 1 and 2 at voltages near 0.6 V is a result of series resistance effects, which invalidate the assumption of flat Fermi levels across the base. In such a case, the simulation is possible only by device simulators that solve the complete system of the transport equations.

4.3. Reverse Bias

Under reverse bias where $V < 0$, the assumption of flat Fermi levels across the space charge region that led to Eq. (22) no longer hold. On the other hand, however, the space charge region can be considered to be fully depleted from free carriers. In such a case, Eq. (11) holds with V_{bi} replaced by $V_{bi} + |V|$. Therefore, the depleted space charge region will expand toward the base according to the square root of the bias for $|V| > 5$ V. In this region, the Shockley-Read-Hall Eq. (15) predicts a negative recombination or generation of electron-hole pairs. This generation current is the basic component of the leakage current in reverse bias. The contribution of the diffusion components from the base and the emitter, $-I_{0b} - I_{0e}$, is usually negligible unless the base is very lightly doped. The bottom line in Fig. 4 shows the reverse-bias current for diode 1. The square-root dependence on voltage is not exactly obeyed because of the Poole-Frenkel effect, which increases the generation rate at higher fields.

5. TRANSIENT RESPONSE OF DIODES

If a diode is subjected to a transient terminal bias, then in addition to currents due to carrier diffusion and

recombination, we also have the dielectric displacement current resulting from the time dependence of the electric field. If low-level injection is observed in the quasineutral regions, the displacement current is restricted in the space charge region. At the same time, low-level injection ensures that linearity holds in the base and the emitter, and Eq. (17) still applies with $\partial p'/\partial t$ replacing zero in the right-hand side of the relation. The solution of the time-dependent edition of Eq. (17) provides the minority-carrier currents at the injecting boundaries of the base and the emitter, $I_b(t)$ and $I_e(t)$, respectively. These currents have now two components: the minority-carrier recombination and the minority-carrier storage current $\partial Q'/\partial t$, where Q' is the total excess minority-carrier charge. To calculate the total transient current, reconsider Eq. (14) in its transient version. Therefore, in addition to $I_b(t)$ and $I_e(t)$, the transient space charge region current is required. Unlike the base and the emitter, this current in addition to the recombination and storage component also includes the displacement current [13]. Insofar as the displacement current is concerned, the space charge region behaves as a parallel-plate capacitor with a plate distance $W = W_A + W_D$, Eq. (11), a dielectric constant ϵ , and a capacitance $C_{SCR} = \epsilon S/W$. During transit, the dielectric displacement current is supplied by the majority carriers from either side of the junction.

To calculate the transient currents in the base and the emitter, the boundary conditions must be defined. Boundary condition Eq. (20) holds because of linearity. The other condition at the injecting boundary depends on the kind of transient to be considered [14]. Here we will assume that the device is in equilibrium for $t < 0$, whereas at $t = 0$ a constant voltage V is applied. We can now assume that Eq. (19) applies with $p'(C_j)$ replaced by $p'(C_j, t)$ for $t > 0$. This assumption has a validity range depending on how fast the flat quasi-Fermi potential condition can be established across the space charge region. In fact, even in the absence of series resistance effects, it takes a short time for this condition to be established. This short time relates to the dielectric response time of the majority carriers and the minority-carrier diffusion time across the space charge region [14]. For almost all practical cases, the delay in establishing a fixed minority-carrier density at the edge of the quasineutral region will not exceed the limit of a few tens of a picosecond [14], in the absence of series resistance effects. Therefore, if the time granularity used in solving the time-dependent version of Eq. (17) is restricted to about a nanosecond, then the solutions will be accurate. In practical cases, however, the very first part of the transient current, following the sudden application of a voltage, will be determined by charging C_{SCR} through the series resistance of the majority carriers in the base and the emitter. The respective time constant could be on the order of a nanosecond. In such a case, the minority-carrier transport in the base will determine the transient only after several nanoseconds have elapsed since the application of the voltage. The transient base transport can be expressed in semianalytical forms using Laplace transform techniques [14], especially in the case of uniform and one-dimensional quasineutral regions. In a long-base diode, the transition will last for about a minority-carrier

lifetime. In a short-base device with an ohmic contact at the base end, the transient will last approximately $l^2/2D_p$, which is the minority-carrier diffusion time through the base.

5.1. Small-Signal Response

In many cases, the device operates under sinusoidal small-signal excitation superimposed on a steady-state excitation. In such cases, Eq. (17) still holds, but now $1/\tau$ will have to be replaced by $1/\tau + j\omega$, where j is the imaginary unit and ω is the angular frequency of the excitation. This is the case because the time derivative of the small-signal carrier density is the carrier density amplitude times $j\omega$. Having done the complex lifetime replacement, the analysis that followed Eq. (17) still holds. Now, however, the small-signal value of the excess minority-carrier density at the injecting boundary will be the steady-state value in Eq. (19) times ev/kT . Here, v is the small-signal terminal voltage, which is supposed to be much less than kT/e . Under low-level injection and in view of the previous transient response discussion, the small-signal version of Eq. (22) will refer to a terminal current I_D^* having a real and an imaginary component:

$$\begin{aligned} I_D^* &= (I_{0e}^* - I_{0b}^*) \frac{ev}{kT} \left[\exp\left(\frac{eV}{kT}\right) - 1 \right] \\ &+ I_{SCR}^* \frac{ev}{nkT} \left[\exp\left(\frac{eV}{nkT}\right) - 1 \right] \\ &+ j\omega C_{SCR} v = v(G + j\omega C) \end{aligned} \quad (28)$$

The star exponents denote the complex values of the saturation currents as a result of the complex lifetime. In Eq. (28), G and C are the diode small-signal parallel conductance and capacitance, respectively. These two components are of great importance because their frequency dependence can reveal minority-carrier properties, such as diffusivity and lifetime [15], and allow the device circuit representation when the diode is part of a greater small-signal circuit. For uniformly doped quasineutral regions, I_{0e}^* and I_{0b}^* can be obtained from Eq. (25) by replacing the diffusion length $L = (D\tau)^{1/2}$ with the complex diffusion length $L^* = L/(1 + j\omega\tau)^{1/2}$. For frequencies sufficiently high, the magnitude of the complex diffusion length will become much shorter than the base thickness. Then, the complex version of Eq. (25) predicts that the base current would change as $1/L^*$. If the base component in Eq. (28) were to dominate, then beyond a certain frequency, C would change as $\omega^{-1/2}$ while G would change as $\omega^{1/2}$.

This frequency dependence is confirmed in Fig. 6, which shows the frequency response of diode 1, from Fig. 4, at two bias points. The theoretical fit to the experimental results was obtained on the basis of the diode equivalent circuit shown in Fig. 7. This circuit includes all the components relating to carrier injection and storage in the device's three regions in accordance with Eq. (28). It also includes the base resistance R_N , which has been ignored in Eq. (28). In Fig. 6, the square root law is better obeyed at the higher bias point and for frequencies less than 1 MHz,

Figure 6. Experimentally measured capacitance (dots) and conductance (squares) at 300 K for diode 1. The bottom and the top curves correspond to two different bias points: 420 mV and 450 mV, respectively. The solid curves are the theoretical fits from the equivalent circuit of Fig. 7.

especially for the capacitance. This is a combined result of the space charge region capacitance, the relative contribution of which increases at lower bias, and the series resistance, the influence of which is stronger at high frequencies. The corner frequencies of the conductance and the capacitance depend on the base thickness and the lifetime. The fit shown in Fig. 6 gave a minority-hole lifetime in the n-type base of about 30 μ s. Such a lifetime and Eq. (25) imply that the saturation current density of 24 pA/cm² at 300 K, as shown in Fig. 4, is 90%, due to base recombination. The emitter contribution of 10% is discussed in Section 6.

The series resistance R_N becomes the bulk majority-carrier resistance under reverse bias or even under forward bias, provided that the frequency is high ($|L^*| \ll l$). The capacitance C_{QNR}^N in parallel with R_N , as shown in Fig. 7, is the geometric capacitance of the quasineutral base [16,17]. For ordinary resistivity devices, it can be ignored unless the frequency is in the gigahertz range. However, for diodes made on high resistivity substrates, this capacitance must be considered especially at reverse bias and high frequencies [17]. From Fig. 7 and in the limit of very high frequencies under forward bias, the parallel conductance saturates at $1/R_N$ whereas the parallel capacitance does so at C_{QNR}^N . This is because of the combination of the increasing injection conductances and the space charge region capacitance. Then, the product $R_N C_{QNR}^N$ becomes the dielectric response time of the majority carriers in a uniform base. At high injection, the parallel conductance will saturate at the sum of the two carrier conductances [18]. Under reverse bias, the circuit of Fig. 7 reduces to the space charge region capacitance in series with the parallel combination of C_{QNR}^N and R_N . Unlike the forward-bias case, where the circuit parameters depend

Figure 7. The equivalent-circuit model of a diode. The base injection currents in Eq. (28) correspond to C_p , imaginary part, and G_p , real part. The injection in the emitter is represented by G_N^+ . The space charge region recombination is represented by G_{SCR} , whereas C_{SRC} is the space charge region capacitance. The rest of the components are accounted for in the text.

roughly exponentially on the terminal voltage V , in reverse bias the voltage dependence would be restricted to $V^{-1/2}$. In the sense of the voltage dependence, the circuit of Fig. 7 is the circuit of a varactor.

6. HEAVY-DOPING EFFECTS IN THE EMITTER

In the previous subsection, the emitter saturation current density was estimated to be about 2 pA/cm². From Eq. (25) and by assuming microsecond lifetimes, we would expect saturation currents on the order of a fA/cm² from an emitter doped in the range 10^{19} – 10^{20} cm⁻³. Such a discrepancy by three orders of magnitude is due to the heavy-doping effects, namely, the short lifetime resulting from Auger recombination and the effective increase of n_i due to bandgap narrowing. In the Auger recombination process, a minority carrier recombines directly with a majority one, and the energy is transferred to another majority carrier. Because of such kinetics, the Auger minority-carrier lifetime is inversely proportional to the square of the majority-carrier density. The proportionality constant is $\sim 10^{-31}$ cm⁶/s for minority electrons in p⁺ emitters and 3×10^{-31} cm⁶/s for minority holes in n⁺ emitters [19]. In heavily doped regions, the Auger recombination rate is by far higher than the Shockley–Read–Hall rate and determines the lifetime. Therefore, nanosecond lifetimes are expected, especially for holes, in emitters doped in the vicinity of 10^{20} cm⁻³.

In a heavily doped region, every minority carrier interacts strongly with the majority carriers because of their high density. The minority-majority carrier attraction along with the carrier–dopant interaction and the semiconductor lattice random disruption by the dopant atoms reduces the bandgap and changes the density of states in both bands [20,21]. The net result is an effective shrinkage of the gap depending on the doping type and density [22–24]. This shrinkage changes the intrinsic carrier density n_i to a much higher effective n_{ie} . The result of the band distortion is that the original system of transport equations [Eqs. (1)–(6)] no longer holds. More specifically,

Eqs. (1b,c) and (2b,c) are not valid for the majority carriers even if n_{ie} substitutes n_i because Boltzmann statistics must be replaced by Fermi–Dirac statistics. Also, Eq. (6) no longer holds in a nonuniform region because the band edges are not parallel any more and each carrier experiences a different field. However, the minority carriers still follow the Boltzmann statistics, and Eq. (17) holds for the minority carriers. Now E is the minority-carrier field ($1/e\nabla E_c$ for electrons), and the boundary condition Eq. (19) is valid with n_i replaced by n_{ie} . Therefore, Eq. (25) still applies for the minority-carrier recombination in a uniformly doped emitter. For an emitter doped at about 10^{20} cm^{-3} , a gap narrowing of about 100 meV is expected [22–24], which makes n_{ie} several tens higher than n_i . If such an n_{ie} as well as nanosecond lifetimes replace n_i and microsecond lifetimes in Eq. (25), an emitter saturation current on the order of pA/cm^2 is predicted, in accordance with the experimental results of the previous section.

7. DIODES OF NONCONVENTIONAL TRANSPORT

So far in this article, devices based on the drift and diffusion model of Eqs. (1) and (2) were studied. Charge carriers can be transported from one region to another by tunneling. Also, they can be temporarily trapped in energy gap states, atom clusters, or crystallites imbedded in insulating films, thereby affecting the tunneling or the conventional transport of the free carriers.

In this respect, the first device to be examined is p-i-n diode 2 of Fig. 4, operating at cryogenic temperatures. Around 4.2 K, the equilibrium Fermi level in the lightly doped n⁻ region is pinned at the donor level. These levels, now, are not ionized except for a fraction to compensate the charge of the unintentionally introduced acceptor ions. At such low temperatures, there are no free carriers in the base, and no measurable conduction is possible unless the voltage is raised enough to achieve the flatband condition [25,26]. For silicon, this voltage V_0 would be about 1.1 V. For even higher voltages, conduction is possible only if electrons and holes can be injected in the frozen substrate from the n and p regions, respectively. In this sense, Eq. (24) based on the assumption of flat majority-carrier Fermi levels no longer holds. For $T < 10 \text{ K}$, injection is possible by carrier tunneling through the small potential barrier existing at each of the p-i and i-n interfaces [26]. These barriers exist because of the band distortion in the heavily doped regions and the smaller gap there, as outlined in the previous section. For $V > V_0$, electrons tunnel in the i layer, and the higher the forward bias, the higher the current due to a field-induced effective lowering of the barriers.

As shown in Fig. 8, for temperatures below 10 K it takes at least several volts to establish a current of few nanoamperes. The injected electrons in the i layer are trapped by the ionized donors and built a space charge and a subsequent potential barrier. For even higher voltages approaching 10 V, the barrier at the i-p interface lowers, holes now enter the i layer in large numbers. Their charge neutralizes the trapped electron charge and causes the voltage breakdown and the negative differential resistance that appears in Fig. 8 for $T < 10 \text{ K}$. The negative

Figure 8. Measured $I - V$ characteristics of diode 2 at cryogenic temperatures. The square points correspond to 4.2 K. The $T < 10 \text{ K}$ plots exhibit a distinct voltage breakdown. [Reprinted from K. Misiakos, D. Tsamakis, and E. Tsoi, Measurement and modeling of the anomalous dynamic response of high resistivity diodes at cryogenic temperatures, *Solid State Electron.* **41**:1099–1103 (1997), with kind permission from Elsevier Science Ltd, The Boulevard, Langford Lane, Kidlington OX5 1GB, UK.]

resistance persists and beyond breakdown as a result of new carrier generation by the impact ionization of occupied shallow donors by the injected carriers. The interaction of free and trapped carriers through impact ionization gives rise to a negative dynamic conductance and capacitance that for frequencies high enough change as ω^{-2} [27]. For $T > 10 \text{ K}$ the injection mechanism changes to thermion emission over the interface potential barriers, whereas the space charge effects are now less pronounced.

Another example of tunneling injection mechanism is the breakdown effect in zener diodes. Here, the base is quite heavily doped ($\approx 10^{18} \text{ cm}^{-3}$), and the strong electric field in the space charge region increases even further by applying a reverse bias. For fields approaching 10^6 V/cm , a valence band electron can tunnel to a conduction band state of the same energy. This way, electron–hole pairs are created, and the reverse current sharply increases. Another diode structure based on tunneling is a new metal–insulator–semiconductor device having silicon nanocrystals imbedded in the thin insulating film [28]. One way to realize such diodes is by depositing an aluminum electrode on a thin (on the order of 10 nm) SiO_2 layer containing silicon nanocrystals. The substrate is n-type crystalline silicon. The silicon nanocrystals can be created either by oxidizing deposited amorphous silicon layers [28] or by low-energy silicon-ion implantation in the SiO_2 film [29]. In the absence of the nanocrystals, by applying a negative voltage of a few volts on the aluminum electrode relative to the n-type silicon substrate, only a small tunneling current would be present.

Figure 9. Current and conductance plots of a reverse-biased quantum dot diode. The conductance peaks correspond to steps in current curve. [Reprinted from P. Normand et al., Silicon nanocrystal formation in thin thermal-oxide films by very low energy Si^+ ion implantation, *Microelectron. Eng.* **36**(1–4): 79–82 (1997) with kind permission of Elsevier Science-NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.]

When the nanocrystals are introduced, much higher currents are observed while the conductance curve exhibits characteristic peaks. Such peaks are shown in Fig. 9 showing the reverse current and conductance of a quantum dot diode formed by low-energy implantation of silicon in a 10-nm SiO_2 layer [29]. The conductance peaks appear when the metal Fermi level is swept across the discrete energy states of the nanocrystals, thus enabling resonant tunneling from the metal to the semiconductor [28]. The three-dimensional confinement of electrons in the quantum box crystallites creates a large separation between energy states, which along with the Coulomb blockade effect of the occupied states explains the large voltage separation of the three first conductance peaks in Fig. 9 [28,29]. Such quantum dot devices hold the promise of single-electron transistors [30] and silicon-based light emitting diodes [31].

Ending this article, we would like to mention the basic uses of the diode as a device. The most frequent use of the diode is the protection of complementary metal oxide semiconductor (CMOS) integrated circuits from electrostatic discharges by clamping the output pads to the power-supply voltages through reverse-biased p-n junctions. In analog integrated circuits, forward-biased diodes are used for voltage shifting. Such diodes usually come from properly wired bipolar transistors (e.g., emitter–base diodes with base–collector short-circuited). Diodes, as discrete devices, find applications mainly as rectifying elements in power circuits. The breakdown effect of zener diodes makes these devices useful as voltage reference sources in power supplies. Photodiodes are widely used for detecting photons or charge particles. Finally, large area

diodes with exposed front surface and proper design and engineering can efficiently convert solar light into electricity and are used as solar cells [32].

1. INTRODUCTION

A dipole antenna is most commonly a linear metallic wire or rod with a feedpoint at the center as shown in Fig. 1. Most often, this type of antenna has two symmetric radiating arms. Because of the symmetry of the antenna relative to the x - y plane containing the feedpoint, the resultant radiation is independent of ϕ (rotationally symmetric about the z axis). Dipole antennas and arrays of dipoles are commonly used for HF and UHF broadcasting, TV, and FM communications, and as electric field probes. This article describes the basic nature and applications of dipole antennas and some of their variations such as biconical and bowtie antennas, slot dipoles, folded dipoles, sleeve dipoles, and shunt-fed dipoles. The commonly used broadband log periodic and Yagi-Uda dipole arrays are also discussed.

2. DIPOLE ANTENNA TYPES

2.1. Infinitesimal Dipole (Hertzian Dipole)

An infinitesimal dipole ($L \ll \lambda$) is a small element of a linear dipole that is assumed to be short enough that the current (I) can be assumed to be constant along its length L . This is also called a *Hertzian dipole*. The electric and magnetic field components of this dipole are [6]

$$\bar{H} = \frac{1}{4\pi} IL \sin \theta e^{-j\beta_0 r} \left(\frac{j\beta_0}{r} + \frac{1}{r^2} \right) \alpha_\phi \quad (1)$$

$$\begin{aligned} \bar{E} = & \frac{j\eta_0 IL}{2\pi\beta_0} \cos \theta \left(\frac{j\beta_0}{r^2} + \frac{1}{r^3} \right) e^{-j\beta_0 r} \alpha_r \\ & - \frac{j\eta_0 IL}{4\pi\beta_0} \sin \theta \left(-\frac{\beta_0^2}{r} + \frac{j\beta_0}{r^2} + \frac{1}{r^3} \right) e^{-j\beta_0 r} \alpha_\theta \end{aligned} \quad (2)$$

where $\eta_0 = (\mu_0/\epsilon_0)^{1/2}$ is the intrinsic impedance ($= 377 \Omega$) for free space and $\beta_0 = \omega(\mu_0\epsilon_0)^{1/2}$ is the propagation constant ($= \omega/c$, where c is the velocity of light). The fields are

*See also Section on Monopole Antennas

Figure 1. Dipole antenna.

seen to decay rapidly ($1/r^3$ and $1/r^2$ variation) very near the antenna, and less rapidly ($1/r$ variation) farther away. The fields with terms $1/r^2$ and $1/r^3$ (the *induction terms*) provide energy that is stored near the antenna. The fields with $1/r$ variation (the *radiation terms*) provide actual energy propagation away from the antenna. The distance away from the antenna where the induction and radiation terms are equal is $d = \lambda/2\pi$. When $d < \lambda/2\pi$, this is the *near field* of the antenna, and the induction terms dominate. When $d > \lambda/2\pi$, this is the *far field*, and the radiation terms dominate. In the far field, the wave propagation is in the transverse electromagnetic (TEM) mode, which is characteristic of far-field radiation from finite structures.

The far-zone radiated fields of the Hertzian dipole follow from (1) and (2) by retaining the $1/r$ varying terms:

$$\bar{H} = \frac{j}{4\pi r} IL \sin \theta e^{-j\beta_0 r} a_\phi \tag{3}$$

$$\bar{E} = \frac{j\eta_0}{4\pi r} IL \sin \theta e^{-j\beta_0 r} a_\theta \tag{4}$$

As expected for TEM wave propagation, the \mathbf{E} and \mathbf{H} fields are perpendicular to each other and to the outward propagation in the \mathbf{r} direction. Also the ratio of $\mathbf{E}/\mathbf{H} = \eta_0 = (\mu_0/\epsilon_0)^{1/2}$, which is the intrinsic impedance of free space.

The radiation pattern of this short dipole is shown in Fig. 2, and exhibits the classical symmetry expected of dipole antennas, which is both independent of ϕ and symmetric about the x - y plane through the center (feedpoint)

Figure 2. Radiation pattern for an infinitesimal (or Hertzian) dipole.

of the dipole. The magnitude of the total radiated power is $P_{\text{rad}} = 40 \pi^2 I_0^2 (L/\lambda)^2$. From Eqs. (3) and (4) it is interesting to note that even for this constant-current infinitesimal dipole, the radiated power density is proportional to $\sin^2 \theta$. Hence, it is maximum for $\theta = 90^\circ$ (i.e., in the x - y plane normal to the orientation of the dipole) and zero for the directions along the length of the dipole ($\theta = 0^\circ$ and 180°). The latter property for zero radiation along the length of the dipole will be seen for all linear dipoles regardless of length. It follows from the fact that a linear antenna may be considered to be composed of infinitesimal dipoles that do not create \mathbf{E} and \mathbf{H} fields or radiated power density for the $\theta = 0^\circ$ and 180° directions.

2.2. Linear Dipole Antennas

The geometry of a linear dipole antenna of length $L = 2h$ is shown in Fig. 1. The current distribution is sinusoidal, and is given by

$$I(z') = \frac{I(0)}{\sin kh} \sin k(h - |z'|) \text{ for } -h < z' < h \tag{5}$$

where $I(0)$ is the current at the feedpoint of the antenna, h is the half-length of the antenna, and $k = \omega(\mu\epsilon)^{1/2}$ is the propagation constant in the material surrounding the dipole. The current distributions for several lengths of dipole antennas are shown in Fig. 3.

Figure 3. Current distributions and associated radiation patterns for several different lengths of dipole antennas.

The electric and magnetic fields around the dipole are calculated by modeling the antenna as a series of Hertzian or elemental dipoles and integrating the fields from each of these elements. The resultant fields far from the antenna at a distance r are

$$\vec{E} = \frac{j\eta I(0)}{2\pi r \sin(kh)} F(\theta) e^{j(\omega t - kr)} \vec{\theta} \quad (6)$$

and

$$\vec{H} = \frac{jI(0)}{2\pi r \sin(kh)} F(\theta) e^{j(\omega t - kr)} \vec{\phi} \quad (7)$$

where $\eta = (\mu/\epsilon)^{1/2}$, and where the θ dependence of the radiated fields $F(\theta)$ is called the *pattern factor* and is given by the following:

$$F(\theta) = \frac{\cos(kh \cos(\theta)) - \cos kh}{\sin \theta} \quad (8)$$

The radiation power density (*radiation pattern*) is given by

$$P(\theta) = \frac{\vec{E} \bullet \vec{E}^*}{2\eta} \vec{r}_0 = \frac{\eta I^2(0)}{8\pi^2 r_0^2 \sin^2(kh)} F^2(\theta) \quad (9)$$

Using $\eta = \eta_0 = 120\pi$, this can also be expressed in terms of the total radiated power $W (= I^2(0)R_a/2)$ and the feedpoint resistance R_a as follows:

$$P(\theta) = \frac{30}{\pi r^2} \frac{W}{R_a} \frac{F^2(\theta)}{\sin^2 kh} \quad (10)$$

The normalized radiation patterns are shown in Fig. 3b for several different lengths of dipoles.

The directivity of a dipole antenna related to the maximum power density that an antenna can create at a distance r is given by

$$D = \frac{P_{\max}}{P_0} = \frac{F^2(\theta)_{\max}}{\frac{1}{2} \int_0^\pi F^2(\theta) \sin \theta d\theta} \quad (11)$$

$$= \frac{120}{R_a} \frac{F^2(\theta)_{\max}}{\sin^2 kh}$$

where $P_0 = W/(4\pi r^2)$ is the isotropic power density that would have been created at the field point if the antenna had a directivity of one and radiated isotropically for all angles (clearly a mathematical possibility but not physically realizable).

The input resistance R_a of a center-fed dipole antenna of length $2h$ is twice that of an end-fed monopole of length h . This may therefore be obtained by using the graphs given in the related encyclopedia article, *MONOPOLE ANTENNAS*.

The ohmic losses of a dipole antenna [given by $I^2(0)R_{\text{ohmic}}/2$] are quite small, particularly for $h/\lambda > 0.1$. The resultant antenna radiation efficiencies (given by $R_a/(R_a + R_{\text{ohmic}})$) are on the order of 90–99%.

Two effects cause the behavior of physical dipoles to slightly differ from that of ideal dipoles: (1) realistic antennas have some finite thickness, and (2) the ends of the dipole capacitively couple to air, effectively making the dipole electrically longer by 2–9% than its physical length. For a half-wave dipole (length = $2h = \lambda/2$), for instance, the physical length must be slightly shortened in order to create a resonant length antenna ($X_a = 0$). Table 1 shows the wire lengths required to produce a resonant half-wave dipole. This shortening varies from 2% to 9%, depending on the thickness of the dipole.

Since a dipole antenna is a physically resonant structure, its feedpoint impedance (particularly the reactance X_a) varies greatly with frequency. Thus, these antennas have a fairly narrow bandwidth. The VSWR of a dipole antenna as a function of frequency and wire thickness is shown in Fig. 4 for an antenna that would be half-wave resonant at 300 MHz. Using a measure of “usable bandwidth” that the measured VSWR should be less than 2–1, this antenna has bandwidths of $310 - 262 = 48$ MHz for the thicker wire and $304 - 280 = 24$ MHz for the thinner wire. As fractions of the design frequency (300 MHz), the bandwidths are 16 and 8%, respectively.

2.3. Slot Dipole

A slot dipole antenna is a dual to the linear dipole antenna. The radiation pattern of a slot antenna is identical to that of the linear dipole of the same length (see Fig. 3) except that orientations of the \mathbf{E} and \mathbf{H} are interchanged. Also the feedpoint impedance Z_s of a slot antenna is related to that of the dual linear antenna by the following equation

$$Z_s = \frac{\eta^2}{4Z_a} \quad (12)$$

where Z_s is the impedance of the slot and Z_a is the impedance of the dual linear antenna.

2.4. Biconical Dipoles

A biconical dipole such as that shown in Fig. 5a is commonly used for broadband applications when the flare angle θ is between 30° and 60° . The exact flare angle is not

Table 1. Wire Lengths Required to Produce a Resonant Half-Wave Dipole for a Wire Diameter of $2a$ and a Length L

Length : diameter ratio $L/(2a)$	Percent Shortening Required	Resonant Length L	Dipole Thickness Class L
5000	2	0.49λ	Very thin
50	5	0.475λ	Thin
10	9	0.455λ	Thick

Figure 4. VSWR of a dipole antenna as a function of frequency and wire thickness (from Ref. 3).

critical, so it is generally chosen so that the impedance of the dipole nearly matches the impedance of the feedline to which it is connected. The impedance of the biconical dipole varies as a function of wavelength and flare angle, with a relatively flat impedance response for wide flare angles. Hence, this antenna is of broader bandwidth than a simple linear dipole.

Some variations of this method of using flaring to increase bandwidth are the flat bowtie antenna (which may be built on a printed circuit board) and the wire version of the biconical antenna shown in Figs. 5b and 5c, respectively.

2.5. Folded Dipole Antennas

A folded dipole antenna is shown in Fig. 6. The dipole is created by joining two cylindrical dipoles at the ends and driving the entire structure by a transmission line (often a two-wire transmission line) at the center of one arm as shown. The feedpoint impedance of a folded dipole of two identical-diameter arms is 4 times larger than that for an unfolded dipole of the same length. This can actually be advantageous, since the feedpoint resistance may now be comparable to the characteristic impedance Z_0 of the transmission line or feedline. The reactance of the antenna may easily be compensated by using a lumped element with a reactance that is negative of the reactance at the terminals of the folded dipole antenna or else by using a foreshortened antenna length to resonant length arms so that $X_a = 0$ (see Table 1).

Figure 5. Biconical dipole antenna and variations: (a) biconical dipole antenna; (b) flat bowtie antenna; (c) wire version of biconical dipole antenna.

Figure 6. Folded dipole antenna.

2.6. Shunt-Fed Dipoles

Matching networks of reactive elements are generally required to match the feedpoint impedance ($R_a + jX_a$) of center-fed dipoles to transmission lines. Typically these lines have characteristic impedance on the order of 300–600 Ω . To alleviate the need for matching networks, the antennas are at times shunt-fed at symmetric locations off the centerpoint as shown in Fig. 7. This procedure using either the delta match (Fig. 7a) or the T-match (Fig. 7b) is often used for half-wave dipoles ($2h = \lambda/2$) with A and B dimensions that are typically on the order of 0.10–0.15 λ .

2.7. Sleeve Dipole

The sleeve dipole antenna and its equivalent electrical model are shown in Fig. 8. In practice, this antenna is built from a coaxial line with the outside conductor and insulation stripped away from the center conductor, which is left protruding. The outer conductor is connected to the ground plane, and the image produced by the ground plane creates an equivalent sleeve dipole antenna. These dipoles are useful, because they have a broadband VSWR over nearly an octave of bandwidth.

3. APPLICATIONS

Dipole antennas and arrays of dipole antennas are used for shortwave (3–30 MHz) and for VHF and UHF (30–900 MHz) radio and TV broadcasting. If directional communication is desired such as for shortwave radio transmission via the ionosphere, a phased array of horizontal dipoles may be used mounted above a ground plane. The spacing is chosen to send the major lobe of radiation toward the sky at a suitable angle to reflect off the ionosphere and provide broadcast coverage over the desired service area.

Figure 7. Shunt-fed dipoles: (a) delta match; (b) T-match.

Figure 8. Sleeve dipole antenna: (a) physical model; (b) equivalent electrical model.

For VHF and UHF radio and TV broadcasting over a 360° azimuthal angle, collinearly mounted vertical dipoles that are excited in phase with each other are often used. Two examples of this are shown in Figs. 9a and 9b. An example variation of this is a three- to eight-bay turnstile antenna used for TV broadcasting shown in Fig. 10a. Each turnstile is made of two perpendicular slot antennas as shown in Fig. 10b.

Figure 9. Collinearly mounted vertical dipoles for VHF and UHF radio and TV broadcasting: (a) pole-mounted array of collinear dipoles; (b) vertical dipoles spaced around a pole.

Figure 10. Variation on collinearly mounted vertical dipoles: (a) turnstile antenna used for TV broadcasting; (b) two perpendicular slot antennas constituting each turnstile.

3.1. Log periodic Antennas

For broadband applications log periodic antennas are commonly used as both transmitting and receiving antennas. The bandwidth is easily controlled by adjusting the relative lengths of the longest and shortest elements in the array. The geometry of a log periodic array is shown in Fig. 11a, which shows how the “phase reversal” feed system for this antenna is constructed. The equivalent antenna model of this array is shown in Fig. 11b. The elements of the array are dipole antennas that increase in both length and spacing according to the formula

$$\tau = \frac{R_{n+1}}{R_n} = \frac{d_{n+1}}{d_n} \tag{13}$$

where $\tau = f_n/f_{n+1}$ is the ratio of the resonant frequencies f_n and f_{n+1} of the adjacent dipole elements. Since lengths and spacings are interrelated, the choice of one initial value controls the design of the remaining elements. The spacing between one half-wave dipole and its adjacent shorter neighbor is given by

$$\sigma = \frac{d_n}{2L_n} = \frac{(1 - \tau)}{4} \cot \alpha \tag{14}$$

Figure 11. Log periodic dipole array: (a) geometry of a log periodic array showing how the “phase reversal” feed system for this antenna is constructed (from Ref. 6); (b) equivalent antenna model of the log periodic array.

Figure 12. LPA with sawtooth wire elements for increased bandwidth. Dots indicate feedpoint locations; heavy wires indicate dipole elements; light wires indicate wires for structural support only.

Log periodic arrays are generally constructed with small values of α ($10^\circ \leq \alpha \leq 45^\circ$ [5]) and large values of τ ($0.95 \leq \tau \leq 0.7$ [5]), which essentially gives a traveling wave propagating to the left in the backfire direction, away from the antenna array. The nature of this array is that only the elements that are approximately half-wavelength long radiate, and since they are radiating to the left, the smaller elements do not interfere with them. This is accomplished by the phase reversal of the feeds. An array that is built without the phase reversal radiates in the endfire direction. The interference of the longer elements to the right of radiating elements results in spurious reflections and erratic impedance behavior, known as “end effect.”

An effective way to further increase the bandwidth of a log periodic antenna is to change from dipole elements to elements with individual broader bandwidths, similar to changing from a dipole antenna to a biconical antenna. This is accomplished for log periodic arrays by using a configuration of wires such as shown in Fig. 12, where each element is a sawtooth element and therefore has broader bandwidth than the individual dipole elements.

3.2. Broadband Dipole Curtain Arrays

A broadband dipole curtain such as shown in Fig. 13 is commonly used for high-power (100–500-kW) HF ionospheric broadcasting and shortwave broadcasting stations. The curtain is composed of several dipoles, usually a half-wavelength long, mounted horizontally or vertically in a rectangular or square array, often backed by a reflecting plane or wire mesh. This array has several desirable features, including high gain, broad bandwidth, independent control of horizontal and vertical radiation patterns, ease of matching (low VSWR), and the ability to efficiently broadcast efficiently. Using a phased-feeds system, this array allows beamsteering of the radiation

Figure 13. A broadband dipole curtain. Dots indicates feedpoint locations.

pattern in both the azimuthal and elevation planes, providing a very high degree of flexibility.

3.3. VHF/UHF Communication Applications:

3.3.1. Yagi–Uda Dipole Array. Yagi–Uda arrays are commonly used as general-purpose antennas from 3 to 3000 MHz, in particular as home TV antennas. They are inexpensive, have reasonable bandwidth, and have gains up to 17 dBi or more if multiple arrays are used. They have unidirectional beams with moderate sidelobes [6].

A typical Yagi–Uda array is shown in Fig. 14. This array is a simple endfire array of dipole antennas where only one of the elements is driven and the rest are parasitic. The parasitic elements operate as either reflectors or directors. In general [6], the longest antenna, which is about $\lambda/2$ in length, is the main reflector, and is generally spaced $\lambda/4$ in back of the driven dipole. The feed element is commonly a folded dipole antenna $0.45\text{--}0.49\lambda$ long. Adding directors, which are generally $0.4\text{--}0.45\lambda$ long, to the front of the driven element increases the gain of the array. The directors are not always of the same length, diameter, or spacing. Common arrays have 6–12 directors and at most two reflectors. Additional improvements in gain by adding more elements are limited; however, arrays have been designed with 30–40 elements [5]. A gain (relative to isotropic) of 5–9 per wavelength of array length is typical for Yagi–Uda arrays, for an overall gain of 50–54 (14.8–17.3 dB).

The Yagi–Uda array is characterized by a main lobe of radiation in the direction of the director elements and small sidelobes. The beamwidth is small, generally $30\text{--}60^\circ$ [5]. Typical *E*- and *H*-plane patterns of a Yagi–Uda array are shown in Fig. 15. Typically, the performance of a Yagi–Uda array is computed using numerical techniques [5, Ref. 17]. For the simple case where all the elements are approximately the same size, the electric field pattern can be computed from the array factors of the various elements.

The input impedance of a Yagi–Uda array is often small. For example, for a 15-element array with reflector length = 0.5λ , director spacing = 0.34λ , and director length = 0.406λ , the input impedance is 12, 22, 32, 50, or 62Ω for reflector spacings of $0.10, 0.13, 0.15, 0.18,$ and 0.25λ , respectively. This can make matching to typical transmission lines (50, 75, or 300Ω) difficult. Folded dipoles used for the driven element are therefore used to boost the input impedance by a factor of ≥ 4 .

Extensive studies of the design of Yagi–Uda arrays have been made [5, Ref. 20], and tables are provided to optimize the Yagi–Uda array for a desired gain.

Figure 14. Yagi–Uda array.

Figure 15. Typical *E*- and *H*-plane patterns of a Yagi-Uda array; total number of elements = 27, number of directors = 25, number of reflectors = 1, number of driven elements = 1, total length of reflector = 0.5λ , total length of feeder = 0.47λ , total length of each director = 0.406λ , spacing between reflector and feeder = 0.125λ , spacing between adjacent directors = 0.34λ , radius of wires = 0.003λ (from Ref. 7).

3.3.2. Dipoles for Circular Polarization. For applications that require a circularly polarized antenna such as TV and FM broadcasts and space communications, at least two dipoles, each of which has a linear polarization, must be combined in an array, often referred to as *crossed dipoles*. In a crossed dipole configuration, dipoles are mounted perpendicular to each other for circular polarization or at other angles for elliptical polarization. Currents are fed 90° out of phase between the two dipoles. These can also be used as probes for sensing vector fields to isolate individual components of the electric field. Adaptations of the crossed dipole are shown in Figs. 16a and 16b. Dipole arrays such as the Yagi-Uda can also be combined to provide circular polarization, as shown in Fig. 16c.

Figure 16. Cross-dipole applications for circular or elliptical polarization (from Ref. 6): (a) two shunt-fed slanted V dipoles; (b) series-fed slanted dipoles; (c) circularly polarized Yagi-Uda array.

DIRECT SATELLITE TELEVISION BROADCASTING

JOHN P. GODWIN
DirecTV

Direct-to-home (DTH) satellite television broadcasting has no strict technical or legal definition. Since the late 1970s the term has been used to delineate commercial systems that deliver television directly to consumer homes using communication satellites in geosynchronous orbit. Systems originally intended for DTH applications have operated at downlink frequencies above 11 GHz and with antennas of 1 m or less. Certain systems operated at 4 GHz were planned for cable television distribution and became, secondarily, DTH systems with customer parabolic antennas in the 2.5–3.0 m range. Most systems have been supported primarily from subscription and pay-per-view revenues rather than advertising revenues. In the

Figure 15. Typical *E*- and *H*-plane patterns of a Yagi-Uda array; total number of elements = 27, number of directors = 25, number of reflectors = 1, number of driven elements = 1, total length of reflector = 0.5λ , total length of feeder = 0.47λ , total length of each director = 0.406λ , spacing between reflector and feeder = 0.125λ , spacing between adjacent directors = 0.34λ , radius of wires = 0.003λ (from Ref. 7).

3.3.2. Dipoles for Circular Polarization. For applications that require a circularly polarized antenna such as TV and FM broadcasts and space communications, at least two dipoles, each of which has a linear polarization, must be combined in an array, often referred to as *crossed dipoles*. In a crossed dipole configuration, dipoles are mounted perpendicular to each other for circular polarization or at other angles for elliptical polarization. Currents are fed 90° out of phase between the two dipoles. These can also be used as probes for sensing vector fields to isolate individual components of the electric field. Adaptations of the crossed dipole are shown in Figs. 16a and 16b. Dipole arrays such as the Yagi-Uda can also be combined to provide circular polarization, as shown in Fig. 16c.

DIRECT SATELLITE TELEVISION BROADCASTING

JOHN P. GODWIN
DirecTV

Direct-to-home (DTH) satellite television broadcasting has no strict technical or legal definition. Since the late 1970s the term has been used to delineate commercial systems that deliver television directly to consumer homes using communication satellites in geosynchronous orbit. Systems originally intended for DTH applications have operated at downlink frequencies above 11 GHz and with antennas of 1 m or less. Certain systems operated at 4 GHz were planned for cable television distribution and became, secondarily, DTH systems with customer parabolic antennas in the 2.5–3.0 m range. Most systems have been supported primarily from subscription and pay-per-view revenues rather than advertising revenues. In the

various direct-to-home systems deployed worldwide, a variety of technologies has been used, including analog and digital modulations and both standard and high-definition television formats. Certain systems have been entirely national in scope, while others have broadcast on a regional basis. From a regulatory viewpoint, both fixed satellite service (FSS) bands and broadcasting satellite service (BSS) bands have been used. Direct-to-home systems are sometimes also referred to as direct broadcast satellite (DBS) systems. This article describes the broadcasting and reception systems of a typical digital DTH broadcasting system, but does not cover the substantial infrastructure necessary for customer service and billing.

1. EVOLUTION AND EXISTING SYSTEMS

Although DTH satellite television was a dream of satellite engineers since the early 1960s, little progress was made until the early 1980s. Satellite technology steadily improved in generating high-radiofrequency (RF) power levels, and ground electronics improved by the introduction of low-cost, low-noise microwave transistors. Through 1994 these early systems used analog frequency modulation.

During the 1980s in the Americas, the earliest major system was the Satellite Technology Corporation project in the United States. This plan intended to deliver five channels to each time zone with a dedicated satellite for each. The user terminals were to employ parabolic dishes of 85 cm diameter. This project was abandoned, primarily for economic reasons. Also, in the United States during the 1980s, home reception began of satellite transmissions intended for delivery to cable television systems. The transmissions were at C band in the frequency range 3.7–4.2 GHz. These early home dishes were 2.5–3.0 m in diameter and cost several thousands of dollars, but increased satellite power permitted new C-band home dishes to drop in size to about 1.5 m by the early 1990s. This United States C-band DTH marketplace peaked at about 3.9 million homes in 1994. In Japan the quasigovernment broadcaster NHK utilized satellite delivery to 45-cm dishes for both standard National Television Systems Committee (NTSC) and multiple sub-Nyquist encoding (MUSE) high-definition television. By 1993 this service, called BS for broadcasting satellite, was received by 4.5 million homes. The inexpensive analog BS receivers also became a typical feature of new television sets for the Japanese marketplace. In Europe the early use of satellites was for delivery of state-owned television networks. In the early 1990s, the Astra satellites became a major vehicle for DTH delivery of private, commercial channels. Multiple television broadcasters utilized Astra, including British Sky Broadcasting (BSkyB), which was providing over 40 analog channels to 6.4 million homes at the end of 1997 [1]. Other European satellites are also providing DTH services, including Eutelsat and Hispasat.

During 1994 the era of multichannel, all-digital DTH satellite delivery began with two systems in the United States, the Primestar system owned by a consortium of

cable firms, and a system operated primarily by DirecTV, Inc., a unit of Hughes Electronics. The Primestar system used “medium-power” satellites and approximately 0.75–1.0 m dishes; the DirecTV broadcast used “high-power” satellites and 45-cm dishes. By late 1997 the Primestar system delivered more than 160 channels to nearly 2 million homes in the United States by year end 1997. The DirecTV service delivered more than 175 channels to 3.3 million homes in the United States by year end 1997. In 1995 another DTH business using “high-power” satellites entered this marketplace; this new entrant, EchoStar, reached approximately 1 million homes by year end 1997. AlphaStar, a short-lived DTH service, acquired only about 51,000 subscribers in the United States before filing for bankruptcy in 1997. Elsewhere in the Americas, three DTH services to Latin America were initiated in the early 1990s. One of these ventures, Galaxy Latin America, began broadcast operations in June 1995. Galaxy Latin America is a joint venture of Hughes and major media firms from Mexico, Venezuela, and Brazil. (The general company information given above was found at the World Wide Web sites listed in the Further Reading list.)

In Japan in 1996, the joint venture PerfectV started multichannel, all-digital broadcasting with approximately a half-million subscribers by year-end 1997 [2]. This firm was joined in the marketplace by DIRECTV JAPAN in December 1997. A third entrant, Japan Sky Broadcasting (JSkyB), announced in 1997 that it would merge with the first broadcaster, PerfectV. All three firms use a Japanese industry variant of the digital videobroadcasting (DVB) format, and all three use medium-power FSS satellites. Within Japan the category of service provided by these three competitors is called *digital communications satellite*, or *digital CS*, in contrast to the high-power broadcasting satellite or BS service by NHK.

By early 1998 in Europe there were plans underway to convert existing analog systems, for example, BSkyB in the United Kingdom, and to launch new digital satellite platforms. New digital satellite systems in operation include DF1 in Germany; Telepiu in Italy; Via Digital (Hispasat) and Canal Satellite in Spain; TPS, AB-sat, and Canal Satellite Numerique in France [3].

2. REFERENCE ARCHITECTURE

Figure 1 shows a simplified diagram of an all-digital multichannel satellite DTH system. Figure 2 shows the exterior of a typical DTH broadcasting site including four 13-m uplink antennas.

2.1. Broadcasting Facility

Most existing DTH systems have been used as delivery systems for existing programs, for example, broadening the market exposure of existing programming or delivering the programming with improved quality or convenience. As a delivery or rebroadcast system, a substantial portion of programming typically arrives at the DTH broadcasting or uplink facility via other “backhaul” satellites or terrestrial fiber. Programming, such as theatrical films, arrives at the facility as prerecorded

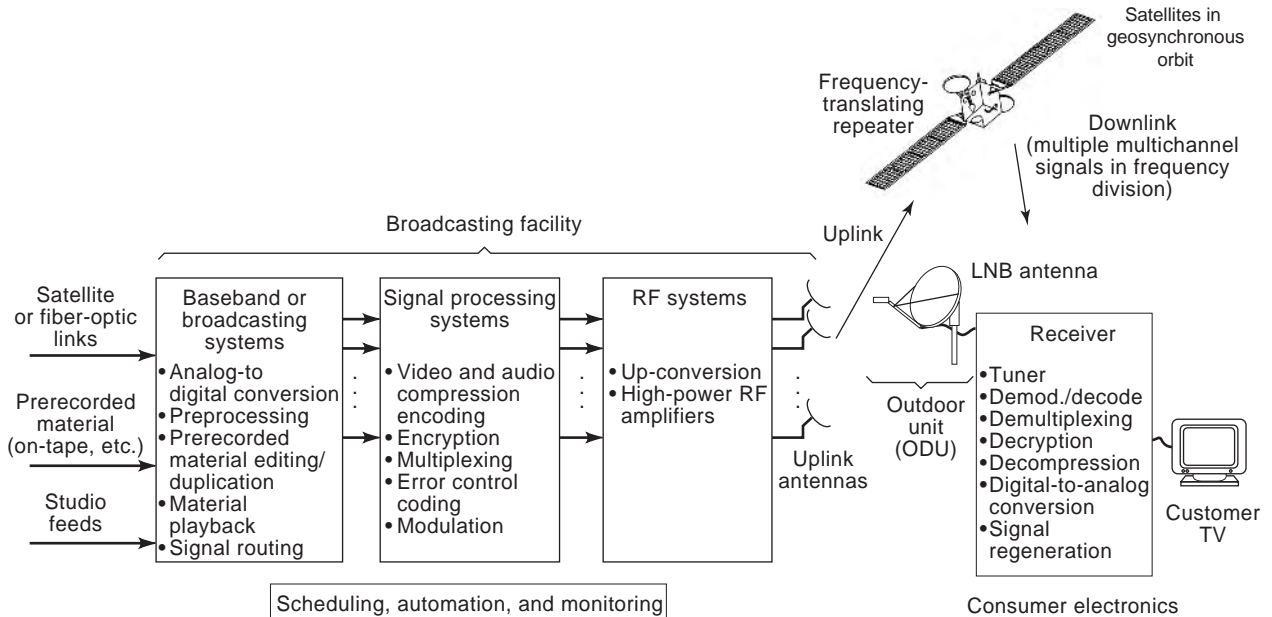

Figure 1. Simplified diagram of an all-digital multichannel satellite DTH system. Major broadcasting and transmission equipment groups are shown but not customer service and billing systems.

digital tapes. In a limited number of systems, the broadcasting facility also includes studios for the creation of unique programming.

The broadcasting facility provides a number of functions common to any broadcasting facility, such as incoming signal monitoring, adjustment, and resynchronization, signal routing within the facility, and for prerecorded material, quality control, cloning, and playback. For playback, broadcast-quality tape players are utilized or, more recently, the material is stored on and played from video file servers using redundant arrays of independent disks (RAID) technology.

Large, multichannel “pay” DTH broadcasting also requires that the broadcast site provide *conditional access*

Figure 2. This DTH site in Colorado uses four 13-m antennas for uplink operations and numerous smaller dishes for programming reception. Courtesy of DirecTV, Inc.

equipment, service information/electronic program guide (SI/EPG) equipment, compression encoders, and multiplexing, error control, and modulation equipment. The conditional access system, which includes equipment within the home, permits customer access to programming services only when certain *conditions* have been met—for example, the customer account is in good standing or the customer is located outside a program blackout area. The SI/EPG equipment prepares specialized broadcast streams that provide the consumer equipment with technical attributes of each view channel (the service information), along with program content information for display by the home receivers. The EPG data typically include program title, start and stop time, synopsis, parental rating, etc. The signal compression equipment performs *redundancy reduction* processing on the television video and separately the audio to reduce the total information rate. A typical digital studio signal at 270 Mbps (megabits per second) is reduced to the range of 2–10 Mbps before broadcast. This dynamically reduces the investment needed to put the transmission path in service (i.e., the satellites) and, conversely, greatly increases the number of available viewer channels for a given satellite investment. Most operational digital DTH systems have utilized the Motion Picture Experts Group (MPEG) MPEG1 or MPEG2 compression standards [4,5], or proprietary systems with similar characteristics. (See Section 4). The *compressed* streams from multiple channels are typically multiplexed into a single high-speed stream. This multiplexing process may be “fixed” in that peak bit rates are allocated to each video channel or, in certain systems, the individual channel rates may vary dynamically depending on their instantaneous bit rate need—the latter approach is called *statistical multiplexing*. The composite bitstream is then coded by error control to add

selective redundancy for error detection and correction. The error control coding permits systems to be designed that offer high-quality operation with a threshold level lower than that possible in previous analog systems. The modulation utilized is commonly a constant envelope modulation such as quadrature phase shift keying (QPSK), which is typical of a satellite system for which the satellite repeater has a limiting final output stage.

2.2. Transmission Path

The transmission path includes the error control coding and modulation described above, the uplink site’s upconverters, transmitters, and antennas, the uplink propagation path, the relay satellite, and the downlink transmission path including the subscriber antenna and receiver front end. In all existing DTH systems, the satellite has been a frequency translating microwave repeater. The expense of generating high satellite RF transmitter levels has caused these systems to be “downlink limited,” meaning that the composite uplink and downlink carrier-to-noise ratio (CNR) is dominated by the downlink CNR. The downlink CNR is determined primarily by the satellite effective isotropic radiated power (EIRP) per transponder, carrier attenuation by rain along the line of sight, and the subscriber antenna gain. The subscriber electronics equipment completing the transmission path consists of a small-aperture antenna, a low-noise block downconverter, tuner, demodulator, and error control decoder. The “error corrected” information stream out of the error control decoder is passed to the remainder of the digital circuitry within the receiver. (See Section 5.)

2.3. Home Electronics

The home electronics in a typical all-digital system include the antenna, low-noise block (LNB) converter, tuner-demodulator-decoder circuitry and other digital circuitry for demultiplexing, decryption under conditional access control, video and audio decompression, and video and audio output signal generation. For example, in digital receivers for the United States marketplace the

final output circuitry recreates an analog composite NTSC or S-video signal for delivery to a standard television set. In a typical digital satellite receiver, a removable device, often in the form of an International Organization for Standardization (ISO) smart card, provides the conditional access control function. (See Section 6.)

3. THEORETICAL MODELS

3.1. Information Theory

Figure 3 shows a theoretical model useful in DTH system design, and the corresponding system elements used to implement the theoretical model. A text such as Ref. 6 describes an “ultimate” system design in which *source encoding* is used to remove redundancy information in the bitstream representing the source, that is, the television signal, and then *channel encoding* to protect the encoded source by carefully adding redundancy. Information theory tells us that source codes exist that can drive the number of bits necessary to encode the source toward a theoretical minimum. MPEG2, shown in the lower portion of Fig. 3, provides a practical realization of the information theory by a complex set of transform, run-length, and other source codes. The MPEG algorithm further reduces the information content by selective removal of detail not subjectively important. Channel-coding theory indicates that channel codes exist that can drive the error rate toward zero while not driving the useful throughput toward zero. In 1966 Forney [7] demonstrated a path to realization of this theory by showing that concatenating multiple, simpler channel codes can create a powerful channel code. Figure 3 illustrates a DTH implementation using concatenated convolutional and Reed–Solomon (RS) codes. A bit interleaver is also used to “smooth” burst error sequences entering the RS decoder.

3.2. Layered Model

Figure 4 provides a “layered” or “protocol” model for DTH systems [8]. The layers shown are for the consumer

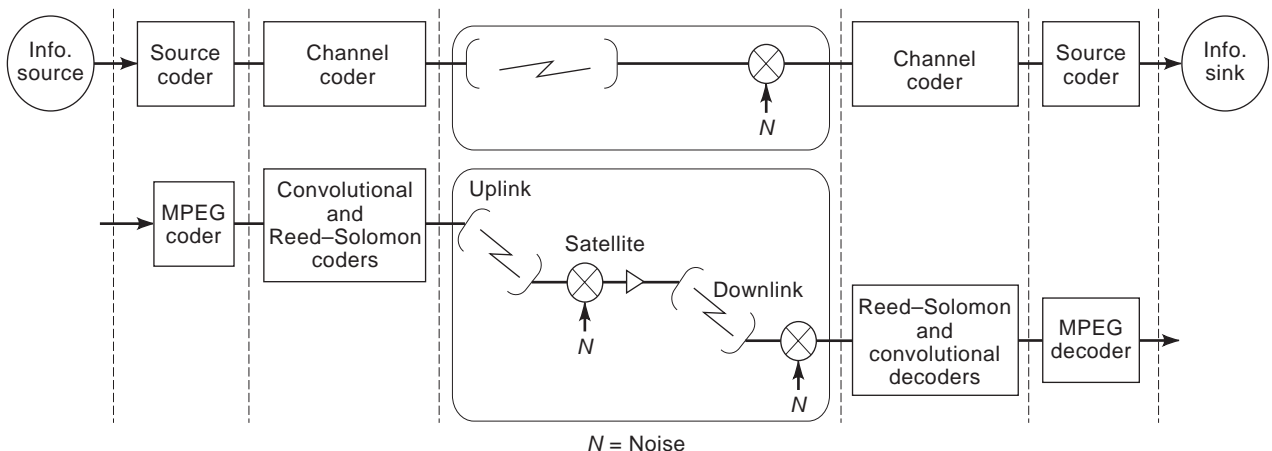

Figure 3. Theoretical source and channel coding are currently implemented by distinct source and channel coding processing.

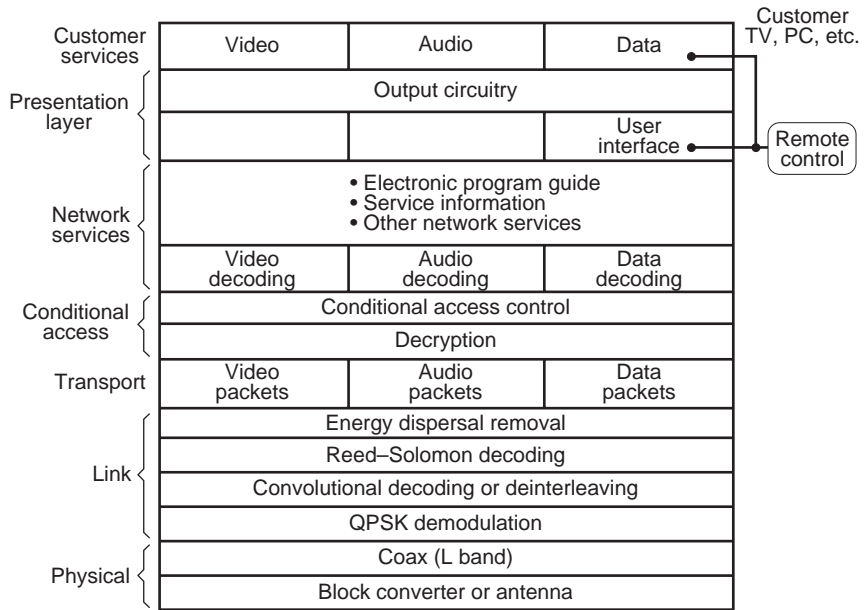

Figure 4. Layered or protocol model provides a practical decomposition of functions in a generic DTH integrated receiver decoder. (Source: International Telecommunication Union, Document 10-11S/TEMP/18, Fig. 1.)

electronics part of the system, but of course the same layers are necessary within the broadcasting facility equipment. As in layered, communications protocols, it is intended that the design tradeoffs of one layer do not interact with the design tradeoffs of the adjoining layers. For example, the design of MPEG decoder chips is largely independent of the design of the video output circuitry, which may be targeted for either NTSC, phase alternation line (PAL), or sequential couleur avec memoire (SECAM) television receivers. As another example, the MPEG coder to decoder syntax was largely designed without great concern about the specific error characteristics of the channel. However, to improve recovery in the event of channel errors, the MPEG standard does include a Macro Block Slice structure that generally limits error propagation to a portion of a frame.

Each layer is discussed in the following and in Sections 4 and 5. The realization of these protocol layers is discussed in Section 6.

3.2.1. Physical Layer. The physical layer at the bottom of Fig. 4 presents the RF to an intermediate-frequency (IF) LNB converter and the resulting IF interface to the digital receiver itself. An IF frequency starting at 950 MHz is typical but not required [8].

3.2.2. Link Layer. This layer is discussed in detail later in Section 5.

3.2.3. Transport Layer. The transport layer is a multiplexing layer or, for example, the systems layer of the MPEG2 standard. In each format given in Ref. 8, this layer provides common, fixed-length packets for all service types including video, audio, data, or overhead data such as electronic program guide information. Fixed-length

packets ease high-speed processing and use of direct memory access.

3.2.4. Conditional Access Layer. This layer provides decoding of specialized conditional access (CA) packets, sometimes called *entitlement management messages* (EMMs) and *entitlement control messages* (ECMs) [9]. The EMMs give instructions to the subscriber electronics regarding the authorized *entitlements*, for example, current subscriptions or pay per view status. The ECMs indirectly provide cryptographic keys for decryption of the individual services. In several systems these packets are passed from the receiver to a smart card with an embedded secure microprocessor. The microprocessor decodes ECMs and returns the corresponding keys. A decryption circuit within the receiver uses the keys and provides decrypted packets for each service to the network services layer. The receiver to microprocessor interface is often similar to the ISO standard [10].

3.2.5. Network Services Layer. This layer delivers the underlying DTH technical services. These services include video plus audio or “television,” standalone audio services, and data delivery services. Separate processes handle the decompression of each service type. For example, video decompression algorithms are quite distinct from those used for audio decompression. Video compression is discussed in greater detail later in Section 4. Other network services include decoding of the electronic program guide and service information syntax.

3.2.6. Presentation Layer. This layer puts the network services in final form for the end user. The layer includes the NTSC or PAL encoders and output circuitry and the on-screen user interface. Although the electronic program guide information delivered by the network is common to all receiver types, each receiver designer may choose a unique user interface concept. For example, for a typical

television program schedule grid, the grid extent (that is, numbers of view channels and time extent) and the color scheme are entirely up to the designer. The presentation layer also receives inputs from the user remote control, which is typically linked to the receiver using infrared or RF.

3.2.7. Customer Services Layer. In most DTH systems the customer provides the final display device such as the television or personal computer. This key assumption bounds the complexity of the satellite receiver and defines the characteristics of its output circuitry. For example, although a typical all-digital DTH system can deliver a three-component television signal, most existing televisions in the United States accept only a composite NTSC input. Since many new sets in the United States also accept a “separate chroma/luma” S-video signal, many satellite receivers in the American marketplace have supplied an S-video output in addition to the composite output. Figure 4 shows the remote control interfacing with both the presentation layer (user interface) and the customer services layer. The latter interface permits control of the display device by the same remote control device—for example, the remote may control the television volume level.

4. COMPRESSION

4.1. Fundamentals

Source coding may be lossless and permit a complete reconstruction by the source decoder, or source coding may be lossy and trade the quality of the reconstructed signal against the bits needed to transmit or store the signal. The nature of the compression algorithms vary with the signal type, its intended audience, and the cost relationship between the value of “saving bits” versus the value of the codec development and production. Reference 11 provides an excellent overview of the television compression state of the art through 1994.

The MPEG1 [4] and MPEG2 standards [5] have been broadly deployed in consumer products. The MPEG1 standard is intended for noninterlace video and data rates up to about 1.5 Mbps. The MPEG2 standard accommodates both noninterlace and interlace video, standard definition applications up to about 10 Mbps, and high-definition formats at bit rates up to about 15–50 Mbps. Note that while these standards provide details on the syntax and semantics between the encoder and decoder and are specific to a standard decoder, they say very little about the encoder. They are very abstract and do not dictate the technology of implementation. Both standards utilize two distinct processes in tandem to achieve high compression levels: discrete cosine transform (DCT) coding and

motion-compensated interframe prediction. The MPEG2 standard makes more complex algorithms available for motion compensation with interlace video. The discussion that follows provides a very simplified description of MPEG processing.

4.2. Discrete Cosine Transform Coder

Figure 5 illustrates the first major MPEG process, a DCT of pixel element values, the *lossy* quantization of these values, and then the *lossless* encoding of the result. Consumer television signals are acquired and displayed as linescan images, but since substantial spatial redundancy exists, the linescan images are first converted to 8×8 pixel blocks for MPEG processing. The DCT represents the horizontal and vertical information in the block using cosine functions as the basis vectors. The quantization step ignores the near-zero coefficients and tends to concentrate the energy in the transform domain into the low-frequency components. The “zigzag” readout of the coefficients starts with the DC coefficient and proceeds in zigzag fashion toward the highest frequency vertical and horizontal component. If insufficient bits are available, the higher-frequency coefficients may not be encoded. The next processing steps use tables of run-length and variable-length codes, which, based on experiment, will require the lowest average number of bits to represent the coefficients. The run-length codes use short codes for very likely bit sequences and long codes for less likely sequences. The variable-length codes are created such that no codeword is the prefix of another codeword. The buffer feedback path recognizes that image redundancy varies substantially across the blocks of a given image, but that for most applications the required output bit rate must be constant. As buffer fullness approaches, quantization can be increased, the bit rate reduced and, unfortunately, the quality will be reduced as well. Note that in multichannel systems, the output of a single encoder need not be at a fixed bit rate. In a DTH system, when a buffer strategy is used across all the video channels carried in a single stream, the technique is called *statistical multiplexing*.

In MPEG the spatial DCT coder described above is supplemented with an interframe predictor to also exploit the temporal redundancy of a given pixel block. Since motion within the image will cause the pixel values to “move” across the frame, the MPEG algorithms also include the technique discussed in the following.

4.3. Motion-Compensated Interframe Prediction

In MPEG, *motion compensation* determines the translation vector of 16×16 pixel blocks of luminance (called *macroblocks*) across multiple frames. Redundancy reduction is achieved by transmitting the vectors and quantized

Figure 5. The discrete cosine transform (DCT) encoder path with its buffer control feedback loop is one of two major elements of the MPEG encoding process.

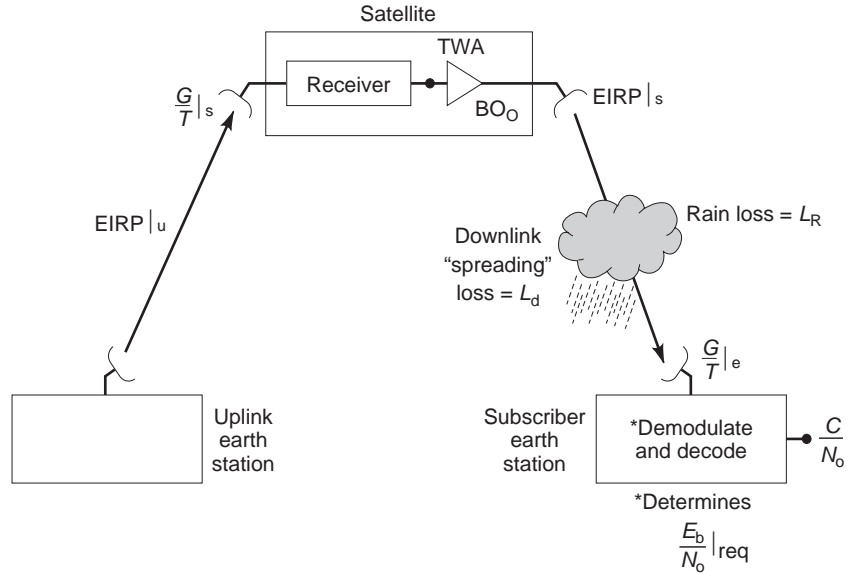

Figure 6. For design analysis purposes, the end-to-end DTH link is often split into “uplink” and “downlink” models. The downlink model assumes a noiseless uplink with the desired signal injected at the satellite TWTA input.

prediction errors, rather than the blocks, and further efficiencies are achieved by differentially encoding the vectors and also using variable length codes. The vectors are determined by finding the best macroblock match in the previous (and possibly also the future) reference frame. These searches generally are restricted in horizontal and vertical extent and can be very computationally intensive.

The MPEG2 algorithm is more sophisticated than MPEG1 in several areas, particularly motion compensation modes. Both compression schemes permit forward prediction, backward prediction, and interpolated prediction between images. The images may be either video frames or fields. MPEG1 can use only frame-based prediction; however, MPEG2 optionally can use field-based prediction, which allows increased coding efficiency for interlaced video. From video material in which the motion is slow, frame prediction is more efficient and MPEG2 performs similarly to MPEG1. As motion increases, field prediction coding becomes more efficient.

The MPEG2 toolkit is very complex. It is impractical to recreate the entire toolkit in every application. The MPEG2 group has therefore defined a handful of subsets or profiles of the full syntax. Also, within a profile, sets of parameter constraints have been identified as levels, with each higher level including all constraints from the lower levels.

5. TRANSMISSION (OR LINK LAYER)

5.1. Link Equation, Antenna Size, and Coverage

The most fundamental design equation in a DTH satellite system is the communications link equation. Ignoring uplink noise and interference contributions, the downlink carrier power (*C*) to noise power density (*N*₀) ratio is, in decibels, as follows [12]:

$$\frac{C}{N_0} = \text{EIRP}|_s - \text{BO}_0 - L_d + \frac{G}{T}|_e - k - L_r \text{ dB} \cdot \text{Hz} \quad (1)$$

where the $\text{EIRP}|_s$ is the effective power of the satellite with respect to an isotropic radiator, BO_0 is the backoff of the satellite transmitter with respect to saturation, L_d is the free space loss at the carrier frequency, $G/T|_e$ is a receive figure of merit for the DTH subscriber terminal, k is Boltzmann’s constant ($-228.6 \text{ dB} \cdot \text{W/K} \cdot \text{Hz}$), and L_r is the link loss due to rain. Figure 6 illustrates the definition of these link parameters. For a typical DTH design, each satellite transmitter handles a single carrier, so carrier intermodulation is not a concern and the transmitter output backoff is nominally zero. As a reference case, assume a downlink frequency of 12 GHz, a path loss of -205.8 dB , and a clear weather situation with $L_r = 0.0 \text{ dB}$. Equation (1) then becomes simplified to

$$\frac{C}{N_0} = \text{EIRP}|_s + \frac{G}{T}|_e + 22.8 \text{ dB} \cdot \text{Hz} \quad (2)$$

Using the parameters of Ref. 13 as an example, the typical edge of coverage EIRP is 52.0 dB·W and the subscriber terminal G/T is 11.3 dB/K for a 45-cm dish. The clear-weather, edge-of-coverage performance is then

$$\frac{C}{N_0} = 86.1 \text{ dB} \cdot \text{Hz} \quad (3)$$

The required C/N_0 is determined by the information bit rate and the required E_b/N_0 , energy per information bit over the noise density, for the system’s modulation and coding with an implementation margin. The equation relating the two ratios is

$$\frac{C}{N_0}|_{\text{req}} = \frac{E_b}{N_0}|_{\text{req}} + r + R \text{ dB} \cdot \text{Hz} \quad (4)$$

where r is the coding rate and R is the transmission rate in dB·Hz. The information bit rate is the product of the code

rate and transmission rate, which is expressed as a sum in decibels.

Using $r = \frac{49}{64}$ and $R = 40$ Mbps (for an information rate of 30.6 Mbps or 74.9 dB · Hz), and a threshold E_b/N_0 value of 7.8 dB · Hz, then

$$\frac{C}{N_0} \Big|_{\text{req}} = 82.7 \text{ dB} \cdot \text{Hz} \quad (5)$$

The clear-weather, edge-of-coverage performance is then the difference of Eqs. (3) and (5), or 3.4 dB. This is the clear-weather margin for a 45 cm dish for the parameters of Ref. 13. Below a 30 cm diameter (for BSS systems in the Americas), intersystem interference sources due to adjacent satellites cause the simplified analysis used above to become quite inappropriate. Above about 90 cm, the narrow beam of the subscriber antenna may actually be detrimental to satisfactory performance. For narrowbeam subscriber antennas, small satellite stationkeeping errors may cause the line of sight to move outside the subscriber antenna’s main beam.

5.2. Propagation Effects at 12 GHz

In the preceding link example, the value L_r is a link margin against rain and other propagation phenomena. In fact, a system design is typically based on statistical and geometric models to predict the rain degradation along the line of sight. Although a variety of propagation-related impairments can occur, the dominant effects are due to rain and wet snow and result in signal attenuation and attendant increases in the received “sky” noise. Experimentation work, as described in Ref. 14, has compared the rain attenuation along a given path with the rain rate measured on the path and found that the specific attenuation (dB/km) can be approximated by the expression

$$\text{Specific attenuation} = a\mathbb{R}^b \quad (6)$$

where \mathbb{R} is the rain rate in the millimeters per hour and a and b are frequency- and temperature-dependent constants.

With this fundamental model, worldwide environmental information and a geometric model of the “rain cylinder” along the line of sight, comprehensive models have been developed for DTH system design. Figure 7 shows the rain regions assumed by the International Telecommunication Union (ITU) for BSS planning for the Americas. Figure 8 illustrates the attenuation predicted by the ITU model for Region K of the Americas. The outage value assumed in Fig. 8 (1% of the worst-case month) is a requirement that should be reevaluated by the designer in each new application.

5.3. Interference

In addition to rain degradations, DTH designs must consider intrasystem and intersystem interference. Interference into the subscriber dish is a primary concern. Received interference includes cross-polarized, cofrequency, intrasystem interference, interference from other

Figure 7. The ITU rain attenuation model for the Broadcasting Satellite Service (12.2–12.7 GHz) has divided the Americas into a number of zones. The model assumes the same rain rate statistics across all areas of a given zone. [Source: International Telecommunication Union, *Radio Regulations*, Vol. 2, App. 30, Fig. 3 (see Ref. 16).]

satellites operating at adjacent orbit locations, and emissions from terrestrial users of the same frequency band. The Broadcasting Satellite Service was carefully planned to separate orbital “slot” assignments for satellites with beams with common coverage [15–17], for example, for the United States the primary orbital assignments have 9° of longitude separation. In the Federal Communications Commission’s (FCC’s) Fixed Satellite Service assignments at 11.7–12.2 GHz, the satellites are separated by as little as 2° of longitude; the 2° separation causes dishes of less than 60 cm in diameter, with relatively little spatial isolation, to have generally unacceptable adjacent satellite interference. In the BSS in the United States, the use of 45-cm dishes is a common practice and one service provider has announced plans to use 30-cm dishes.

5.4. Satellite Design

Figure 9 illustrates a typical DTH satellite platform. All operational DTH systems have used satellites in geosynchronous orbit (GSO) with microwave frequency translation repeaters. After placement in a GSO, the satellite orbital period is equal (synchronous) with the rotational period of Earth, and the satellite appears to be stationary over a given longitude at the equator. This greatly simplifies the design of the millions of receive terminals that point toward the satellite.

A frequency translating repeater typically receives an uplink carrier via the receive coverage antenna beam,

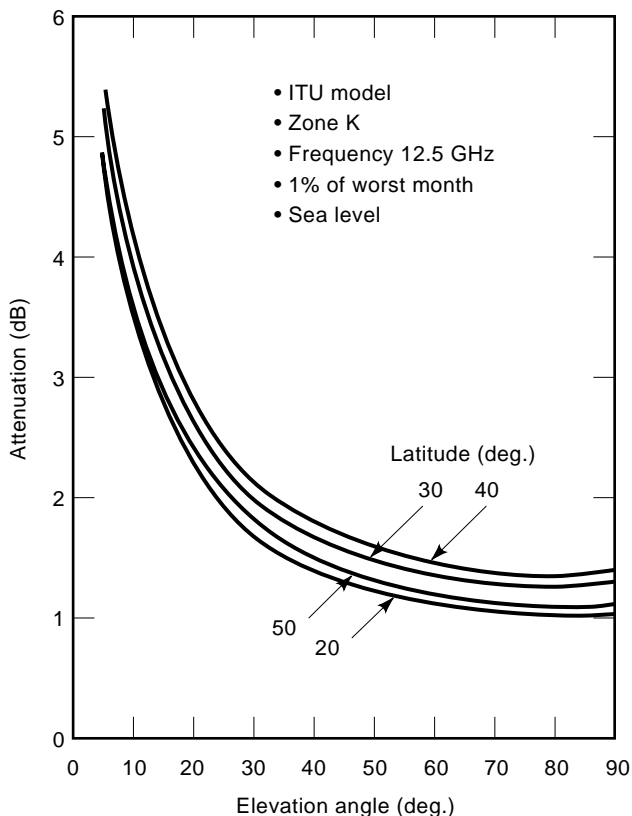

Figure 8. Rain-related downlink attenuation decreases as the elevation angle above the horizon increases but the attenuation does not increase monotonically with latitude. These curves are based on the ITU propagation model and apply to rain zone K. [Source: International Telecommunication Union, *Radio Regulations*, Vol. 2, App. 30, Fig. 4h (see Ref. 16).]

mixes the signal to the downlink frequency, and then amplifies it for transmission to the transmit coverage beam. This type of translating design is highly reliable and flexible. The receive and transmit coverages need not

Figure 9. The deployed configuration of DTH satellites is dominated by the solar panels used for power generation. (Courtesy of DirecTV, Inc.)

be identical—for example, for a typical national system the receive beam coverage may be the 48 contiguous states while the transmit beam coverage may consist of all 50 states. (See *SATELLITE ANTENNAS*.) The DTH satellite’s total DC and total RF power levels are key attributes since most of the satellite weight and hence cost are involved in generating high power levels. This relationship between weight and cost is largely due to the high cost and relative unreliability of launch vehicles. As one example, the Galaxy Latin America satellite launched at the end of 1997 had an end-of-life solar array power capability of about 8.0 kW. (See Ref. 18.)

The satellite electronics associated with processing and amplifying a single carrier, such as a multiplexed digital television carrier, is called a satellite *transponder*. The final output stage or transmitter is normally a traveling-wave-tube amplifier (TWTA), a device with very high gain, high efficiency, perhaps in excess of 50%, and wide bandwidth. Although high-power TWTA reliability was a DTH design issue through 1990, dozens of transmitters with power levels above 100 W have operated without apparent incident for more than three years during the 1990s.

5.5. Regulatory Considerations

Direct-to-home systems are typically regulated at the national level. Until relatively recently virtually all nations had a government-owned post, telephone, and telegraph (PTT) or quasigovernment agency that owned and operated all national telecommunication facilities. With the worldwide trend toward commercialization and competition, the government role is tending toward regulation of DTH businesses via RF and business licensing. For example, in Japan, the Ministry of Post and Telecommunications (MPT) has allowed three new commercial DTH businesses to compete with the traditional quasigovernment broadcaster NHK. Each of these businesses has required MPT approval over multiple aspects including the provider (consignor) of each programming channel, the content of the channel, the business viability of each channel, the RF licensing of the uplink site, and the RF licensing of the satellite.

The situation in the United States is somewhat unique in that competing private telecommunication businesses have existed since the 1970s. The FCC licenses and regulates satellite systems primarily via licensing of the satellites themselves. Small receive-only antennas do not require licensing, and the FCC has ordered that, in general, dishes smaller than 1 m cannot be regulated by state or local authorities [19].

Broadcasting from one nation into another commonly requires official *landing rights* in the distant nation, particularly if the broadcaster intends to collect subscriber fees. Issues of frequency use and coordination between nations are handled by an agency of the United Nations, the International Telecommunication Union [20]. The regulatory agency, that is, the PTT, MPT, or FCC, of each UN nation sends representatives to various ITU working groups to establish mutually agreed international regulations. In general, each agency makes the international

regulations a part of their national regulations; the ITU itself has no powers of enforcement. The ITU has established a number of frequency bands for satellite communications; for DTH applications the bands utilized have been both in the FSS and BSS. The FSS name comes from the fact that, for frequency coordination purposes, the transmitters and receivers are assumed to be at fixed locations, that is, not mobile. The BSS bands also assume “fixed” RF sources but with the added assumption that the primary usage is direct broadcast. In the early 1980s, when the international BSS arrangements were completed, this distinction was quite important since the representatives to the ITU sessions wished to be sure that their nations would someday have the benefit of DTH service. Thus the use of the BSS band (around 12 GHz) has been strictly planned such that every nation existing at the time of the agreement has a specific set of assigned frequencies, polarizations, and satellite antenna coverage. Note that the difference between the FSS and BSS bands is entirely regulatory, not technical—in fact, the BSS band in the United States is the same frequency as the FSS band in Japan and vice versa.

The ITU regulations are based on dividing the world into three regions with specific geographic boundaries. These regions are roughly defined as follows: Region 1 consists of Europe, Africa, and the former Soviet Union; Region 2 consists of the Americas; and Region 3 consists of Asia, excluding the former Soviet Union. Among these different regions the specific regulations can vary substantially, and within a given country the national administration may impose additional regulations. For example, under ITU auspices the BSS frequency bands vary by region, the frequency assignments vary by country, and each country assigns frequencies to a system or company. The downlink plan for all regions is contained in App. 30 of the ITU Radio Regulations [16]. The uplink or “feeder” link plan is contained in Appendix 30A of the ITU Regulations [17]. The 1997 World Radio Conference made changes to certain parameters for Regions 1 and 3 only.

Traditionally, telecommunications standardization has been performed by international groups such as the ITU, International Organization for Standardization (ISO), International Electrotechnical Committee (IEC), and the Joint Technical Committee (JTC1) of the ISO and IEC [21]. As a growing trend, standards are being addressed by regional groups such as the European Telecommunications Institute (ETSI) or the T1 committee in the United States, an organization accredited by the American National Standards Institute. Additionally, specialized, ad hoc groups have been formed to address certain areas of technology, for example, the Asynchronous Transfer Mode (ATM) Forum, the Internet Engineering Task Force (IETF), and the Digital Audio Visual Council (DAVIC).

The ITU has developed a standard for “Digital multi-programme television emissions by satellite” [8], but this is an international recommendation, not a requirement, unless implemented by a national agency as a national standard. This ITU recommendation includes three closely related broadcast formats that can be decoded by the same or similar receiver circuitry. Table 1 compares the characteristics of the three formats. All three utilize

QPSK modulation, concatenated convolutional and Reed–Solomon coding, MPEG compression, and fixed-length transport packets.

In Europe the Digital Video Broadcasting (DVB) Project to develop specifications for all aspects of digital television broadcasting was launched in 1993, following a two-year effort. Since producing its first digital satellite standard, the DVB Project has developed specifications, guidelines, and recommendations for the many ancillary parts of digital broadcasting. These have been accepted as standards for DTH systems by more than 200 broadcasters, manufacturers, network operators, and by regulatory bodies in over 30 countries [9].

In Japan, the Association of Radio Industries and Businesses (ARIB) has selected a DVB variant as the standard for digital CS systems [22]. In the United States, the FCC has not required specific requirements for DTH services.

In general, these various standards have dealt with the link, transport, and network services layers, but not the conditional access layer. Certain governments have standards to restrict or specify the encryption method controlled by the conditional access system. For example, Japan’s MPT has specified the encryption algorithm for the new digital CS systems. Recently, DVB, DAVIC, and the Advanced Television Systems Committee (ATSC) in the United States have begun work on conditional access standardization. (See also TELEVISION BROADCAST TRANSMISSION STANDARDS.)

6. CONSUMER ELECTRONICS

Consumer electronics equipment for DTH applications has achieved very low cost, high performance, and excellent perceived value by carefully designed very-large-scale integration (VLSI) and mass production. By use of standards, for example, MPEG2, and standard techniques, many VLSI have been used in more than one platform and thus achieved greater economies of scale.

6.1. Outdoor Electronics

The offset fed parabolic reflector continues to be the dominant antenna type due to its simplicity and high gain for a given aperture size. The offset geometry achieves an aperture efficiency greater than 60% by eliminating the “feed blockage” present in a focus fed geometry. Figure 10 shows a 45 cm parabolic dish, digital receiver, and remote control produced by Panasonic in 1997 for the CS market in Japan. Single-polarization, fixed-scan, phased array antennas are also used, but generally not where their size would be greater than 60 cm × 60 cm, when distribution losses become significant.

6.2. Receivers

In the design shown in Fig. 10, the receiver supplies DC power to the outdoor electronics via the coaxial cable delivering the digital signals to the receiver. Additionally, biasing this supply voltage above or below the nominal value implements polarization selection at the feed. Figure 11 gives a reference architecture for a digital

Table 1. Summary of ITU Direct-to-Home Formats

Function	System A	System B	System C
Randomization for energy dispersal	Yes	Explicit	Yes
Reed-Solomon outer code	(204, 188, $T=8$)	(146, 130, $T=8$)	(204, 188, $T=8$)
RS field generator polynomial		$X^8 + X^4 + X^3 + X^2 + 1$	
Interleaving	Forney	Ramsey II	Forney
Inner coding		Convolutional, $K=7$	
Basic code		$\frac{1}{2}$	$\frac{1}{3}$
Generator polynomial		171, 133 (octal)	117, 135, 161 (octal)
Forward error correction (FEC)	$\frac{1}{2}$, $\frac{2}{3}$, $\frac{3}{4}$, $\frac{5}{6}$, and $\frac{7}{8}$	$\frac{1}{2}$, $\frac{2}{3}$, and $\frac{6}{7}$	$\frac{1}{2}$, $\frac{2}{3}$, $\frac{3}{4}$, $\frac{4}{5}$, $\frac{5}{6}$, $\frac{11}{11}$, and $\frac{7}{8}$
Signal modulation		QPSK	
Symbol rate	Variable	20 Mbaud	19.5 and 29.3 Mbaud
Transport layer	MPEG2	System B	MPEG2
Packet size (bytes) [payload]	188 [184]	130 [127]	188 [184]
Identification ID (bit)	13	12	13
Statistical multiplexing	Not restricted	Capable	Capable
Method of synchronization for video and audio		Timestamping (27 MHz reference)	
Video source decoding			
Syntax		MPEG2	
Levels		At least main level	
Profiles		At least main profile	
Audio source decoding	MPEG2 layers I and II	MPEG1 layer II (included in MPEG2)	ATSC A/53 or MPEG2 layers ^b I and II
Typical transponder bandwidth (MHz)	Not specified	24 or 27 MHz	24, 27, or 36 MHz
Selectable conditional access		Yes	
Service information	ETS 300 468 ^c	System B	ATSC A/56 + [†] SCTE ^c DVS/011 ^b
Electronic program guide	ETS 300 707 ^c	System B	User-selectable
Teletext	Supported		Not specified
Subtitling		Supported	
Closed caption	Not specified		Yes
Delivered TV standards	Not specified	NTSC and PAL M	NTSC and PAL
Aspect ratios	4:3 and 16:9 (2.21:1 optionally)	4:3 and 16:9	4:3 and 16:9
Video resolution formats	Not restricted	MPEG subset	MPEG subset
Frame rates (frames/s)	Not specified	29.97	25 (PAL) 29.97 (NTSC)
Compatibility with other MPEG2 delivery systems	ISO/IEC 13818 ^d	Some processing required	ISO/IEC 13818 ^d

DTH receiver [8]. This common architecture can be applied to any of the three digital formats contained within the reference.

6.2.1. Hardware. In implementing the reference hardware architecture of Fig. 11, the underlying large-scale integrated circuits (LSI) have since 1994 undergone multiple stages of evolutionary development. As an example, Table 2 summarizes the LSI evolution of the RCA-brand receivers produced for the United States marketplace. Each generation has seen greater levels of integration [23] with the fourth generation being a "two-chip" receiver.

Similar levels of LSI integration are also expected with the availability of such chips as the Texas Instruments Series AV 7000 shown in Fig. 12. This chip provides the

equivalent of 2.5×10^6 transistors using 0.35 μm complementary metal oxide semiconductor (CMOS) technology. Advance information [24] indicates that this circuit will incorporate the following:

- 32-bit reduced instruction set computer (RISC) central processing unit (CPU) [40 million instructions per second (mips)]
- Advanced graphics accelerator
- Memory manager
- Transport/decryption (DES)
- MPEG2 video decoder (MPEG1 and MPEG2)
- Audio decoder (MPEG1)
- NTSC/PAL encoder

Figure 10. Direct-to-home consumer electronics includes a *mini-dish*, a receiver, and remote control. This Panasonic equipment for the DIRECTV JAPAN system went on sale in December 1997. Courtesy of Matsushita Electric Industrial Co., Ltd.

To complete a typical receiver, the designer will add the following:

- Tuner
- Link integrated chip
- Memory [read-only memory (ROM), random-access memory (RAM), dynamic RAM (SDRAM)]
- Smart card
- Telephone modem
- Other peripherals

The AV 7000 chip also provides an interface to external consumer electronics or computer devices using the IEEE 1394 aerial digital protocol.

6.2.2. Software. Software architectures have been driven by the functionality of the major VLSI. The “transport” chips have provided some degree of logical filtering of the high-speed data streams—and hence not required filtering by the primary processor. The MPEG chips have, in general, relied on the processor to perform group of pictures (GOP) and picture sequence-level processing. The primary processor also typically handles program guide and user interface tasks.

From a subscriber standpoint new product generations have exhibited faster response times and improved graphical interfaces. As a point of reference for 1998 technology, the Texas Instruments AV 7000 chip [24] was designed to provide graphics support for up to eight windows, 8 bit color depth, 16 levels of blending and transparency, overlapping windows, and other features.

More recent products have also included *interactive* or *multimedia* software layers, which include, for example, Panasonic’s DVX for DIRECTV JAPAN and Thomson Sun Interactive LLC’s OpenTV. The latter, a forerunner of an emerging interactive services industry, began in 1994 as an alliance of Thomson Multimedia and Sun Microsystems. OpenTV supplies interactive operating systems and services for digital receivers used by pay television services, among other activities [25].

7. MORE RECENT DEVELOPMENTS

7.1. Technology

Technological progress continues in most disciplines important to DTH digital systems. Satellite manufacturers have announced platforms with total DC power levels of at least 15 kW [26]. With a power generation capability 4 times that of DTH satellites launched in 1995, these newer platforms were in orbit before the year 2001.

Modulation and coding show continuing improvements, particularly in turbo coding [27], and advanced modulation formats with higher information content per unit bandwidth (bps/Hz) [28] are under consideration in newer system designs. Compression standards development continued with the MPEG4 standard [29], finally approved in late 1998 for version 1 and late 1999 for version 2. The MPEG4 architecture permits different compression algorithms to be applied to different source material. The proposed inventory of algorithms includes image decomposition into multiple objects and the existing transform-based algorithms such as MPEG2.

7.2. Proposed Systems and Services

New system filings in 1997 at the FCC included a DTH system [30] operating at a downlink frequency of

17.3–17.8 GHz, a band commonly referred to as the *Ka band*. This system filing proposed to accelerate initial use of this frequency band as a new *BSS expansion band*, planned by the ITU to first come into operation in 2007. Also in 1997 a group proposed a system called Skybridge [31], which would reuse the existing BSS band but with nongeosynchronous satellites. The system design uses 64 satellites in 1457 km altitude orbits for a variety of telecommunications services. The plan suggests that frequency reuse can be achieved by not broadcasting from a particular Skybridge satellite to a particular region unless, as seen from the user location, the separation angle is sufficiently large between the line of sight to Skybridge and to the geosynchronous satellite arc. According to the Skybridge plan, if the separation angle is large, and certain other conditions are met, the discrimination of the user antenna will lower the Skybridge interference to an acceptable level.

In the area of new service offerings, the Hughes DirecPC service is one example of DTH satellite broadcasting to a personal computer platform. This service, available in the United States, Japan, and Europe, utilizes a small, outdoor dish and, installed in a conventional PC, a digital satellite receiver card. During 1998 in the United States, the DirecPC services included both *pull* (two-way) and *push* (one way) Internet access. In early 1998, DirecTV, Inc., demonstrated high-definition DTH broadcasting with delivery of 1280 × 1080 picture elements (pixels) in interlaced signals to a television provided by Thomson Consumer Electronics. DirecTV announced that it would initiate nationwide high-definition (HD) broadcasts before the end of 1998 and coincident with the first terrestrial digital broadcasts [32].

DIRECTION OF ARRIVAL ESTIMATION AND ADAPTIVE PROCESSING USING A CONFORMAL PHASED ARRAY

TAPAN K. SARKAR
 Syracuse University
 Syracuse, New York
 MAGDALENA SALAZAR-PALMA
 Madrid Polytechnic University
 Madrid, Spain

1. INTRODUCTION

The phased arrays are used to sort out signals in space specifically when there are coherent multipaths of the

signal, as the information about the multipaths does not exist in the temporal domain. A more sophisticated form of phased arrays is an adaptive array which spatially filters out the signal of interest in the midst of clutter, jammer, and interference. The science of adaptive phased arrays, which started in the early 1950s, was implemented primarily through analog processing, as during that period of time the analog correlation processing was the only way. However, with the advent of digital signal processing we are currently using the same algorithms in the digital scenario without taking a critical look at whether such a methodology is really meaningful. For example, when using an analog adaptive algorithm, it is imperative that the adaptive weights can never be greater than unity as that would be equivalent to using an amplifier for the weights. Hence, the antenna array pattern for analog systems has a great physical significance. Therefore, with analog processing the array resolution is essentially limited by the size of the aperture and how closely one can resolve spatially spaced signals are dictated by the Rayleigh resolution criteria. So with the advent of digital signal processing one can go beyond the Rayleigh resolution and resolve signals within the width of the mainbeam of the array. Moreover, the adaptive weights can take any complex value numerically as we are now processing the signals digitally, and the purpose of the weights is equivalent to multiplying the voltages at the antenna feed points by some numbers. In such scenarios, the antenna array pattern loses to have any special significance at all.

The second shortcoming of the current phased-array methodology is that the mathematical description of the adaptive problem is set up as a detection problem rather than as an estimation problem. To illustrate this point, when we are dealing with radars, we are sending out a waveform, and the assumption is that we are trying to detect the same transmitted waveform delayed in time and attenuated, since the radar signal is not getting dispersed as it is propagating through free space. Hence, in such a situation we only want to know whether the transmitted radar signal reflected from the target exists. If the radar return exists then we know how far is the target from the time delay and from the Doppler shift, the velocity of the target. The optimum way to detect the existence of a particular waveshape we transmitted is to use a matched filter whose transfer function is the complex conjugate of the Fourier transform of the transmitted radar waveform. However, in a multi-path-rich mobile communication, detection is not the problem that we want to address, because we know that the signal is there; what we want to do is to estimate its correct amplitude, as that will correct for fading. The current mathematical approach of adaptive filtering is to use a Wiener filter-based model where a pilot signal is transmitted before every transmission and the channel along with the array is calibrated before the actual signal is sent. This leads to serious problems for real-time transmission as the assumption that the environments are identical when the pilot signal was sent and when the actual transmission is arriving may not be the same in a mobile environment. That is why a direct data domain least-squares approach based on a single snapshot of the voltages measured at the feedpoint of the

antenna elements at a particular instance of time has been used to solve the estimation problem directly [1].

In this article we are going to extend the single-snapshot-based direct-data-domain approach to deal with conformal adaptive phased arrays. In the current way of thinking one wants to use essentially an antenna element that has as close to an omnidirectional pattern as possible and then derive the gain by using hundreds and even thousands of them to get any significant gain from the array. Now one has to put a receiver channel at each of these antenna elements and that exponentially increases the cost. So, in order to minimize the cost, one then defines a subaperture and then sums up all the voltages in an analog fashion at the feedpoint of these antennas. Then either (1) a sum-and-difference beam pattern is formed to resolve the target or (2) digital beamforming using these summed up voltages is employed. This is not a sound procedure as it defeats the entire purpose of digital beamforming. It can easily be seen that this sub aperture summation negates the basic fundamental model of any adaptive signal processing algorithm! What is proposed in this section is to use directive elements on a conformal surface to perform adaptive processing. Use of directive elements will significantly reduce the number of antenna elements, and then, if one places these directive elements on a conformal surface to do adaptive processing, a significantly smaller number of antenna elements will be required, without sacrificing the gain. Such a methodology is illustrated here.

2. DOA ESTIMATION USING A CONFORMAL MICROSTRIP PATCH ARRAY ON THE SIDE OF AN AIRCRAFT

Estimation of direction of arrival (DoA) is one of the primary applications of phased arrays. One DoA estimation algorithm that deals with nonuniformly spaced antenna array elements is the MUSIC (multisignal classification) algorithm [1,2]. However, the performance of this signal processing technique deteriorates if the mutual coupling between the antenna elements and the effect of near-field scatterers are not accounted for in the analysis. Through this example we illustrate how to merge the electromagnetic analysis with the signal processing. In addition, we use a complex antenna element such as a microstrip patch antenna to illustrate how the antenna effects can be taken into account.

In this example, we estimate the DoA of the various signals impinging on a conformal microstrip patch array on the side of a Fokker aircraft. As seen in Fig. 1, the elements of the 11-element microstrip patch array are not placed uniformly, as the two groups of six and five elements are separated much more widely than those in a uniform interelement spacing, nor do they lie on a flat surface. A detailed view of the microstrip patch antenna element is also shown in Fig. 1. The half-wave rectangular microstrip patch element is fed by a probe and is situated on a high-dielectric-constant substrate so that it resonates at an operating frequency of 100 MHz. The thickness of the dielectric substrate is 0.01λ and has an $\epsilon_r = 32$. There is a strong mutual coupling between the antenna elements, including the wings and fuselage of the

Figure 1. Geometry of a microstrip patch array on the side of an aircraft and an equivalent ULVA representing the microstrip patch array mounted on a conformal surface.

aircraft. To account for the effects of the mutual coupling between the antenna elements and the various near-field scatterers, we take the actual electromagnetic field scenario containing the 11-element patch array and then transform and interpolate the actual voltages that exist at the feedpoint of the antenna elements to an equivalent set of antenna voltages that would exist in a uniform linear virtual array (ULVA) containing isotropic omnidirectional radiators radiating in free space. The real 11-element array is interpolated into a virtual array consisting of 11 uniformly spaced omnidirectional point sources separated by 0.25λ at 100 MHz as shown in Fig. 1. We consider three signals arriving from 139° , 99° , and 60° , and impinging at the microstrip patch array from the side of the aircraft. The azimuthal angle is defined from the nose of the aircraft. The intensities and associated DoAs of the three signals to be simulated for this real case are summarized in Table 1. The simulation is done using the electromagnetic simulation tool WIPL-D as described in Ref. 3. In this example the elevation dimension has been neglected as there was only one layer of the microstrip array. Later on we will illustrate how DoA estimation can be done in both azimuth and elevation.

Hence, our problem can be stated as follows. Given the complex array manifold matrix $[A(\varphi)]$ of a nonuniformly spaced array in the presence of mutual coupling between the elements of the array and near-field coupling effects between the platform and other electromagnetic obstacles, our first objective will be to transform the voltages induced in an actual array to a set of voltages that would be induced in ULVA consisting of omnidirectional isotropic point radiators radiating in free space. This is numerically carried out by using a transformation matrix $[\mathfrak{A}_q]$, which,

when operating on $[A(\varphi)]$, produces numerically a modified manifold $[A_v(\varphi)]$, which is due to a ULVA manifold matrix. The elements of this virtual array are isotropic omnidirectional point radiators radiating in free space. Thus, we compensate not only for the lack of nonuniformity but also for the presence of mutual coupling between the elements in the real array in addition to near-field coupling effects between the elements of the array and the aircraft.

After we account for the strong electromagnetic coupling effects between the elements of the microstrip patch array and the aircraft at 100 MHz, such as the effects of nonuniformity in the spacing between the elements on a conformal nonplanar surface and the effects of mutual coupling between the elements of the patch array and their interactions with the wings and fuselage by using the approach described in Chap. 6 of Ref. 1, we first transform the 11 voltages available at the terminals of the antennas to that induced in a ULVA as explained in Ref. 1. Then the matrix pencil approach [1,4,5] is applied to the processed voltages to estimate their DoAs and their complex amplitudes. The matrix pencil approach is also a direct data domain approach to estimate the DoAs of the signals and had been shown to have the least Cramer–Rao bound in the estimation of the poles as compared to various other contemporary methods. Since no covariance matrix is formed from the data, the matrix pencil approach can resolve coherent signals and is computationally very efficient as the poles are found in a direct fashion as the solution of a generalized eigenvalue problem. The simulation results from the two-step process is presented in Table 2. First, the electromagnetic analysis is carried out to compensate for the mutual coupling and near-field effects and then the matrix pencil method is applied to estimate the DoA of the three signals and their complex amplitudes. From Table 2 it is seen that not only the DoAs but also the complex amplitudes of the coherent signals have been recovered with engineering accuracy using a conformal phased array consisting of nonuniformly spaced microstrip patch elements.

3. ADAPTIVE PROCESSING USING A SINGLE SNAPSHOT FROM A NONUNIFORMLY SPACED ARRAY OPERATING IN THE PRESENCE OF MUTUAL COUPLING AND NEAR-FIELD SCATTERERS

In this section, we illustrate how to employ the same interpolation technique of Chap. 6 in Ref. 1 to carry out adaptive processing using a single snapshot of the data using a nonuniformly spaced array in the presence of mutual coupling and near-field scatterers. In all the

Figure 2. Geometry of a nonuniformly spaced linear array (NLA) and a ULVA (shown by dots) electromagnetically representing the NLA.

examples, we are basically interested in three different kinds of antenna configurations. The three different arrangements we have used are as follows:

1. A nonuniformly spaced linear array (NLA) (as shown in Fig. 2)
2. A semicircular array (SCA) (as shown in Fig. 3)
3. A spatially sinusoidally modulated array (SSA) (as shown in Fig. 4)

In all the antenna configurations, as shown in Figs. 2–4, the antenna elements of the real array are considered to be half-wavelength-long thin-wire dipoles. Each element of the array is identically point loaded by 50 Ω at the center. The dipoles are all z-directed and hence are parallel to each other. They are of length $L = \lambda/2$ and radius $r = \lambda/200$. The details of the antenna array elements are presented in Table 3.

Figure 3. Geometry of a semicircular array (SCA) and a ULVA (shown by dots) electromagnetically representing the SCA.

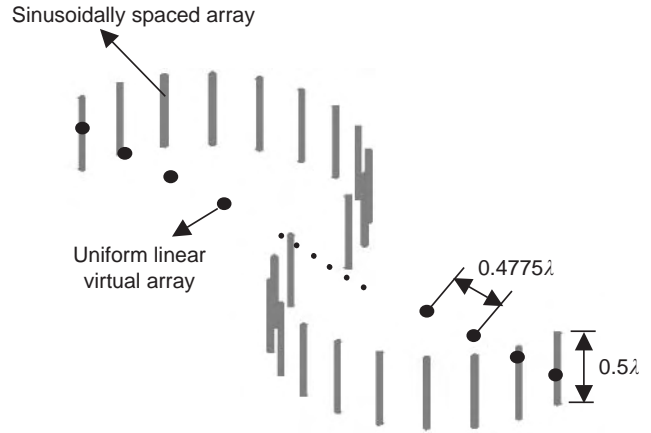

Figure 4. Geometry of a sinusoidally spaced array (SSA) and a ULVA (shown by dots) electromagnetically representing the SSA.

As described in Ref. 1, all the real arrays operating in the three different configurations mentioned above are interpolated into a similar ULVA consisting of 17 uniformly spaced omnidirectional point sources separated by a distance d/λ . Typically d is chosen to be close to $\lambda/2$. By choosing the reference point at the center of the real array in configuration 2 for the SCA and configuration 3 for the sinusoidally modulated array, the steering vectors associated with the virtual array is given by the following equation:

For configuration 1 (NLA = a nonuniformly spaced linear array), we choose the first element in the array as a reference point. Then the steering vectors for the ULVA are given by

$$[A_v(\varphi)] = \{[1, e^{[j2\pi\Delta/\lambda]\cos\varphi}, e^{[j2\pi2\Delta/\lambda]\cos\varphi}, \dots, e^{[j2\pi(2k)\Delta/\lambda]\cos\varphi}]^T\}_{(2k+1) \times 1} \tag{1}$$

Here the number $(2k + 1)$ of elements of the virtual array is considered to be odd and equal to 17, and λ is the wavelength of the signal located in the far-field region of the array, and the distance Δ between the elements in the virtual array is 0.4775λ . Here we want to correct for all the electromagnetic effects in the azimuth sector of $[\Phi] = [\varphi_q, \varphi_{qq}] = [30, 150^\circ]$. The incremental angle ϕ for the computation of the transformation matrix is chosen to be 1° . The sector chosen here is of width 120° symmetrically located around the broadside. Then, a set of voltages induced at the antenna elements are measured and computed for far-field sources located at each of the angles $\varphi_q, \varphi_q + \phi, \varphi_q + 2\phi, \dots, \varphi_{qq}$. The measured/computed vector $A(\varphi)$ is then distorted from the ideal steering vector defined by (1), due to the presence of mutual coupling between the elements of

Jammer 2	1.0–500.0	0.0°	60°

the real array. The actual steering vectors having all the undesired electromagnetic effects are computed using the electromagnetic analysis code WIPL-D [3]. We compute the transformation matrix to compensate for the effects of non-uniformity in spacing and the presence of mutual coupling between the elements of the real array. The induced voltages at the elements of the antenna array result in a compensated set of input voltages in which the nonuniformity in spacing and mutual coupling effects are eliminated from the actual measured/computed voltages. We then apply the direct-data-domain least-squares approach described in Ref. 1 to estimate the complex amplitude of the signal of interest (SoI) given its DoA. Next we illustrate the performance of these three complex arrays through numerical electromagnetic simulations.

3.1. Constant Signal

First, we consider a case where we have two jammers arriving at the array along with the SoI. The interference-to-signal ratio for the jammers impinging on the array from an angle of 60° is varied from 0 to 54 dB. The other jammer arrives at the array at an angle of 70° with respect to the x axis. The SoI is incident at an angle of 80° at a frequency of 300 MHz. The various electrical parameters of the signals are summarized in Table 4. The received signal-to-thermal-noise ratio (SNR) at the antenna elements is set at 20 dB in this example. For this input, the signal strength is estimated while rejecting jammers. This estimation is applied to all the three antenna configurations.

The output signal-to-interference-plus-noise ratio (SINR) is an indicator of the accuracy of our estimate. It is defined as

$$\text{SINR}_{\text{out}} = 20 \log \left| \frac{\alpha}{\alpha - \alpha_{\text{est}}} \right| \quad (2)$$

where α is the amplitude of the desired signal and α_{est} is the estimate of the amplitude of the reconstructed signal.

The results are shown in Figs. 5 and 6 for all the three configurations. The thermal noise is ignored in Fig. 5, while the signal-to-noise ratio is set at 20 dB in Fig. 6. The noise is additive and is modeled as a Gaussian random variable. The x axis of the graph corresponds to the second jammer-to-SoI power level (as defined in Table 4), while the y axis corresponds to the output signal-to-interference-plus-noise ratio, as defined in (2). It can be observed in these figures that the interpolation technique using measured/computed steering vector shows proper compensation for all the electromagnetic effects of the real arrays to estimate the magnitude of the SoI based on the direct-data-domain approach.

Figure 5. Output SINR as a function of interference-to-SoI ratio in decibels (dB) without noise.

3.2. Effect of Variation of Angular Separation between Signal and Jammer

Next we consider the fidelity in the performance for various angular separations between a signal and a closely spaced jammer inside the mainlobe for all three antenna configurations. We consider a case where we have one jammer signal arriving at the array along with the SoI. The DoA of the jammer is varied from 101° to 110° while the SoI is arriving from 100° with respect to the x axis. The signal-to-interference ratio is fixed at 0 dB, as shown in Table 5.

The results are shown in Fig. 7 for the three antenna configurations. The x axis corresponds to the angular separation between the SoI and the jammer, while the y axis corresponds to the output signal-to-interference-plus-noise ratio. These plots indicate that, after compensation of the various unwanted electromagnetic effects, good estimates for the amplitude of the SoI based on a direct-data-domain approach have been obtained. It is seen from the figures that the performance of a semicircular array

Figure 6. Output SINR as a function of interference-to-SoI ratio in dB with additive thermal noise.

Table 5. Complex Amplitudes of Various Signals and Their DoAs

	Magnitude (V/m)	Phase	DoA
Signal	1.0	0.0°	100°
Jammer	1.0	0.0°	$101\text{--}110^\circ$

and a spatially sinusoidally modulated array in estimating the DoA when the interferer is in the mainlobe is better than that for a nonuniform linearly spaced array.

3.3. Effects of Blockage Produced by Near-Field Scatterers

Next, we consider the effects of a near-field scatterer located near each array configuration. The near-field scatterer is located within a distance that is twice the radius of the array and is located along the direction of 60° in such a way that this near-field scatterer interferes with the direct line of sight of the SoI. The length and width of this square cylindrical near-field scatterer are 1.26 wavelengths, and the height of the scatter is 3.28 wavelengths. The desired signal and the jammers are as summarized in Table 5. The results are shown in Fig. 8 for the three different array configurations. It can be observed in these figures that the output signal-to-interference-plus-noise ratio is much lower than where there was no blockage of the SoI, due to a near-field scatterer. However, one can still obtain a proper estimate for the complex amplitude of the SoI after compensating for the various unwanted effects even when the jammer is in the mainlobe and operating in the presence of a large near-field scatterer.

4. DOA ESTIMATION USING A PHASED ARRAY LOCATED ON A CONFORMAL HEMISPHERICAL SURFACE

In this section, we describe how to carry out DoA estimation using directive antenna elements over a conformal surface like a hemisphere. We consider the use of three

**Figure 7.** Output SINR as a function of separation between SoI and jammer.**Figure 8.** Output SINR as a function of separation between SoI and jammer with blockage.

directive antenna elements, such as a short-circuited dual-patch antenna, a dielectric resonator antenna, and a horn antenna as elements in a conformal array. The surface selected for the implementation is a hemisphere. The procedure is to carry out the analysis to obtain the steering vectors over a conical scan subtended by the azimuth angles $[\varphi_q, \varphi_{q+1}]$ and from elevation angles spanning $[\theta_q, \theta_{q+1}]$. This is illustrated by Fig. 9. In the examples to follow, we transform the real array where the antenna elements are located over a hemispherical surface into a two-dimensional uniform planar linear virtual array (2D ULVA) lying in the x - y plane containing the projection of the hemisphere, as shown in Fig. 10. The 2D ULVA have been formulated in the form of a cross, a L-shaped, or a two-dimensional grid configuration. Here, in this methodology, the one-dimensional transformation matrix, for azimuth angles is extended to two dimensions to handle both elevation and azimuth angles [1]. Through

**Figure 9.** Parameters of the sector in which the signals of interest lie.

Figure 10. Different configurations of the two-dimensional uniform linear virtual arrays (d_{va} = distance between the virtual elements): (a) cross-configuration; (b) L configuration; (c) grid configuration.

this 2D transformation matrix, we map the voltages that are induced at the feedpoint of these real antenna elements operating in the presence of mutual coupling and other near-field scatterers to a planar 2D ULVA.

4.1. Short-Circuited Dual-Patch Antenna on a Hemispherical Surface

The first structure to be considered in this technique is the application of a short-circuited dual-patch antenna (SDPA) to form an array over a hemispherical surface. An antenna element representing a SDPA is shown in Fig. 11, and the specific dimensions are given in Fig. 12 [6]. A SDPA consists of two layers, in which the upper patch, which is of trapezoidal shape, is connected along one edge to the ground by a vertical metal wall and the other edge is connected to the lower patch by another vertical wall. These novel features produce a significant reduction in the resonant frequency of the antenna. The numerical results obtained by using a dynamic electromagnetic simulator such as WIPL-D [3] are very similar to the experimental results described in Ref. 6. The actual geometry of the SDPA is shown in Fig. 12, and the input impedance for this geometry as a function of frequency is given in Fig. 13. For this structure the resonant frequency occurs at about 2.41 GHz, as shown in Fig. 13. Finally, the radiation pattern of the SDPA along the E plane is shown in Fig. 14, illustrating that the element pattern has some directivity and the frontlobe is larger than the backlobe. These results are close to the measured ones given in Ref. 6. The SDPA is considered to be fabricated over a finite square ground plane of size G centimeters on each side. We now consider a 48-element array consisting of an SDPA that is distributed over a hemisphere of radius 1.4λ . The elements are placed in a star configuration as seen in Fig. 15. We now transform the actual voltages that are induced at the feedpoint of these antenna elements located on the surface of a hemi-

Figure 11. A short-circuited dual-patch antenna element.

Figure 12. Geometry of the short-circuited dual-patch antenna: $h^1 = 2$ mm; $h^2 = 6$ mm; $d = 4$ mm; $t = 15$ mm; $l = 10$ mm; $L = 16.5$ mm; $W = 17.5$ mm; $G = 27.4$ mm.

isphere to a 16-element planar 2D ULVA located on the x - y plane with $z = 0$. The 2D ULVA consists of omnidirectional point antennas radiating in free space as shown in Fig. 16. The spacing between the virtual elements is 0.5λ at 2.41 GHz, and all the omnidirectional point sources are placed as a 4×4 array located within the base of the hemisphere as seen in Fig. 16.

For all the examples that we will present, the azimuth scan angle φ varies from φ_q to φ_{qq} with an angular step of 1° (i.e., $\varphi = 1$). The step size for the elevation angle is also

Figure 13. Impedance versus frequency of a SDPA; resonance frequency = 2.41 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 14. Radiation pattern of the short-circuited dual-patch antenna; normalized; E plane.

1° (i.e., $\theta = 1^\circ$). This information is now used to calculate the transformation matrix $[\mathfrak{S}_q]$.

We next define a transformation error to check the accuracy of this interpolation in both φ and θ . The error is defined by

Interpolation error

$$= \sqrt{\frac{1}{IJ} \sum_{i=1}^I \sum_{j=1}^J |[A_v(\Phi_q; \Theta_q)]_{i,j} - [\mathfrak{S}_q][A(\Phi_q; \Theta_q \Theta)]_{i,j}|^2} \quad (3)$$

The interpolation error and the condition number of the transformation matrix for different values of the sectors q are given in Table 6. The condition number is defined as the ratio of the largest singular value to the smallest singular value of the transformation matrix. It is an indicator of how sensitive is the solution to changes of the physical dimensions of the antenna array. As observed from Table 6, the error in the transformation to a ULVA remains more or less constant until $0^\circ \leq \theta \leq 50^\circ$. The azimuth scan is the entire 360° . We do not present results beyond $\theta \leq 50^\circ$ because all the SDPA elements on the hemisphere do not see the signal, and hence the transformation matrix $[\mathfrak{S}_q]$ becomes undefined. In that case we restrict the azimuth angle scan, as will be seen later on in this section. Therefore this procedure works if the interpolation error is reasonably small. This can be determined a priori for the structures of interest.

Figure 15. Short-circuited dual-patch antenna array.

Figure 16. Location of the 16-element virtual array when the scanned sector is defined by the azimuth angle $(\varphi_q, \varphi_{qq}) = (30^\circ, 150^\circ)$ and elevation angle $(\theta_q, \theta_{qq}) = (0^\circ, 40^\circ)$.

For this example, the goal here is to estimate the directions of arrival and the amplitudes of three signals that are incident on the array, from $(\varphi, \theta)_1 = (50^\circ, 5^\circ)$, $(\varphi, \theta)_2 = (80^\circ, 20^\circ)$, and $(\varphi, \theta)_3 = (140^\circ, 30^\circ)$. The amplitudes of all the signals are 1V with zero phase. The scan for the transformation matrix is carried out spanning over all the azimuth angles $(\varphi_q, \varphi_{qq}) = (30^\circ, 150^\circ)$ and the elevation angles $(\theta_q, \theta_{qq}) = (0^\circ, 40^\circ)$. The scan for the transformation matrix is carried out spanning over all the azimuth angles $(\varphi_q, \varphi_{qq}) = (30^\circ, 150^\circ)$ and the elevation angles $(\theta_q, \theta_{qq}) = (0^\circ, 40^\circ)$. We now use the matrix pencil method [1,4,5] in two dimensions to estimate the DoA of three signals impinging on the 48-element array, which has been interpolated to a 16-element 2D ULVA as shown in Fig. 16. The distance between the elements of the virtual array is 0.5λ and is centered at a distance $R/2$, where R is the radius of the hemisphere and is oriented along the direction shown in Fig. 16.

To solve this problem, we first generate the transformation matrix that electromagnetically maps the voltages induced on a 16-element SDPA situated on a hemisphere as shaded in Fig. 17 situated over a quadrant of a hemispherical surface to a 16-element 2D ULVA as shown by

Table 6. Interpolation Error and Condition Number for Transformation Matrix $[\mathfrak{S}_q]$ When Interpolating to a 16-Element ULVA

The estimated DoAs of all the three signals given by the matrix pencil method using the voltages induced in the 2D ULVA are given in Table 7. The estimated amplitudes of all three signals are also shown in Table 7.

4.2. Dielectric Resonator Antennas on a Hemispherical Surface

The next example deals with an antenna array consisting of rectangular dielectric resonator (RDRs) antennas as antenna elements located on a hemispherical surface. The reason that the dielectric resonators are chosen as antenna elements is because they have a high radiation efficiency, typically greater than 98%.

An antenna element representing a RDR is shown in Fig. 18, where the specific dimensions of the RDR are as given in Fig. 19 [7]. The coaxial probe extends into a dielectric of relative permittivity of 8.9. The antenna element is situated over a square finite ground plane of dimension $G = 6.0$ cm along each side. The input impedance as a function of frequency is shown in Fig. 20 and was obtained using WIPL-D [3]. The results are similar to those in Ref. 7. The actual resonant frequency of this RDR occurs at 3.07 GHz, as in Fig. 20. Finally, the radiation pattern along the E plane is shown in Fig. 21.

Table 7. Estimation of DoA of Three Signals: $(\varphi, \theta)_1 = (50^\circ, 5^\circ)$, $(\varphi, \theta)_2 = (80^\circ, 20^\circ)$, $(\varphi, \theta)_3 = (140^\circ, 30^\circ)$

140°	30°	141.38°	30.51°	0.93

Figure 18. A rectangular dielectric resonator antenna element.

A total of 48 RDR elements are placed on a hemisphere of radius 2.1λ , as shown in Fig. 22, in order to create an RDR hemispherical array (RDR HA). We now transform the voltages induced in these real antenna elements to those that will be induced by the same incident fields if they were to illuminate the ULVA. The 18 antenna elements that are used in this transformation are represented by the black squares in Fig. 23. The sector over which the transformation is carried out is covered by the azimuth angle of $(\varphi_q, \varphi_{qq}) = (30^\circ, 150^\circ)$, and the elevation scan angle varies from 10° to 50° . The actual voltages induced in the 18 real elements are mapped to the voltages induced that will be induced in the 16-element 2D ULVA, as shown in Fig. 16. For the ULVA the elements are point radiators radiating in free space. These virtual elements are separated by 0.5λ . The results of the accuracy and stability of this transformation are given in Table 8. To carry out an estimation of DoA for three signals impinging on this 48-RDR-element array, we transform the voltages induced in the real 18-element array (as shown by the black squares in Fig. 23) to a 16-element ULVA. The goal here is to estimate the directions of arrival and the amplitudes of three signals that are incident on the array from $(\varphi, \theta)_1 = (50^\circ, 5^\circ)$, $(\varphi, \theta)_2 = (80^\circ, 20^\circ)$, and $(\varphi, \theta)_3 = (140^\circ, 30^\circ)$. The amplitude of all the signals is 1 V with a zero phase angle. The scan to generate the transformation matrix is carried

out over the azimuth angles of $(\varphi_q, \varphi_{qq}) = (30^\circ, 150^\circ)$ and the elevation angles of $(\theta_q, \theta_{qq}) = (0^\circ, 40^\circ)$.

The estimated DoAs of all the three signals given by the matrix pencil method using the voltages induced in the 2D ULVA are given in Table 9. The estimated amplitudes of all three signals are also shown in Table 9.

4.3. An Array of Horn Antennas on a Hemispherical Surface

Finally, we consider an array of horn antennas located on a hemispherical surface. The probe-fed horn antenna is shown in Fig. 24, and its dimensions are shown in Fig. 25. The input impedance at the probe feed is shown in Fig. 26, as a function of frequency demonstrating that the resonant frequency of the horn occurs at 2.41 GHz. At that frequency the element radiation pattern is given by Fig. 27.

A nonplanar conformal array on a hemispherical surface is formed by using 48 horn antennas placed on a

Figure 21. Radiation pattern of the rectangular dielectric resonator antenna element; normalized.

Figure 22. Rectangular dielectric resonator arrays on a hemispherical surface.

Figure 24. A horn antenna.

hemispherical surface of radius 2.4λ as shown in Fig. 28. The properties of the transformation matrix when we transform the voltages induced in the actual array consisting of 18 elements (see Fig. 28) to the voltages that will be induced in a 16-element planar ULVA (see Fig. 16) are given in Table 10. The sector scan in azimuth and in elevation is limited by $(\varphi_q, \varphi_{qq}) = (30^\circ, 150^\circ)$ and $(\theta_q, \theta_{qq}) = (0^\circ, 40^\circ)$, respectively. The interpolation error and the condition number of the transformation matrix $[\mathfrak{S}_q]$ for different sectors q are shown in Table 10.

To carry out DoA estimation of the three signals $(\varphi, \theta)_1 = (50^\circ, 5^\circ)$, $(\varphi, \theta)_2 = (80^\circ, 20^\circ)$, and $(\varphi, \theta)_3 = (140^\circ, 30^\circ)$ impinging on the hemispherical horn array, we transform the voltages that are induced on the shaded 18-horn antenna elements as shown in Fig. 17 to the 2D ULVA of Fig. 16. The amplitude of all the signals is 1 V.

The estimated DoAs of all three signals given by the matrix pencil method using the voltages induced in the 2D ULVA are given in Table 11. The estimated amplitudes of all

three signals are also shown in Table 11. The estimates using a single snapshot of the data voltages are quite accurate. It is important to note that the error in the transformation matrix increases as we increase the azimuth angle θ toward 90° because the increase in degrees of freedom is not commensurate with the number of antenna elements. The error can be controlled either by adding additional arrays or by reducing the scan angle for the group of active elements.

It is seen that it is possible to carry out a DoA estimation by using directive antenna elements located on a hemispherical surface. The 2D matrix pencil method is applied to the outputs from the 2D ULVA to estimate the DoAs of the various signals illustrates that the results can be obtained with engineering accuracy. The use of directive elements is made possible through this methodology, which increases the efficiency of the system, as we now have a larger signal-to-noise ratio to operate in. In addition, such a

system significantly reduces the cost of a phased-array system, as there are fewer antenna elements and hence fewer receiver channels and therefore fewer number of A/Ds are required to carry out digital beamforming.

5. CONCLUSION

This article has presented a preprocessing technique that transforms a nonuniformly spaced array operating in the presence of mutual coupling between the elements of the array and near-field scatterers into a virtual array of omnidirectional isotropic point elements operating in free space that is suitable to the application of a direct data domain algorithm. Through such a transformation formulated using an interpolation technique, we have shown that one can not only compensate for the effects of mutual coupling in a nonuniformly spaced array but also eliminate the effects of strong near-field scatterers. Since the transformed output voltages are those of a uniformly spaced linear array consisting of omnidirectional point

radiators, a conventional adaptive algorithm can easily be applied to extract the SoI in the presence of jammers. Finally, it is shown how to use directive antenna elements located on a conformal hemispherical surface is used to perform DoA estimation using a single snapshot of the data.

DIRECTIONAL COUPLERS

TULLIO ROZZI
ANTONIO MORINI
Università di Ancona
Ancona, Italy

The directional coupler (DC) is the most useful four-port microwave device. Substantially, it consists of a four-port device, where a wave entering any port excites two other ports with prescribed amplitudes, whereas the remaining port is isolated. This property makes the DC an essential component when dealing with microwave devices, as it allows to distinguish reflected waves from incident ones. After a definition of the ideal DC, the typical parameters and the electrical characteristics of actual devices are illustrated, then, the main applications of DC are considered and, finally, some common realizations of DC are shown, particularly focusing the attention on different coupling mechanisms and technologies.

1. DEFINITION

An ideal directional coupler is a linear, reciprocal, and lossless four-port device, often indicated as in Fig. 1, with the following properties [1]:

1. The ports are matched.
2. Each port is only coupled to other two ports, the fourth one being isolated.

Figure 1. Schematic representations of a directional coupler.

Therefore, the scattering matrix of an ideal directional coupler takes the form

$$S = \begin{bmatrix} 0 & s_{12} & s_{13} & 0 \\ s_{12} & 0 & 0 & s_{24} \\ s_{13} & 0 & 0 & s_{24} \\ 0 & s_{24} & s_{34} & 0 \end{bmatrix} \quad (1)$$

apart from an insignificant permutation of the port indices. Thus, a wave incident at port 1, not being reflected at all, splits between ports 2 and 3, while port 4 is isolated. Conversely, a wave incident at port 2 is coupled to ports 1 and 4, with port 3 isolated under that excitation (hence the name directional coupler). The fundamental parameter characterizing the ideal directional coupler is the so-called coupling C , defined as the reciprocal of the magnitude of the transmission coefficient between ports 1 and 3 (i.e., $C = -20 \log |s_{13}|$).

It is also shown that any linear, reciprocal, lossless, and matched four-port must be a directional coupler. Its scattering matrix S is in fact

$$S = \begin{bmatrix} 0 & s_{12} & s_{13} & s_{14} \\ s_{12} & 0 & s_{23} & s_{24} \\ s_{13} & s_{23} & 0 & s_{24} \\ s_{14} & s_{24} & s_{34} & 0 \end{bmatrix} \quad (2)$$

Since losslessness implies the unitarity of the scattering matrix, $SS^+ = I$, where I is the unit matrix, the following equations must be satisfied:

$$|s_{12}|^2 + |s_{13}|^2 + |s_{14}|^2 = 1 \quad (3)$$

$$|s_{12}|^2 + |s_{23}|^2 + |s_{24}|^2 = 1 \quad (4)$$

$$|s_{13}|^2 + |s_{23}|^2 + |s_{34}|^2 = 1 \quad (5)$$

$$|s_{14}|^2 + |s_{24}|^2 + |s_{34}|^2 = 1 \quad (6)$$

$$s_{13}s_{23}^* + s_{14}s_{24}^* = 0 \quad (7)$$

$$s_{12}s_{23}^* + s_{14}s_{34}^* = 0 \quad (8)$$

$$s_{12}s_{24}^* + s_{13}s_{34}^* = 0 \quad (9)$$

By multiplying Eq. (7) by s_{12} and Eq. (8) by s_{13} and subtracting one from the other, one obtains the equation

$$s_{14}(s_{12}s_{24}^* - s_{13}s_{34}^*) = 0 \quad (10)$$

whose solutions are

$$s_{14} = 0 \quad (11)$$

$$s_{12}s_{24}^* = s_{13}s_{34}^* \quad (12)$$

Let us consider the first solution. From Eq. (7) it also follows that $s_{23} = 0$ [otherwise we would have $s_{12} = s_{13} = 0$, in contradiction with Eq. (3)]. Moreover, by subtracting Eq. (4) from Eq. (3) and Eq. (5) from Eq. (3), one obtains $|s_{13}| = |s_{24}| = \alpha$ and $|s_{12}| = |s_{34}| = \beta$. By setting $\phi_{ij} = \angle S_{ij}$, from Eq. (9) one obtains the relationship linking the phases:

$$(\phi_{12} - \phi_{13}) + (\phi_{34} - \phi_{24}) = \pi \quad (13)$$

Therefore, the scattering matrix of the device takes the form

$$S = \begin{bmatrix} 0 & \beta e^{j\phi_{12}} & \alpha e^{j\phi_{13}} & 0 \\ \beta e^{j\phi_{12}} & 0 & 0 & \alpha e^{j\phi_{24}} \\ \alpha e^{j\phi_{13}} & 0 & 0 & \beta e^{j\phi_{34}} \\ 0 & \alpha e^{j\phi_{24}} & \beta e^{j\phi_{34}} & 0 \end{bmatrix} \quad (14)$$

Note that when $\phi_{12} - \phi_{13} = \phi_{34} - \phi_{24}$, as often occurs in practical cases when the coupler is symmetric ($s_{13} = s_{24}$ and $s_{12} = s_{34}$), we obtain

$$\phi_{12} - \phi_{13} = \pi/2 \quad (15)$$

Therefore, the outputs from ports 2 and 3 are in quadrature. In this case, it is always possible to choose the reference planes in such a way that the scattering matrix takes the form

$$S = \begin{bmatrix} 0 & j\beta & \alpha & 0 \\ j\beta & 0 & 0 & \alpha \\ \alpha & 0 & 0 & j\beta \\ 0 & \alpha & j\beta & 0 \end{bmatrix} \quad (16)$$

When we consider Eq. (12), we note immediately that the solutions $s_{12} = 0$ and $s_{34} = 0$, or $s_{13} = 0$ and $s_{24} = 0$, respectively, are the same as that obtained previously, after exchanging the coupled ports with the isolated ones. For instance, under excitation of port 1, the isolated port becomes port 2 while port 3 and port 4 are coupled. Therefore, the first case examined can be taken as typical.

An alternative picture representing a directional coupler commonly used in measurement benches is shown in Fig. 2. The figure emphasizes that port 4 of the DC is terminated on a matched load. Actually, in many applications, port 4 is not used at all. Nevertheless, this port must be loaded in order to suppress the secondary line signals due to its mismatch. Moreover, the sketch suggests an intuitive idea of the realization of a directional coupler: two parallel transmission lines electromagnetically coupled to each other. A portion of the wave traveling from port 1 toward port 2 couples to port 3. According to common

Figure 2. Schematic representations of a directional coupler in the configuration commonly used in microwave measurements.

parlance, the branch connecting ports 1 and 2 is called the “main arm,” while the one linking ports 3 and 4 is called the “secondary arm.”

2. REAL DIRECTIONAL COUPLERS

Of course, it is impossible to obtain both perfect match at the four ports and full isolation of the uncoupled ports [2,3]. Therefore, in order to characterize an actual coupler, it is necessary to define, in addition to the coupling, the directivity D

$$D = 20 \log \frac{|s_{13}|}{|s_{14}|} \tag{17}$$

which represents the ratio between the power flowing from 1 to 3 and that from 1 to 4. In the ideal case the directivity is infinite. Sometimes it is preferred to use another parameter, the isolation I , defined by

$$I = 20 \log \frac{1}{|s_{14}|} = C + D \tag{18}$$

Additionally, actual devices are typically characterized by the following quantities:

- *Frequency range*—operational band of the coupler. Typically, commercial waveguide couplers operate over the whole waveguide band. Over that band the following parameters are defined:
- *The nominal coupling C* —typical values are 3, 6, 10, 20, 30, and 40 dB.
- *Coupling sensitivity/deviation*—the maximum deviation C with respect to its nominal value.
- *Minimum directivity D* —typically between 30 and 50 dB.
- *Insertion loss*—the maximum insertion loss on the main path (ports 1–2).
- *Primary-arm VSWR*—the VSWR on the main path.
- *Secondary-arm VSWR*—that of the secondary path.
- *Power-handling capability (cw)/(peak)*—the maximum continuous or peak power that can be carried by the coupler.
- *Connectors*—indicate the connectors by which the coupler is fed.

Figure 3. Coupling and directivity of a commercial 10 dB multi-hole waveguide directional coupler.

3. MEASUREMENT OF THE COUPLER PARAMETERS

Since a directional coupler is a linear four-port device, its characteristic parameters C and D are commonly deduced by measuring the scattering parameters with the help of a network analyzer. This is very easy in coaxial and rectangular waveguides, where analyzer flanges are the same as those of the device under test. In microstrip and in planar circuits, some attention must be paid to the feed transitions. Such transitions could noticeably alter the response of the coupler. Figure 3 shows the typical measured parameters of a commercial 10-dB directional coupler in a rectangular waveguide.

4. APPLICATIONS

The main feature of the coupler is its ability to detect whether a wave traveling along the main branch is propagating from 1 to 2 or in the opposite direction. That makes the coupler an essential component in telecommunication and measurement systems. A few of the most important applications are discussed next.

4.1. Reflectometer

From the detection of the propagation direction of a wave follows the possibility of measuring the reflection of an unknown device. This is achieved by arranging the measurement bench as depicted in Fig. 4.

In the ideal case [i.e., when the scattering matrix of the directional coupler is given by Eq. (1), and assuming port 4 to be perfectly matched], the signal detected at port 3, b_3 , is proportional to ρ_1 , the reflectivity of the device under test (DUT) loading port 1, while port 2 is fed by a microwave generator (4). In fact

$$b_3 = s_{13}s_{12}\rho_1 \tag{19}$$

Figure 4. Bench for reflectometry measurements. By means of the DC, part of the signal reflected by the device under test flows to port 3, where it is detected and measured.

The measurement requires knowledge of the term $s_{13}s_{12}$, which can be easily measured by substituting the unknown load ρ_1 with a known one, typically a totally reflecting load, as a short circuit ($\rho_k = -1$). Under such a condition, the signal delivered at port 3 is

$$b_{3k} = -s_{13}s_{12} = -s_{13}s_{12} \quad (20)$$

Once this step, commonly referred to as the calibration, has been completed, one can find the reflection ρ_1 as

$$\rho_1 = -b_3/b_{3k} \quad (21)$$

4.2. Monitoring, Feedback, and Power Measurements

In the configuration of Fig. 5 the coupler is used for the purpose of monitoring the output level of a given source. The signal at port 3 can also be used as a feedback for the source itself—for instance, when a leveled output power is required (see FEEDBACK AMPLIFIERS).

The use of coupler with large coupling is very useful when dealing with measurements of high power signals, which could destroy power meters. The typical bench for such measurements is shown in Fig. 6.

4.3. Couplers as Part of More Complex Systems

The coupler often represents an essential part of more complex devices, such as the mixer or the four-way circulator, shown in Figs. 7 and 8, respectively. In the first case the coupler provides a strong separation between the local oscillator (LO), while in the second case two 3 dB couplers, connected as shown in Fig. 8, permit one to obtain (in the

Figure 5. Monitoring and feedback of a source output. Part of the signal outgoing from the amplifier is coupled into the detector and used to control the gain of the amplifier.

Figure 6. Measurement of power signals. Only a small amount of the power signal is delivered to the power meter in order to prevent damage.

ideal case) the following scattering matrix:

$$S = \begin{bmatrix} 0 & 0 & 0 & e^{j\phi_{14'}} \\ 0 & 0 & e^{j\phi_{41'}} & 0 \\ 0 & e^{j\phi_{1'4}} & 0 & 0 \\ e^{j\phi_{4'1}} & 0 & 0 & 0 \end{bmatrix} \quad (22)$$

When port 1 is fed, the power equally splits between ports 2 and 3, while port 4 is isolated. Then, thanks to the phase shifter, the signal traveling from port 3 to port 3' is shifted by 180° with respect to the signal directly arriving at port 2'. The output of the combination of the two signals 180° out of phase is different from zero only at port 4'. Therefore, $s_{14} = 0$, $s_{14'} \neq 0$ and $s_{11'} = 0$. Analogously, when port 4 is fed, ports 1 and 4' are isolated, while port 1' is coupled. It is easy to repeat the same reasoning when ports 1' and 4' are fed and to recover the scattering matrix of Eq. (22).

5. COUPLING MECHANISMS

The two lengths of transmission line forming the coupler can be coupled to each other by different mechanisms. Schematically, a first distinction can be made between lumped and distributed coupling [5].

Considering that at microwave frequencies purely lumped coupling does not exist, since propagation effects occur, we will consider the coupling as lumped if the region where the coupling physically takes place is much shorter

Figure 7. Microwave mixer. The radiofrequency (RF) low power signal, coming from the antenna, is mixed with the one generated by the local oscillator (LO) via a nonlinear device (diode). The filter separates the intermediate frequency (IF) while the directional coupler provides a strong isolation between RF and LO channels.

Figure 8. A four-way circulator is supposed to feed one port at a time. For instance port 1: In that case port 4 is uncoupled and the signal is split equally among the remaining ports of the first junction. At the second junction, the two signals combine 180° out of phase because of the phase shifter inserted in the lower pattern. Therefore, due to the symmetry, they can couple only to port 4', while port 1' is isolated. The same reasoning applies when port 4' is being fed. In that case, however, the phase shifter does not operate as the signal flows counterclockwise in the lower pattern. Therefore, the signals arriving at the first coupler are in phase and combine only to port 1. Analogous reasoning holds for ports 1' and 4.

than the wavelength. Lumped coupling can be achieved in both waveguide and planar technology.

In the first case, a further distinction can be made as to whether the coupling is directive. Coupling may be made directive by shaping the coupling region in such a way that on the secondary guide it produces two waves that are in phase opposition in one direction. The double aperture invented by Saad and Riblet [6] (Fig. 9a) provides a clear example of such a mechanism. In fact, in the secondary guide the thin vertical slot produces two waves 180° out of phase, propagating in opposite direction, while the thin horizontal slot produces two waves in phase. It is therefore possible to choose the dimensions and the positions of the two slots so that the amplitudes of the waves that are separately excited are almost the same. Thus, in one direction the two waves sum in phase, while in the opposite direction they cancel. Note that the bandwidth of this coupler is wide enough since the aforementioned mechanism does not take advantage of resonance effects. The same mechanism can be exploited by collapsing the two thin apertures into an elliptical one and adjusting eccentricity

Figure 9. Riblet and Saad directional aperture. In the second arm, the magnetic current M_v excites two waves whose amplitudes are 180° out of phase and propagating in opposite directions. On the contrary, the waves excited by the magnetic current M_h are in phase. Hence, it is possible to adjust the dimensions of the apertures in such a way that the two scattered waves cancel in one direction and sum in the opposite over a broad band.

Figure 10. Waveguides coupled via two circular holes spaced by a distance $d = \lambda_g/4$. At the resonant frequency the waves propagating toward the right, C_1 and C_2 , coupled to the secondary arm by the holes, sum in phase while those propagating toward the left, D_1 and D_2 , cancel, because of the 180° phase shift due to the different pattern.

and the position according to the preceding criteria [7,8], as shown in Fig. 9b.

Of course, coupler performance can be strongly improved by cascading several properly spaced apertures. To understand the principle of operation, let us consider two lengths of rectangular waveguides positioned side by side and coupled via two apertures drilled in the broad wall, as illustrated in Fig. 10. We want to couple them in such a way that a fraction of the power traveling from port 1 to port 2 is delivered to port 3 while port 4 is isolated. On the contrary, a wave traveling from 2 to 1 must couple only to port 4. If C_k and D_k denote the fraction of signal delivered to ports 3 and 4, respectively, when a wave travels from port 1 to 2, then the amplitude of the wave at port 3 is given by

$$A_3 \approx |(C_1 + C_2)| \tag{23}$$

while at port 4 we have

$$A_4 \approx |(D_1 + D_2 e^{-j2\beta d})| \tag{24}$$

Therefore, if $D_1 \approx D_2$, $C_1 \approx C_2$, and $2\beta d = \pi$ (that is, the apertures are equal and spaced by $\lambda_g/4$), $A_4 = 0$. Hence, the structure shows, at least at one frequency, the characteristics we are looking for. It is apparent that the design of a directional coupler providing given performance over almost the whole waveguide band is quantitatively much more complicated and requires the use of an appropriately dimensioned array of apertures, as schematically sketched in Fig. 11.

Under the hypothesis that the power coupled by a single aperture to the secondary waveguide is small, let us assume C_n and D_n to be the coupling coefficients of the n th aperture in the forward and reverse directions. Let us also suppose to separate the apertures by a distance d . Hence, the whole coupling into port 3 (B_3), computed in correspondence of the last aperture, is

$$B_3 = A e^{-j\beta N d} \sum_{n=0}^N C_n e^{-j\beta(N-n)d} \tag{25}$$

Figure 11. Multiaperture waveguide directional coupler. Dimensions and positions of the coupling holes are chosen so as to optimize DC performance over the whole waveguide band.

The whole coupling coefficient into port 4, B_4 , computed in correspondence of the first aperture is

$$B_4 = A \sum_{n=0}^N D_n e^{-j2\beta nd} \quad (26)$$

Coupling and directivity are given by the following formulas [2]:

$$C = -20 \log \left| \sum_{n=0}^N C_n \right| \quad (27)$$

$$D = -C - 20 \log \left| \sum_{n=0}^N D_n e^{-j2\beta nd} \right| \quad (28)$$

Bethe showed that the forward and the reverse couplings between two waveguides via a circular aperture of radius r_n , normalized with respect to the waveguide width a , are, respectively, $C_n = T_f r_n^3$ and $D_n = T_b r_n^3$. Under the hypothesis that the wall separating the two waveguides is infinitesimally thin, the coefficients T_f and T_b assume closed-form expressions [9]. Therefore, we can rewrite C and D in terms of the latter

$$C = -20 \log |T_f| - 20 \log \left| \sum_{n=0}^N r_n^3 \right| \quad (29)$$

$$D = -C - 20 \log |T_b| - 20 \log |F| \quad (30)$$

where we have used the array factor F , defined as $F = \sum_{n=0}^N r_n^3 e^{-j2\beta nd}$.

The radii r_n are then chosen in such a way as to obtain C and D over the prescribed band. This is analogous to the design of filters and impedance transformers. As in those cases, a Chebyshev characteristic often represents the best tradeoff in terms of performance/number of array elements. Apertures are chosen in such a way as to equate the coefficients of the array factor to those of the

Chebyshev polynomial of order N , T_N :

$$F = \left| \sum_{n=0}^N r_n^3 e^{-j2n\theta} \right| \quad (31)$$

$$= K |T_N(\sec \theta_m \cos \theta)| \quad \text{where } \theta = \beta d$$

The midband frequency is $\theta = \pi/2$ and corresponds to $d = \lambda_g/4$, and θ_m is the value of βd at the band edges. The positive constant K is chosen to obtain the desired coupling at the midband frequency:

$$C = -20 \log K |T_f| |T_N(\sec \theta_m)| \quad (32)$$

When $\theta = 0$, $F = |\sum_{n=0}^N r_n^3| = |T_N(\sec \theta_m)|$. Therefore, the directivity is given by the formulas

$$D = 20 \left[\log \left| \frac{T_f}{T_b} \right| + \log \left| \frac{T_N(\sec \theta_m)}{T_N(\sec \theta_m \cos \theta)} \right| \right] \theta \neq \frac{\pi}{2} \quad (33)$$

$$D = 20 \left[\log \left| \frac{T_f}{T_b} \right| + \log |T_N(\sec \theta_m)| \right] \theta = \frac{\pi}{2} \quad (34)$$

Although T_f/T_b depends on frequency and the characteristic is, in principle, different from the Chebyshev one, nevertheless such a shift is almost negligible, except very close to the midband frequency. Therefore, in the wide-band case that contribution is negligible in the band where $\beta d = \theta_m$. Correspondingly

$$D = D_m = 20 \log |T_N(\sec \theta_m)| \quad (35)$$

where D_m is the minimum directivity in the passband, due to the array factor. Hence, once the coupler specifications are set in terms of midband frequency f_0 , bandwidth Δ_f , coupling, and directivity, the distance d separating two adjacent apertures is given by

$$d = \frac{\pi}{2\beta(f_0)} \quad (36)$$

It is immediate to compute $\cos \theta_m \approx d\beta(f_0 \pm \Delta f)$ and, from Eq. (35), the degree N of the Chebyshev polynomial yielding the specifications on directivity. Because of the non-linearity of $\beta(f)$, $\cos \theta_m$ is only approximately calculated.

The constant K is obtained from Eq. (32):

$$K = 10^{-C/20} |T_f| |T_N(\sec \theta_m)| \quad (37)$$

Once the coefficients T_f are properly computed, either by means of an electromagnetic analysis or by Bethe's more accurate closed formulas, one has only to equate the coefficients of the array factor to those of T_N and to determine the aperture radii. The preceding theory could be further improved with the help of a more accurate analysis of the coupling mechanisms, as the one proposed by Levy [10,11]. At present, however, thanks to the availability of efficient and accurate field theory based computer-aided design (CAD), it seems to be more convenient to improve the design by performing an optimization directly on the

Figure 12. The branchline coupler.

electromagnetic model of the actual physical structure. The resulting design is exact, and device tuning is unnecessary [12] (see ELECTROMAGNETIC FIELD MEASUREMENT) [13].

In planar technology, lumped coupling is often obtained by physically connecting two lines. In the preceding configuration, coupling due to electromagnetic induction can be considered negligible with respect to direct coupling. The main couplers employing such a coupling mechanism are the branchline coupler and the hybrid ring coupler. Both permit one to obtain large coupling values easily, since the lines are electrically connected. In particular, the electromagnetic analysis of the first one (Fig. 12) is difficult to carry out rigorously; a circuit analysis, however, is simple if one takes advantage of the four-fold symmetry. In fact, it is easy to study the equivalent circuit under four independent excitations: (1,1,1,1), (1, -1, -1,1), (1, -1,1, -1), (1,1, -1, -1). The corresponding reflections at the port 1, $\Gamma_a, \Gamma_b, \Gamma_c, \Gamma_d$ are given by [5]

$$\Gamma_a = \frac{1 - jY_t t_t - jY_b t_b}{1 + jY_t t_t + jY_b t_b} \tag{38}$$

$$\Gamma_b = \frac{t_t + jY_t - jY_b t_t t_b}{t_t - jY_t + jY_b t_t t_b} \tag{39}$$

$$\Gamma_c = \frac{t_b - jY_t t_t t_b + jY_b}{t_b + jY_t t_t t_b - jY_b} \tag{40}$$

$$\Gamma_d = \frac{t_t t_b + jY_t t_b + jY_b t_t}{t_t t_b - jY_t t_b - jY_b t_t} \tag{41}$$

where $t_t = \tan \beta_t d_1/2$, $t_b = \tan \beta_d d_2/2$, and Y_t and Y_b are the normalized characteristic admittances of the throughline and the branchlines, respectively. The characteristic admittance of the input line is normalized to 1.

It is immediate to combine Eqs. (38)–(41), thus finding the scattering parameters of the branchline coupler:

$$S_{11} = \frac{1}{4}(\Gamma_a + \Gamma_b + \Gamma_c + \Gamma_d) \tag{42}$$

$$S_{12} = \frac{1}{4}(\Gamma_a - \Gamma_b + \Gamma_c - \Gamma_d) \tag{43}$$

$$S_{13} = \frac{1}{4}(\Gamma_a - \Gamma_b - \Gamma_c + \Gamma_d) \tag{44}$$

$$S_{14} = \frac{1}{4}(\Gamma_a + \Gamma_b - \Gamma_c - \Gamma_d) \tag{45}$$

Figure 13. Ring coupler. A wave entering port 1 is split into two waves that recombine in phase at ports 2 and 4. On the other hand, port 3 is isolated, since the waves propagating clockwise and counterclockwise respectively are 180° out of phase. The same reasoning applies to the remaining ports.

If $t_t = t_b = 1$ (i.e., the electrical lengths of the throughline and the branchline are the same) and also $Y_t^2 - Y_b^2 = 1$, the four ports are matched, $S_{14} = 0$, and

$$S_{31} = -\frac{Y_b}{Y_t} \tag{46}$$

$$S_{21} = -j\frac{1}{Y_t} \tag{47}$$

S_{31} and S_{21} are in quadrature, which is predictable because of the symmetry of the coupler. The coupling $C = 20 \log 1/|S_{31}|$ depends on the ratio between the two characteristic impedances. When $Y_t/Y_b = \sqrt{2}$, $C = 3$ dB. In that case a coupler, also having the outputs in quadrature, is commonly called “hybrid.” The preceding characteristics hold exactly only in a narrow interval around of the working frequency. However, it is possible to enlarge considerably the bandwidth of the coupler by cascading sections [14,15].

The principal of operation of the hybrid ring (Fig. 13) is similar to that of the branch coupler. When port 1 is fed, the signal splits equally into two signals traveling clockwise and counterclockwise that recombine at the remaining ports. At ports 2 and 3 the signals sum in phase, while at port 4 they are 180° out of phase and their combination is negligible. Therefore, ports 2 and 3 are coupled while port 4 is isolated. The reasoning can be easily extended to the other ports, thus recovering the characteristic of a DC.

6. DISTRIBUTED COUPLING

In planar structures (e.g., microstrip, stripline, finline, slotline, which are the most common), as well as in TEM lines (e.g., coaxial cables), the coupling is often obtained by placing the two lines parallel and close to each other over a certain length, in such a way that a portion of the field wave traveling along the first guide couples by electromagnetic induction into the second one in contraflow, as schematically sketched in Fig. 14 [16–18]. The coupling depends mainly on the gap separating the two strips: The wider the gap, the weaker the coupling.

Figure 14. Distributed coupling between strips on the same substrate: A wave traveling on a line couples electromagnetically to the other one. Coupling depends both on the distance between the lines and on their length.

We take as typical the coupler shown in Fig. 14 consisting of two parallel strips of length l placed on a grounded substrate and separated by a distance d . The twofold symmetry of the circuit with respect to the planes $x = 0$ and $z = 0$ enforces the following relationships linking the scattering parameters:

$$s_{11} = s_{22} = s_{33} = s_{44} \quad (48)$$

$$s_{12} = s_{34} \quad (49)$$

$$s_{13} = s_{24} \quad (50)$$

$$s_{14} = s_{23} \quad (51)$$

Hence, the scattering matrix takes the form

$$S = \begin{bmatrix} s_{11} & s_{12} & s_{13} & s_{14} \\ s_{12} & s_{11} & s_{14} & s_{13} \\ s_{12} & s_{14} & s_{11} & s_{14} \\ s_{14} & s_{13} & s_{12} & s_{11} \end{bmatrix} \quad (52)$$

The scattering parameters can be calculated by considering two independent sets of excitations. The first is $a_1 = 1$, $a_2 = 0$, $a_3 = 0$, $a_4 = 1$ and corresponds to a magnetic wall on the symmetry plane $x = 0$. The second is $a_1 = 1$, $a_2 = 0$, $a_3 = 0$, $a_4 = -1$ and corresponds to an electric wall on the same symmetry plane. The reflected waves at ports 1 and 2 are given by

a under the first excitation

$$b_1^e = s_{11} + s_{13} \quad (53)$$

$$b_2^e = s_{12} + s_{14} \quad (54)$$

b under the second excitation

$$b_1^o = s_{11} - s_{13} \quad (55)$$

$$b_2^o = s_{12} - s_{14} \quad (56)$$

It is immediate to calculate the parameters of the four-port:

$$s_{11} = \frac{b_1^e + b_1^o}{2} \quad (57)$$

$$s_{12} = \frac{b_2^e + b_2^o}{2} \quad (58)$$

$$s_{13} = \frac{b_1^e - b_1^o}{2} \quad (59)$$

$$s_{14} = \frac{b_2^e - b_2^o}{2} \quad (60)$$

The preceding two situations can be modeled by two transmission lines having normalized characteristic impedances Z_0^e and Z_0^o and, correspondingly, electrical lengths θ^e and θ^o . Although the physical lengths of the lines are the same, their electrical lengths are different in the non-TEM case, and the propagation constants are different in the two cases. Let us suppose both lines are fed by transmission lines with unit characteristic impedance. The transmission matrices are given by

$$T = \begin{bmatrix} \cos \theta^{e/o} & jZ_0^{e/o} \sin \theta^{e/o} \\ \frac{j}{Z_0^{e/o}} \sin \theta^{e/o} & \cos \theta^{e/o} \end{bmatrix} \quad (61)$$

As observed previously, losslessness implies that the condition under which the device is a directional coupler is $s_{11} = 0 = b_1^e + b_1^o$. Such a condition is satisfied when

$$\frac{\left(Z_0^e - \frac{1}{Z_0^e}\right)j \sin \theta^e}{2 \cos \theta^e + \left(Z_0^e + \frac{1}{Z_0^e}\right)j \sin \theta^e} = \frac{\left(Z_0^o - \frac{1}{Z_0^o}\right)j \sin \theta^o}{2 \cos \theta^o + \left(Z_0^o + \frac{1}{Z_0^o}\right)j \sin \theta^o} \quad (62)$$

An immediate solution is obtained when $\theta^e = \theta^o = \theta$, as occurs when the strips are embedded in a homogeneous medium, and $Z_0^o = 1/Z_0^e$. The more immediate solution is therefore to place over the strip a dielectric layer that has the same permittivity as the substrate. This particular case pertains to TEM couplers. In such a case, the coupling C is given by the formula

$$C = 20 \log \frac{[1 - c^2 \cos^2 \theta]^{1/2}}{c \sin \theta} \quad (63)$$

where $c = Z_0^e - Z_0^o/Z_0^e + Z_0^o$. Since in microstrip technology $c_{\max} \approx \frac{1}{2}$, the maximum coupling achievable by the ordinary photolithographic technique is about 6 dB and occurs when $\theta = \pi/2$. Moreover, its bandwidth is rather narrow and the directivity moderate. Much better performances are obtained by the Lange interdigitated coupler, shown in Fig. 15 [19].

This configuration permits one to achieve 3 dB coupling easily, as well as an octave bandwidth and a good

Figure 15. Lange interdigitated coupler. Bond wire connects strips to suppress the propagation of unwanted modes.

directivity. This coupler is, however, difficult to realize and the bond wires are critical at the higher frequencies. Moreover, the higher the frequency, the more difficult it is to equalize the phase velocities of the even and odd modes. Nevertheless, its good electrical characteristics and compactness make the Lange coupler suitable for applications up to 30 GHz with standard technology, but the gallium arsenide (GaAs) monolithic version is used up to 100 GHz. A comprehensive and accurate analysis of the interdigitated coupler is reported in Ref. 20.

The compensation of the different phase velocities over a wide band is one of the more difficult tasks in microstrip couplers. At present, designers often adopt one of the following strategies:

1. Placing two capacitances across the lines at the input and the output
2. Using nonuniform planar transmission lines
3. Shaping the two strips in a serpentine form or in a shark teeth form (wiggly coupler) as shown in Fig. 16
4. Combining the preceding techniques (for instance, by shaping as shark teeth the strips of a nonuniform coupler)

Similar to waveguide couplers, bandwidth and directivity can be much improved by cascading many coupled line sections, as indicated in Fig. 17 [21–23].

A detailed description of planar directional couplers can be found in Ref. 24. Planar couplers are also affected

Figure 16. The wiggly and serpentine coupler. These configurations are meant to equalize even the odd phase velocities, in order to optimize the coupler response over a wide band.

Figure 17. An example of a multisection microstrip coupler.

by high conductor losses. In this regard, the use of superconductor technology is attractive, though unfortunately not mature enough for large-scale production. Microstrip couplers do not achieve performances comparable to the ones realized in waveguide; therefore, they are hardly employed in measurement benches, where high directivity and low losses are required. However, their use in civil telecommunication systems is widespread.

DIRECTIVE ANTENNAS

IGOR ALEXEFF
 MARK RADER
 WENG LOCK KANG
 The University of Tennessee
 Knoxville, Tennessee

Radio antennas that are directive have many advantages over stationary antennas. They can observe in one direction while ignoring much larger signals coming in from the sides. In addition, as transmitting antennas, they can direct a small amount of radiation directly to the proper receiver. Conventional directive antennas use large mirrors for short waves, such as are used in radar. For longer-wave antennas, they use reflector and director elements aligned with the antenna. The basic problem with such arrays is that they are mechanically steered, which is slow and difficult to do with large antennas, especially in the presence of wind, ice, or snow.

One way of having a large steerable antenna with no moving parts is to use a phased array. A phased array is based on Huygen's principle, which states that a wavefront can be determined at a point in time by constructing a surface tangent to a collection of secondary waves. Thus, if one has a large number of small antennas located on a line, and if the antennas are excited in phase, the resultant wavefront is normal to the line. If each small antenna is excited with a small phase shift relative to the next antenna, the wave propagates at an angle to the line. Conversely, if the array is used for reception, the small antenna signals, combined with the individual phase shifts, allow the array to scan in azimuth. The principle can be improved by using a two-dimensional array located on a plane to scan in altitude as well as azimuth. In fact, by properly adjusting the

Figure 1. Three sources of waves giving a directed wavefront. The phase of the middle and left sources have been delayed.

phase shifts, such an antenna can be located on a curved surface, such as the nose or wing of an aircraft. The basic principle is shown in Fig. 1. Since the subject of directive antennas is so large, Professor Herb Neff, UTK Emeritus (an antenna specialist), recommends using Refs. 1 and 2 for reference.

Newer antennas being developed include the “agile mirror” [3,4] designed by Dr. Wallace M. Manheimer of the US Naval Research Laboratory. In this concept, a sheet of ionized air or other gas forms a reflecting surface. Since the sheet is not a mechanical body, it can be tilted and re-formed in a very short span of time. Thus, the direction of transmission or reception can be varied extremely rapidly. A magnetic field is used to help direct the sheet electron beam that forms the plasma. A second advantage of such an antenna is that it vanishes when the electrical discharge is terminated. This is a great advantage for stealth technology, because a mechanical antenna presents a large scattering cross section to radar signals near the antenna resonant frequency. One disadvantage of the “agile mirror” is that it must be formed in a gas at reduced pressure.

A second new type of antenna is the “stealth antenna,” which is being developed by the Patriot Scientific Corporation in San Diego, California. The idea, originally developed by Dr. Igor Alexeff at the University of Tennessee [5], uses glow discharge tubes to comprise elements of an antenna. When the tubes are energized, the antenna is a complete conducting structure. When the tubes are deenergized, the antenna becomes either a large number of separate, nonresonant conducting components or just a nonconducting structure of glass tubing. By selectively energizing various tubes, the antenna also can be directed.

DISTRIBUTED AMPLIFIERS

T. KORYU ISHII
Marquette University
Milwaukee, Wisconsin

1. DEFINITION AND STRUCTURE

The objective of this article is to present various aspects of distributed amplifiers. Distributed amplifiers are by definition, electronic amplifiers consisting of distributed circuit parameters. However, in practice, amplifier systems that consist of a number of discrete amplifiers associated with distributed parameter circuits are often termed *distributed amplifiers*; this latter amplifier is actually a pseudodistributed amplifier.

In practice, the distributed parameter circuit often takes the form of a transmission line. The circuit parameters, the inductance, the capacitance, and the resistance are distributed throughout the transmission line. If the transmission line is a conventional passive transmission line, the electrical output power of the transmission line is either equal to or less than the electrical input power depending on the power loss of the transmission line.

If the transmission line is active, then the output power is greater than the input. In this case, the transmission line is considered as an amplifier; this is actually a distributed amplifier.

For example, an ordinary optical fiber cable is a passive transmission line for lightwaves. The output light of the optical cable is always less than the input light because of the cable loss. But an erbium-doped optical fiber cable is different. The lightwave output of the cable is greater than the lightwave input. The input lightwaves (which are electromagnetic waves) are amplified. The erbium-doped optical fiber cable is an active transmission line and is one form of distributed amplifier. A schematic diagram of a generic distributed amplifier is shown in Fig. 1a. In this distributed amplifier, the transmission line is continuously loaded by the continuously distributed power-pumping active substrate.

In a pseudodistributed amplifier, a number of discrete amplifiers are periodically loaded as shown in Fig. 1b. The input power is amplified by these discrete amplifiers; therefore the output of the transmission line is greater than the input power.

The objective of the distributed amplifiers is to obtain a high-frequency bandwidth with high-gain amplification. The operating frequency ranges are in RF, microwaves, and lightwaves. Depending on the operating frequency range, the amplifier configurations are markedly different. The transmission line can be a two-wire line, a coaxial ("coax") line, a waveguide, a microstripline, a coplanar waveguide, or an optical fiber cable.

The term "distributed amplifier" contrasts against "discrete amplifier" or "lumped amplifier." A lumped amplifier is represented in a block diagram as shown in Fig. 2. In a lumped or discrete amplifier, where point *A* is the input and point *B* is the output, the geometric distance between

Figure 1. Generic configuration of distributed amplifiers. Signals to be amplified are fed at the left terminal. The signals are amplified during propagation on the line. The amplified signals exit from the right. (a) Distributed amplifier. The amplifier consists of a continuous active transmission line. (b) Pseudodistributed amplifier. Lumped amplifiers are periodically loaded on a passive transmission line.

these two points is negligibly small in comparison with the operating wavelength. A distributed amplifier can also be represented by a block diagram as shown in Fig. 2, but the geometric distance between the actual point *A* and the actual point *B* is comparable to the operating wavelength.

1.1. Continuous Active-Diode Distributed Amplifiers

Activated tunnel diodes, Gunn diodes, and varactor diodes are considered as active diodes. When tunnel diodes and Gunn diodes are properly biased, these diodes exhibit negative resistance. Ordinarily a resistance is positive. A positive resistance consumes electrical energy. A negative resistance generates electrical energy. Therefore, if the amount of negative resistance is adjusted by material composition, configuration, and the bias current and if the circuit impedance of the transmission line is properly adjusted, then the active-diode-loaded transmission line can amplify propagating electromagnetic waves on the transmission line. One possible biasing method is illustrated in Fig. 3a. The transmission line is most likely a microstripline or a coplanar coupled waveguide. The microstripline is DC-biased through a RF choke. If the active substrate is a tunnel diode of long degenerate pn junction, the properly forward-biased pn junction exhibits negative resistance by the tunnel effect [1]. If the active substrate is a long Gunn diode of properly doped n-type GaAs, the substrate exhibits negative resistance by the carrier momentum transfer effect [2].

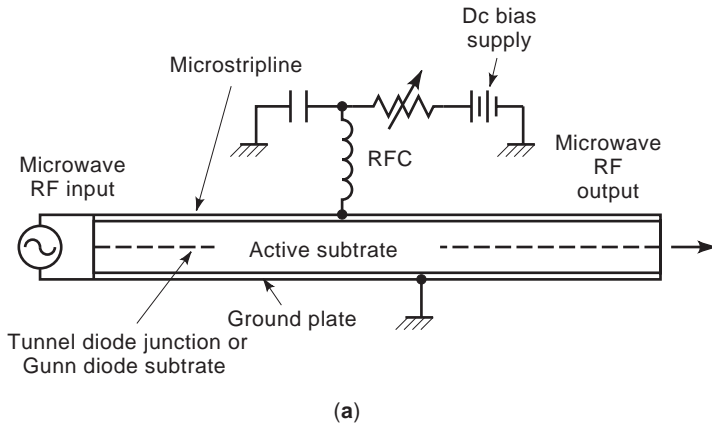

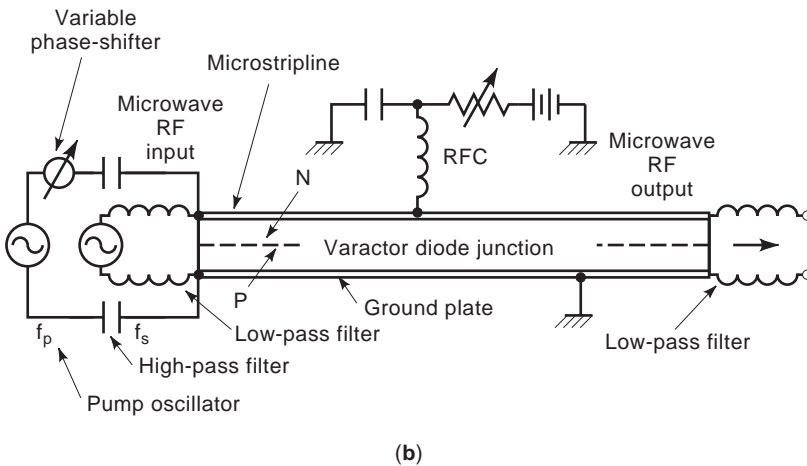

Figure 2. A block diagram representation of a discrete amplifier, a lumped amplifier, or a distributed amplifier. Generic symbols of a generic amplifier: *G* represents the gain of the amplifier (which can be the voltage, current, or power gain); *A* is the input, and *B* is the output terminal.

(a)

(b)

Figure 3. Continuous diode distributed amplifiers. Electromagnetic waves to be amplified are fed from the left end, and amplified signals exit at right. (a) Continuously loaded tunnel diode or Gunn diode transmission-line distributed amplifier. The entire transmission line consists of a long and narrow section of tunnel diode junction or Gunn diode active region. (b) Continuously loaded varactor diode transmission-line parametric distributed amplifier. The entire section of the transmission line consists of a reverse-biased variable capacitance pn junction.

The negative resistance can also be created by a properly biased and pumped long varactor diode junction. The varactor diode is a reverse-biased pn-junction diode. This is a variable-capacitance diode, and the junction capacitance is varied depending on the bias voltage across the diode. The junction capacitance in the case of Fig. 3b is controlled by the DC bias and the pump oscillator voltage launched on the microstripline transmission line. Some varactor diodes work without DC bias. The pump oscillator frequency f_p is approximately twice of the signal frequency f_s for the best results. When the pump oscillator frequency and phase are properly adjusted, the energy of the pump oscillator transfers to the signal through the variable-junction capacitance and the signal waves are amplified as the waves propagate on the microstripline. The amplifier that functions by use of a junction capacitance is termed a *varactor parametric amplifier* [1]. The type of parametric amplifier shown in Fig. 3b is a traveling-wave varactor parametric amplifier. Since the junction capacitance is continuously distributed along the microstripline, this is a distributed amplifier.

1.2. Periodically Loaded Active-Diode Distributed Amplifiers

A schematic diagram of a periodically loaded active-diode microstripline distributed amplifier is shown in Fig. 4a. The active diodes are either discrete tunnel diodes or

Gunn diodes. The periodicity L is usually less than a quarter-wavelength to avoid resonance. When the periodicity is made equal to either a quarter-wavelength or a half-wavelength, the amplifier will be at resonance. In such cases, the frequency bandwidth becomes narrow and it may also become unstable and oscillate; therefore the resonance should be avoided. One objective of the distributed amplifier is to obtain a wide frequency bandwidth; thus it is safe to keep the periodicity L less than a quarter-wavelength. The diodes must be DC-biased properly at the middle of the negative-resistance region.

A schematic diagram of a periodically loaded variable-capacitance diode (varactor diode) parametric distributed amplifier is shown in Fig. 4b. As seen from the diagram, varactor diodes are reverse-biased by the DC bias supply and are pumped by the pump oscillator. The pump frequency f_p is approximately twice of the signal frequency f_s to be amplified. The pump wave on the line must be synchronized with the signal wave. The synchronization is accomplished using a variable phase shifter as shown in the pump oscillator circuit. The pump oscillator power is transferred into the signal through the varactor, and the signal wave is amplified [1,2]. The varactor diodes are pumped so that when and where the signal waves crest the junction, the capacitance becomes minimum. This phasing makes the microwave signal voltage amplified. The transmission line can be a microstripline as shown or

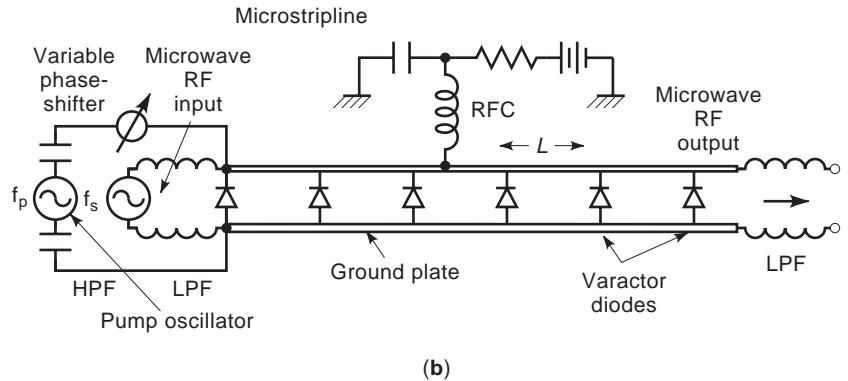

Figure 4. Periodically loaded active-diode distributed amplifiers. (a) Periodically loaded active-diode microstripline distributed amplifier. A microstripline is periodically loaded by active diodes with periodicity L . A properly biased active diode is capable of amplifying electromagnetic signals. (b) Periodically loaded active capacitive parametric distributed amplifier. A microstripline is loaded periodically by properly biased and pumped varactor diodes with periodicity L . Such a varactor diode acts as a lumped amplifier.

a coplanar coupled waveguide. An example of a coplanar coupled waveguide distributed amplifier is sketched in Fig. 5. As seen from this figure, fabrication of a coplanar coupled waveguide amplifier is easier than fabrication of a microstripline amplifier.

1.3. Continuous Transistor Distributed Amplifiers

A schematic diagram of a continuous transistor distributed amplifier is shown in Fig. 6. This is a FET (field-effect transistor) of long configuration. The length of lines must be greater than a wavelength of the operating carrier signals. The microwave input signals are fed into the coplanar coupled waveguide that consists of a gate strip and a source strip. As the input microwaves propagate along

this input gate–source coplanar coupled waveguide, the amplified signal waves appear on the drain–gate coplanar coupled waveguide. Then the amplified microwaves exit at the end of the drain–gate coplanar coupled waveguide. The long transistor must be properly DC-biased as shown in Fig. 6.

1.4. Periodically Loaded Transistor Distributed Amplifiers

A schematic diagram of a periodically loaded transistor distributed amplifier is shown in Fig. 7. To qualify as a distributed amplifier, the length of the coplanar coupled waveguide must be longer than a wavelength of operating microwaves. If the length is very short, this is a simple

Figure 5. An example of coplanar coupled waveguide distributed amplifier. This is an example of a case in which the transmission line is a coplanar coupled waveguide. Lumped diodes are mounted on it periodically.

Figure 6. A schematic diagram of a continuous transistor distributed amplifier. This is a case of extremely long gate field-effect transistor. The length of the gate can be several wavelengths longer than the operating wavelength. As the input signals propagate on the gate–source line, the amplified output signals travel on the drain–gate line. The amplified signals exit at the right.

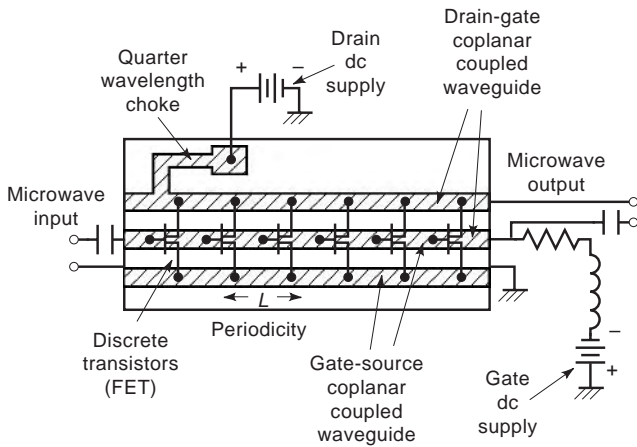

Figure 7. A schematic diagram of a periodically loaded transistor distributed amplifier. Discrete transistors are periodically loaded on a coplanar coupled waveguide. The input signals fed on the gate-source coplanar waveguide are amplified as the signals propagate on the line. The amplified output appears on the drain-gate coplanar coupled waveguide. The output propagates on the line and exit from the right.

parallel operation of the transistors. The input microwave signals are fed to the input of the gate-source coplanar coupled waveguide as shown in Fig. 7. As microwaves propagate down the gate-source waveguide, the amplified microwaves appear on the drain-gate coplanar coupled waveguide. The amplified microwaves propagate toward the output and exit from there. The coplanar coupled waveguides are periodically loaded by discrete FETs. The periodicity L must be less than a quarter-wavelength to avoid resonance. Otherwise, $n(\lambda_l/2) < L < (2n + 1)(\lambda_l/4)$, where λ_l is the transmission line wavelength and $n = 0, 1, 2, 3, \dots$

1.5. Thermionic Traveling-Wave Distributed Amplifiers

A thermionic traveling-wave amplifier is a vacuum tube [2]. Electrons are emitted from an electron gun into a vac-

Figure 8. A schematic diagram of a thermionic traveling-wave distributed amplifier. The pitch of the helical transmission line is adjusted so that the axial speed of microwave propagation on the line is almost equal to the speed of electrons in the electron beam. Under this condition, The kinetic energy of electrons is transferred into the traveling microwaves on the line, and the propagating microwaves are amplified.

uum as shown in Fig. 8. The emitted electrons are pulled by the anode, which is a helical transmission line focused by the longitudinally applied DC magnetic flux B . The electron beam is shot through the helix line and hits at an endplate termed the *electron collector*. The electron collector collects used (“spent”) electrons. The helix transmission line is a distributed parameter transmission line. The pitch angle of the helix transmission line, the diameter of the helix, and the electron acceleration voltage are adjusted in such a way that the speed of the electron beam is equal to the axial propagation speed of microwaves on the helical line. Then the kinetic energy of the electron beam is transferred to the microwave energy on the helical line through the distributed capacitance between the electron beam and the helical line. As the microwaves on the line and the electrons in the beam travel together, the microwaves are amplified and exit from the output of the tube as shown in Fig. 8 [2]. The helical transmission line is replaced by a meander line or an interdigital transmission line (2).

1.6. Fiberoptic Distributed Amplifiers

A schematic diagram of a fiberoptic distributed amplifier is shown in Fig. 9. The main part of this amplifier is a section of erbium-doped optical glass fiber cable [3]. As seen from this figure, if a lightwave of proper wavelength is pumped into the fiber cable through a directional coupler from a pump laser, and the lightwave signal to be amplified is fed into the input of the fiber cable thorough an isolator, then, while the signal lightwave is propagating in the fiber cable, the signal lightwave is intensified by the emission of radiation from the erbium atoms that are pumped by the lightwave that is propagating in the fiber cable from the pump laser. The pump lightwave travels with the signal lightwave and pumps energy into the signal lightwaves through the stimulated emission of radiation from erbium atoms. The particular optical fiber is considered to be a distributed parameter transmission-line amplifier for propagating optical electromagnetic wave signals.

Figure 9. A schematic diagram of a fiber cable lightwave distributed amplifier. The active part is a long section of erbium-doped fiber cable. The erbium atoms are pumped by a light from the pump laser at left. The input lightwave signals are amplified by the stimulated emission of radiation from the pumped erbium atoms in the active fiber cable.

Figure 10. An equivalent circuit of a generic distributed amplifier. The negative conductance $-G$ generates energy and amplifies signals that are traveling on this line.

2. GENERAL GOVERNING EQUATIONS

2.1. Gain

A generic configuration of a distributed amplifier transmission circuit is shown in Fig. 10. In this diagram, R is

$$G(f) = \alpha(f)l$$

$$= \frac{(2\pi f)(C(f)R(f) - L(f)G(f))l}{\sqrt{2} \left\{ ((2\pi f)^2 L(f)C(f) + R(f)G(f)) + \sqrt{(2\pi f)^2 (C(f)R(f) - L(f)G(f))^2 + (R(f)G(f) + (2\pi f)^2 L(f)C(f))^2} \right\}^{1/2}} \tag{5}$$

the series resistance per meter of the distributed amplifier, L is the series inductance per meter of the distributed amplifier, $-G$ is the negative conductance per meter of the distributed amplifier, and C is the capacitance per meter of the distributed amplifier. The amplification constant of this amplifier is [1]

$$\alpha = \frac{\omega(CR - LG)}{\sqrt{2} \left\{ (\omega^2 LC + RG) + \sqrt{\omega^2 (CR - LG)^2 + (RG + \omega^2 LC)^2} \right\}^{1/2}} \tag{1}$$

[nepers (napiers)/meter (Np/m)]

where G is the magnitude of the negative conductance parameter. In a distributed amplifier, if the propagating power increase per meter is ΔP (W/m) and the propagating voltage increase parameter is ΔV (V/m), the magnitude of the negative conductance per meter is $G = 2\Delta P/(\Delta V)^2$ (S/m).

The phase constant of this amplifier is [1]

$$\beta = \frac{\left\{ (\omega^2 LC + RG) + \sqrt{\omega^2 (CR - LG)^2 + (\omega^2 LC + RG)^2} \right\}^{1/2}}{\sqrt{2}} \tag{2}$$

If the length of the active region of the amplifier is l meters long, then the voltage gain of the amplifier

is

$$A = \alpha l \text{ (Np)} \tag{3}$$

The total phase shift across the active region of the amplifier is

$$\Delta l = \beta l \text{ [radians (rad)]} \tag{4}$$

2.2. Frequency Bandwidth

In a generic distributed amplifier, the circuit parameters R , L , C , and G are functions of operating frequency f . Therefore, the gain of the amplifier is

At the edge of the frequency bandwidth at a frequency f'

$$G(f') = \frac{1}{\sqrt{2}} G(f_0) \tag{6}$$

where f_0 is the center frequency of the amplifier. Usually Eq. (6) is at least the second-order equation of f' . One root is f'_H , which is greater than f_0 and the other is f'_L , which is less than f_0 . Then the frequency bandwidth is

$$\Delta f = f'_H - f'_L \tag{7}$$

2.3. Sensitivity

According to the *IEEE Standard Dictionary* [4], sensitivity is defined as “the minimum input signal required to produce a specified output signal having a specified signal to noise ratio.” This means that

$$\frac{P_s A}{KTBAF} = \frac{S_0}{N_0} \tag{8}$$

where A is the power gain of an amplifier, K is the Boltzmann constant (1.38054×10^{-23} J/K), T is the absolute temperature of the input circuit to the amplifier, B is the overall frequency bandwidth of the amplifier, P_s is the input signal power, F is the noise figure of the amplifier, and S_0/N_0 is the signal-to-noise power ratio of the amplifier at

the output. Then

$$P_s = KTBF \frac{S_0}{N_0} \quad (9)$$

As “a specified signal to noise ratio,” often

$$\frac{S_0}{N_0} = 1 \quad (10)$$

is used for the definition of the sensitivity of the amplifier. Then, the sensitivity is

$$P_s |_{S_0/N_0=1} = KTBF \quad (11)$$

For a distributed amplifier, the value of B is obtained using Eq. (7). The value of the noise figure F can be obtained from the next section. Then the sensitivity is

$$P_s |_{S_0/N_0=1} = \frac{N_0}{A} \quad (12)$$

where A is given by

$$A = e^{2\alpha l} \quad (13)$$

where αl is given by Eq. (5).

2.4. Noise Figure

The noise figure F of an amplifier is given by [1]

$$F = \frac{N_0}{KTBA} \quad (14)$$

where N_0 is the noise output of the amplifier (W). For a distributed amplifier, both the frequency bandwidth B and the power amplification A are given by Eqs. (7) and (5), respectively.

2.5. Dynamic Range

A range of input signal level in which the gain of the amplifier is constant is termed the *dynamic range* of the amplifier. Usually, the gain of an amplifier is less at an extremely small input signal level or at a large input signal level.

In the semiconductor distributed amplifiers, thermionic distributed amplifiers or even in fiberoptic distributed amplifiers, the values of L , C , R , and G are inherent functions of operating signal levels V_s . (Therefore, in Eq. (1)

If the gain constant in the linear region of the distributed amplifier is α_0 , then the power gain of the amplifier is

$$A_0 = e^{2\alpha_0 l} \quad (16)$$

where l is the length of the active region of the distributed amplifier. In a large-signal level V_s , the gain will be compressed by saturation and

$$A(v_s) = e^{2\alpha(v_s)l} \quad (17)$$

where $\alpha(V_s)$ is as given in Eq. (15).

If the gain compression of $-n$ dB is chosen, then

$$-n \text{ (dB)} = 10 \log_{10} \frac{A(v_s)}{A_0} \quad (18)$$

or

$$n \text{ (dB)} = 10 \log_{10} e^{2[\alpha_0 - \alpha(v_s)]l} \quad (19)$$

or

$$n \text{ (dB)} = 8.686\{\alpha_0 - \alpha(v_s)\}l \quad (20)$$

In practice, $n = 1$ is often chosen, and the value of the input voltage for $n = 1$ is termed the *input signal voltage* at 1 dB compression point. The 1 dB compression point input signal voltage is then

$$\alpha(v_s) = \alpha_0 - \frac{1}{8.686l} \quad (21)$$

2.6. Stability

As seen from Eq. (1), a generic distributed amplifier is inherently stable. A controlling parameter in Eq. (1) is the magnitude of the negative conductance per meter G . Equation (1) does not show any singularity due to the size of G within the range of practical operation.

3. PERIODICALLY LOADED ACTIVE-DIODE DISTRIBUTED AMPLIFIERS

3.1. Periodically Loaded Tunnel Diode Distributed Amplifiers

In a periodically loaded tunnel diode disturbed amplifier, a number of discrete tunnel diodes are periodically loaded on a RF transmission line as shown in Fig. 4a. A generic volt-

$$\alpha(v_s) = \frac{\omega(C(v_s)R(v_s) - L(v_s)G(v_s))}{\sqrt{2} \left\{ (\omega^2 L(v_s)C(v_s) + R(v_s)G(v_s)) + \sqrt{\omega^2(C(v_s)R(v_s) - L(v_s)G(v_s))^2 + (R(v_s)G(v_s) + \omega^2 L(v_s)C(v_s))^2} \right\}^{1/2}} \quad (15)$$

ampere curve of a tunnel diode is shown in Fig. 11. This is a plot of the diode current and the voltage across the diode. When the diode is biased in a negative-conductance region, the amount of the negative conductance is given by

$$G = \frac{\partial I}{\partial V} < 0 \tag{22}$$

An equivalent circuit of a discrete tunnel diode is shown in Fig. 12, where L is the lead inductance, R_s is the spreading resistance, C_j is the junction capacitance, C_p is the package capacitance, and $-G$ is the negative conductance of the tunnel junction created by the tunnel effect. With the help of additional impedance matching components, it is possible to tune out the inductances and capacitances, and under a matched and tuned condition, the tunnel diode can be represented by a negative conductance of magnitude G_D .

The RF power gain due to a discrete negative conductance G_D that is matched to a characteristic impedance of the transmission line Z_0 is [3]

$$A = \frac{1}{1 - G_D Z_0} \tag{23}$$

At any diode in Fig. 4a, half of the amplified power goes back to the input and only another half of the power amplified continues to travel toward the output. So, the actual power gain of traveling waves toward the output is

$$A^+ = \frac{1}{2(1 - G_D Z_0)} \tag{24}$$

If N diodes are used in a distributed amplifier as shown in Fig. 4a, after matching and tuning, the total power gain of the amplifier is

$$A_T = (A^+)^N = \frac{1}{2^N(1 - G_D Z_0)^N} \tag{25}$$

Figure 11. Generic voltampere (V - A) curve of a tunnel diode. Note that the V - A curve does not follow Ohm's Law. Note also the negative differential conductance at the midvoltage region. This is a plot of the diode current versus the diode bias voltage.

Figure 12. Equivalent circuit of a tunnel diode for a packaged diode that is properly biased. *Key:* C is the package capacitance, C_j is the junction capacitance; R_s is the spreading resistance, L is the lead inductance, and $-G$ is the negative conductance of the packaged tunnel diode.

For the impedance matching and tuning, in addition to attaching the impedance-matching circuit components to the diode mount, the adjustment of periodicity together with the diode biasing must be done properly.

3.2. Periodically Loaded Gunn Diode Distributed Amplifiers

A voltampere characteristic of a generic Gunn diode is in a similar shape as shown in Fig. 11, except that the negative conductance is smaller than that of a tunnel diode. The negative conductance of Gunn diode is created by the transfer of the electronic momentum between a high-electric-field domain and a low-field domain in the bulk of a semiconductor diode. The equivalent circuit of a Gunn diode is similar to the circuit shown in Fig. 12. Therefore the principle of periodically loaded Gunn diode distributed amplifiers is similar to the principle of periodically loaded tunnel diode distributed amplifiers. Then the power gain equation of a Gunn diode distributed amplifier consists of N Gunn diodes in the negative conductance G_D with the characteristics impedance Z_0 is

$$A_T = \frac{1}{2^N(1 - G_D Z_0)^N} \tag{26}$$

3.3. Periodically Loaded Varactor Diode Distributed Parametric Amplifiers

When discrete variable capacitance diodes (varactor diodes) are periodically mounted on a transmission line as shown in Fig. 4b, RF voltage is amplified by the parametric effect of the junction capacitance. The voltage gain across a single parametric capacitance diode is given by [5]

$$A = \frac{v_p \sqrt{Q_i}}{4(V_0 + V_{r0})} + \sqrt{Q_s} \tag{27}$$

where v_p is the pump voltage across the junction capacitance of the varactor diode, V_0 is the magnitude of the contact potential barrier of the diode, V_{r0} is the DC reverse bias voltage, and Q_i and Q_s are the quality factors of the idler circuit and the signal circuit per diode, respectively.

In a parametric amplifier, the idler frequency in Fig. 4b is usually

$$f_i = f_p - f_s \quad (28)$$

and

$$f_p \simeq 2f_s \quad (29)$$

for a high gain [5]. So

$$Q_i \simeq Q_s \quad (30)$$

Applying the same concept expressed in Eqs. (25) and (26), the total voltage gain of N -diode distributed parametric amplifier is, after matching and tuning

$$A_{vT} = \left\{ \frac{v_p \sqrt{Q_i}}{4(V_0 + V_{r0})} + \sqrt{Q_s} \right\}^N \quad (31)$$

4. PERIODICALLY LOADED TRANSISTOR DISTRIBUTED AMPLIFIERS

Similar concepts of Eqs. (25), (26), and (31) are applicable to a periodically loaded discrete-transistor amplifier. The transistors can be either junction transistors or field-effect transistors. If the s parameter of the discrete transistor from the gate (or base) to the drain (or collector) is S_{21} , then, after impedance matching and tuning, the voltage gain of N -transistor distributed amplifier is given by

$$A_{vT} = S_{21}^N \quad (32)$$

5. THERMIONIC DISTRIBUTED AMPLIFIERS

Thermionic distributed amplifiers are vacuum tubes referred to as *traveling-wave tubes* (TWTs). A schematic diagram of a generic TWT is shown in Fig. 8, and the principle of the TWT distributed amplifier was briefly explained earlier in this article. While microwaves travel along the helical transmission line with the axial propagation speed approximately equal to the speed of electron beam, the kinetic energy of the electron beam is gradually transferred to the propagating microwaves in the transmission circuit and hence the microwaves are amplified. The propagation constant of a TWT is given by [1,2]

$$\dot{\gamma} = \beta_e \left[-\frac{\sqrt{3}}{2} C + j \left(1 + \frac{C}{2} \right) \right] (m^{-1}) \quad (33)$$

where β_e is the phase constant associated with the DC electron beam and

$$\beta_e \equiv \frac{\omega}{u_0} \quad (34)$$

where ω is the operating angular frequency and u_0 is the speed of the electrons in the beam. C in Eq. (33) is termed the *gain parameter* [1,2] and is given by

$$C^3 = \frac{Z_0 I_a}{4V_a} \quad (35)$$

where Z_0 is the characteristic impedance of the helical line, I_a is the DC electron-beam current, and V_a is the acceleration anode voltage of the traveling-wave tube.

If the length of the active interaction region on the helical transmission line is l meters long, then the voltage gain of this TWT is [2]

$$A = e^{(\sqrt{3}/2)C\beta_e l} \quad (36)$$

6. QUANTUM ELECTRONIC DISTRIBUTED AMPLIFIERS

A quantum electronic distributed amplifier can be a continuous configuration as shown in Fig. 9. If the signal to be amplified is a lightwave, then this distributed amplifier is a traveling-wave laser. If the signal to be amplified is a microwave, then this distributed amplifier is a traveling-wave maser. For a traveling-wave maser, instead of the optical fiber cable, a microwave transmission line that is continuously loaded with maser material such as a ruby or a rutile crystal, and instead of the pump laser, a microwave local pump oscillator is used.

At any rate, the gain constant of a traveling-wave maser or laser distributed amplifier is given by [6]

$$\alpha = \frac{\omega}{2Q_{m0}v_g} \quad (37)$$

where ω is the angular frequency of the signal to be amplified, Q_{m0} is the quality factor/meter of the active cable, and v_g is the group velocity of the signal in the cable. The quality factor Q_{m0} is given by

$$Q_{m0} = \omega \frac{W_{s0}}{\Delta P} \quad (38)$$

where W_{s0} is the electromagnetic energy of the signal stored per meter of the cable and ΔP is the signal power loss per meter of the cable.

The voltage gain of this continuously loaded distributed laser or maser amplifier is

$$A = e^{\omega l / (2Q_{m0}v_g)} \quad (39)$$

where l is the length of active part of the cable.

A quantum electronic distributed amplifier can be a periodical loading configuration as shown in Fig. 13. A

Figure 13. A schematic diagram of a periodically loaded quantum electronic maser distributed amplifier. The ruby maser crystal is pumped by the pump oscillator input in the waveguide. Microwave input signals are amplified by the stimulated emission of radiation from the pumped maser crystal, while propagating down the meander line. The meander line is structured to lengthen the interaction time between the input signals and the stimulated emission of radiation.

microwave transmission line of a periodical structure is continuously loaded with an activated maser crystal and placed in a rectangular microwave waveguide. The pump power from a pump oscillator is fed to the rectangular waveguide to activate the maser crystal. The pumped-up maser crystal emits radiation when stimulated by the input microwave signals.

In a manner similar to the case of continuously loaded quantum electronic distributed amplifier, the voltage gain of the periodically loaded quantum electronic distributed amplifier is given by

$$A = e^{(\omega l / 2Q_{mp} v_g)} \tag{40}$$

where Q_{mp} is the quality factor within the periodicity of the periodical structure. Then

$$Q_{mp} = \omega \frac{W_{sp}}{\Delta P} \tag{41}$$

where W_{sp} is the signal energy stored within the periodicity of the structure of the transmission line and ΔP is the signal power loss within the periodicity.

7. EXAMPLES OF DISTRIBUTED AMPLIFIERS

7.1. RF Distributed Amplifiers

In practice, at RF < 300 MHz, a distributed amplifier can be built using discrete components or surface-mountable discrete components. An example of such distributed amplifiers is shown schematically in Fig. 14 [3,6,20,23,24]

Discrete FETs are sequentially excited through the gate delay line or the gate artificial transmission line consisting of $C_g, \frac{1}{2}L_g, L_g, L_{gg},$ and R_g . These are discrete components. C_g is a DC blocking input coupling capacitor, L_g is an inductor to produce the desired phase delay between stages of the FET amplifiers, and R_g is the matched terminating resistor for the artificial transmission line. The idea is to generate RF traveling waves on the gate artificial transmission line. L_{gg} is a stray inductance of the gate lead. In most cases L_{gg} is negligibly small at most RF frequencies. R_s and C_s are the source bias resistor and bypass capacitor, respectively. L_{dd} is the stray inductance of the drain of the FET. By making the drain lead as short as possible, it is possible to make L_{dd} negligibly small at RF frequencies.

The drain delay line or the drain artificial transmission line is formed by $R_d, L_d,$ and C_d . R_d is an impedance-matched resistor to the drain artificial transmission line,

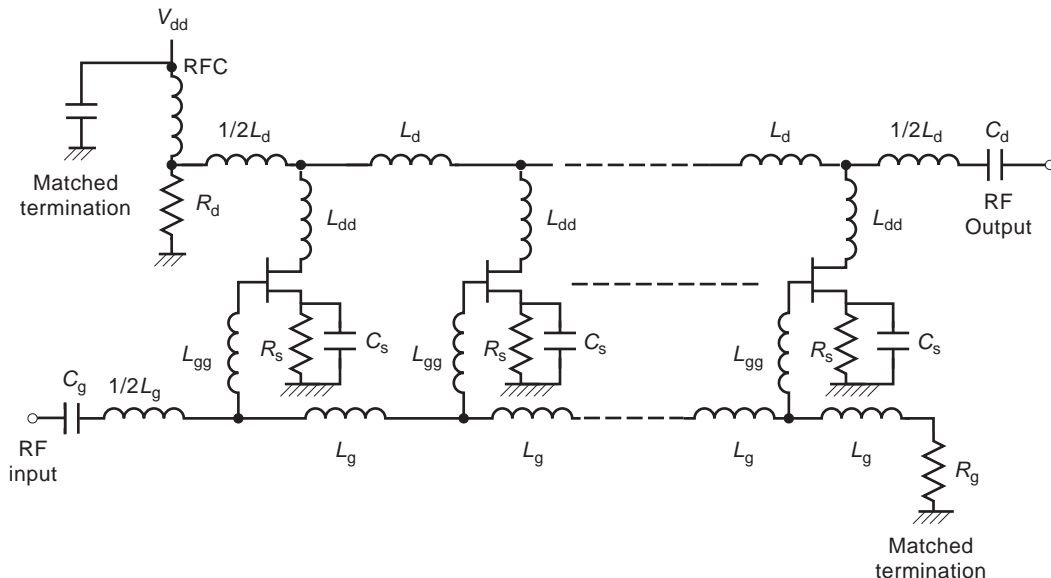

Figure 14. A schematic diagram of an example of an RF distributed amplifier. The input signals are successively and sequentially amplified by properly phased multistage FET amplifiers.

and L_d is the phase-delaying inductor between stages. The value of L_d must be determined so that the phase of waves on the drain artificial transmission line synchronize with the phase of waves on the gate artificial transmission line. C_d is a DC blocking RF coupling capacitor to the output load. The transistors are biased through a RF choke coil and a decoupling capacitor.

7.2. Microwave Distributed Amplifiers

Various types of distributed amplifiers in microwave frequency have been built in the past [7–9]. In microwave frequencies, the distributed amplifiers take forms of monolithically developed integrated circuits as shown in Fig. 15 as an example. As is the case in Fig. 14, the microwave input signals to be amplified are fed to the gate microstripline with impedance-matched terminating resistance R_g through a DC blocking coupling capacitor C_{cg} . The gate of each FET that is properly biased is sequentially excited. Amplified microwave drain current propagates along the drain microstripline toward the output and is coupled out to the output circuit through a DC blocking coupling capacitor C_{dd} . The drain microstripline is terminated with an impedance-matched resistor R_d . The drain microstripline is biased through a RF choke coil and a bypass capacitor with V_{DD} .

Most microwave monolithic integrated-circuit (MMIC) distributed amplifiers have extremely wide frequency bands even though the total gain is not so high. They are extremely compact. For example, Kimura and Imai [11] monolithically integrated a seven stage distributed amplifier on a 1.5×2.5 -mm IC substrate and reported a flat gain of 9 dB over the frequency range 0–55 GHz with a 6 dB noise figure. Further examples can be found in the literature [11–19,25–27].

7.3. Lightwave Distributed Amplifiers

Actual configuration of a lightwave distributed amplifier is shown in Fig. 9. These amplifiers are actually deployed to boost lightwave signals for a long-haul lightwave signal transmission such as transoceanic lightwave cables. For example [3], the lightwave input signal to be amplified has a wavelength of 1500 nm. The pump laser is a 980-nm

solid-state laser diode that feeds the pump power through a directional coupler to the main cable. The directional coupler is a pair of lightwave waveguides placed in proximity to each other so that the lightwaves can couple with one waveguide to another. The end of the lightwave guide for the pump laser that is the primary waveguide of the directional coupler is reflectionlessly terminated using a lightwave-absorbing component. The pump laser light is fed into the main lightwave waveguide, which is an erbium-doped optical fiber. The pump laser light excites or “pumps up” the atoms of erbium to prepare for emission of radiation at 1500 nm. When these pumped-up erbium atoms receive stimulating radiation at 1500 nm by the input lightwaves, they emit radiation at the same wavelength 1500 nm. This is a laser amplifier. The emission of radiation continues as the input lightwave travels in the erbium-doped optical fiber. The emitted wave travels together with the stimulating lightwave. The amplified lightwave exits from the output connector. The lightwave gain of 15 dB is reported for several-meters-long erbium-doped plastic optical fiber cable.

The amplifier cable can be a praseodymium-doped fluoride fiberglass cable for a wavelength of 1300 nm [3]. A gain of 40 dB for several-meters-long cable has been reported [3].

8. CONTINUOUS DISTRIBUTED AMPLIFIERS

8.1. Continuous Active-Diode Distributed Amplifiers

In Fig. 5, by removing all discrete diodes and using an intrinsic semiconductor substrate instead of the dielectric substrate, it is possible to monolithically develop a continuous tunnel diode junction or Gunn effect diode contact between the two strips of metallization. Then, if the conducting strips form a coplanar waveguide that is properly biased at the negative resistance of the diode, the microwaves fed into one end of the coplanar waveguide will be amplified by the distributed negative resistance as it travels along the coplanar waveguide, and the amplified microwave will exit from the other end of the coplanar waveguide.

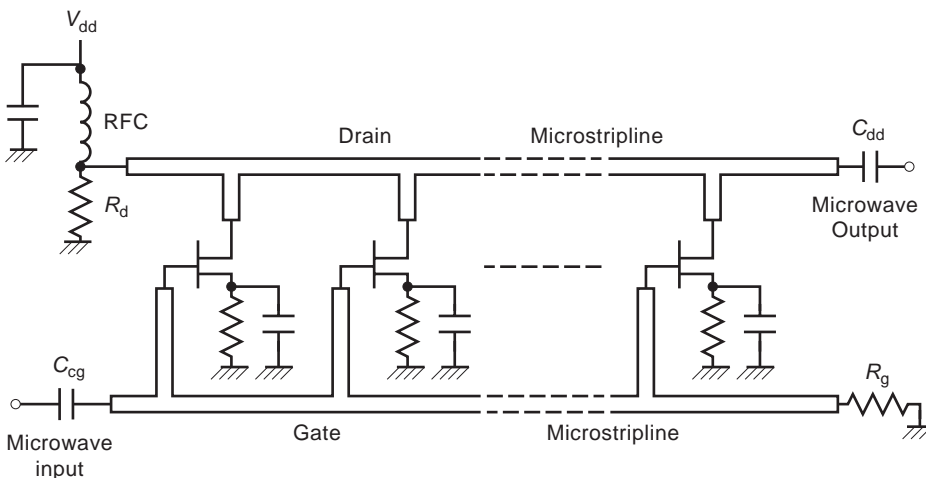

Figure 15. A schematic diagram of a microwave monolithic distributed amplifier. Both the gate and drain lines are microstriplines. The gate line feeds the FET sequentially. On the drain microstripline, the amplified signals are sequentially combined and propagate out at right.

8.2. Continuous Transistor Distributed Amplifiers

A conceptual diagram of a continuous transistor distributed amplifier is shown in Fig. 6. The length of the microstrips must exceed several wavelengths of the transmission-line wavelength. The transmission-line wavelength on the coplanar waveguide is smaller than the free-space wavelength and is inversely proportional to the square root of the effective relative permittivity of the substrate in the gap between the conducting strips. For a semiconductor substrate, it is not uncommon for the effective relative permittivity to be 10 or higher.

8.3. Continuous Parametric Varactor Diode Distributed Amplifier

A conceptual schematic diagram of a continuous parametric varactor diode distributed amplifier is shown in Fig. 3b. Here, the concept is the same and as that for an MMIC amplifier, but an alternate method and a more convenient approach to MMIC technology is shown. Instead of using the microstripline as shown in Fig. 3b, the configuration is changed to a coplanar waveguide as shown in Fig. 5. A long junction varactor diode is monolithically developed flatly between the gap of long parallel metallization strips of a coplanar waveguide.

8.4. Continuous Ferrimagnetic Distributed Amplifiers

The space between the long gap of metallization strips of either the microstripline as shown in Fig. 3b or the coplanar waveguide as shown in Fig. 5 can be filled with a magnetized ferrimagnetic material or a ferrite. This constitutes a ferrimagnetic continuous distributed amplifier [1,10]. The nonlinear magnetism of a ferrite renders the system as a variable-inductance parametric amplifier when both the pump oscillator power and the signal power are launched into a same transmission line; then the pump oscillator power gradually transfers into the signals through the distributed nonlinear inductance of the ferrites as both signals and the pump oscillator power travel together along the ferrite-loaded transmission line.

9. TRENDS OF DISTRIBUTED AMPLIFIER TECHNOLOGY

One of the most common concepts of a distributed amplifier consists in a number of amplifier units distributed along a transmission line [6,7,16,20–22]. An alternate approach to obtain the wide frequency bandwidth and higher gain is to use the concept of matrix amplifiers [27]. A generic concept of a matrix amplifier is illustrated in Fig. 16. As seen from this figure, a matrix amplifier consists of several tiers of distributed amplifiers. Each tier is connected by bleeder lines. The bleeder lines connect the

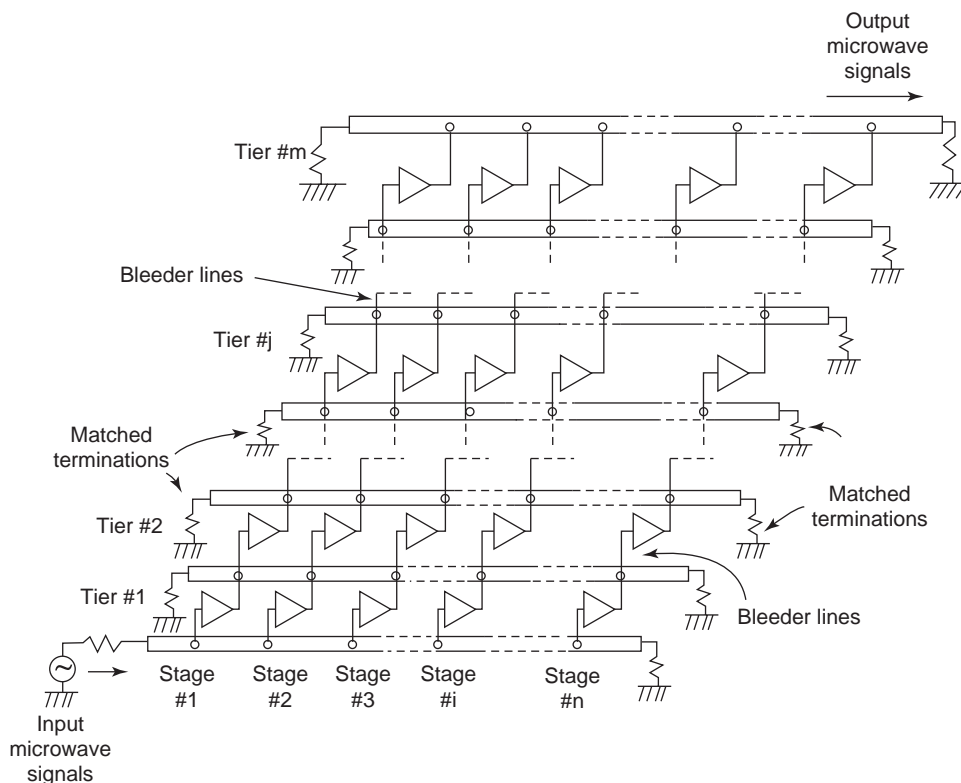

Figure 16. A schematic diagram of a generic n -stage \times m -tier matrix distributed amplifier. Types of stage amplifiers in each tier are not necessarily identical. This feature gives flexibility in design to meet given requirements on amplifier performance. The RF or microwave input signals to be amplified are fed at the lower left corner of this diagram. The amplified output is taken out at the upper right corner of this diagram.

output points of each (amplification) stage of a distributed amplifier and the input points of each stages of the next tier distributed amplifier. Thus, when the signal travels down the first tier of the distributed amplifier, each stage of the amplifiers of the second tier are successively excited. This process is repeated until the output signal reaches the output point of the final stage of the amplifier unit in the final tier. In a matrix amplifier, a part of the signal travels in a longitudinal direction along the direction of the transmission line of each distributed amplifier. The remainder of the signal travels in a transverse direction along the amplifier tiers through bleeder lines.

In a matrix amplifier, the amplifiers in each tier need not be identical in type. This feature gives design flexibility for the required performance of an amplifier.

Another, unorthodox, type of distributed amplifier is the transversely distributed amplifier. In a transversely distributed amplifier a number of amplifier units are distributed on a screen that is oriented in transversely to the direction of the incoming microwave propagation. Incoming microwave signals are amplified by the amplifier units distributed throughout the screen and reradiated from the other side of the screen. This structure may be considered simply as an array of amplifiers rather than a distributed amplifier. But the spacing among amplifier units is comparable in distance to the operating wavelengths for proper phasing. Therefore, the transversely distributed amplifiers are distributed amplifiers of a special kind.

A schematic diagram of a generic transversely distributed amplifier is shown in Fig. 17. Incoming microwave or

Figure 17. A schematic diagram of a generic transversely distributed amplifier. A number of amplifier units are distributed on a transversely extended screen against incident microwave radiation. Incident microwave radiation is received by receiving antennas and amplified by the amplifier units. The amplified microwaves are reradiated from the transmitter antennas toward the other side or the same side of the screen in a desired direction. The frequency of the output may be identical to the frequency of the input signals. The output frequency may be different from the input by mixing or regeneration.

RF signals are amplified by a properly distributed amplifier on a screen and reradiated to space in the other side of the screen in the required direction [28–30]. Usually the transversely distributed amplifier is placed at a midpoint in a microwave transmission beam between the transmitter and the receiver for the microwave signal booster [28], with microwave signal booster and microwave beam steering [29], or in accordance with microwave distribution analysis within the beam [30]. Usually, the direction of the output reradiation is the same as or collinear with that of the incoming radiation. But the direction of the output radiation can be at any desired direction by proper phasing of the distributed amplifier units.

Research and development trends for the traditional distributed amplifier are pushing the already extremely broad frequency band even wider [24], in a search for a new design approach to obtain optimal amplifier performance [26,31,32], and for ultra-high-speed digital signal-processing amplification [33]. For example, an ultrabroadband distributed amplifier designed to cover 100 MHz–20 GHz has been reported by Virdee and Birdee [24]. In MMIC technology, beside the traditional silicon, gallium nitride [26] and indium phosphide [32] technologies are developing and producing good results. In the digital signal processing, a distributed amplifier capable of handling 40 Gbps has been reported by Shigematsu et al. [33].

Today, the technology of conventional distributed amplifiers is a mature one. Commercial products of distributed amplifiers are available on the market [34,35].

10. CONCLUSION

Distributed amplifiers are electrical transmission lines with periodically or continuously loaded amplifiers. The main feature of the distributed amplifier is the wide frequency bandwidth. Wide-bandwidth amplifiers have a large channel capacity and are also capable of handling extremely short or fast pulses. Distributed amplifiers are useful for fast digital data transmission systems of gigabit rates. Distributed amplifiers can be made compact by the use of the monolithic integrated-circuit technology.

1. INTRODUCTION

There are many applications in wireless communications that involve two or more distinct frequencies. Because of the attractive features of the microstrip patch antenna, such as planar profile, ruggedness, and low cost, there has been considerable interest in the development of these antennas to meet the dual- or multifrequency specifications. It is sometimes possible that a broadband microstrip antenna can cover the frequencies of interest. However, the disadvantage of using a broadband antenna is that it also receives undesired frequencies unless some kind of filtering network is introduced to reject such frequencies. On the other hand, the advantage of a dual- or multifrequency design is that it focuses only on the frequencies of interest and is thus more desirable. It is the purpose of this article to present several such designs. Dual-frequency designs will be emphasized since they are much more developed than multifrequency designs, which have become a topic of current interest.

In Section 2, dual-frequency single and stacked patches are reviewed. Section 3 presents dual-frequency designs obtained by loading the patch with either a reactive load or with slots. Section 4 describes a more recent design introduced by the present authors using the proximity

Figure 1. Geometry (in centimeters) of a rectangular patch antenna with six possible short-circuiting pins and a short circuit matching. (From Zhong and Lo [1], reproduced with permission from IEE.)

coupling of a U-shaped patch with unequal arms and a wideband E-shaped patch. Dual-frequency wideband patches using a L-probe feed, also introduced by the present authors, are presented in Section 5. Section 6 discusses two methods of designing multi-frequency patch antennas. The article ends with some concluding remarks.

2. DUAL-FREQUENCY SINGLE AND STACKED PATCHES

2.1. Single-Element Dual-Frequency Microstrip Antennas

It is possible for a single-element microstrip antenna to operate at many frequencies corresponding to the various resonant modes pertaining to the structure. However, for most applications, it is required that the radiation pattern, the polarization, and the impedance be similar, if not identical, in all the frequency bands of operation. This immediately rules out many modes. Furthermore, for a given geometry, all the resonant frequencies are related in fixed ratios.

If for a particular patch shape two modes can be found that produce similar radiation patterns with the same polarization, dual frequency is possible with a single patch.

Table 1. Resonant Frequencies of the TM_{01} and TM_{03} Modes against Short-circuiting Pins Used

Number of Pins	Pin Position	f_{01} (MHz)	f_{03} (MHz)	f_{03}/f_{01}
0	—	613	1861	3.04
1	(1)	664	1874	2.82
2	(1)(2)	706	1865	2.64
3	(1)(2)(3)	792	1865	2.36
4	(1)(2)(3)(6)	813	1865	2.29
5	(1)(2)(3)(5)(6)	846	1865	2.20
6	(1) to (6)	891	1865	2.09

Source: From Zhong and Lo [1], reproduced with permission from IEE.

Figure 2. Typical radiation patterns in H and E planes for antennas shown in Fig. 1 with six pins inserted. (From Zhong and Lo [1], reproduced with permission from IEE.)

For the rectangular patch, the two modes TM_{01} and TM_{03} satisfy this requirement. However, their resonant frequencies are related by a ratio of approximately 3; the exact value is dependent on the edge effect. It has been

Figure 3. Dual-frequency stacked microstrip antenna. (From Long and Walton [2], © 1979 IEEE.)

shown that placement of short-circuiting pins on the nodal lines of the TM_{03} mode field has little effect on this mode but a strong effect on the TM_{01} mode. Zhong and Lo [1] demonstrated that this offers a way of altering not only the separation of the two frequency bands but also the input impedance of the TM_{01} mode. The geometry of the rectangular patch in their experiment is shown in Fig. 1. It is made of $\frac{1}{8}$ -in. copper-cladded Rexolite 2200 with six short-circuiting pin positions. The effects of successively adding more and more pins (each approximately 0.05 cm in diameter) at the positions indicated in Fig. 1 are shown in Table 1. It is seen that the ratio of the two operating frequencies f_{03}/f_{01} can be varied from approximately 3 to 2. Since all these pins are located on the TM_{03} mode null lines, f_{03} remains constant at about 1865 MHz while f_{01} is varied from 613 to 891 MHz. In order for the impedances of the two bands to be close to 50Ω at resonance, it is necessary to

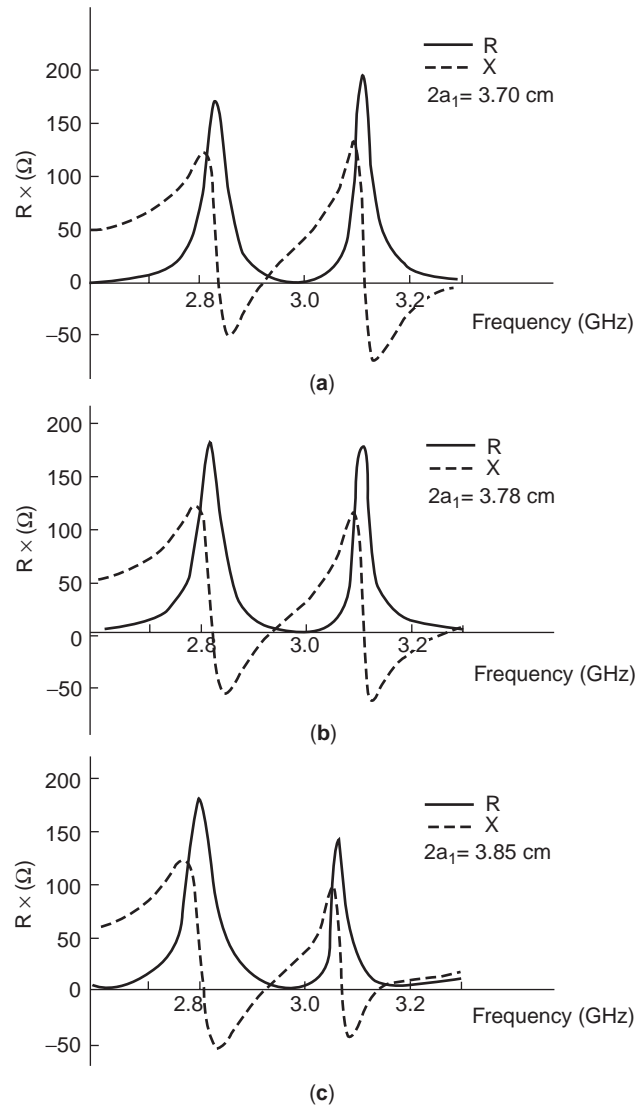

Figure 4. Real and imaginary parts of impedance of stacked circular patches etched on a dielectric with $\epsilon_r = 2.47$: (a) $2a_1 = 3.70$ cm; (b) $2a_1 = 3.78$ cm; (c) $2a_1 = 3.85$ cm. (From Long and Walton [2], © 1979 IEEE.)

attach a short capacitive stub of 0.6×2.1 cm. With the stub added, the bandwidth with reference to a standing-wave ratio (SWR) of 3:1 is about 2% for the lowband and almost 8% for the highband. Typical low- and highband patterns in both E and H planes are shown in Fig. 2. It is seen that, while the two modes radiate strongest in the broadside, the directivities of the two modes are quite different.

The rectangular patch is not the only geometry capable of providing dual-frequency operation. It will be shown in Section 6 that the TM_{01} , TM_{20} , and TM_{21} modes of the equitriangular patch are all broadside modes with similar polarizations in the broadside direction (refer to Fig. 31 for a detailed radiation pattern). By choosing the location of the feed properly, the impedances of these modes do not vary greatly. Section 6 discusses the utilization of the equitriangular patch for dual- or triple-frequency operations.

2.2. Dual-Frequency Stacked Patches

By using a stacked geometry consisting of two patches on two substrate layers, dual-frequency operation is obtained. The first experiment, reported by Long and Walton [2], utilized two stacked circular patches. The geometry is shown in Fig. 3.

The disks were photoetched on separate substrates and aligned so that their centers were along the same line. The sizes of the two disks and their spacings were varied and the resultant behavior of the antenna characteristics measured. The antenna was fed by means of a coaxial line. The center conductor passes through a clearance hole in the lower disk and is connected electrically to the upper disk. If one considers the two regions under the patch as two resonant cavities, it is clear that the system behaves as a pair of coupled cavities. Since the fringing fields are

different for the upper and lower cavities, two resonant frequencies are expected even if the diameters of the two disks are the same. Long and Walton [2] showed that,

Figure 15. Measured patterns for SPA ($W = 15.5$ mm; $L = 11.5$ mm; $l = 0.5$ mm; $w = 1$ mm; $d = 1$ mm; $W_p = 5.5$ mm; $\epsilon_r = 2.2$; $t = 0.8$ mm) (— TM_{10} mode, $f_{10} = 5.515$ GHz; - - - TM_{30} mode, $f_{30} = 10.44$ GHz). (From Maci et al. [7], reproduced with permission from IEE.)

unlike the single-element dual-frequency rectangular patch operated in the TM_{01} and TM_{03} modes, in which the frequency ratio is approximately 3 when no short-circuiting pins are used, this design can produce resonant frequencies that are considerably closer. A typical frequency ratio is 1.2; the exact value is determined by the relative diameters of the upper and lower disks, the thicknesses of the substrate layers, and the relative permittivities of the substrates.

Figure 4 shows the real and imaginary parts of the input impedance for $2a_2 = 3.78$ cm, $t_1 = t_2 = 0.075$ cm, and three values of $2a_1$. The relative permittivity of both layers is 2.47. The resonant frequencies as a function of the

upper disk diameter are shown in Fig. 5. Also shown is the resonant frequency of the lowest mode for a single disk of diameter $2a$ and substrate thickness $t = 0.075$ cm, taking into account the fringing field through the effective diameter. It is seen that the lower resonant frequency is relatively constant, remaining near the value of a single disk with $2a = 3.78$ cm and $d = 0.075$ cm. The upper resonance, on the other hand, is highly dependent on the size of the upper disk. Radiation patterns were also given in Ref. 2, which showed that they were similar to the radiation pattern of the lowest mode of the single circular patch. The radiation pattern is shown in Fig. 6.

Dahele and Lee [3] have applied the airgap concept to the design of dual-frequency stacked disks. The geometry is shown in Fig. 7, in which an airgap between the two substrates is introduced. By increasing the width of the airgap, the upper resonant frequency increases, accompanied by a broadening of the bandwidth of the lower resonance.

Dahele et al. [4] also studied a structure consisting of two stacked annular ring patches as shown in Fig. 8. This structure was also found to exhibit dual-frequency behavior. As in the case of circular disks, an upper airgap was found to be a convenient method of altering the separation between the frequency bands. A theoretical analysis of the stacked circular disks and stacked annular rings using Hankel transforms was given by Fan and Lee [5]. The predicted resonant frequencies showed excellent agreement with the measurements in Refs. 2 and 4.

In the two designs discussed in this section, the stacked geometry is suitable when the frequency ratio is in the range of 1.1–1.2, while the single element incorporating short-circuiting pins yields frequency ratios in the range of 2–3. In the next section, two additional designs are presented: patch with reactive loading and patch with slots. The former also yields similar frequency separation as the stacked patches, while loading a rectangular patch with slots can reduce the frequency ratio from about 3 to as low as 1.57.

3. DUAL-FREQUENCY LOADED PATCHES

3.1. Patch with Reactive Loading

A dual-frequency microstrip antenna can be obtained by loading it with a reactive load, such as a short-circuited

coaxial line or a short-circuited microstrip line. The latter preserves the low-profile characteristics of the microstrip patch antenna. Such a structure, shown in Fig. 9, was demonstrated experimentally by Davidson et al. [6]. In the experiment, a rectangular patch of dimensions 6×4 cm etched on a substrate with $\epsilon_r=2.17$ and thickness

spacing G between the line and the patch, as shown in Fig. 11. The results for the resonant frequencies are shown in Table 2. It is seen that the frequency ratio varies between 1.017 and 1.172.

Figure 23. Measured return loss S_{11} . (From Luk et al. [15], reproduced with permission from IEE.)

3.2. Patch with Slots

A dual-band rectangular patch antenna with a frequency ratio of < 2 can be obtained by loading the patch with two narrow slots etched inside the patch, which are close to and parallel to the radiating edges [7]. Such a slotted patch antenna (SPA) is shown in Fig. 12.

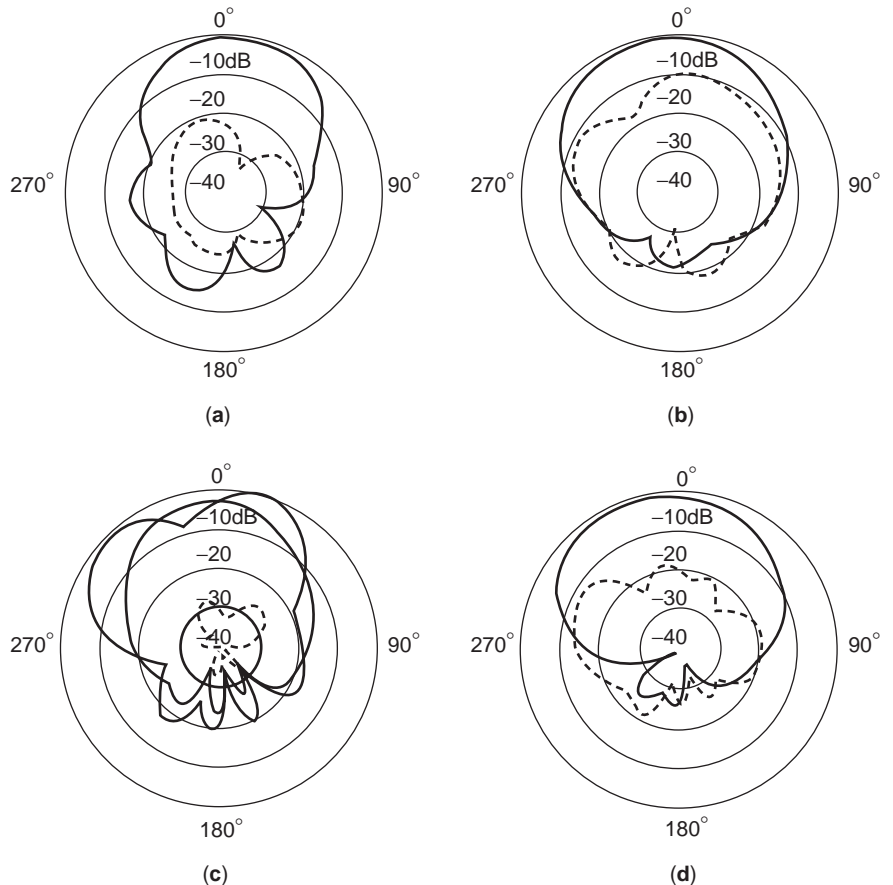

Figure 24. Radiation pattern: (a) E plane at 953.5 MHz; (b) H plane at 953.5 MHz; (c) E plane at 1.7855 GHz; (d) H plane at 1.7855 GHz (— copolarization; ···· copolarization; ——— copolarization without slots—for (c) only). Figure 25. Geometry of L-probe dual-band antenna with DC ground.

The reduction in frequency separation can be explained as arising from the perturbation of the TM_{10} and TM_{30} modes, as shown in Figs. 13a and 13b. These narrow slots are placed close to the radiating edges, where the current is nearly minimum for the TM_{10} mode. Consequently, the

current distribution for this mode is only slightly perturbed. Hence, its resonant frequency is only slightly different from that of the rectangular patch without a slot. For the TM_{30} mode, slots are located where the current of the unperturbed TM_{30} mode is significant, leading to

Figure 26. Measured standing-wave ratio and gain of the dual-band antenna. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

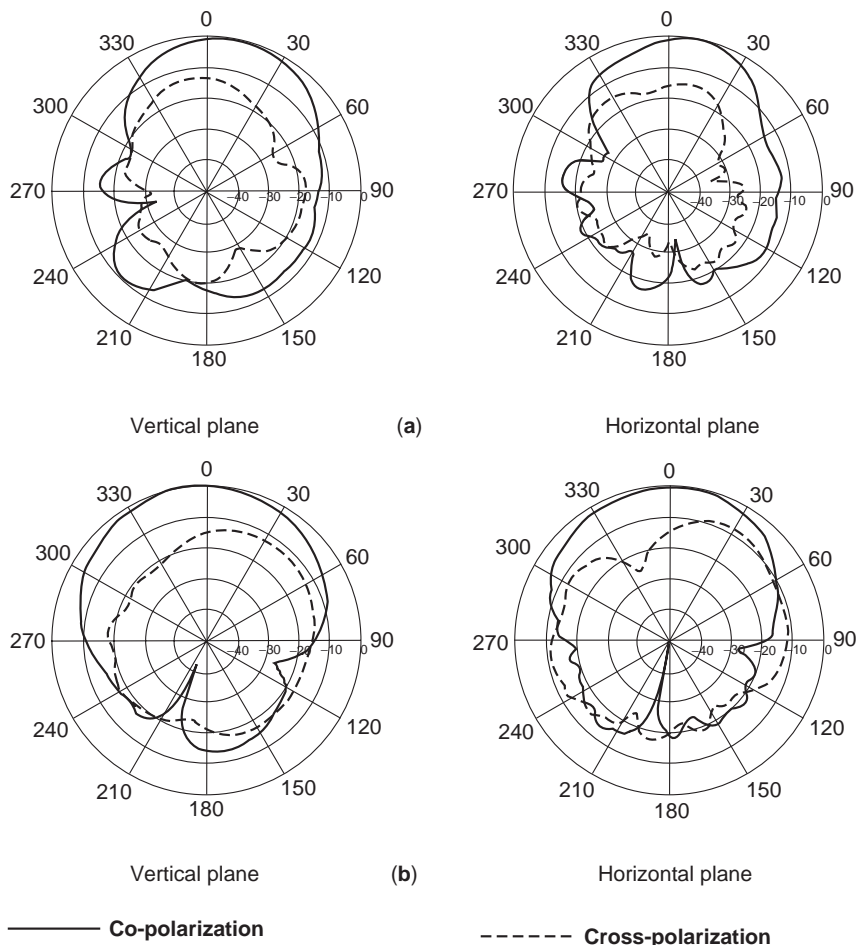

Figure 27. Measured radiation patterns of the antenna of Fig. 25 at 0.9 GHz (a) and 1.8 GHz (b). (— copolarization; - - - cross polarization).

strong modification of the current distribution. As a result, the resonance frequency decreases, due to the increase in the current pathlength introduced by the slot.

Maci et al. [7] performed numerical analysis based on the method of moments (MoM) and fabricated several prototypes at C and X bands. Design criteria were obtained from the MoM analysis. Figure 14 shows the amplitude of the reflection coefficient for a patch with the dimensions shown in the caption. Two resonances were obtained at $f_{10} = 5.515$ GHz and $f_{30} = 10.446$ GHz. The frequency ratio was 1.89. The experimental curve (continuous line) compares well with the results obtained by MoM analysis (dashed line). The central resonance of lower amplitude that appears in the Fig. 14 is associated with the TM_{20} mode that is excited in the structure owing to the asym-

metric feed. The measured radiation patterns of this antenna in the E and H planes are shown in Fig. 15. The dashed and continuous lines correspond to the lower and the upper frequencies, respectively. A gain of 6.5 dB was found for the lower frequency and 6.8 dB for the upper frequency. The *E*-plane radiation pattern at the upper frequency is broader than that for the lower frequency.

Maci et al. also showed that, by introducing resonant tuning stubs, the frequency ratio can be further reduced to about 1.57 [7].

3.3. Slot-Loaded Short-Circuited Patch Antenna

It is well known that the size of a rectangular patch can be reduced by short-circuiting along the vertical central axis,

Table 3. Summary of Radiation Characteristics

	Vertical Plane			Horizontal Plane			
	Frequency (GHz)	3 dB Beamwidth	Cross-polarization (dB)	Backlobe (dB)	3 dB Beamwidth	Cross-polarization (dB)	Backlobe (dB)
Lower band	0.9	56.3°	-13	-12	83.0°	-15	-13
Upper band	1.8	40.4°	-12	-15	74.9°	-9	-19

Figure 28. Geometry of equilateral triangular patch antenna. (From Lee et al. [16], © 1988 IEEE.)

which corresponds to the zero-potential plane for the TM_{10} and TM_{30} modes, and by using only one-half of the patch. The size of the antenna can be further reduced by decreasing the short-circuiting plane width [8]. Guo et al. [9] showed that this technique can be applied to reduce the size of the dual-frequency slot-loaded patch antenna.

The geometry of this antenna is shown in Fig. 16. A single slot with dimensions $L_s \times W_s$ is cut in a rectangular patch with dimensions $a \times b$ with a short-circuited plane with width s placed at its other side. The patch is separated from the ground plane by a foam substrate of thickness h . The slot is placed a small distance d_s from the radiating edge of the patch. The parameters of the slot were selected using the design criteria given in Ref. 7. It is found that, by controlling the short-circuiting plane width, both the TM_{10} and TM_{30} modes are strongly perturbed.

Many designs of the proposed antenna with various short-circuiting plane widths were fabricated and measured by Guo et al. [9]. Figure 17 shows typical results of the measured return loss for the cases with $s/a = 1, 0.5, 0.25,$ and 0.1 for the dimensions shown in the caption. It is seen that the perturbed TM_{10} and TM_{30} modes are excited with good impedance matching. However, when $s/a < 0.1$, no feedpoint can be found for exciting the two frequencies with good matching. This indicates that there are limitations to the present dual-band design. It is seen that the frequency ratio f_{30}/f_{10} varies in the range $\approx 1.6 - 2.2$. For the case $s/a = 0.1$, the frequency f_{10}

occurred at 1.535 GHz, which is about 0.29 times the frequency f_{10} (5.35 GHz) for a regular half-wavelength patch of the same patch size. The partial shorting plane therefore significantly reduces the resonant length of the patch.

Typical measured far-field radiation patterns at the two operating frequencies for the case with $s/a = 1$ and $s/a = 0.1$ are shown in Fig. 18. For the experiment, the shorted patch was mounted on a large ground plane (a circular disk with diameter $= 3\lambda_0$) to reduce diffraction off the edges. Similar radiation patterns and polarizations for the two operating frequencies f_{10} and f_{30} are observed. It can be seen that for $s/a = 1$, there is a mainbeam squint of about 32° and 43° in the E plane for f_{10} and f_{30} , respectively. For $s/a = 0.1$, the corresponding mainbeam squint is about 30° and 6° . For $s/a = 1$, the measured gain in the maximum direction is 2.2 and 2.75 dBi for f_{10} and f_{30} , respectively, while for $s/a = 0.1$, the corresponding gain is 0.4 and 1.9 dBi. It should be noted that although the H -plane cross-polarization level is quite high, it may not be a disadvantage in some applications, such as indoor mobile communications.

4. DUAL-FREQUENCY COUPLED PATCHES

In this section, we present a dual-frequency design that makes use of the concept of a low-frequency (outer) patch coupled to a high-frequency (inner) patch [10]. The low-frequency element is a U-shaped patch with unequal arms, while the high-frequency element is a E-shaped patch [11], which is a variation of the wideband U-slot patch [12]. The geometry is shown in Fig. 19. The inner patch is fed by a coaxial probe, and the outer patch is excited through proximity coupling to the inner patch.

It is noted that the two arms of the U patch are not equal. This introduces two closely spaced resonances at the lower frequency, making the bandwidth of the low-band wider than the case when the arms are of equal length. Moreover, a short-circuiting wall is introduced in the U patch to reduce the size of the patch. An antenna of this type was designed to operate at both 900 and 1800 MHz, using FR4 substrate material with relative permittivity equal to 4.4 [10]. It has the following parameters: $W = 40$ mm, $W_1 = 5$ mm, $W_2 = 5$ mm, $W_3 = 16$ mm, $L_1 = 45$ mm, $L_2 = 50$ mm, $L_3 = 42.5$ mm, $L_4 = 42.5$ mm, $a = 4$ mm, $b = 2$ mm, $c = 44$ mm, $d_1 = 2$ mm, $d_2 = 2$ mm, $e_1 = 3.5$ mm, $e_2 = 3.5$ mm, $s_1 = 1.5$ mm, $s_2 = 1.5$ mm, $f = 41$ mm, $g = 10$ mm, and $h = 11$ mm.

The measured SWR of the dual-band antenna is shown in Fig. 20. The bandwidth of the lower-frequency element is 13.3% with a frequency range of 807–922 MHz, and that of the upper band is 20% with a frequency range of 1625–1982 MHz when $SWR \leq 2$. The substrate thickness corresponds to 0.033 free-space wavelength at 900 MHz, while the length L_2 and the width W are $0.15\lambda_0$ and $0.12\lambda_0$, respectively. Figure 21 shows the copolarization E - and H -plane radiation patterns at 900 and 1800 MHz, respectively. At 900 MHz, the 3 dB beamwidth in the E plane is 109° and in the H plane, 127° . At 1800 MHz, the 3 dB beamwidth in the E plane is 72° and

Figure 29. Theoretical input impedance at resonance as function of feed position. (From Lee et al. [16], © 1988 IEEE.)

in the H plane, 73° . The beamwidth in the lower band is larger than that in the upper band. The measured gain of the antenna was 2 ± 1.5 dBi and 4.5 ± 1.8 dBi at the lower and upper bands, respectively. The measured results confirm that the lower band is due to the short-circuited U-shaped patch with two unequal arms and the upper one is due to the inner coaxially fed E-shaped patch. Note that the cross-polarization was significantly higher than with the single-patch antenna. However, for indoor mobile communications, this would lead to better transmission capabilities in a multipath environment.

5. DUAL-FREQUENCY WIDEBAND L-PROBE PATCH

5.1. Basic L-Probe Dual-Band Antenna

The L-probe patch [13,14] is a wideband patch antenna. This technique can be further extended to dual-band operation [15]. For ease of operation and to reduce cost, the antenna should have only one input for both frequency bands. In this section, the design of a dual-band patch antenna excited by two L probes through one feed is described.

The geometry of a dual-band band patch antenna [15] consisting of two L probes is shown in Fig. 22. The

antenna operates at 900 MHz (λ_1 , lower-band operation) and 1.8 GHz (λ_2 , upper-band operation). The probes are combined together to form a feed structure. The lower-band patch has length $l_1 = 102$ mm ($0.312\lambda_1$) and width, $w_1 = 110$ mm ($0.336\lambda_1$) and is 45.4 mm ($0.139\lambda_1$) above the ground. Two slots with width = 2 mm and length = 90 mm are etched l_1 away from the radiation edge of the lower-band patch. These two slots are used to suppress the excitation of the TM_{20} mode that would influence the upper-band radiation pattern. The upper-band patch with sides $l_2 = 37$ mm ($0.227\lambda_1$) is 21.5 mm ($0.128\lambda_1$) above the ground. Because of the coupling effect of the lower-band patch, the resonant length of this patch is less than that of an isolated patch operated at the same frequency.

The measured return loss S_{11} is as shown in Fig. 23. The impedance bandwidth ($S_{11} < -10$) of 20.8 and 17.9% was found for the lower and upper bands, respectively. It is wide enough to cover GSM 900 and 1800 cellular phone systems. The maximum gain of 8.4 dBi was found in the upper band. The measured radiation patterns are shown in Fig. 24. The 3 dB beamwidths of lower and upper bands are 71° and 75° in the H plane and are 56° and 60° , in the E plane. The cross-polarization is -10 and -13 dB in the lower and upper bands, respectively.

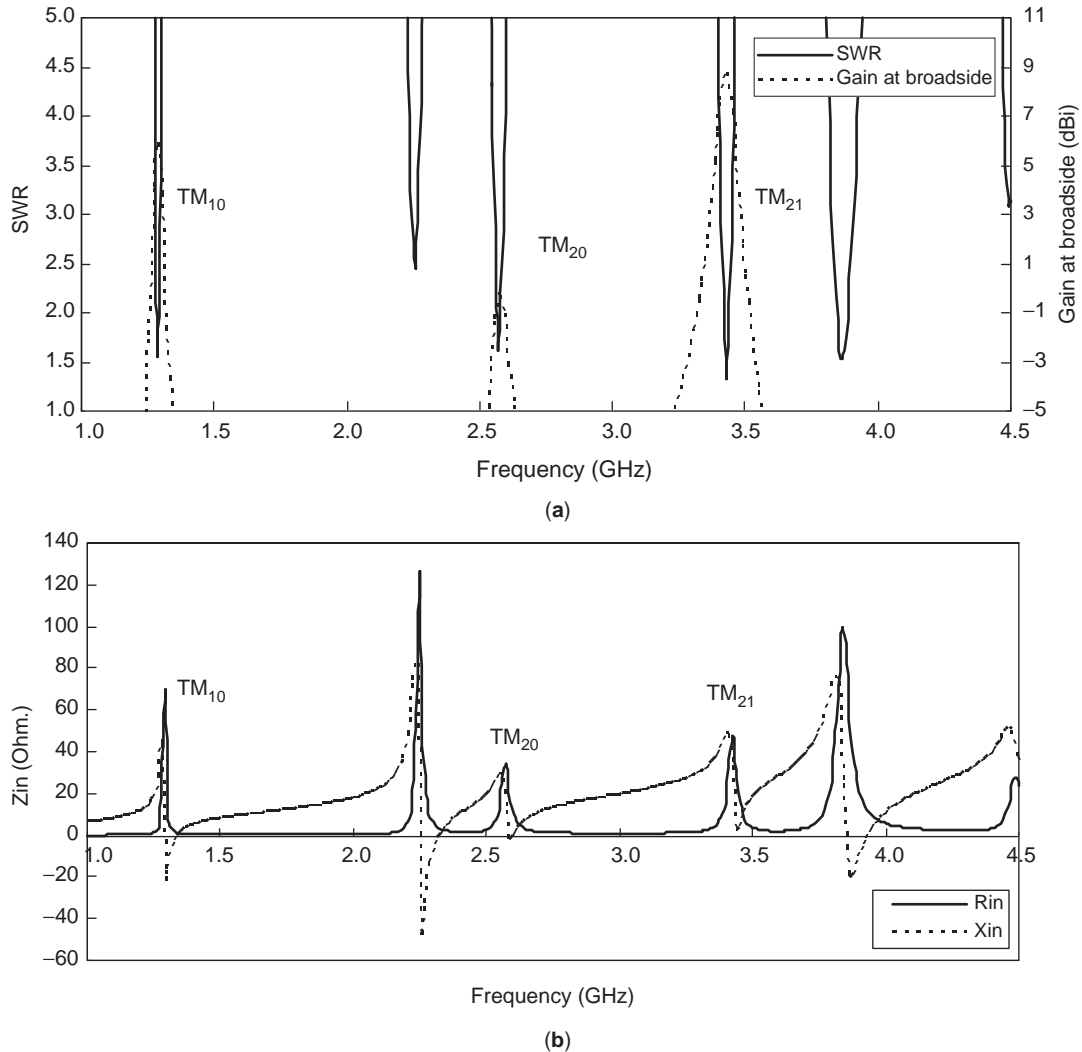

Figure 30. Standing-wave ratio and gain (a) and input impedance (b) of triangular patch antenna.

5.2. Advanced Design For L-Probe Dual-Band Antenna Bandwidth

The L-probe dual-band patch antenna can be modified to have a DC grounded feature, which protects the antenna against the lightning hazard. This is accomplished by adding a short-circuit stub in the feeding network of the antenna. Such a design is presented in this section.

The geometry of the antenna, which operates at both 900 MHz (f_1) (lower band) and 1800 MHz (f_2) (upper band), is shown in Fig. 25. The antenna consists of two rectangular patches of different sizes. The thickness of each aluminum patch is 1 mm. The lower-band patch (patch L) with dimensions 100 mm ($0.33\lambda_1$) \times 15 mm ($0.35\lambda_1$) is supported 45.37 mm above the ground by plastic pins. The height and length of the larger probe are 29.265 and 57.8 mm, respectively, and the antenna is located 55.55 mm (about $1/4\lambda_1$) away from the short-circuiting pin. In order to suppress the TM_{02} mode of the larger patch, two slots with sides 80×2 mm are etched on the

patch. The upper-band patch (patch U) with dimensions 63.5 mm ($0.381\lambda_2$) \times 54 mm ($0.324\lambda_2$) is located 22.9 mm ($0.137\lambda_2$) above the ground. The height and length of the smaller probe are 15.22 and 32.44 mm, respectively, and the probe is located at 141.38 mm (about $0.75\lambda_2$) away from the short-circuiting pin. The thickness and dielectric constant of the microwave substrate are, respectively 1.5 mm and 2.65. The characteristic impedance transmission line is 50 Ω . The size of the ground plane is 200×275 mm.

Figure 26 shows the measured standing-wave ratio (SWR) and gain of the dual-band patch antenna. For $SWR < 2$, the impedance bandwidth of 27.5% was found for lower-band operation and 14.1% for the upper-band operation. The results show the antenna is wide enough to cover the GSM 900 and 1800 mobile phone systems. An average gain of 8 dBi was found for the lower band and 7.5 dBi for the upper band. The measured radiation patterns of the antenna are shown in Fig. 27. The characteristics of the vertical and horizontal planes are summarized in Table 3.

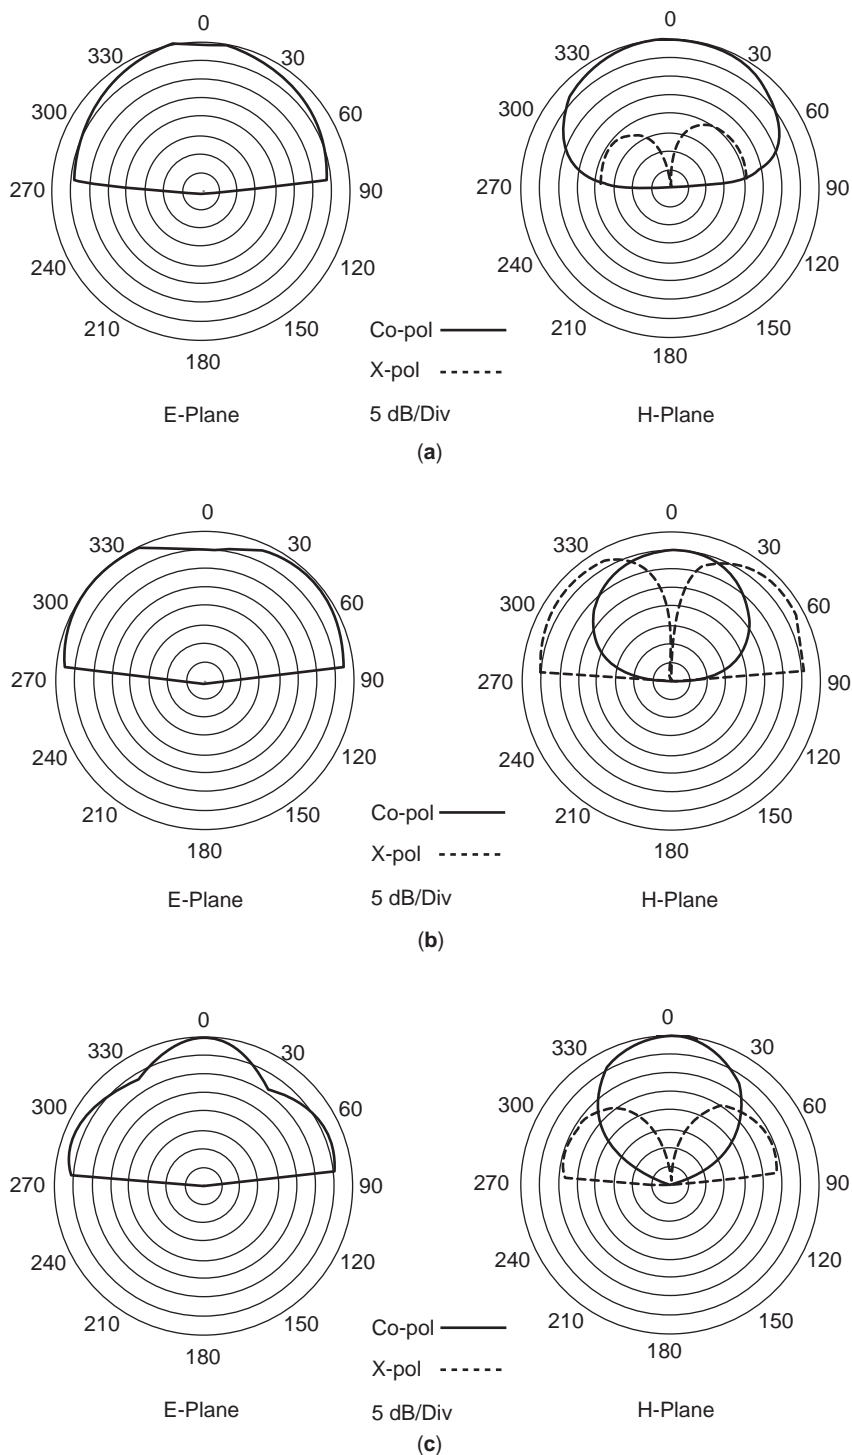

Figure 31. Radiation patterns of triangular patch antenna: (a) TM_{10} mode; (b) TM_{20} mode; (c) TM_{21} mode.

6. MULTIFREQUENCY PATCH ANTENNAS

6.1. Single-Element Triple-Frequency Triangular Patch Antennas

As mentioned in Section 2.1, it is possible for a single-element patch antenna to operate at several frequency bands corresponding to the various resonant modes

pertaining to the patch structure. For dual-band operation, we can simply select the rectangular patch, which can be operated at the TM_{01} and TM_{03} broadside modes with a single feed. For triband operation, other patch shapes have to be considered.

From the cavity model analysis of equilateral triangular patch antennas [16], it appears that we can excite the three broadside modes, namely, TM_{10} , TM_{20} , and TM_{21}

Figure 32. A coaxially fed square patch antenna loaded with stubs (substrate thickness = 0.79 mm, dielectric constant = 2.17).

modes, with a single feed. In particular, if we select the length of each edge of an equilateral triangular patch to be 10 cm, as shown in Fig. 28, we can ensure that the antenna matches at the three modes by choosing the feed position $g = 50$ mm (Fig. 29) from an edge of the triangle.

Using the IE3D¹ simulation tool, we have analyzed the performance of the triangular patch antenna. The gain, SWR, input impedance, and radiation pattern are shown in Figs. 30 and 31. It can be observed that the antenna does resonate at the TM_{10} , TM_{20} , and TM_{21} modes with resonant frequencies of 1299, 2599, and 3499 MHz, respectively. The three modes basically have broadside radiation patterns.

6.2. Multifrequency Stub-Loaded Patch Antennas

As described in Section 3.1, a patch antenna can be operated in dual frequency if the patch is loaded with a single stub. The technique can be generalized for designing patch antennas with triple-band operation. As demonstrated by Daniel and Kumar [17], it is possible to design a square patch antenna with the triband characteristic by loading the two radiating edges with two open-circuited stubs of unequal lengths, as shown in Fig. 32.

To confirm the results presented in Ref. 17, we have employed the IE3D software to simulate the performance of this antenna. The simulated SWRs of the antenna with and without the two stubs are shown in Fig. 33. It can be observed that without the stubs, only one resonant mode is found within the frequency range 1.2–2 GHz. With the addition of the two stubs, three modes are generated. The antenna can now be operated at around 1.252, 1.540, and 1.935 GHz. This antenna has a frequency ratio of 1:1.23:1.55, which indicates that the three operating bands are more closely packed than those of triangular patch antenna with multimode operation. The radiation patterns of the antenna are shown in Fig. 34. It can be observed that the three modes radiate strongly in the broadside direction.

Figure 33. Return loss of square patch antennas.

6.3. Multifrequency Microstrip Antenna Consisting Of Parallel Microstrip Dipoles

Although the two designs presented in Sections 6.1 and 6.2 can be operated at three frequency bands, the gain varies substantially between different bands. In particular, a very low gain is observed at the middle frequency. Also, in these techniques, it is difficult to generate more than three broadside modes with a single feed. Alternatively, multifrequency operation can be realized by using electromagnetically coupled parallel microstrip dipoles of different lengths excited by the aperture-coupling technique [18]. As shown in Fig. 35, six dipoles and the feed-line are centered on the coupling aperture. To achieve a uniform excitation of the dipoles, the longest pair of dipoles is located closer to the center of the aperture and the shortest closer to the edges of the aperture. With appropriate selection of dimensions [18], a triple-band patch antenna operated at $f_1 = 5.3$ GHz, $f_2 = 6.28$ GHz, and $f_3 = 7.19$ GHz was successfully designed. The bandwidth at bands 1, 2, and 3 are respectively 4%, 4.5%, and 2.1%. This is an attractive feature as the difference between the bandwidths at the different frequency bands is small. Moreover, the antenna has similar broadside radiation patterns at the three bands.

6.4. Multifrequency Microstrip Antenna Using Multiple Stacked Elements

Another technique has been proposed for the design of a multifrequency patch antenna with similar bandwidth and gain at different frequency bands. As shown in Fig. 36, the antenna consists of a driven patch and four parasitic patches placed underneath the driven patch [19].

The driven patch, which has dimensions of 51×51 mm, is fed by capacitive coupling in order to mitigate the mismatching due to the probe inductance. It is etched on a thin dielectric substrate of thickness 0.8 mm and dielectric constant 3.38. The parasitic patches are supported by foam layers and are slightly larger than the driven patch. Their dimensions are adjusted for optimum

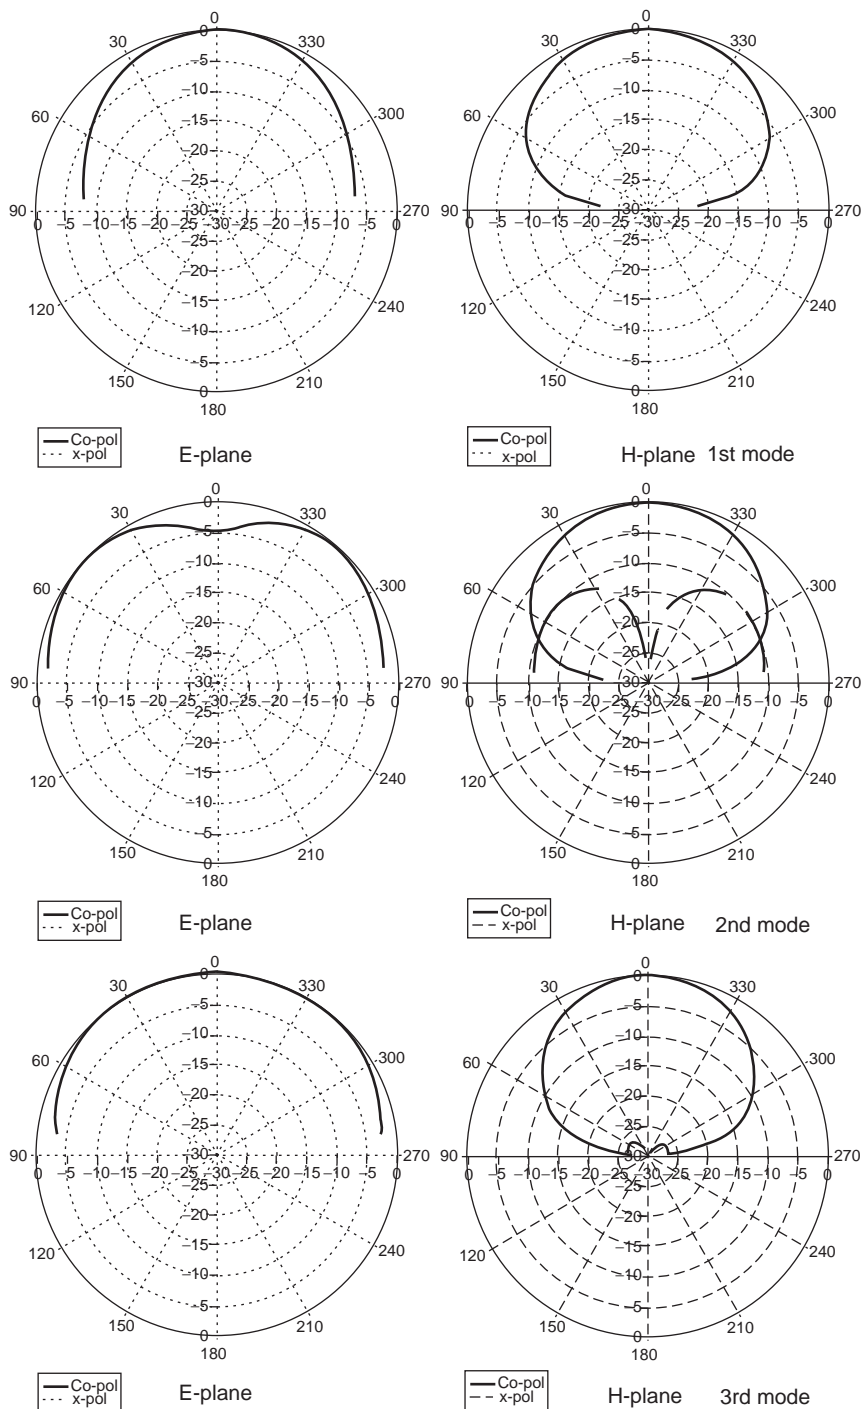

Figure 34. Radiation patterns of square patch antenna. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

performance based on simulation. The total thickness of the antenna is 15.6 mm. Measured results of the antenna are listed in Table 4.

It was found that the antenna could be operated at five frequency bands with gains varying from 7 to 9 dB, and bandwidth varying from 1.5% to 5.5%. The operating bands are closely packed in this design (small frequency ratios). Moreover, the radiation patterns at different frequencies are similar and stable. The radiation pattern is shown in Fig. 37.

7. CONCLUDING REMARKS

Many present-day wireless applications demand aesthetically pleasing devices operating at dual- or triple-frequency bands. Examples include triband GSM mobile phones, integrated GPS/GSM receivers, and dual-band wireless local-area networks. Because of its low-profile characteristic, multiband microstrip antennas are becoming the most popular choice as an embedded or conformal antenna in modern wireless devices or systems.

Table 4. Bandwidth and Gain Experimental Data

Band	Frequency (GHz)	Bandwidth (%)	Gain (dB)
1	1.634	5.5	9.2
2	1.819	2.0	8.4
3	1.954	2.7	7.6
4	2.092	1.5	6.9
5	2.289	5.3	7.3

In this article, major techniques available in the literature for designing dual-band and multiband microstrip antennas have been reviewed, with emphasis on the principles of operation and design guidelines. It has been demonstrated that if a large frequency ratio is required, the multimode technique is preferable, whereas if a small frequency ratio is required, the multiple-resonator techniques, including the stacked patch or coplanar patch geometry, are good choices.

1. INTRODUCTION

The new millennium has brought many broadband design challenges, with the memory-hungry multimedia contents and new-generation wireless mobile communications demand for larger ever bandwidth to satisfy very high data rates. The demand can be met with the design with high functionality per unit volume. Naturally frequency agile and unwanted frequency immune responses from RF and microwave devices are needed. Electromagnetic bandgap structures (EBGSs) are playing a vital role in enhancing the performance of microwave devices. EBG materials are periodic structures, that exhibit wide bandpass and band-rejection properties at microwave frequencies. The introduction of periodic perturbation such as dielectric rods, holes, and patterns in waveguides and PCB substrates has resulted in the development of EBGSs, which are also termed *photonic bandgap* (PBG) materials. As in a photonic crystal (PC), photon propagation is impeded by electrons and the electromagnetic (EM) waves in a EBG material are impeded by the periodic discontinuity, hence resulting in a slow-wave structure. Because of their unique properties of distinct passband and stopband characteristics, planar PBG materials find potential applications in antennas, amplifiers, waveguides, filters, power dividers/combiners, phased arrays, electromagnetic compatibility (EMC) measurements, and many other microwave devices [1–18]. The passband characteristic of the PBG structure (PBGs) is used as a slow wave medium, which reduces the size of electronics boards. The wide stopband is applied to suppress spurious transmission and leakage in guided structures such as conductor-backed coplanar waveguides (CPWs) and striplines. Careful design of the PBGS can improve antenna matching and hence bandwidth, and can suppress spurious harmonics, sidelobes, and backlobes of antenna elements and arrays. In filters PBGSs are used for harmonic suppressions such that in a filterbank the interference with other filters can be minimized.

This article investigates PBG-assisted asymmetric coupled-line bandpass filters (BPFs). Both conventional circular patterned PBGs and defected ground structures (DGSs) are used to suppress the harmonics of the filter. Since PBG is a periodic structure, the theory of periodic structures is reviewed first. The passband and stopband phenomena are explained with the help of capacitively

loaded transmission line. The formulation for full-wave analysis of 1D PBG structure is also reported. The transmission-line model of a modified uniplanar compact PBG structure (UCPBGS) is analyzed and a dispersion diagram of the UCPBGS is presented. The calculated stopband and passband properties of the modified UCPBGS validate the model. This structure is used in harmonic suppression of a hairpin filter [37].

Before presenting the PBG-assisted BPF design, we will analyze a PBG-engineered 50- Ω transmission line realized by 2D and 1D circular patterned uniform PBGSs (UPBGSs). A comparison of the 1D and 2D UPBGSs shows that there is no significant difference in passband and stopband properties between the two. Next, UPBGSs are used to suppress the harmonics of a four-section asymmetric coupled-line BPF. Different designs of UPBG-assisted BPFs are investigated and the *S*-parameter performance is described to investigate the effectiveness of harmonic suppression. This comprehensive investigation reveals that a careful design procedure is required to achieve the optimum suppression of harmonics without affecting the passband performance of PBG-assisted BPFs. The strong interaction between the poles and zeros of PBGS and BPFs drastically distorts the passband performance of BPF.

We investigated nonuniform PBGSs in 2003 [15]. Nonuniform PBGSs provide better passband return loss (RL) and minimum passband ripples compared with those for the conventional UPBGSs. We also observe that the nonuniform PBGSs yield better harmonic suppression compared with the UPBGSs. In our investigation nonuniform *binomially* distributed PBGSs are used for significant harmonic suppression. Few designs are investigated to observe the effects of different numbers and positions of the unit cells of binomially distributed PBGSs on the harmonic suppression and passband performances.

Finally, DGS has been used in the BPF. The wide stopband property of the DGS is exploited to suppress both second and third harmonics of the BPF. The uniform and nonuniform PBGSs are designed at a single stopband frequency, which is the second- or third-harmonic frequency of BPFs. Therefore, two sets of PBGSs are needed to suppress the second and third harmonics. The new dumbbell-shaped DGS reported in the open literature [19] is more compact and yields very wide stopband performance [20]. These DGS assisted BPFs are investigated for simultaneous second- and third-harmonic suppressions of BPF. Detailed investigations into DGS-assisted BPFs are presented toward the end of the article, followed by the conclusion.

2. THEORY OF PBG STRUCTURES

PBGSs have occupied significant portions of the microwave engineering literature. PBGSs enhance the performance of many microwave devices and components. The acronym PBG is actually used in optical communication.

More recently, PBG-related terminology has been scaled down for RF engineering applications. PBGSs are old concepts because they generate stopband- and passband-like periodic structures. To understand the stopband and passband phenomena of PBGSs, we first review the conventional periodic structure [21].

Waveguides and transmission lines loaded at periodic intervals with identical reactive elements are referred to as *periodic structures* [21]. This type of period structure yields two distinct properties:

1. Passband–stopband characteristics
2. Stemming waves with phase velocity lower than the velocity of light in free space

In the passband EM waves does not attenuate along the structure. There is some incidental conductor loss only. On the other hand, in the stopband the EM waves are totally attenuate so that they cannot propagate throughout the structure. Stopband characteristics are very important to suppress surface waves. EM waves having the velocity lower than the velocity of light in free space are called *slow waves*. Periodic perturbation in the ground plane provides periodic discontinuity. Thus the slow-wave property of the EM waves is achieved. Slow-wave structures (SWSs) are promising candidates for compact design.

2.1. Periodic Structures

2.1.1. **Capacitively Loaded Transmission Line.** A simple capacitively loaded transmission line can be analyzed to conceive the idea of periodic structures. The velocity of EM wave in a physically smooth transmission line can be written as

$$V_p = \frac{1}{\sqrt{LC}} = \frac{1}{\sqrt{\mu_0 \epsilon_0 \epsilon_r}} \tag{1}$$

where V_p is the phase velocity of EM wave, L is the series inductance per unit length, C is the shunt capacitance per unit length, ϵ_r is the dielectric constant of the medium surrounding the conductor, and ϵ_0 and μ_0 are free-space values of the permeability and permittivity, respectively.

From Eq. (1) it is seen that with the value of the dielectric constant (ϵ_r), the phase velocity of EM waves reduces. One problem arises from this simple way of reducing the phase velocity. If we increase the value of dielectric constant, then higher-order modes propagate. To avoid this propagation, the cross-sectional dimensions of the line must be reduced accordingly. This is the limitation of increasing the value of dielectric constant to get the reduced value of the phase velocity of EM waves.

We know $LC = \mu_0 \epsilon_r \epsilon_0$ for dielectric media, so any attempt of increasing the value of C to reduce the phase velocity is restricted here, because if we increase the value of C , the value of L will automatically reduce to maintain the relation $LC = \mu_0 \epsilon_r \epsilon_0$ in a physically smooth transmission line. Under this circumstance, we can relax the restriction of a physically smooth transmission line instead of an electrically smooth line. An effective increase in the shunt capacitance per unit length (C) can be

achieved without disturbing the value of inductance per unit length (L) by loading lumped shunt capacitance at periodic intervals where the spacings between the loaded shunt capacitance are small compared with the wavelength. At this stage, although the line is not physically smooth, it will be an electrically smooth line. Under this condition the capacitance will increase, which can be observed from the following equation of the phase velocity

$$V_p = \frac{1}{\sqrt{(C + C_0/d)L}} = \frac{\omega}{\beta} \tag{2}$$

where C_0/d is the loaded lumped capacitance per unit length, ω is the angular frequency, and β is the phase constant.

There are many ways of obtaining periodic structures. One of the simplest ways is to load a thin diaphragm at a regular interval in a coaxial transmission line. The diaphragm may be machined as the integral part of the center conductor. The fringing electric field in the vicinity of the diaphragm increases the local storage of electric energy and gives more extra shunt capacitance.

2.1.2. **Circuit Analysis of a Periodic Structure.** We may assume a transmission line to be a combination of the finite unit cell of the structure. Figure 1a illustrates the equivalent circuit of a basic unit cell of a capacitively loaded coaxial line, and Fig. 1b shows the complete transmission line composed of the basic unit cells.

The unit cell may be divided into three parts: two transmission lines of length $d/2$ on either side of a normalized shunt susceptance B .

2.1.2.1. **Relationship between Input and Output Variables.** Let V_n and I_n be the input voltage and current variables, respectively, and let V_{n+1} and I_{n+1} be the output voltage and current variables, respectively.

The relationship can be found by using the *ABCD* transmission matrix. Overall, the *ABCD* parameters of a unit cell can be written as

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} = \begin{bmatrix} \cos \theta/2 & j \sin \theta/2 \\ j \sin \theta/2 & \cos \theta/2 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ j\bar{B} & 1 \end{bmatrix} \tag{3}$$

$$\begin{bmatrix} \cos \theta/2 & j \sin \theta/2 \\ j \sin \theta/2 & \cos \theta/2 \end{bmatrix}$$

where $\theta = k_0 d$ and k_0 is the free-space wavenumber.

Figure 1. (a) Equivalent-circuit model of a unit cell of capacitively loaded line; (b) a transmission line cascaded by unit cells.

Our unit cells are symmetric where $A=D$. When an EM wave propagates through periodic structures, the voltage and current at the $(n+1)$ th terminal are equal to the values of the voltage and current of the n th terminal except for the phase delay. Please note that we assume the transmission lines to be lossless. Therefore, the relations of V and I are as follows:

$$V_{n+1} = e^{-\gamma d} V_n \quad (4)$$

$$I_{n+1} = e^{-\gamma d} I_n \quad (5)$$

Using Eqs. (4) and (5), we find that Eq. (6) generates a matrix eigenvalue equation for the solution of V_{n+1} and I_{n+1} :

$$\begin{bmatrix} V_n \\ I_n \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} V_{n+1} \\ I_{n+1} \end{bmatrix} = e^{\gamma d} \begin{bmatrix} V_{n+1} \\ I_{n+1} \end{bmatrix} \quad (6)$$

Nontrivial solutions for V_{n+1} and I_{n+1} are obtained if the determinant of this matrix vanishes:

$$\begin{bmatrix} A - e^{\gamma d} & B \\ C & D - e^{\gamma d} \end{bmatrix} = 0 \quad \text{or} \\ AD - BC + e^{2\gamma d} - e^{\gamma d}(A+D) = 0$$

Assuming reciprocal circuit and letting $AD - BC = 1$, we have $1 + e^{2\gamma d} - e^{\gamma d}(A+D) = 0$ or

$$\cosh \gamma d = \frac{A+D}{2} \quad (7)$$

Expansion of (3) shows that $A=D = \cos \theta - (\bar{B}/2) \sin \theta$. Substituting these values in Eq. (7), we have

$$\cosh \gamma d = \cos \theta - \frac{\bar{B}}{2} \sin \theta \quad (8)$$

Equation (8) is a very vital equation for understanding passband and stopband phenomena created by periodic structure.

2.1.2.2. Explanation. We can explain the phenomena with the following cases.

Case 1. When the right-hand side (RHS) of Eq. (8) is less than 1, $\cosh \gamma d = \cos \theta - (\bar{B}/2) \sin \theta < 1$, then, under these circumstances $\gamma = j\beta$ and

$$\cos \beta d = \cos \theta - \frac{\bar{B}}{2} \sin \theta \quad (9)$$

Case 2. When $\cos \theta - (\bar{B}/2) \sin \theta > 1$, we have $\cosh \gamma d = \cos \theta - (\bar{B}/2) \sin \theta > 1$. Under these circumstances $\gamma = \alpha$, $\beta = 0$, and

$$\cosh \alpha d = \cos \theta - \frac{\bar{B}}{2} \sin \theta \quad (10)$$

Case 3. When $\cosh \gamma d = \cos \theta - (\bar{B}/2) \sin \theta < -1$, then $\gamma d = j\pi + \alpha$ and $\cosh \gamma d = \cosh(j\pi + \alpha d) = -\cosh \alpha d$ or

$$-\cosh \alpha d = \cos \theta - \frac{\bar{B}}{2} \sin \theta < -1 \\ \cosh \alpha d = - \left(\cos \theta - \frac{\bar{B}}{2} \sin \theta \right) \quad (11)$$

Equations (9)–(11) are very important for understanding the propagation of EM waves through periodic structures. It is apparent that there will be frequency bands for which unattenuated wave propagation is possible, separated by frequency bands in which the wave is attenuated. Fully attenuated waves yield stopband, and unattenuated waves generate passband. Thus these equations help us understand stopband and passband phenomena of PBGS.

Let us consider $d \ll \lambda_0$ in our case. So the electrical length $\theta = k_0 d$ will be small and βd will also be small. Under these conditions

$$\cos \theta = 1 - \frac{\theta^2}{2} \quad (12)$$

$$\cos \beta d = 1 - \frac{\beta^2 d^2}{2} \quad (13)$$

Equation (9) then assumes either of the following forms:

$$\Rightarrow 1 - \frac{\beta^2 d^2}{2} = 1 - \frac{k_0^2 d^2}{2} - \frac{B k_0 d}{2} \\ \beta^2 d^2 = k_0^2 d^2 + \bar{B} k_0 d \quad (14)$$

$$\beta^2 = k_0^2 + \frac{\bar{B} k_0}{d}$$

We have the relations:

$$k_0^2 = \omega^2 \mu_0 \epsilon_0 = \omega^2 LC \quad (15)$$

$$\bar{B} = \frac{B}{Y_c} = \omega C_0 \sqrt{\frac{L}{C}} \quad (16)$$

(where characteristic impedance $Z_c = \sqrt{L/C} = 1/Y_c$). Substituting k_0 and \bar{B} from (15) and (16) in Eq. (14), we have

$$\beta^2 = \omega^2 LC + \omega^2 \frac{LC_0}{d}$$

or

$$\beta = \omega \sqrt{L \left(C + \frac{C_0}{d} \right)} \quad (17)$$

Equation (17) is very important in understanding the slow-wave effect of periodic structures. We can observe new value of capacitance $C + C_0/d$ in which capacitance has been increased by C_0/d . Therefore, we find that at low frequencies where $d \ll \lambda_0$, the loaded line has a shunt

capacitance $C + C_0/d$ per unit length. Increased β value results in reduction of the phase velocity.

2.2. Full-Wave Analysis of One-Dimensional PBG Structure

2.2.1. Fundamental Equation. Maxwell's equations are fundamental equations to form the foundation for electromagnetic theory. These equations can be written in differential form as follows:

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad (18)$$

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \quad (19)$$

$$\nabla \cdot \mathbf{D} = \rho \quad (20)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (21)$$

where \mathbf{E} is the electric field intensity, \mathbf{B} is the magnetic flux density, \mathbf{H} is the magnetic field intensity, and \mathbf{D} is the electric flux density. The electric current density \mathbf{J} and electric charge density ρ are the sources of the electromagnetic fields.

The constitutive relations are

$$\mathbf{D} = \epsilon_r \epsilon_0 \mathbf{E} \quad (22)$$

$$\mathbf{B} = \mu_r \mu_0 \mathbf{H} \quad (23)$$

where ϵ_r and ϵ_0 are the relative permittivity and free-space permittivity, respectively and μ_r and μ_0 are the relative permeability and free-space permeability, respectively. The relation between the electric charge density and electric current density is defined as the continuity equation

$$\nabla \cdot \mathbf{J} = -\frac{\partial \rho}{\partial t} \quad (24)$$

Finally, Lorentz' force equation determines the total electromagnetic force on a charge q to be

$$\mathbf{F} = q(\mathbf{E} + \mathbf{u} \times \mathbf{B}) \quad (25)$$

where \mathbf{u} is the velocity of the moving charge.

Equations (18)–(25) provide the necessary framework for predicting all macroscopic electromagnetic interactions.

2.2.2. Analytical Techniques. The use of Maxwell's equations in the wave equation and the understanding of Floquet's principle yield the eigenvalue equation for the periodic structure. The solution of the eigenvalue equation for the periodic structure can be obtained by the use of Fourier series. The EM wave may be transverse electric (TE) or transverse magnetic (TM) depending on the orientation of the structure. We present a mathematical model for a rectangular patterned UPBGS. The structure of rectangular patterned uniform PBGSs is shown in Fig. 2.

2.2.2.1. Transverse Electric (TE_x) Case. The electric field can be expanded [22] as a periodic function of plane waves

in x with period d and prescribed propagation constant of k_{x0} as follows

$$\mathbf{E}(x, y) = \hat{z}E_z(x, y) = \hat{z}E_p(x)e^{-jk_{x0}x}e^{-jk_y y} \quad (26)$$

where $E_p(x)$ is the periodic electric field that propagates only in the xy plane, that is, $k_z = 0$. The electric field must satisfy the wave equation, so applying the operator $(\nabla_{xy}^2 + k^2)$ to $E_z(x, y)$ of Eq. (26) and noting that the dielectric constant is a function of x , we obtain

$$\nabla_{xy}^2 E_z(x, y) + k_0^2 \epsilon_r(x) E_z(x, y) = 0 \quad (27)$$

Assuming the parallel slabs to be infinite in the y and z directions, Eq. (27) can be simplified to

$$\begin{aligned} -\frac{d^2}{dx^2} E_z(x, y) + k_y^2 E_z(x, y) \\ = k_0^2 \epsilon_r(x) E_z(x, y) \end{aligned} \quad (28)$$

The periodic electric field is expanded in a Fourier series in x with unknown coefficients a_n , which serves to represent the dependence on y :

$$E_p(x) = \sum_n a_n e^{-j(2\pi n/d)x} \quad (29)$$

Since the dielectric function is also periodic, it is appropriate to expand it in another Fourier series with coefficient b_m :

$$\epsilon_r(x) = \sum_m b_m e^{-j(2\pi m/d)x} \quad (30)$$

Substituting the Fourier expansions for the field and the dielectric into Eq. (28) and carrying out the algebraic

Figure 2. One-dimensional lattice of dielectric slabs having width b and period d .

operations, we obtain

$$\begin{aligned} & \sum_n \left[\left(\frac{2\pi n}{d} + k_{x0}^2 \right)^2 + k_y^2 \right] a_n e^{-j(2\pi n/d)x} \\ &= k_0^2 \sum_n \sum_m a_n b_m e^{-j(2\pi m/d)x} e^{-j(2\pi n/d)x} \end{aligned} \quad (31)$$

In order to determine the unknown coefficients a_n and b_m , Eq. (31) is multiplied by an orthogonal function and integrated over one unit cell, which produces a Krönecker delta function for a specific index:

$$\begin{aligned} & \sum_n \left[\left(\frac{2\pi n}{d} + k_{x0} \right)^2 + k_y^2 \right] a_n \delta \left(\frac{2\pi p}{d} - \frac{2\pi n}{d} \right) \\ &= k_0^2 \sum_n \sum_m a_n b_m \delta \left(\frac{2\pi p}{d} - \frac{2\pi m}{d} - \frac{2\pi n}{d} \right) \end{aligned} \quad (32)$$

The convolution in Eq. (32) is easily cast into the following general matrix form

$$\left[\left(\frac{2\pi n}{d} + k_{x0} \right)^2 + k_y^2 \right] a_n = k_0^2 \sum_m b_{n-m} a_m \quad (33)$$

where

$$\begin{aligned} b_{n-m} &= \frac{1}{d} \int_{-(b/2)}^{b/2} (\epsilon_r - 1) \exp \left[-j \frac{2\pi(n-m)}{d} x \right] dx \\ &+ \frac{1}{d} \int_{-(d/2)}^{d/2} (1) \exp \left[-j \frac{2\pi(n-m)}{d} x \right] dx \\ &= \frac{b}{d} (\epsilon_r - 1) \text{sinc} \frac{\pi(n-m)b}{d} + \delta_{n-m} \end{aligned} \quad (34)$$

A generalized linear eigensystem problem is represented by $Ax = \lambda Bx$, where A and B are $n \times n$ matrices. The value λ is an eigenvalue and $x \neq 0$ is the corresponding eigenvector. The propagating modes in the TE_x case are solutions of the generalized linear eigensystem in (33).

The solution of Eq. (33) is obtained [22] using the commercial software Matlab. The resulting eigenvalues of the matrix are the squares of the frequencies of the propagating modes in the structure. The solutions of the frequencies of the propagating modes in the structure are obtained for the specific values of phase shift. The band structures for a 1D lattice of dielectric slabs with filling factor (b/d) of 0.5 is shown in Fig. 3 for $k_{x0}a \in [-\pi, \pi]$. The dielectric constant of the dielectric slab is 13.

Figure 3 shows the dispersion diagram of a square patterned PBGSs. It can be seen that a stopband is present from normalized frequencies of 0.15–0.255 GHz.

2.2.3. Transmission-Line Model of PBG Structures. This section presents the analytical approach of the bandgap performance of UCPBG. The mathematical formulation of UCPBGs is described that has been developed using a transmission-line model [23].

Figure 3. Band structure for 1D lattice of dielectric slabs with Filling Factor of 0.5 having dielectric constant of 13.

Basically, a unit UCPBGS consists of a square metallic patch with four connecting branches. The period of each cell is approximately a half-wavelength of the center frequency of the attenuation pole. The slow-wave effect of the periodic structures causes contraction of the transmission-line wavelength; the period is no longer a half-wavelength of the same center frequency. Hence, the slow-wave effect gives rise to a unique compact device structure. Yang and Itoh [10] designed a periodic UCPBGS using a complex finite-difference time-domain (FDTD) method. The method requires numerous numeric codes to be written for analysis of the specific frequency characteristic of a LPF (lowpass filter) response. The slow-wave factor (SWF) of the UCPBG structure is approximately 1.2–2.4 times higher than that for the unperturbed line at passband. Rahman and Stuchly [23] proposed a transmission-line model to calculate the impedance of each section followed by analysis of the whole structure. The following section presents the transmission-line model of a unit UCPBG cell and the dispersion diagrams.

2.2.3.1. UCPBG Theory. The analytic models of two high-impedance surfaces of UCPBGS are shown in Figs. 4a and 4b. The lattice in Fig. 4a consists of a distribution of square metal patches; each patch is short-circuited to the ground plane by a thin pin. The lattice in Fig. 4b consists of square patches; each is indented with four narrow connecting branches. The circuits can be considered as the arrays of reactively loaded resonators coupled by gap capacitors. If the short-circuiting pins or the connecting branches are disregarded, the period of each cell would be a half-wavelength of the resonant frequency. However, the additional short-circuiting pins or connecting branches increase the reactive loading of the cell and consequently cause a lower resonant frequency. This agrees with the slow-wave effect of the PBG structure. Thus, the 2D

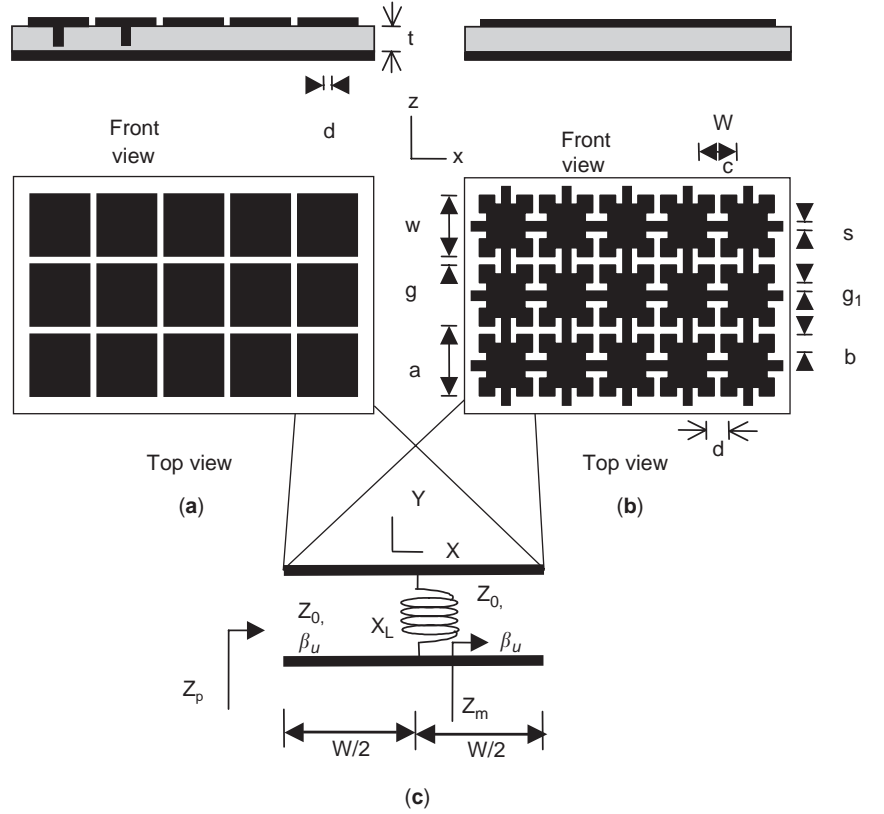

Figure 4. (a) Array of square metal plates with short-circuiting pins; (b) array of square metal plates with connecting branches; (c) equivalent circuit of each resonator section.

UCPBGs arrays shown in Figs. 4a and 4b can be considered as structures periodically loaded with gap capacitances and inductances provided by either the short-circuiting pins or the connecting branches.

The equivalent circuit of the reactive loading part for Figs. 4a and 4b can be represented by Fig. 4c, where Z_p is the reactance of the resonator. The capacitive reactance X_c represents the coupling gap capacitance between the neighboring resonators.

With reference to Fig. 4c, the impedance Z_p of each resonator section is calculated in two steps using the following transmission-line formula (where subscript u is for unloading conditions, l is the length of the transmission line):

$$Z_{in} = Z_0 \frac{Z_1 + jZ_0 \tan(\beta_u l)}{Z_0 + jZ_1 \tan(\beta_u l)} \quad (35)$$

Step 1: Taking $Z_1 = \infty$ at $l = 0$ and calculating Z_m at $l = w/2$ using Eq. (35), we obtain

$$Z_m = -jZ_0 \cot \frac{\beta_u w}{2} \quad (36)$$

Step 2: Taking $Z_1 = X_L/Z_m$ at $l = w/2$, including the reactance X_L represented by a coil, Z_p can be calculated using Eq. (35) as follows:

$$Z_p = Z_0 \frac{Z_1 + jZ_0 \tan(\beta_u w/2)}{Z_0 + jZ_1 \tan(\beta_u w/2)} \quad (37)$$

For each cell in Fig. 4a, using the numerical method given, we can express the inductive loading X_L of the

central short-circuiting pin, with inductance equal to [24]

$$L = 2 \times 10^{-7} t \left[\ln \left(\frac{4t}{d} \right) + 0.5 \left(\frac{d}{t} \right) - 0.75 \right] \quad (38)$$

where t and d are the length and diameter of the pin, respectively.

The coupling capacitance between resonators can be written as [24]

$$C = \frac{w\epsilon_0(1 + \epsilon_r)}{\pi} \cosh^{-1} \left(\frac{a}{g} \right) \quad (39)$$

where a, w, g denote the dimensions as shown in Fig. 4. In Fig. 4 Z_0 is the characteristic impedance of the line and β_u is the phase constant of a lossless line.

Similarly, considering each cell in Fig. 4b, using the numerical method given, the total inductance provided by the four connecting branches, can be calculated as [24]

$$L = 0.25 \times 10^{-7} d \left[\ln \left(\frac{d}{s} \right) + 0.2235 \left(\frac{s}{d} \right) + 1.193 \right] k_g \quad (40)$$

where k_g is a correction factor for the ground plane, which is given as [24]

$$k_g = 0.57 - 0.145 \ln \left(\frac{s}{t} \right) \quad (41)$$

and the coupling capacitance between resonators is [24]

$$C = \frac{2b\epsilon_0(1 + \epsilon_r)}{\pi} \cosh^{-1}\left(\frac{w_c}{g}\right) \quad (42)$$

Both Z_p from Eq. (37) in parallel with reactance of the coupling capacitor X_c of Fig. 4c contributed to the impedance of unit PBG. Hence, the UCPBG array in Figs. 4a and 4b can be treated as a transmission line periodically loaded with lumped impedance Z consisting of Z_p in parallel with X_c with a period of a :

$$Z = \frac{Z_p X_c}{Z_p + X_c} \quad (43)$$

The equivalent circuit for the wave propagation in the x direction shown in Fig. 5 is also an analogous circuit corresponding to the propagation in the y direction. According to Shumpert [22], the $ABCD$ matrix of a cascade of unit UCPBG cell, consisting of a transmission-line section of length $a/2$, series impedance Z as defined in Eq. (43) and another transmission-line section of length $a/2$ is

$$\begin{aligned} \begin{bmatrix} A & B \\ C & D \end{bmatrix} &= \begin{bmatrix} \cos \frac{\beta_u a}{2} & jZ_0 \sin \frac{\beta_u a}{2} \\ jY_0 \sin \frac{\beta_u a}{2} & \cos \frac{\beta_u a}{2} \end{bmatrix} \begin{bmatrix} 1 & Z \\ 0 & 1 \end{bmatrix} \\ &= \begin{bmatrix} \cos \frac{\beta_u a}{2} & jZ_0 \sin \frac{\beta_u a}{2} \\ jY_0 \sin \frac{\beta_u a}{2} & \cos \frac{\beta_u a}{2} \end{bmatrix} \\ &= \begin{bmatrix} \cos \beta_u a + j \frac{Z}{2Z_0} \sin \beta_u a \\ \frac{Z_0}{2} \cos \beta_u a + jZ_0 \sin \beta_u a + \frac{Z}{2} \\ \frac{Z}{2Z_0} \cos \beta_u a + \frac{j}{Z_0} \sin \beta_u a - \frac{Z}{2Z_0^2} \\ \cos \beta_u a + j \frac{Z}{2Z_0} \sin \beta_u a \end{bmatrix} \end{aligned} \quad (44)$$

For the conditions of a reciprocal network, $AD - BC = 1$ and nontrivial solution, the determinant of the matrix must vanish. We derived the following equation of propagation constant γ along with the infinite periodic UCPBGS as

$$\cosh(\gamma a) = \cos(\beta_u a) + j \frac{Z}{2Z_0} \sin(\beta_u a) \quad (45)$$

where Z_0 is the characteristic impedance and β_u is the phase constant of the unloaded line; they are the same as those of the resonators.

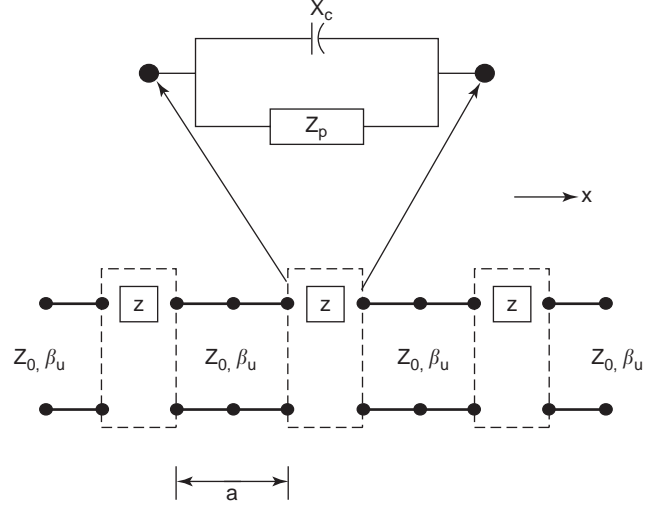

Figure 5. Equivalent circuit of a periodic structure.

With $\gamma = \alpha + j\beta$, Eq. (45) can be rearranged as follows

$$\begin{aligned} &\cosh(\alpha a) \cos(\beta a) + j \sinh(\alpha a) \sin(\beta a) \\ &= \cos(\beta_u a) + j \frac{Z}{2Z_0} \sin(\beta_u a) \end{aligned} \quad (46)$$

where α denotes attenuation of the wave propagation.

Since Z is purely reactive for lossless (ideal-case) resonators, thus rendering the RHS of Eq. (46) a real value, a purely real value is produced for the left-hand side (LHS) of Eq. (46) with the condition of either $\alpha = 0$ or $\beta = 0$, $n\pi/a$. This corresponds to passband and stopband conditions, which are considered below for the wave propagation in PBG structures:

1. The passband condition of the periodic structure $\alpha = 0$ and $\beta \neq 0$, $n\pi/a$, in Eq. (46) is reduced to

$$\cos(\beta a) = \cos(\beta_u a) + j \frac{Z}{2Z_0} \sin(\beta_u a) \quad (47)$$

2. The stopband condition of the periodic structure $\alpha \neq 0$ and $\beta = 0$, $n\pi/a$, in Eq. (46) is reduced to

$$\cosh(\alpha a) = \cos(\beta_u a) + j \frac{Z}{2Z_0} \sin(\beta_u a) \quad (48)$$

We have designed the UCPBGS and simulated the structure using Matlab software. The dimensions of the UCPBGS presented here are $w = 15.0$ mm, $a = 15.13$ mm, $g = 0.13$ mm, $g_1 = 2.615$ mm, $b = 1.885$ mm, $d = 3.8$ mm, $s = 6.0$ mm, and $W_c = 9.1$ mm. The geometry of a modified UCPBG structure is shown in Fig. 6. This type of UCPBG structure can find applications in harmonic suppression of hairpin filters [25–33,37].

The bandgap performance is shown in Fig. 7. As can be seen in the dispersion diagram in Fig. 7, the first stopband is created at 2–2.8 GHz, followed by a passband.

Figure 6. Geometry of a modified UCPBG structure to yield stopband at lower frequency. Dimensions: $w = 15.0$ mm, $a = 15.13$ mm, $g = 0.13$ mm, $g_1 = 2.615$ mm, $b = 1.885$ mm, $d = 3.8$ mm, $s = 6.0$ mm, $W_c = 9.1$ mm.

2.3. Uniform PBG Configurations Applied to Microstrip Lines

In the preceding sections the theory and analysis of periodic structures followed by UCPBG configurations are presented. In modern microwave devices, microstrip transmission lines are commonplace. Therefore, in the following sections, we shall concentrate our investigation only on PBG-assisted microstrip transmission lines. To derive the characteristic performance of PBG-assisted lines, it is more logical to use scattering parameters

Figure 7. Plot of propagation wavenumber, passband, and stopband frequency range of the 2D UCPBG array. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

(S parameters) instead of showing the K - β diagram. S parameters are the universally accepted format for device characterization. Moreover, we shall use the commercially available software tool IE3D (from Zeland Software, Inc.) to design and extract S parameters for all designs due to the flexibility of IE3D. IE3D is a method-of-moment (MoM)-based full-wave analysis tool and hence is very accurate.

The perturbation in the ground plane of any microstrip transmission line in the form of PBGS creates stopband. This stopband is useful for suppression of surface waves, leakage, and spurious transmission and to improve the performance of antennas, filters, and other microwave devices and components. The stopband characteristic is significantly influenced by the shape, size, and period of the PBGS located on the ground plane. Therefore it is useful to investigate the performance of the standard 50- Ω microstrip transmission line on PBGSs. We will investigate the PBG-assisted line to verify the performance of three rows of uniform PBGSs as reported by Radisic et al. [33]. In this section we will investigate uniform circular patterned PBGSs (UPBGSs). It is well known that the EM field is highly concentrated under the microstrip line. We will investigate one-dimensional (1D) uniform PBGS (one row) and compare the results with those for two-dimensional (2D) structures (three rows).

2.3.1. Design of Microstrip Transmission Line over Uniform PBGS (UPBGS). With the inclusion of PBGSs, the dispersion characteristics of a transmission line change. First we design a microstrip transmission line with unperturbed ground plane that does not provide any stopband characteristics. Then we observe the effect on the dispersion characteristics in the form of scattering matrices versus frequency by perturbing the ground plane with UPBGSs.

Bragg’s condition is used [34] in the PBGS design to calculate the central stopband frequency. Under this condition, intercell separation (we call it “period”) is approximately equal to half a wavelength of the stopband center frequency. From the intercell separation, the size of the PBG element is calculated on the basis of the filling factor (FF).

The center frequency of the stopband is calculated approximately with the following expression:

$$\beta a = \pi \tag{49}$$

where a is the period of the PBG pattern and β is the wavenumber in the dielectric slab and is defined by the following expression:

$$\beta = \frac{2\pi f_0}{c} \sqrt{\epsilon_e} \tag{50}$$

where f_0 is the center frequency of the stopband, ϵ_e is the effective relative permittivity of the dielectric slab, and c denotes the speed of light in free space.

On the basis of Eqs. (49) and (50), we designed three-row and one-row circular PBGSs in the ground plane of a 50- Ω microstrip transmission line. The geometries of the

two designs are shown in Fig. 8. The S -parameter performances are shown in Fig. 9. It can be seen that both designs provide identical S -parameter performances. Impressive agreement between the two results justifies the fact that the EM field is highly concentrated under the microstrip transmission line. The two side rows in three-row PBGSs have a minimal effect on the dispersion characteristics of the line. This finding motivates us to use 1D PBGSs under only the lines of BPF for harmonic suppression. PBG-assisted BPF will be discussed in the next section.

2.4. PBGSs in Harmonic Suppression of BPF

Nowadays microstrip BPFs are extensively used in modern microwave integrated circuits. The performance of the overall RF system is affected by the spurious transmission of a conventional BPF. Yang et al. [1] propose the use of UCPBGS to suppress the spurious transmission. The UCPBGS is a complex design on a 2D plane and occupies more space in a circuit. On the other hand, classical circular-patterned PBGSs are simple in design and can be made 1D. 1D PBGSs need less space and create fewer problems in electronic packaging. We have shown in Fig. 9 that 1D UPBGS provides stopband performance very similar to that of 2D UPBGS. Therefore 1D UPBGS is used in a filter to suppress harmonics. The numbers of PBG elements have significant influence on S -parameter performance [35]. In this section we will investigate the effect of the number of PBG elements on harmonic suppression of a BPF.

Nonuniform PBGSs realized by the implementation of binomial and Chebyshev distributions yield better S -parameter performance [15]. We will determine whether the configuration of nonuniform PBGSs can improve harmonic suppression. We will use only binomially distributed PBG elements.

Figure 8. Uniform circular PBG-engineered microstrip transmission lines: (a) three rows; (b) one row.

Figure 9. S parameters versus frequency of PBG-assisted transmission lines as shown in Fig. 7.

The harmonics are the multiplication of the fundamental frequency. 1D and 2D PBGSs generate distinct stopbands at a single frequency; therefore it is not possible to achieve significant multiple harmonic suppression by 1D or 2D PBGSs. DGS can yield wider stopbands [19]. We will use this unique property of DGSs to suppress second and third harmonics of a filter simultaneously.

2.4.1. Design of UPBGSs for Harmonic Suppression. We investigate five UPBGSs assisted BPFs with different lattices and numbers of UPBGSs: (1) BPF on a 2D array

of UPBGSs with square lattice (Fig. 10b), (2) BPF on dense 2D UPBGSs of rectangular lattice (Fig. 10c), (3) BPF on 1D UPBGSs located exactly under the two extreme 50-Ω lines and the central coupled line (Fig. 10d), (4) BPF on UPBGSs that are located under two extreme 50-Ω lines only (Fig. 10e), and finally (5) BPF on UPBGSs that are located under all the lines of a BPF (Fig. 10f). As periodic structures, both PBGSs and BPFs have their own poles and zeros. Theoretical formulation of the combined structure is not a trivial task. Only full-wave analyses of some structures are reported in the open literature. So far no thorough investigations into the effect of the position, number, and lattice structures of UPBGS on BPFs have been reported. The design investigation of UPBGS-assisted BPF reveals that PBGS drastically degrades the

passband performance. The design objective of simultaneous excellent passband and harmonics suppression is not fulfilled. Although many PBGS-assisted BPFs have been reported in the open literature, this problem has been overlooked. The motivation of thorough full-wave analysis has been derived to address this issue. In this section we investigate these effects on BPF with the aid of IE3D. These thorough investigations are very useful in understanding the behavior of BPFs in the presence of PBGSs.

2.4.1.1. Standard BPF. We first designed a four-section asymmetric coupled-line BPF (shown in Fig. 10a) on RT/Duroid with $\epsilon_r = 10.2$ and $h = 0.635$ mm. The dimensions of the coupled lines were $W_1 = 0.425$ mm, $W_2 = 0.525$ mm,

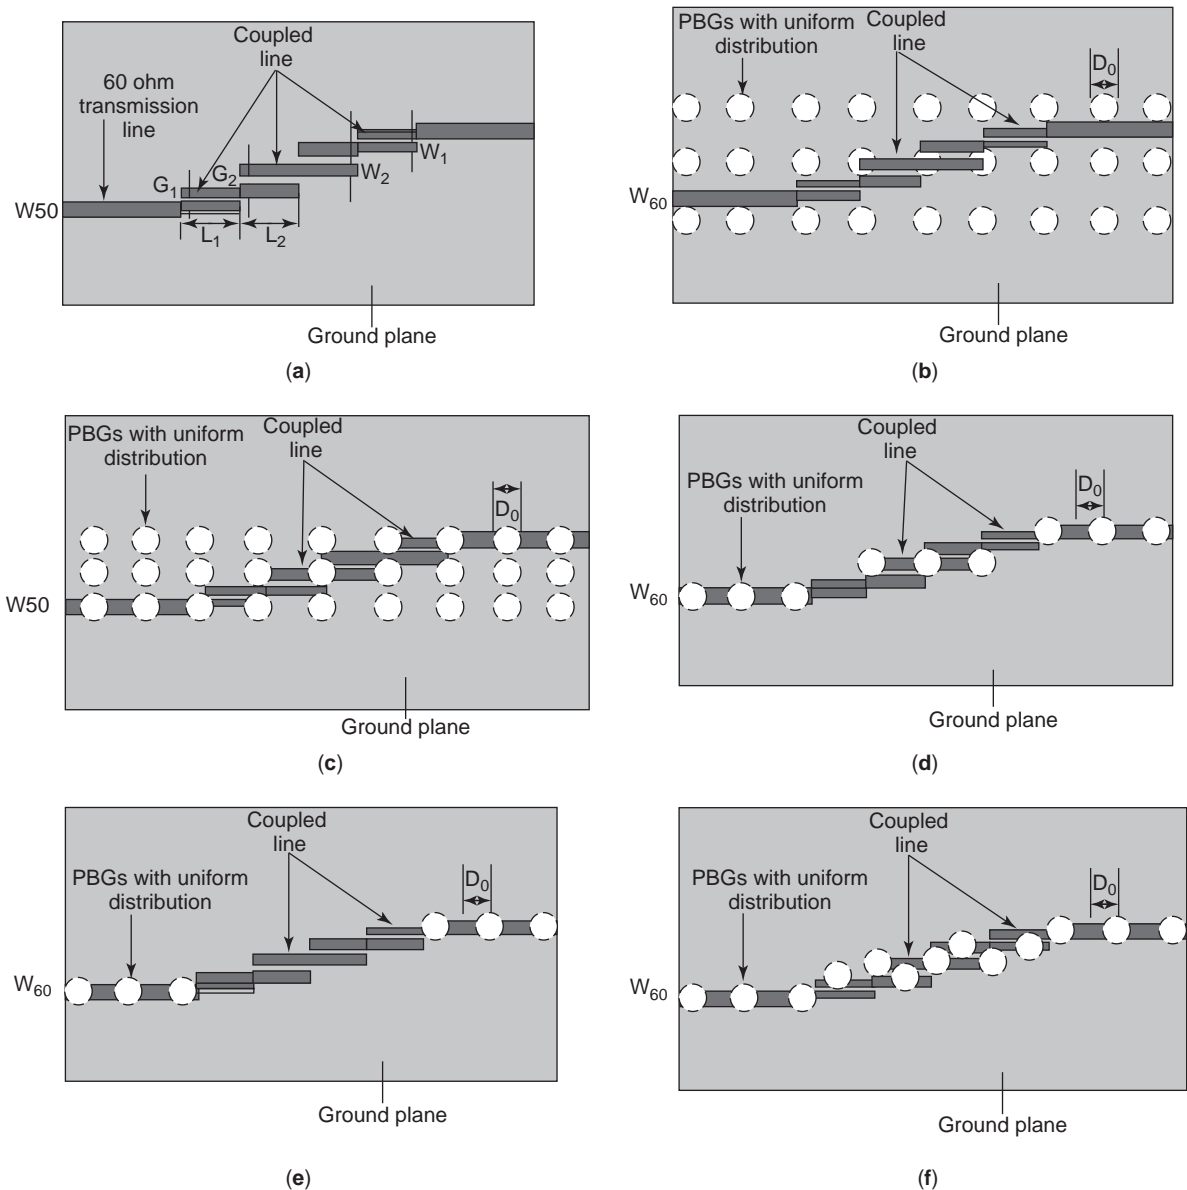

Figure 10. Various designs of BPFs assisted by uniform circular PBGSs: (a) standard four-section asymmetric coupled-line BPF; (b) BPF on 2D square lattice PBGSs; (c) BPF with dense 2D PBGSs (rectangular lattice); (d) BPF with PBGSs under 50-Ω and central coupled lines; (e) BPF with PBGSs under two extreme 50-Ω lines only; (f) BPF with PBGSs under all lines only.

$G_1 = 0.2$ mm, $G_2 = 0.7$ mm, $L_1 = L_2 = 3.625$ mm, and $W_{50} = 0.6$ mm. The passband design frequency was 7.5 GHz.

2.4.1.2. BPF on 2D Array of UPBGs. In this design the UPBGs are etched in the ground plane of the BPF and their periodicities in the X and Y directions form a square-patterned lattice structure. The geometry, shown in Fig. 10b, consists of three rows of nine PBG elements. The UPBGs generate the first stopband at 15 GHz to suppress the second harmonics of the filter.

2.4.1.3. BPF with Dense 2D UPBGs. Next a 2D array of UPBGs is situated beneath all the lines of BPF having rectangular lattice structures. The Bragg's condition is applied in the x direction to create a stopband at 15 GHz. The geometry is shown in Fig. 10c.

2.4.1.4. BPF with PBGs under 50- Ω and Central Coupled Lines. In this design PBG elements are etched under 50- Ω and central coupled lines only. This design consists of nine PBG elements total. The geometry of this design is shown in Fig. 10d. The objective of the design is to eliminate redundant PBG cells.

2.4.1.5. BPF with PBGs under 50- Ω Lines Only. In this design, PBG elements are located under 50- Ω lines only. There are six PBG elements in this design as shown in Fig. 10e.

2.4.1.6. BPF with UPBGs under All Lines. UPBGs are under all the microstrip lines of BPF, based on the assumption that the field is confined below the lines. Beyond the lines there are no PBG elements. The geometry is shown in Fig. 10f.

2.4.2. Results. All the designs are simulated with the EM Zeland IE3D software. The ground plane has been assumed to be infinite. We used the RT/Duroid substrate having a dielectric constant of 10.2 and a height of 0.635 mm. We produced theoretical results for different geometries of UPBGs-assisted BPF. To see the effect of UPBGs in harmonic suppression, we show the performance of the reference BPF. Finally, the results of the measured insertion loss (IL) performances of a standard BPF and a UPBGs-assisted BPF are compared in Sections 2.4.2.1–2.4.2.7.

2.4.2.1. Performance of Reference BPF. An IE3D-simulated S -parameter/frequency plot of a standard asymmetric coupled-line BPF is shown in Fig. 11. The presence of spurious transmission around 15 GHz is obvious in the reference BPF. At this frequency the maximum value of return loss (RL) is found to be 9 dB and IL is found to be 2.5 dB. At 7.5 GHz, which is the passband, the maximum value of return loss (RL) is -22.5 dB and IL is 0.5 dB. At third harmonic, the IL is 0 dB.

2.4.2.2. Performance of BPF on 2D Array of UPBGs. For harmonics suppression we applied a 2D array of UPBG in the ground plane of a reference BPF. The harmonic is suppressed by application of 2D array of UPBGs as

Figure 11. IE3D-simulated S -parameter performance of a standard coupled-line BPF as shown in Fig. 10a. Substrate is RT/Duroid having dielectric constant 10.2 and height 0.635 mm.

shown in Fig. 12. The RL performance at second harmonic should ideally be zero for proper harmonic suppression. But the maximum value of RL is here 2 dB and the value of the transmission coefficient is 9 dB. The IL at third harmonic is 0 dB. We understand that the UPBGs are not exact under the lines, so they are not sufficiently effective to suppress the transmission at second-harmonic frequency.

Figure 12. Theoretical S -parameter performances of a BPF with square lattice 2D UPBGs (Fig. 10b). Substrate is RT/Duroid having dielectric constant 10.2 and height 0.635 mm.

2.4.2.3. Performance of BPF on Dense 2D Array of UP-BGSs. Figure 13 shows the simulation result of a BPF with 2D PBGSs that are denser than the conventional 2D square lattice structure. In this case they conform to a rectangular lattice. We see that at 7.5 GHz the maximum RL is 25 dB and the maximum RL at 15 GHz is about 0 dB. The IL at 15 GHz is about 40 dB. Significant second-harmonic suppression is achieved here. The third-harmonic value of IL is 0 dB.

2.4.2.4. Performance of BPF with Three-Line UP-BGSs. We simulated the BPF where the PBGSs are under two 50-Ω lines and the central coupled lines. The performance is shown in Fig. 14. In this design (Fig. 10d), two sides of the UPBGSs are situated under two 50-Ω lines and three UPBGSs are under the central coupled line. From the simulation results it can be seen that at 15 GHz the maximum value of RL is about 1 dB; only and the transmission coefficient is found to be approximately 14 dB. The third-harmonic value of IL is 2 dB. Harmonic suppression is not satisfactory. In addition to this, the passband performance at fundamental frequency is distorted significantly.

2.4.2.5. Performance of BPF with UPBGSs under Two Extreme 50-Ω Lines. Considering the possibility that EM propagation takes place through the 50-Ω line, we first used UPBGSs under two 50-Ω lines only to see their effects on harmonic suppression. The simulation result, shown in Fig. 15, does not seem promising at all; rather, at fundamental, second, and third harmonic frequencies, the performances are poor.

2.4.2.6. Performance of BPF with UPBGSs under All Lines. Finally we used PBG under all the lines. The design

Figure 13. Simulated S-parameter performance of BPF with dense rectangular lattice 2D UPBGSs (Fig. 10c). Substrate is RT/Duroid having dielectric constant of 10.2 and height 0.635 mm.

Figure 14. Simulated S-parameter performance of a BPF with UPBGSs on 50-Ω lines and central coupled line (Fig. 10d). Substrate is RT/Duroid having dielectric constant 10.2 and height 0.635 mm.

provides S-parameter performances as shown in Fig. 16. It can be seen that at 7.5 GHz the maximum RL is more than 30 dB. At 15 GHz the maximum RL is approximately 0 dB and IL is approximately 30 dB. In this case significant improvements in fundamental and second harmonic frequencies are achieved. Only a small ripple in the transmission band is noticed, and this can be controlled by resizing the UPBGS elements.

Figure 15. Simulated S-parameter performances of a BPF with PBGSs on two 50-Ω lines only (Fig. 10e). Substrate is RT/Duroid having dielectric constant of 10.2 and height of 0.635 mm.

Figure 16. Theoretical S -parameter performances of a BPF when UPBGSs are situated under all the lines (Fig. 10f). Substrate is RT/Duroid having dielectric constant 10.2 and height 0.635 mm.

2.4.2.7. Comparison of S_{21} Performances. Finally we fabricated the optimized reference BPF and UPBGS-assisted BPF. The measured IL performances up to 20 GHz are shown in Fig. 17. Compared to the simulation results in Fig. 11, the measured results in Fig. 17 have shifted in both fundamental frequencies; this frequency shift may be due to the fabrication errors. For the reference BPF the average 3-dB IL bandwidth (IL BW) is 7.18%. Average IL at second harmonic is found to be 10 dB for the reference

Figure 17. Measured IL performances of an optimized BPF. Substrate is Taconic, having dielectric constant of 10 and height 0.635 mm.

Table 1. Performance of UPBGS-Assisted BPF

Designs	IL at 2nd Harmonic (dB)	IL at 3rd Harmonic (dB)
Reference BPF	2.5	0
BPF on 2D array of UPBGSs	9	0
BPF on dense 2D array of UPBGSs	40	0
BPF on 3-line UPBGS (PBGSs on two 50- Ω lines + central coupled line)	14	2
BPF on two-line UPBGS (UPBGSs on two 50- Ω lines)	5	2
BPF on 1D UPBGS (UPBGSs on all lines)	30	15

BPF. UPBGS-assisted BPF provides an average IL of 30 dB. The 3 dB IL BW is found to be 16.02%. It can be concluded that UPBGS-assisted BPF improves performance in terms of IL BW and second-harmonic suppression.

The performance levels of UPBGS-assisted BPF are shown in Table 1.

2.4.3. Designs of B-PBGs for Harmonic Suppression. We have designed BPFs with *binomially* distributed PBGSs (B-PBGSs). We investigate harmonic suppression due variation in the number of PBG elements in B-PBG-assisted BPF (B-BPF). Various designs of B-BPFs are shown in Fig. 18.

In Fig. 16, the B-PBGSs have a FF of 0.4 (0.4 is the optimum FF for binomially distributed PBGSs [36]). Using conducting copper Foil to vary the number of PBG elements, we compare the IL performances for B-BPF in several different designs:

Design 1. The ground plane of the reference BPF is perturbed by PBGSs with binomial distribution. In this design three lines (consisting of two extreme 50- Ω lines and one central coupled line) are perturbed by B-PBGSs having an FF of 0.4. The rests are loaded with uniform PBGSs having FF 0.25. The total number of PBG elements in B-BPFs is 13. The geometry is shown in Fig. 18a.

Design 2. In this design we use only two PBG elements from the two extremes and PBG elements of B-BPF are closed as shown in Fig. 18b.

Design 3. In this case the two 50- Ω lines of BPF are loaded by four PBG elements. The remaining PBG elements are closed. The geometry is shown in Fig. 18c.

Design 4. In this design the BPF is loaded by six PBG elements from the two extremes. The PBG elements are under 50- Ω lines only as shown in Fig. 18d.

Design 5. In this design 10 PBG elements of B-BPF are used. The design is shown in Fig. 18e. No PBG elements are situated under the central coupled line.

Design 6. This design consists of 12 PBG elements in the ground plane of a BPF. Here the central PBG

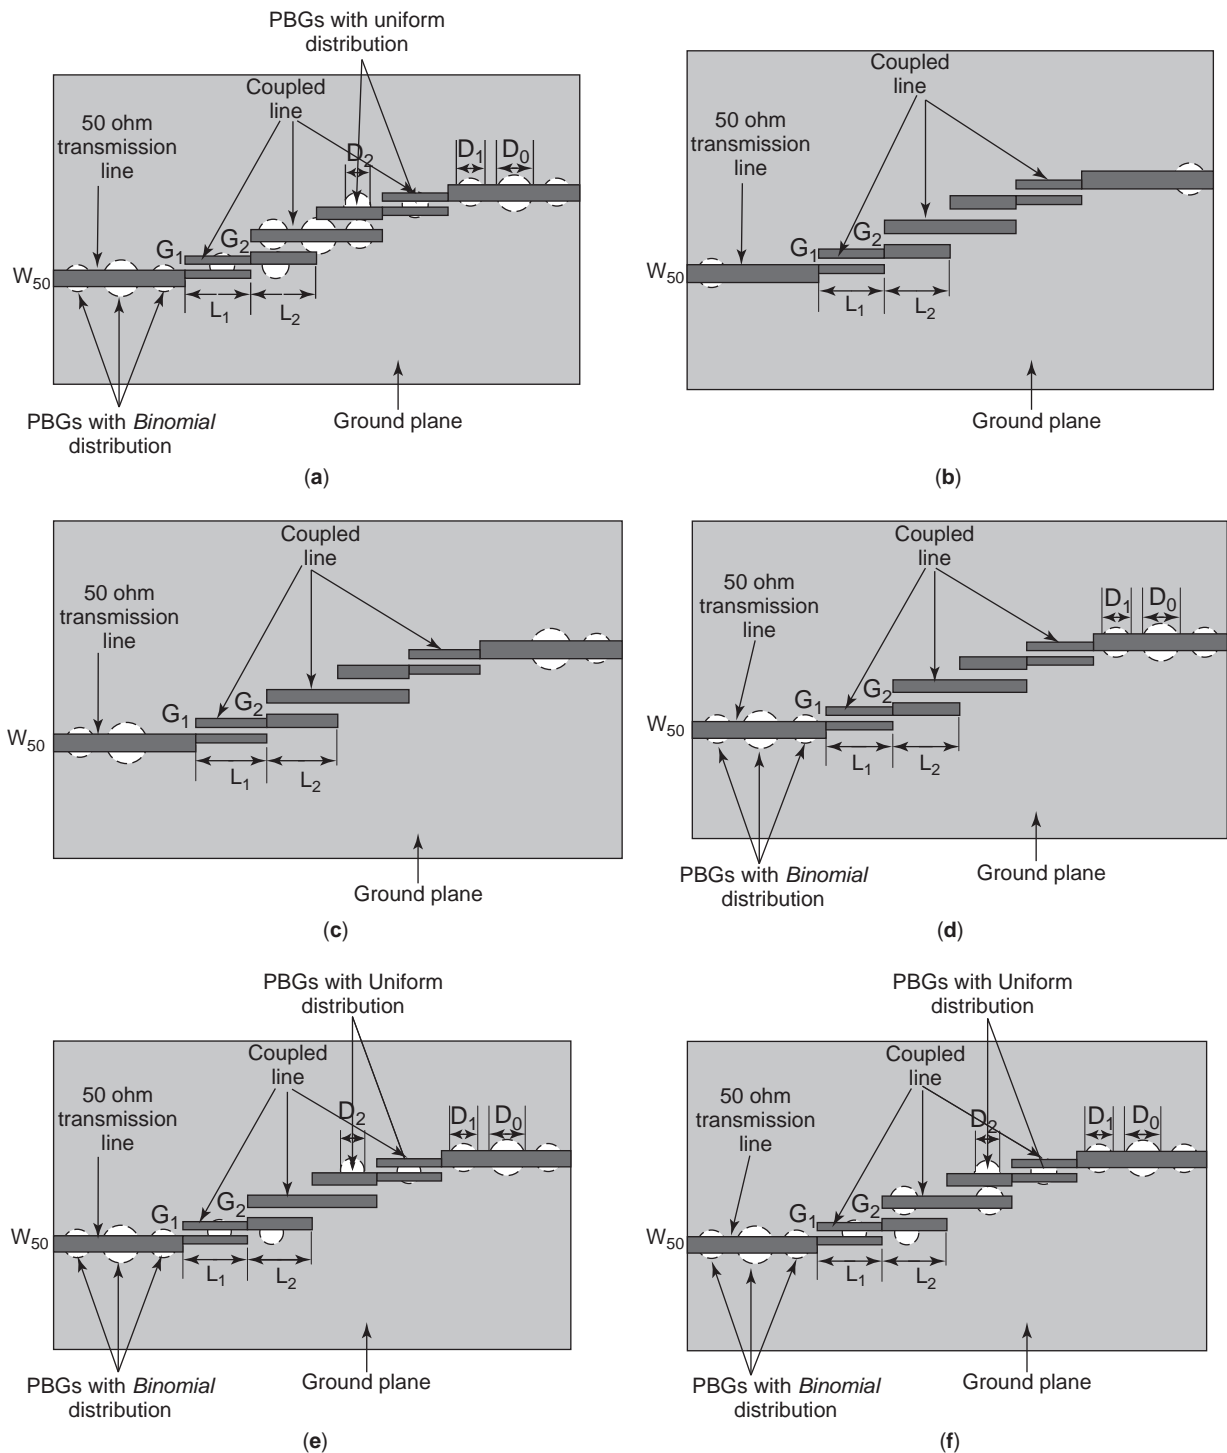

Figure 18. Various designs of B-BPFs with B-PBGSs: (a) elements under all lines; (b) two elements under 50-Ω lines only; (c) four elements under 50-Ω lines; (d) six elements under 50-Ω lines; (e) elements under all lines except central coupled lines; (f) elements under all lines except the central larger PBG elements in the central coupled line.

element of the central coupled line is omitted. The design is shown in Fig. 18f.

We present the RL performances for other designs below. We show only IL performances to indicate harmonic suppression.

2.4.3.1. Reference Optimized BPF. The experimental S -parameter performance of a standard BPF is shown in Fig. 19. We are investigating the harmonics (second and third harmonics) by varying the number of PBG elements. For standard BPF the measured second and third harmonics are found to be 13 and 8 dB, respectively.

Figure 19. Measured S -parameter performance of a standard BPF. Substrate is Taconic having dielectric constant 10 and height 0.635 mm.

2.4.4. Performance of B-BPF. We fabricated all the designs and measured performance by vector network analyzer (VNA). The measured IL and RL performances of a BPF loaded by binomially distributed PBGS are as follows:

Design 1. The IL performance of the B-BPF (Fig. 18a) is shown in Fig. 20. In this design a total of 13 PBG

Figure 20. Measured IL performance of a B-BPF shown in Fig. 18a where PBG elements are periodically loading under all the lines. Substrate is Taconic having dielectric constant 10 and height 0.635 mm.

elements are used to suppress the harmonics. B-BPF provides second and third harmonics as 32 and 20 dB; the harmonics are suppressed by 19 and 12 dB, respectively. However, the IL performance in the transmission band is seen to be poor. Under these circumstances we will investigate the influence of different numbers of PBG elements on the performance of BPF.

Design 2. We investigate the BPF as shown in Fig. 18b with two PBG elements. During the measurement the IL performances show second and third harmonics to be 30 and 17.5 dB, respectively (the graph is not shown here).

Design 3. Four PBG elements etched in the ground plane of a BPF as shown in Fig. 18d yields the IL performance, providing second and third harmonics as 37 and 16 dB, respectively (the graph is not shown here).

Design 4. During measurement of the IL performance of a BPF (Fig. 18d) loaded by six PBG elements, second and third harmonics are found to be 34 and 14 dB, respectively. It is worthwhile to mention that this configuration hold completely *binomially* distributed PBGS under two 50- Ω lines of a BPF (the graph is not shown here).

Design 5. The design in Fig. 18e provides 40 and 22 dB IL as second and third harmonics. The transmission band at the fundamental frequency is also seen to be improved. The IL performance for 10 PBG elements is shown in Fig. 21.

Design 6. As can be seen from Fig. 22, design 5 (Fig. 18f) yields ILs of 38 and 21 dB at second and third harmonics. The transmission band at the fundamental frequency is similar to that for design 5.

Figure 21. Measured IL performance of BPF when 10 PBG elements are under all lines except the central coupled line.

Figure 22. Measured IL performance of a BPF loaded by 12 PBG elements. Only one larger element under the central coupled line is closed.

The IL performances for all the designs are compared in Table 2, where it can be seen that the 10-PBG element provides the best performance. 12-PBG elements also provide almost similar performance. It is also clear from the investigation that suppressions of second and third harmonics do not follow the number of PBG elements; rather, their position and size are the important issues in harmonic suppression of coupled-line BPF. The important finding is the role of larger PBG elements of the central coupled line. Comparing results from Figs. 21 and 22, it can be concluded that the middle larger element under the central coupled line degrades the performance.

2.4.4.1. Binomially/Uniformly Assisted BPF Comparison.

In order to investigate the improved performance of B-BPF over the UPBG-assisted BPF, the combined performances are shown in Fig. 23. It can be seen in Fig. 23 that the average 10 dB RL BW at fundamental frequency for both B-BPF and U-BPF is 16.2%. The 3 dB IL BW is found to be 19.56%. The average isolation at second

Table 2. Performance of a Coupled-Line BPF with Binomially Distributed PBGS along with Different Numbers of PBG Elements

Number of PBG Elements	Insertion loss (IL) (dB)	
	2nd Harmonics	3rd Harmonics
0 (reference BPF)	13	8
2	30	17.5
4	37	16
6	34	14
10	42.5	22
12	38	21
13	20	17.5

Figure 23. Measured S-parameter performance of an optimized BPF along with the IL performances of B-BPF and UPBGs-assisted BPF.

harmonic is -39 dB for B-BPF, compared to the U-BPF of -29 dB. The performances of an optimized BPF, UPBGs-assisted BPF, and B-BPF are compared in Table 3.

2.5. DGS for Harmonic Suppression

2.5.1. Design. In this subsection we report the novel idea for simultaneous suppression of second- and third-order harmonics generated in a conventional BPF. We have already reported that the dumbbell-shaped DGS can yield a wider stopband [20]. Now we implement this unique property in an asymmetric four-section coupled-line BPF to suppress the second- and third-order harmonics. We propose using 1D EBGSs (dumbbell-shaped DGSs) that are located just under standard $50\text{-}\Omega$ lines. No DGS will be used under the coupled lines. We also present a novel idea that the dumbbell-shaped DGSs, which are designed at two different frequencies, are to be located under two end $50\text{-}\Omega$ lines only. This design is sufficient to suppress the second- and third-order harmonics. We investigate a few different designs. Figure 24 shows one of the various designs investigated. It is noted

Table 3. Performance of an Optimized BPF with UPBGs and B-PBGS

Type	Average	Average	Average
	3 dB IL BW (%)	10 dB RL BW (%)	2nd Harmonics (dB)
Standard BPF	7.18	5.96	6
UPBGs-assisted BPF	16.02	15.2	29
B-BPF (with omission of central PBG elements)	19.56	16.2	39

Figure 24. Geometry of a DGS-assisted BPF; four DGSs are located under two 50- Ω lines.

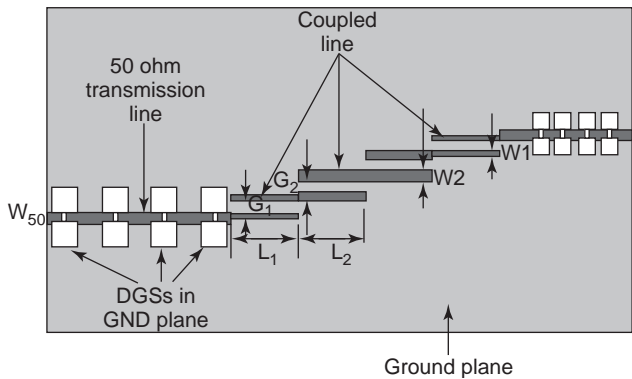

Figure 25. Geometry of a DGS-assisted BPF having four larger DGSs under LHS 50- Ω line and four smaller DGSs under RHS 50- Ω line.

Figure 26. S -parameter performances of an optimized reference BPF.

that the designs differ from each other with respect to the number of DGSs only. The designs are as follows:

Design 1. Here we use a total of four DGSs under two 50- Ω lines. Two DGSs will be located under each 50- Ω line. The larger square slot of the DGS unit measures $52 \times 52 \text{ mm}^2$, and the vertical narrow slot is $20 \times 15 \text{ mm}^2$. The geometry of a BPF with four DGSs in the ground plane is shown in Fig. 24.

Design 2. In this case we use four DGSs under only the left-side 50- Ω line. There are no DGS elements under the right-side 50- Ω line. The geometry is identical to Fig. 24, with the exception that DGS elements are located only on the left side rather than on both left and right.

Design 3. Four DGSs are located under the left 50- Ω line designed for second-harmonic suppression. Another set of four DGSs is located under the right 50- Ω line, which is suitable for third-harmonic suppression. The RHS (right-hand-side) DGSs are smaller in size than the LHS DGSs. This is obvious, as they are designed at higher frequency to suppress third harmonics. The geometry is shown in Fig. 25.

Design 4. Four DGSs are located under the LHS 50- Ω line and eight DGSs are placed under the RHS 50- Ω line. The eight DGS elements are designed for significant third-harmonic suppression. The geometry is identical to that in Fig. 25.

2.5.2. Results. Theoretical investigations have been carried out on DGS-assisted BPFs for effective suppression of second (at 15 GHz) and third (at 22.5 GHz) harmonics. The S -parameter performances for the various designs are given below (theoretical performances of the standard optimized BPF used in all designs are shown in

Figure 27. S -parameter performances of a DGS-assisted BPF having a total of four DGSs (2 + 2) lying under two 50- Ω lines.

Figure 28. S-parameter performances of a BPF assisted by four DGSs lying under the LHS 50-Ω transmission line.

Fig. 26; the second and third harmonics are 6 and 0 dB, respectively):

Design 1. The S-parameter performances for four DGS (2+2) located under two 50-Ω lines are shown in Fig. 27. From the IL performance it can be seen that the ILs at second and third harmonics are 28 and

Figure 29. S-parameter performances of DGS-assisted BPF where two sets of four (i.e., total eight) DGSs have been placed under two 50-Ω lines.

Figure 30. S-parameter performances of DGS-assisted BPF where four DGSs are used under the LHS 50-Ω line and eight DGSs are designed for third-harmonic suppression and placed under the RHS 50-Ω line.

6 dB, respectively. Input matching is seen to be improved.

Design 2. The S-parameter performances of a BPF assisted by four DGSs under the LHS 50-Ω line are shown in Fig. 28. It can be seen that this design provides the ILs at second and third harmonics of 38 and 20 dB, respectively.

Design 3. In this design we have placed four DGSs under the LHS 50-Ω line for use in second-harmonic suppression, and four other DGSs are placed under the RHS 50-Ω line, designed for use in third-harmonic suppression. This is a new technique, in which we have designed DGSs at two frequencies for effective harmonic suppression. The S-parameter performances of this design are shown in Fig. 29. It can be seen that this design provides second and third harmonics as 40 and 20 dB, respectively.

Design 4. In this case we attempted to suppress the third harmonic significantly. For this purpose eight DGSs are used under the RHS 50-Ω lines to generate deeper and wider stopbands to suppress the third harmonics. The S-parameter performances of this design are shown in Fig. 30. It can be seen that the suppression at third harmonic has improved significantly to 30 dB.

3. CONCLUSIONS

We have reviewed the theory of periodic structures to understand the passband and stopband phenomena of PBGSs. The dispersion diagram of a modified UCPBG

structure is presented, based on the transmission-line model [23] of PBGSs. We have compared the S -parameter performances of three rows with those of one row of PBG-assisted transmission lines. It can be seen that they provide almost identical performances. Therefore we have placed 1D PBG elements just under the lines of BPF for the suppression of higher-order harmonics.

We have theoretically investigated BPF for UPBGSs with different conditions. From all the results it can be seen that the performance improves if the PBG elements are located just under the lines. We have also fabricated optimized reference BPF and a BPF with UPBGS. It can be seen that, due to inclusion of PBG elements in a conventional BPF, the IL performance improves significantly in terms of passband performance and harmonic suppression.

We designed binomially distributed PBGSs for the suppression of spurious transmission in a BPF. A compact microstrip BPF with intrinsic spurious suppression was reported [1] in which 2D UC-PBGSs are used. 2D UC-PBGSs are more complex and take more space to describe; thus we have proposed BPBGSs that yield ripple-free transmission with wider stopband in microstrip lines. We investigated IL performances of a BPF with a variable number of PBG elements. It can be seen that BPBGSs suppress second harmonics significantly; they also suppress third harmonics. It is very interesting to note that in a microstrip transmission line the stopband scales with the number of PBG elements. But our present study reveals that it does not hold true for harmonic suppression of a BPF. This can be explained as the coupling phenomenon of the poles of BPF and PBG elements. The PBG elements situated under the central coupled line may provide significant coupling of PBGS and BPFs and may drastically degrade the passband performances.

Random usage of PBGS under BPF does not always lead to descent passband and harmonic suppression. In most cases, passband performance is drastically distorted; therefore careful design and investigation is required. In our investigation we observed that the strong coupling between the central coupled line of BPF and the central PBG element under the coupled line destroys the bandpass performance of BPF. After careful design of elimination of central PBG elements, the designs with both 10 and 12 PBG elements provide better IL performance.

Finally, we have investigated DGS-assisted BPF. Of the few designs that we have investigated, all suppress both second and third harmonics significantly. A new technique of using two sets of DGSs designed at two different frequencies works well in second- and third-harmonic suppression.

ELECTROMAGNETIC COMPATIBILITY

CLAYTON R. PAUL
Mercer University
Macon, Georgia

1. INTRODUCTION

Electromagnetic compatibility (EMC) concerns the reduction of interference in electronic systems. For a more complete discussion of EMC, see Ref. 1. All figures in this article are taken from that reference. Interference has occurred when an electromagnetic emission causes the unintended operation of a device. A typical interference scenario consists of a *source* (or emitter), a *transfer* (or coupling) *path*, and a *receptor* (or receiver) as shown in Fig. 1. Hence there are three ways to reduce the interference in the receptor: (1) reduce the level of the source, (2) increase the attenuation of the transfer path, and (3) reduce the susceptibility of the receptor. Generally the optimal procedure is to work from left to right, that is, first reduce the level of the source, then increase the attenuation of the transfer path, and finally, if needed, reduce the susceptibility of the receptor. The source and the receptor may be intended or unintended. Examples of intended sources are the emissions from an FM radio transmitter or an airport surveillance radar. Arcing at the brushes of a DC motor and the radiated emissions from a digital computer are examples of unintended emissions. Generally, the transfer path is either through air or via metallic conduction as in wires. An unintended receptor for the energy might be a television set that has received the emissions from a digital computer. In the case of unintended sources such as the clock in a digital computer, the levels of emission can be reduced, as we will see, by increasing the rise/falltimes of the clock pulses. This serves to reduce the levels of the high-frequency components without affecting the functionality of the computer. The levels of intended sources such as an FM radio transmission can rarely be reduced. Shielding and filtering are common ways of increasing the attenuation of the transfer path. Separating the source and receptor, when possible, also accomplishes this. In some cases the susceptibility of the receptor can be reduced by use of error correcting codes.

Generally interference occurs through radiated emissions or conducted emissions. Susceptibility also occurs through these two mechanisms. Hence there are four basic EMC subproblems shown in Fig. 2. These are radiated emissions, radiated susceptibility, conducted emissions, and conducted susceptibility. It should be pointed out that *time-varying currents radiate*. Hence currents, whether on cables or on metallic cabinets cause radiated

Figure 1. The basic decomposition of the EMC coupling problem.

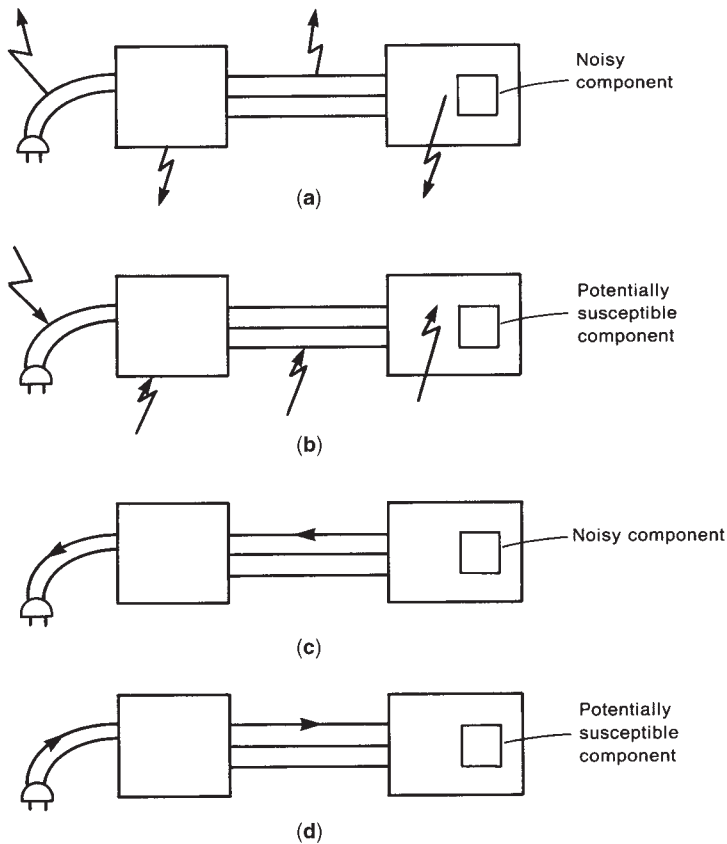

Figure 2. The four basic EMC subproblems: (a) radiated emissions; (b) radiated susceptibility; (c) conducted emissions; and (d) conducted susceptibility.

emissions. Typically long cables in the systems that carry high-frequency noise currents are the primary mechanisms for radiated emissions. These radiated emissions may cause interference with adjacent electronic systems. External sources such as the emissions from an FM radio transmitter or an airport surveillance radar may impinge on an electronic product. These emissions induce unintended currents on the metallic cabinets or cables of the systems that may create interference with the system. This is referred to as a *radiated susceptibility problem*. The power cord of an electronic device carries, in addition to the necessary 60-Hz power signal, other higher-frequency signals. For example, the harmonics of a digital clock in a product frequently show up on the power cord. These “noise” signals are then conducted onto the power net of the installation. The power net of an installation is in essence a large antenna in that the phase wires, and the neutral wires are “hardwired” together. When high-frequency noise is conducted out of the product via the power cord and placed on this large power net, they then radiate which can cause interference. A frequent example of this is the interference with a TV set caused by the arcing at the commutator of a motor as in a vacuum cleaner. These noise signals, in addition to radiating, also proceed out the power cord of the vacuum cleaner and hence onto the power net. These are examples of conducted emissions. And finally high-frequency signals are conducted along wires and the metallic cabinets of a device. Hence they may appear in unintended places within the device causing interference. A common such case is where noise on

the AC power net is conducted into the product via the device power cord. Switching on a motor such as in an air conditioner somewhere in the building will induce noise on the power net, which can be conducted into a product via the power cord. Lightning during thunderstorms induces signals on the power transmission lines. These also may be conducted into the product, causing interference. These scenarios constitute conducted susceptibility problems.

In addition to these primary concerns in EMC, there are also other aspects of EMC shown in Fig. 3. Electrostatic discharge or ESD is becoming a frequent mechanism for causing interference in digital systems. When a human wearing rubber-soled shoes walks across a nylon carpet, charge is deposited on the person’s body. When the person approaches a digital device such as a computer keyboard, this accumulation of charge on the finger creates an intense electric field that may be of sufficient magnitude to break down the air, resulting in an intense discharge much like a miniature lightning discharge. This discharge can cause improper operation of the device such as loss of data or permanent destruction of some of the electronic components in the device. The detonation of a nuclear device creates an intense radiated electric field that can damage or destroy electronic systems. This is referred to as an *electromagnetic pulse (EMP)*. Even though a communication center does not receive direct blast damage, this intense electromagnetic field can damage the communication electronics and prevent a retaliatory action. Lightning occurs frequently and can result in large

Figure 3. Other aspects of EMC: (a) electrostatic discharge (ESD); (b) electro-magnetic pulse (EMP); (c) lightning; (d) TEM-PEST (secure communication and data processing).

current channels. Although a direct strike can cause severe damage, indirect strikes can also induce damaging currents in electronic devices. And finally, it has been shown that it is possible to indirectly determine information being transmitted by monitoring the electromagnetic emissions. Communication security is obviously of extreme importance in the military context, but it is also important in the business world in order to protect trade secrets.

2. REGULATORY REQUIREMENTS FOR ELECTRONIC SYSTEMS

In the United States, the Federal Communications Commission (FCC) has regulatory authority over wire and radio communications, and has the responsibility for limiting interference with communications. Around 1979, the personal computer was being introduced to consumers in the United States. Residents of apartments began complaining to the FCC about interference being caused in their television receivers by a personal computer in an adjacent apartment. In order to limit the

interference potential of these personal computers, the FCC instituted regulations in Title 47 of the *Code of Federal Regulations*, Part 15, Subpart J which limited the radiated and conducted (exiting the power cord) emissions of all “digital devices” that are intended to be sold in the United States. (Look on the back of your calculator, personal computer, or laser printer to see the FCC compliance notice.) The FCC defines a “digital device” rather broadly as “Any unintentional radiator (device or system) that generates and uses timing pulses at a rate in excess of 9000 pulses (cycles) per second and uses digital techniques.” This definition is rather broad and covers, in addition to personal computers, virtually anything “digital” such as electronic typewriters and laser printers. These regulations prescribe limits on the maximum radiated and conducted emissions of a “digital device.” The conducted emissions are defined as those exiting the power cord of the digital device, and the frequency of the regulation ranges from 150 kHz to 30 MHz. The radiated emission limits extend from 30 MHz to well over 1 GHz, with this upper limit depending on the fifth harmonic of the system clock. See Ref. 1 for a discussion of these specific limits. For example, for a digital device intended for residential use (as opposed to business use), the limit on noise current exiting the power cord is on the order of $5\ \mu\text{A}$, whereas the limit on the electric field of radiated emissions is on the order of $100\text{--}500\ \mu\text{V/m}$ when measured at a distance of 3 m.

It is very important to emphasize that if the conducted or radiated emissions of a “digital device” exceed the FCC limits at any frequency within the regulation frequency range, *it cannot be legally sold in the United States!* The FCC has the statutory authority for imposing fines and/or jail sentences if anyone intentionally violates the regulation. Hence, even though a company develops, for example, a revolutionary device (e.g., a laser printer that has the dimensions of a laptop computer, prints 50 pages per minute in color, and can be sold for under \$50 U.S.), this is all for naught if the device fails to meet the FCC limits. Even if the device fails the FCC limits, additional suppression measures can be taken to bring those emissions into compliance. However, adding the suppression measures such as filters and shielding will add to the cost of the product yet not enhance its functionality and hence will affect its marketability. Therefore, one of the most important design goals of electronic products today is to design the system to comply with the FCC limits.

Virtually all other countries in the world have similar and sometimes more stringent limits on the emissions of digital products. Hence EMC is a global concern. For example, prior to the institution of the FCC limits in the United States, most countries in Europe had individual limits on radiated and conducted emissions of digital devices that were similar to those instituted later in the United States. Most of these limits were those developed by CISPR (the French translation meaning International Special Committee on Radio Interference). CISPR is a committee of the International Electrotechnical Commission (IEC), an international body that promulgates standards in order to facilitate trade between countries. CISPR published a recommended standard known as CISPR 22 that concerns information technology equipment

(ITE) which also includes digital devices. Many countries in Europe and throughout the world have adopted the CISPR 22 standard. The CISPR 22 limits are quite similar to the FCC limits. In recent years many countries in Europe have come together to form the European Economic Community or European Union in order to facilitate trade between the member nations. They have essentially adopted the CISPR 22 standard for radiated and conducted emissions of digital devices that are to be sold in those countries. This is called a *European Norm*, and the standard is EN 55022. Hence, complying with limits on radiated and conducted emissions of digital devices is a worldwide concern. In addition, the European standards impose additional regulatory requirements on digital devices that limit the *susceptibility* of a digital device to electromagnetic emissions. This requirement has not yet been imposed by the FCC but has created considerable concern for manufacturers of digital products that are intended for sale in Europe.

The measurement of these levels must be conducted by strict rules that are described in related standards. The measurement of radiated emissions is generally conducted in a semianechoic chamber as illustrated in Fig. 4. A shielded room encloses the test and prevents external emissions from contaminating the test results. The walls are lined with materials (carbon-impregnated foam or more recent ferrite tiles) that absorb electromagnetic waves in the frequency range of the regulations. This is done to prevent reflections from the shielded room walls and hence to simulate free space. The floor is a ground plane; hence the prefix “semi” in the chamber name. The conducted emissions are noise currents exiting the power cord of the device. These are routinely measured with a

line impedance stabilization network (LISN) as shown in Fig. 5. The digital product under test has its power cord plugged into the LISN, and the LISN is plugged into the commercial power outlet. The purposes of the LISN are twofold:

1. The impedance seen between phase and ground and between neutral and ground of the commercial power net *over the regulatory frequency range of 150 kHz–30 MHz* varies widely; thus the first purpose of the LISN is to present a constant $50\ \Omega$ impedance between phase and ground and between neutral and ground over the regulatory frequency range.
2. The second purpose of the LISN is to prevent noise on the commercial power net from contaminating the test. Inductors L1 are present to block this, and capacitors C2 are present to divert this noise to ground. Of course, the LISN must also pass the 60 Hz commercial power to the product. At 60 Hz, L1 is essentially a low impedance and C2 is essentially a high impedance. Hence the LISN is transparent to the 60 Hz power but appears as shown in Fig. 6 at the regulatory frequencies of 150 kHz–30 MHz.

These EMC regulatory requirements *cannot be waived*. If a digital device fails to meet these limits at any frequency, it cannot be legally sold in that country! There are certain other EMC requirements that can be relaxed if deemed necessary. These are for military products, commercial aircraft and automobiles, and other commercial

Figure 4. Illustration of the use of a semianechoic chamber for the measurement of radiated emissions.

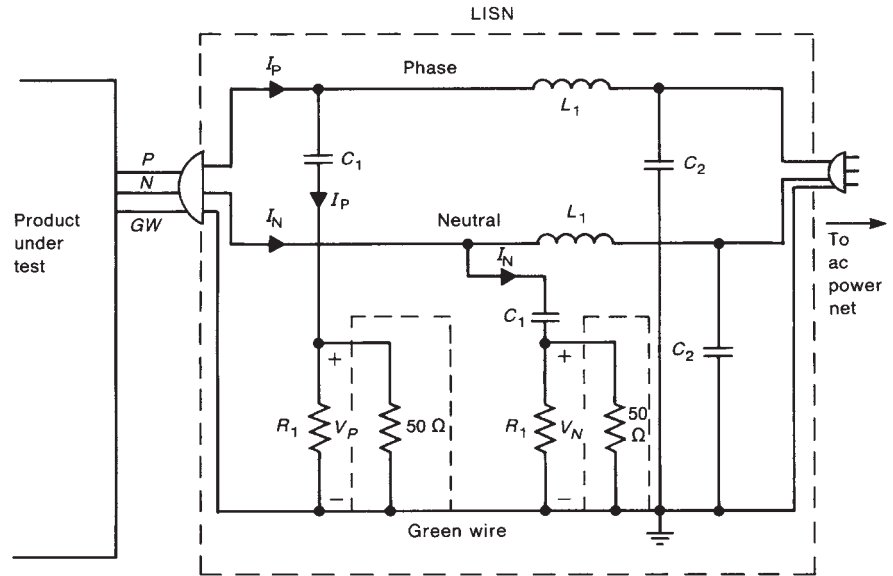

Figure 5. The line impedance stabilization network (LISN) for the measurement of conducted emissions.

vehicles. In the United States, in the early 1960s the Department of Defense (DoD) instituted a broad range of EMC requirements concerning, among other things, limits on the radiated and conducted emissions from virtually all electronic products that are sold to DoD units (U.S. Army, Navy, Coast Guard, etc.) These are military standards and the EMC regulation is MIL-STD-461E. The frequency range of regulation of the emissions is drastically greater than the FCC or CISPR 22 regulations, extending in some cases from 30 Hz to 40 GHz. However, the project officer for the contract has the authority to “tailor” these limits to fit the particular requirements of the system in which the electronic device is to be installed. In addition to the military, commercial aircraft manufacturers in the United States voluntarily comply with a standard on radiated and conducted emissions of commercial aircraft known as DO-160D. These voluntary standards prescribe limits on radiated and conducted emissions (on cables) as well as susceptibility in order to prevent or reduce the potential for interference with critical flight systems on the aircraft. Manufacturers of commercial automobiles and trucks in the United States also voluntarily comply with a standard such as SAE J551-2, which provides, among other things,

limits on the radiated and conducted emissions of the vehicle as well as its susceptibility to external electromagnetic emissions. Again these limits are intended to prevent or reduce the potential for interference with electronic systems on the vehicle from either internal or external sources. Once again, these are voluntary but manufacturers generally comply because introduction into the market of an airplane or vehicle that is susceptible to everyday emissions from radio towers and other ambient emitters that the airplane or vehicle routinely encounters would create a devastating loss of confidence with consumers.

3. TIME-DOMAIN VERSUS FREQUENCY-DOMAIN DESCRIPTION OF DIGITAL SIGNALS

The abovementioned regulatory requirements on digital devices are given in the frequency domain, that is, at each frequency within a frequency range. Hence it is important to investigate the relation between the time-domain waveforms of digital signals and their spectral content. The primary waveform in a digital device is its clock(s) signals. These are periodic, pulses with period T that are approximately trapezoidal in shape and have risetimes and

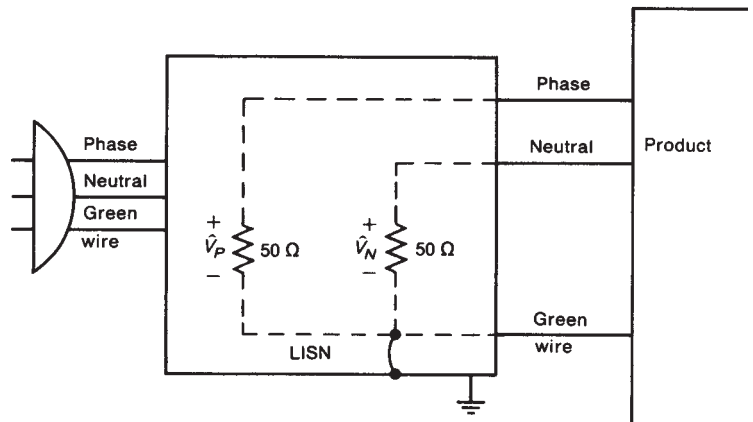

Figure 6. Equivalent circuit of the LISN as seen by the product over its intended frequency range of use.

Figure 7. The periodic, trapezoidal pulse-train representing clock and data signals of digital systems.

falltimes of τ_r and τ_f , respectively, as illustrated in Fig. 7. Typical clock signals have equal risetimes and falltimes or approximately so. Digital data signals have a similar waveform but are random in occurrence as opposed to the deterministic clock signal. Since the clock is periodic, we may decompose it into its spectral components with the Fourier series, giving the representation [1]

$$\begin{aligned} x(t) = & X_0 + X_1 \cos(\omega_0 t + \theta_1) \\ & + X_2 \cos(2\omega_0 t + \theta_2) \\ & + X_3 \cos(3\omega_0 t + \theta_3) + \dots \end{aligned} \quad (1)$$

Hence, the signal consists of the sum of a DC or average value X_0 , plus an infinite number of harmonics having magnitude X_n and phase θ_n and frequencies $n\omega_0$, where $\omega_0 = (2\pi/T)$ and the fundamental (repetition) frequency is $f_0 = (1/T)$. For the trapezoidal waveform in Fig. 7 having equal risetimes and falltimes, the magnitudes of these spectral components are [1]

$$X_n = 2AD \left| \frac{\sin(n\pi D)}{n\pi D} \right| \left| \frac{\sin(n\pi\tau f_0)}{n\pi\tau f_0} \right| \quad (2)$$

where the duty cycle is

$$D = \frac{\tau}{T} = \tau f_0 \quad (3)$$

and the pulsewidth between 50% points is τ .

In order to facilitate an understanding of how the time-domain properties affect the spectral content, it is possible

Figure 8. Bounds on the one-sided magnitude spectrum of a trapezoidal pulse-train.

to obtain spectral bounds on the magnitude as shown in Fig. 8 [1]. This Bode plot shows that the magnitudes of the spectral components fall off with increasing frequency as 0 dB/decade out to the first breakpoint, which occurs at $1/\pi\tau = f_0/\pi D$. Above this breakpoint the levels fall off as 20 dB/decade up to the next breakpoint, which is $1/\pi\tau_r$. Above this the levels fall off as 40 dB/decade. Hence, *to reduce the high-frequency spectral content, we must increase the pulse rise/falltimes*. This is a primary method of *reducing the source*. Figure 9 shows a comparison between the exact levels and the spectral bounds for a 1-V, 1-MHz clock having a rise/falltime of 20 ns, a 50% duty cycle, and a 30% duty cycle. Figure 10 shows a spectrum analyzer display of a 1-V, 10-MHz, 50% duty cycle digital clock signal having rise/falltimes of 20 and 5 ns illustrating the considerable reduction of the high-frequency spectral content achieved by increasing the rise/falltimes of the pulse.

4. METHODS FOR REDUCING EMISSIONS FOR COMPLIANCE

4.1. Radiated Emissions

We first describe methods for reducing radiated emissions. Again, time-varying currents radiate whether they are on cables or metallic cabinets. However, the predominant radiated emissions for digital products seem to emanate from wires or printed circuit board (PCB) traces in the system. The PCB traces are also referred to as “lands” because of their rectangular cross sections. There are two possible types of current. Consider a two-conductor (wire or PCB land) transmission line as shown in Fig. 11. *Differential-mode* currents are the usual functional currents on these conductors, and these phasor currents are denoted as \hat{I}_D in Fig. 11a. At a line cross section these are equal in magnitude but opposite in phase. These are the functional or desired currents that are designed for. If we view each conductor current as a Hertzian dipole (assuming that the conductor is electrically short and the observation point is in the far field at this frequency), then the radiated electric fields, \hat{E}_1 and \hat{E}_2 , subtract. Since the two currents are not collocated, they do not cancel. Conversely, there also exist *common-mode* currents on the conductors and these phasor currents are denoted as \hat{I}_C . At a cross section of the line the two currents have the same magnitude and are in phase as shown in Fig. 11b. Again viewing these as Hertzian dipoles, we see that their radiated electric fields add. Common-mode currents are sometimes referred to as *antenna-mode currents*. One way of viewing

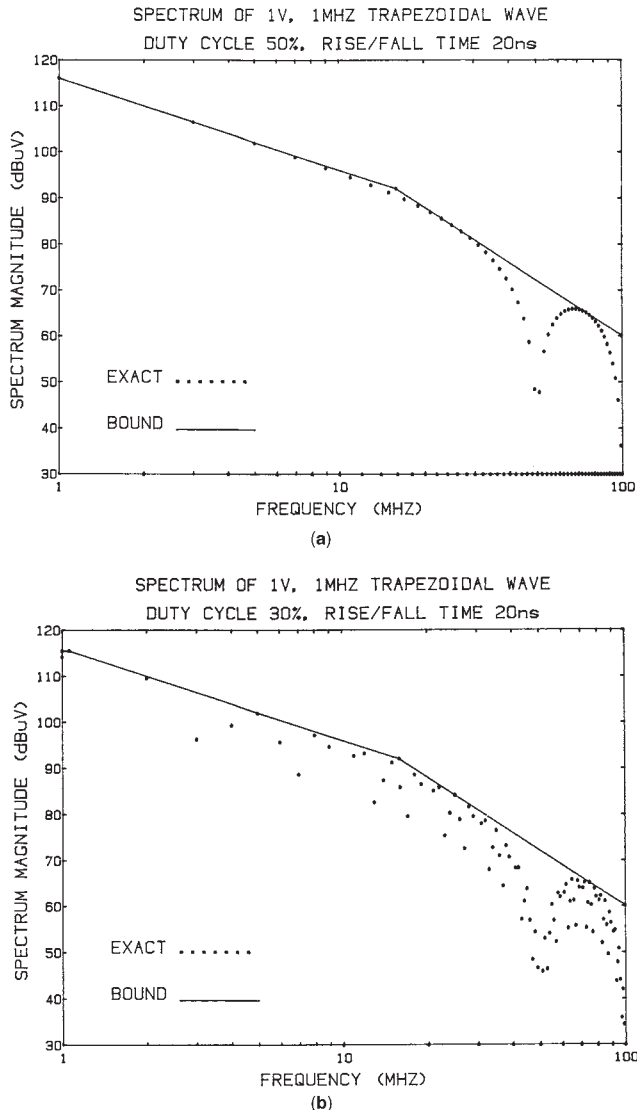

Figure 9. Examples illustrating the spectral bounds for various duty cycles of a 1-V, 1-MHz, trapezoidal pulsetrain having rise/falltimes of 20 ns: (a) 50% duty cycle; (b) 30% duty cycle.

them is as having a return path to their source consisting of, for example, parasitic capacitances to a third adjacent conductor (which is always present). The differential-mode currents are easily calculated, but the common-mode currents are not easily calculated (if at all). The common-mode currents are usually measured with a current probe [1]. The important observation here is that, because the differential-mode current emissions subtract but the common-mode emissions add, a common-mode current of magnitude much smaller than that of the differential-mode current can cause equal or greater emission levels. Radiated emissions from common-mode currents can be devastating in terms of radiated emissions and tend to be one of the major causes (if not the sole cause) of radiated emission and product noncompliance with the regulations for digital products today. For example, one can compute that for a 1 m length of ribbon cable (wire separation of 50 mils or 1.27 mm) a level of

differential-mode current at 30 MHz of some 20 mA will cause radiated emissions at 3 m that will exceed the FCC limit, whereas only 8 μ A of common-mode current will cause the same level of emission at 30 MHz.

Suppressing the emissions of these two currents requires different techniques. In the case of differential-mode currents, capacitors can be placed between the two wires to divert the current and keep it off the cable. In general, the longer the cable, the greater the potential for the current to radiate. The value of the capacitor is chosen to give a relatively low impedance (relative to the cable termination impedance) at the frequency of the emission current. In addition to the technique of current diversion, as with a parallel capacitor, there is the technique of current blocking where inductors or ferrite beads are inserted in series with each line to block the differential-mode currents of each line. In this case the value of the series impedance must be chosen to give a large impedance (relative to the cable termination impedance). It must be remembered that these differential-mode currents are required for the product to operate properly. Hence these suppression measures must be chosen with care so that these intended currents are not corrupted to the point that functionality of the product is impaired.

Suppressing the radiated emissions of common-mode currents requires a different technique. The common technique is to use common-mode chokes as illustrated in Fig. 12. A common-mode choke can take many forms. We have shown a toroid where the two cable wires are wound the same direction. In the case of differential-mode currents as shown in Fig. 12b, the magnetic fluxes of the differential-mode currents tend to cancel, and hence the choke is transparent to these currents. However, the magnetic fluxes of the common-mode currents add in the core, and hence the common-mode currents see a net impedance inserted in each line. These chokes are constructed of ferrite materials such as manganese-zinc or nickel-zinc materials with additional materials added to produce high-frequency losses. In addition to inserting inductances selectively in the lines as shown in Fig. 12c, these ferrite chokes also insert high-frequency resistances (not shown) and provide selective loss, thus dissipating the energy in the common-mode currents. There are also chokes consisting of a ferrite core that is clamped around both wires such as is frequently seen in personal computer systems on the keyboard and video cables.

We now will derive a simple model for these emissions that will illustrate the factors that can be controlled in order to reduce their emissions. First consider the case of differential-mode currents on the two wires as shown in Fig. 13, where the wires are separated by a distance s and are a total length \mathcal{L} . If we assume that the line length is much less than a wavelength and the observation point is in their far field (typically a wavelength or more), then we may view these as Hertzian dipoles and simply superimpose their fields. The resulting maximum electric field is then [1]

$$|\hat{E}_{D,\max}| = 1.316 \times 10^{-14} \frac{|\hat{I}_D| f^2 \mathcal{L} s}{d} \quad (4)$$

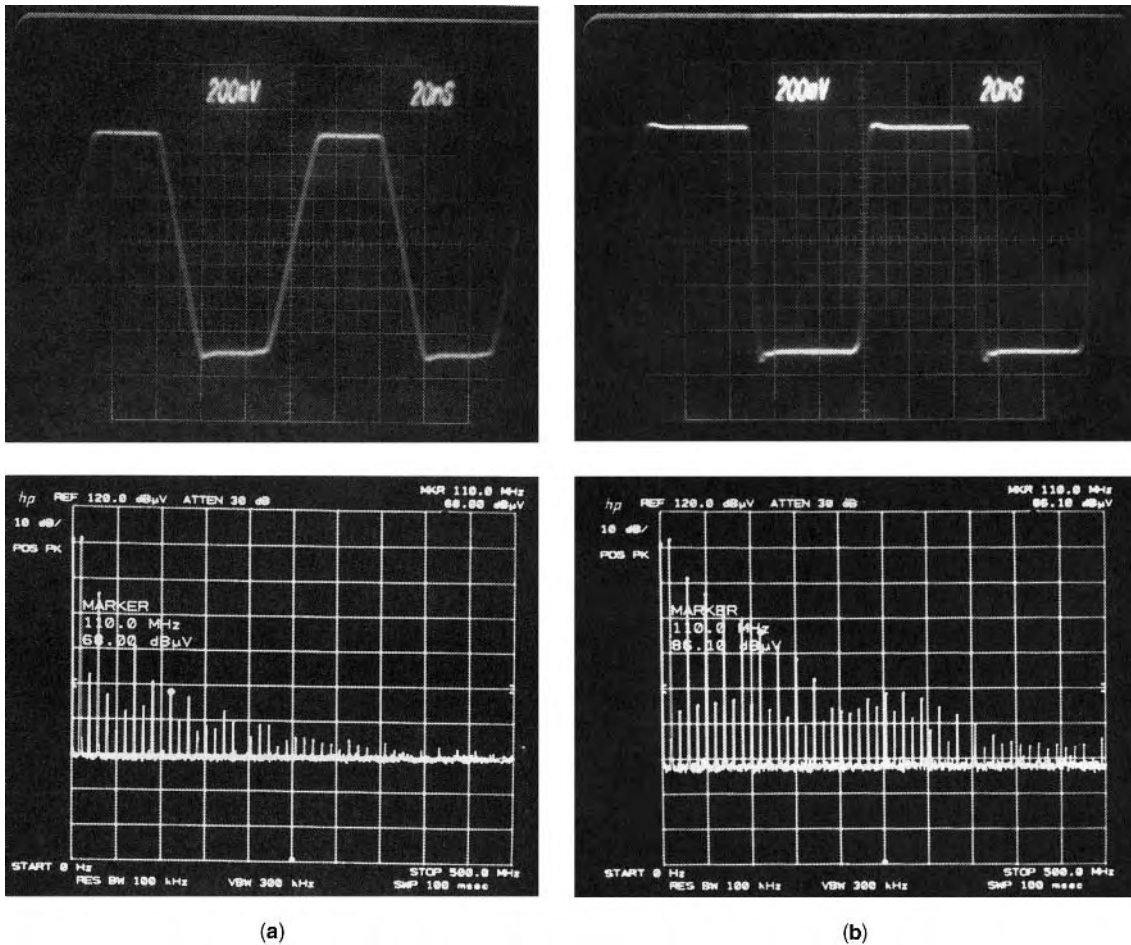

Figure 10. Experimentally measured spectra of 1-V, 10-MHz, 50% duty cycle trapezoidal pulse-trains for rise/falltimes of (a) 20 ns; (b) 5 ns.

where d is the distance to the observation point. For residential digital devices in the United States, this is the regulatory measurement distance of 3 m. At 30 MHz, the FCC limit is $100 \mu\text{V}/\text{m}$ at 3 m. We can calculate from this that a level of about 20 mA on a 1 m length of ribbon cable at this frequency will just exceed this limit. The reason we derive a simple result such as in (4) is not so much to calculate emission levels but more importantly to determine the factors that control the emission. For example,

Figure 11. Illustration of the relative radiated emission potential of (a) differential-mode currents and (b) common-mode currents.

(4) shows that the factors affecting the level of the radiated field are (1) the level of the current (the level of the Fourier *component* of this current) at this frequency, (2) the frequency (squared), and (3) the loop area formed by the conductors, $A = \mathcal{L}s$. The level of the current (perhaps a high-frequency component of a clock signal) can be reduced by increasing pulse rise/falltimes. These can be reduced only up to a point where the functionality of the product becomes impaired. Usually there is considerable latitude in doing this in the original design. The frequency here is the frequency of the emission (and the regulation), which cannot be changed. The final item, loop area formed by the two conductors can be easily controlled. Two cases are illustrated in Fig. 14. Figure 14a shows a digital clock that serves an application-specific integrated circuit (ASIC). The loop area of the two connection leads must be kept to a minimum. This can be easily done by (1) placing the clock as close as possible to the device being served and (2) placing the two connection leads as close together as possible. In the layout of a PCB, this would be the initial order of business. Figure 14b shows a ribbon cable attached to a stepper motor. The pin assignments in the connectors are as shown. The prime items, such as A' , are the returns for the currents on the unprimed wires, such as A . Because of the pin assignments, each return

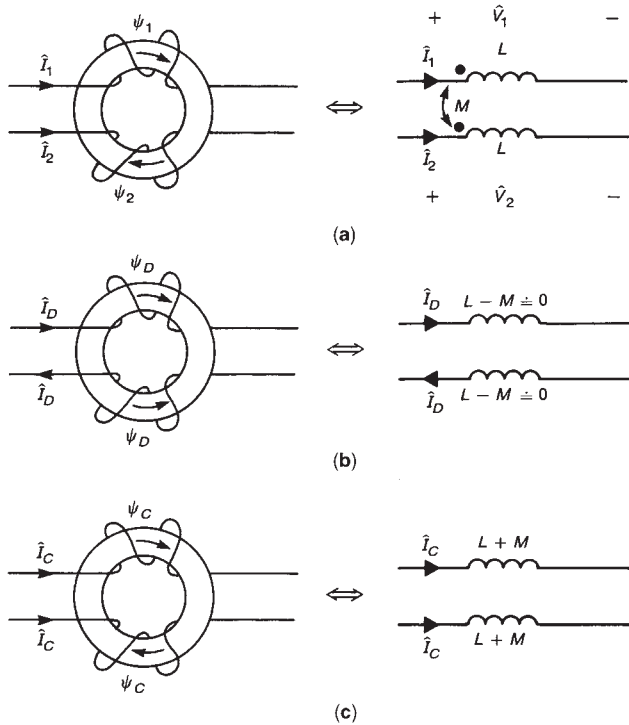

Figure 12. Modeling the effect of a common-mode choke on (a) the currents of a two-wire line, (b) the differential-mode components, and (c) the common-mode components.

encompasses three loop areas between wires. If the pin assignments had been as shown in Fig. 14c, then the individual loop areas would be reduced by one-third and the radiated emissions would be, according to the model in Fig. 14, reduced by about 10 dB. Simple understanding of the basic mechanisms will often lead to “cost-free” EMC suppression.

Next we consider a simple model for the emissions from common-mode currents shown in Fig. 15. Once again considering the two conductors as Hertzian dipoles and

Figure 13. A simplified estimate of the maximum radiated emissions due to differential-mode currents with constant distribution.

Figure 14. Common mistakes that lead to unnecessarily large differential-mode emissions: (a) large clock land areas; (b,c) choices of connector pin assignments in ribbon cables to minimize loop area.

superimposing their fields gives [1]

$$|\hat{E}_{C,max}| = 1.257 \times 10^{-6} \frac{|\hat{I}_D| f \mathcal{L}}{d} \quad (5)$$

For a 1 m length of ribbon cable at 30 MHz, we can calculate that a level of common-mode current of some 8 μA will cause an electric field at the regulatory measurement distance of 3 m that exceeds the FCC limit. Hence very small levels of common-mode currents can be devastating from the standpoint of complying with the regulatory limits. In (5) we observe that the two factors that control these

Figure 15. A simplified estimate of the maximum radiated emissions due to common-mode currents with constant distribution.

Figure 16. An experiment illustrating common-mode currents on PCBs: (a) device schematic; (b) PCB cross-sectional dimensions.

emission levels are (1) the level of the current and (2) the *length* of the cable. Reducing the levels of the differential-mode currents tends to also reduce the levels of the common-mode currents, although the precise relationship is not clear. Also, we should endeavor to make all connections (wires and PCB lands) as short as possible.

In order to illustrate the devastating nature of common-mode currents, we investigate the simple experiment shown in Fig. 16. Two PCB lands of width 25 mils (0.635 mm) and length 6 in (15.2 cm) are mounted on a typical PCB substrate. A 10-MHz dual-inline package (DIP) oscillator is powered by a 5-V battery (no connection to the commercial power system) and is connected to the two lands. The two lands are terminated in a 330-Ω

resistor. The characteristic impedance of this line is about 330 Ω, and hence the line is matched. The radiated electric fields measured in a typical semianechoic chamber at 3 m are shown in Fig. 17. On these measured emissions are superimposed the predictions of the common-mode model in (5) denoted as “x.” The common-mode currents used in this model were measured with a current probe. In addition, the emissions of the differential-mode currents were measured on each individual wire and also predicted with a transmission-line model. The emissions computed with the measured differential-mode currents with (4) are shown as “o” and the emissions computed with the computed differential-mode currents with (4) are shown as “+.” These results show that (1) the emissions of common-mode currents greatly exceed those from differential-mode currents and are dominant, and (2) the simple models in (4) and (5) are sufficiently accurate to illustrate the factors that affect these emissions.

4.2. Conducted Emissions

Now we turn to the suppression of conducted emissions. As stated earlier, the standard regulatory test for conducted emissions of a digital product is to plug the product’s power cord into a LISN and the LISN into the commercial power outlet. Again the noise currents (150 kHz–30 MHz) exiting the phase and neutral conductors of the power cord consist of differential-mode and common-mode currents. The differential-mode currents flow out of the phase conductor and return on the neutral conductor. The common-mode currents flow out of the phase and neutral conductors and return on the safety or green wire of the product. The primary method of suppressing these emissions is with a power supply filter shown in Fig. 18. Ordinarily the power supply filter is at the last point of exit of the power cord from the product. The important components in the filter are (1) a

Figure 17. Measured and predicted emissions of the device of Fig. 16.

Figure 18. A typical power supply filter topology.

common-mode choke denoted by self- and mutual inductances L and M , (2) line-to-line capacitors denoted as C_{DR} and C_{DL} , and (3) line-to-ground capacitors denoted as C_{CR} and C_{CL} . The subscripts “L” and “R” denote left and right, respectively. The common-mode choke acts as described before; it selectively blocks the common-mode noise current and is transparent to the differential-mode noise current. It is necessary to use a common-mode choke rather than individual inductors here since the differential-mode current contains the important 60 Hz power current. The 60 Hz power current has a very large magnitude, on the order of 1–10 A in typical digital products and hence would saturate the ferrite cores of individual inductors. The common-mode choke is transparent to the high-level 60 Hz current, and hence the core of the common-mode choke is not saturated by it. The line-to-line capacitors are present to divert the differential-mode noise currents, and the line-to-ground capacitors are present to divert the common-mode noise currents.

4.3. Shielding

Another suppression measure is obtained with *shielding*. Generally, shielding should be used as a last resort for suppression since (1) it is difficult to implement in its ideal form (shielding effectiveness values of > 200 dB can easily be calculated but are impossible or too costly to implement), and (2) shielding is generally quite expensive compared to other simple methods. A shield is a contiguous

metal enclosure. There are two purposes for shields as illustrated in Fig. 19. One is to keep internal fields from being radiated (possibly causing noncompliance with radiated emission levels) and the other is to keep external fields from interfering with internal electronics (preventing susceptibility to, for example, a FM radio transmitter or an airport surveillance radar).

The simplest model of a shield is a large, conducting plane of conductivity σ and thickness t as shown in Fig. 20. The most common measure of shielding effectiveness (SE) is the ratio of the electric field that is incident on the shield to the electric field that exits the shield. In decibels this is [1]

$$SE_{dB} = 20 \log_{10} \left| \frac{E_{incident}}{E_{transmitted}} \right| \tag{6}$$

This gives the shielding effectiveness as a positive value. For example, a SE of 100 dB means that the electric field is reduced by a factor of 100,000 as it transits the shield wall. If we assume that (1) the shield is in the far field of the source (such as a radar) so that the incident field is a uniform plane wave and (2) the incident wave strikes the shield wall normal to its surface, then a simple result for the shielding effectiveness can be obtained as [1]

$$SE_{dB} = \underbrace{20 \log_{10} \left| \frac{\eta_0}{4\eta} \right|}_{R_{dB}} + \underbrace{20 \log_{10}(e^{t/\delta})}_{A_{dB}} \tag{7}$$

Figure 19. Illustration of the use of a shielded enclosure to (a) contain radiated emissions and (b) exclude radiated emissions.

Figure 20. Illustration of multiple reflections within a shield.

where the intrinsic impedance of free space is $\eta_0 = 377 \Omega$, the intrinsic impedance of the conducting shield is $\hat{\eta} = \sqrt{j\omega\mu/(\sigma + j\omega\epsilon)}$, and $\delta = 1/\sqrt{\pi f\mu\sigma}$ is the skin depth. The first term in (7) is said to be the reflection loss and accounts for the reflection at the left and right interfaces of the shield walls. The second term is said to be the absorption loss and accounts for attenuation of the waves as they pass through the shield. This absorption term can be written as $A_{dB} = 8.69(t/\delta)$. Hence a shield thickness of one skin depth gives ~ 9 dB of absorption loss, and a shield thickness of five skin depths gives ~ 44 dB.

From this result one can compute shielding effectiveness values on the order of 100–500 dB. Rarely will these be realized in actual systems because of the inevitable penetrations of the shield by openings to allow for cooling and by cables that must exit the shield. These penetrations must be properly treated (such as placing gratings with many small, closely spaced holes over openings or placing filters in every exiting cable), or else the shielding effectiveness will be drastically reduced.

Other types of “shielding” act to divert rather than reflecting magnetic fields. Ferromagnetic materials have relative permeabilities greater than unity. For example, sheet steel has $\mu_r = 2000$, and mumetal has $\mu_r = 30,000$. These materials present a low reluctance path for the magnetic fields and hence divert them away from electronics that may be susceptible to them.

4.4. Crosstalk

There is another aspect to EMC that is often overlooked: the ability of the system to interfere with itself. A common such situation is crosstalk between adjacent transmission lines. Consider a three-conductor line shown in Fig. 21. One conductor is called the *generator* conductor and forms, with the *reference* conductor (a ground plane, a wire, a PCB land, or an overall shield), the generator circuit. It is driven by a source that has an open-circuit voltage $V_S(t)$ and source resistance R_S , and is terminated by a resistor R_L . Another conductor, the receptor conductor, with the reference conductor forms the receptor circuit. This circuit is terminated at the near end (with reference to the source on the generator circuit) with a resistor R_{NE} and at the far end with a resistor R_{FE} . The line has total length of \mathcal{L} . The electric and magnetic fields of the generator circuit interact with the receptor circuit and cause induced voltages, V_{NE} and V_{FE} , at the terminals of the receptor circuit. These induced voltages may cause interference with the devices that are represented by R_{NE} and R_{FE} . This is referred to as *crosstalk*.

Computing this crosstalk is generally a formidable task. (See COUPLED TRANSMISSION LINES in this Encyclopedia). We may, however, obtain a simple model for this crosstalk as long as (1) the line length is much less than a wavelength at the highest significant frequency of the source, that is, electrically short, and (2) the two circuits are weakly coupled [1]. This simple model is shown in Fig. 22. The electric field and voltage of the generator circuit induce a current source in the receptor circuit, via a per unit length (PUL) mutual capacitance c_m , whose value is $j\omega c_m \mathcal{L} \hat{V}_{G,DC}$ where $\hat{V}_{G,DC}$ is the phasor voltage between the conductors of the generator circuit. Because the line length is assumed electrically small, this voltage is approximately constant along the line and can be computed as though it were DC as

$$\hat{V}_{G,DC} \cong \frac{R_L}{R_S + R_L} \hat{V}_S \tag{8a}$$

Similarly, the magnetic field and current of the generator circuit induce a voltage source (according to Faraday’s law) in the receptor circuit, via a PUL mutual inductance l_m , whose value is $j\omega l_m \mathcal{L} \hat{I}_{G,DC}$ where $\hat{I}_{G,DC}$ is the phasor

Figure 21. The general three-conductor transmission line, illustrating crosstalk.

Figure 22. The simple inductive–capacitive coupling model of the receptor circuit for sinusoidal excitation.

current along the conductors of the generator circuit. Because the line length is assumed electrically short, this current is also approximately constant along the line and can be computed as though it were DC as

$$\hat{I}_{G,DC} \cong \frac{1}{R_S + R_L} \hat{V}_S \quad (8b)$$

Hence the near-end and far-end phasor crosstalk voltages can be computed from this circuit as

$$\begin{aligned} \hat{V}_{NE} = & \underbrace{\frac{R_{NE}}{R_{NE} + R_{FE}} j\omega l_m \mathcal{L} \hat{I}_{G,DC}}_{\text{inductive coupling}} \\ & + \underbrace{\frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} j\omega c_m \mathcal{L} \hat{V}_{G,DC}}_{\text{capacitive coupling}} \end{aligned} \quad (9a)$$

$$= j\omega \left[\frac{R_{NE}}{R_{NE} + R_{FE}} \frac{1}{R_S + R_L} l_m \mathcal{L} + \frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} c_m \mathcal{L} \frac{R_L}{R_S + R_L} \right] \hat{V}_S$$

$$\begin{aligned} \hat{V}_{FE} = & - \underbrace{\frac{R_{FE}}{R_{NE} + R_{FE}} j\omega l_m \mathcal{L} \hat{I}_{G,DC}}_{\text{inductive coupling}} \\ & + \underbrace{\frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} j\omega c_m \mathcal{L} \hat{V}_{G,DC}}_{\text{capacitive coupling}} \end{aligned} \quad (9b)$$

$$= j\omega \left[- \frac{R_{FE}}{R_{NE} + R_{FE}} \frac{1}{R_S + R_L} l_m \mathcal{L} + \frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} c_m \mathcal{L} \frac{R_L}{R_S + R_L} \right] \hat{V}_S$$

These phasor crosstalk voltages are the sum of an inductive coupling term due to the mutual inductance and the current of the generator circuit, and a capacitive coupling term due to the mutual capacitance and the voltage of the generator circuit. Observe that the final results in (9) vary directly with the frequency ($\omega = 2\pi f$) of the source. Hence the magnitudes of the crosstalk “transfer functions” $|\hat{V}_{NE}/\hat{V}_S|$ and $|\hat{V}_{FE}/\hat{V}_S|$ increase with frequency at 20 dB/decade while the phase is 90° . A substantial amount of experimental as well as computed data given in Ref. 1 confirm this behavior and the predictions of this simple model.

The model presented above is for single-frequency, sinusoidal source waveforms. For more general time-

domain waveforms we may substitute

$$j\omega \Leftrightarrow \frac{d}{dt} \quad (10)$$

to give the time-domain crosstalk as

$$\begin{aligned} V_{NE}(t) = & \underbrace{\left[\frac{R_{NE}}{R_{NE} + R_{FE}} \frac{1}{R_S + R_L} l_m \mathcal{L} + \frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} c_m \mathcal{L} \frac{R_L}{R_S + R_L} \right]}_{M_{NE}} \\ & \times \frac{dV_S(t)}{dt} \end{aligned} \quad (11a)$$

$$\begin{aligned} V_{FE}(t) = & \underbrace{\left[- \frac{R_{FE}}{R_{NE} + R_{FE}} \frac{1}{R_S + R_L} l_m \mathcal{L} + \frac{R_{NE} R_{FE}}{R_{NE} + R_{FE}} c_m \mathcal{L} \frac{R_L}{R_S + R_L} \right]}_{M_{FE}} \\ & \times \frac{dV_S(t)}{dt} \end{aligned} \quad (11b)$$

Hence the near-end and far-end crosstalk voltages depend on the derivative of the source voltage waveform, also known as its “slew rate.” Consider the source waveform to be that of a digital clock or data signal. The resulting crosstalk waveforms are shown in Fig. 23. Observe that (1) the crosstalk pulses occur during the transitions of the clock or data pulses and (2) their levels depend, in addition

Figure 23. Time-domain crosstalk prediction of the inductive–capacitive coupling model for a trapezoidal pulsetrain excitation.

to the mutual inductance and capacitance, on the rise/fall-times of the source waveforms. Hence again we see that in order to reduce the crosstalk magnitudes, we should increase the rise/falltimes of the clock and data pulses. This rule of thumb also applied to radiated emissions.

We now turn to other methods of reducing crosstalk useful for wire-type conductors. Clearly, since the crosstalk depends on the PUL mutual inductance and capacitance between the two circuits, we can reduce the crosstalk by (1) separating the two circuits further and (2) orienting the two circuits so that they are orthogonal to each other. When these methods along with increasing the rise/falltimes fail to reduce the crosstalk to acceptable levels, we have two other options: (1) enclosing the generator and/or receptor wires with a shield and (2) twisting the two wires of the generator circuit together and/or twisting the two wires of the receptor circuit together to form twisted pairs. First we address the use of shielded wires. Suppose that we enclose, for example, the receptor wire with a concentric shield as shown in Fig. 24. The mutual capacitance between the generator wire and the receptor wire will be eliminated, and we obtain the capacitive coupling model shown in Fig. 24. From this we see that the capacitive coupling can be eliminated if we make the shield voltage (with respect to the reference conductor, e.g., a ground plane) zero. Since the line is assumed to be electrically short, we can “ground” the shield at only one end and make the voltage all along it approximately zero. In order to eliminate inductive coupling with a shield, the shield must be “grounded” at both ends as shown in Fig. 25. The process is as follows. The current of the generator circuit induces a magnetic field that threads the shield-reference conductor loop thereby inducing a current flowing back along the shield \hat{I}_S , which produces its own magnetic flux that tends to cancel the original flux penetrating this loop. If the shield were not connected to the reference conductor (“grounded”) at both ends, no shield current could flow and hence no counteracting mag-

Figure 25. Illustration of the effect of placing a shield around a receptor wire on inductive coupling.

netic field would be produced. Hence, surrounding the generator wire and/or the receptor wire with a concentric shield will ideally eliminate (1) capacitive coupling as long as it is grounded at at least one end and (2) inductive coupling as long as it is grounded at both ends.

The other alternative is to replace the receptor wire with two wires (a dedicated return) and twist them together to form a twisted pair. A similar scheme can be applied to the generator wire producing the same effect. The basic process whereby a twisted wire eliminates magnetic field or inductive coupling is illustrated in Fig. 26. The current of the generator circuit causes magnetic fluxes to penetrate the loops of the twisted pair, inducing in them, by Faraday’s law, voltage sources. When we “untwist” this twisted pair, we see that the Faraday voltage sources in adjacent twists cancel out. Suppose, for example, that the reference conductor is a ground plane and the receptor wires are twisted together as shown in Fig. 27. Although a twisted pair is truly a bifilar helix, we have shown an approximate model consisting of

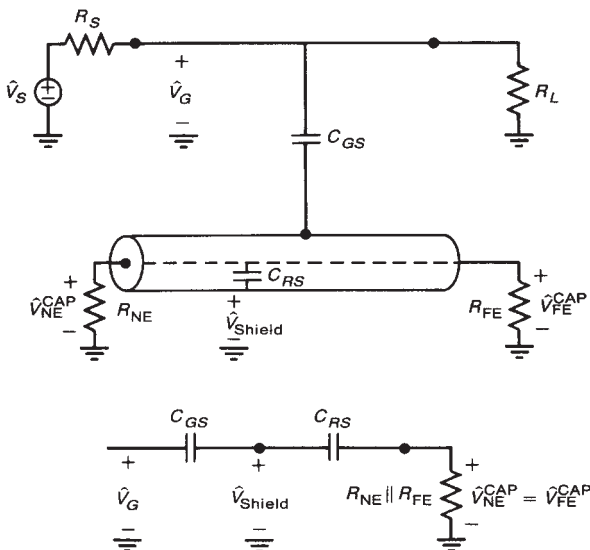

Figure 24. A lumped equivalent circuit for capacitive coupling for the shielded receptor wire.

Figure 26. Illustration of the effect of a twisted pair of receptor circuit wires on magnetic field (inductive) coupling.

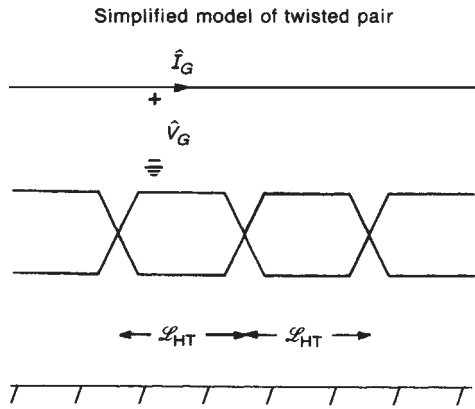

Figure 27. A simple “abrupt loop” model of a twisted pair of receptor circuit wires.

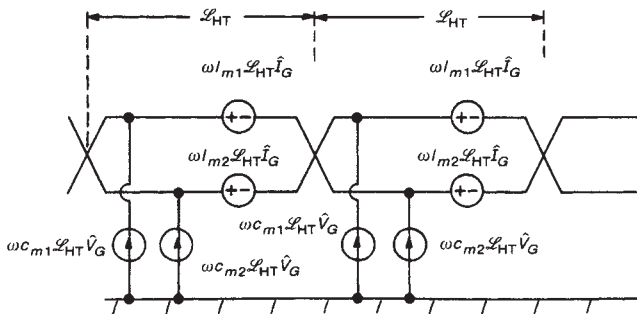

Figure 28. The simple inductive-capacitive coupling model for the twisted pair of receptor circuit wires.

adjacent loops abruptly interchanged. The length of each half-twist is denoted by \mathcal{L}_{HT} . We can view this as superimposing two of our previous generator-receptor coupling circuits; that is, we may view the twisted receptor pair as being two receptor wire-ground plane circuits. Hence the induced sources are as shown in Fig. 28. There are two ways of “terminating” a two-wire line as shown in Fig. 29. In the unbalanced case, one end is single-ended while the other is floating. In the balanced case, either center-tapped transformers or balanced line drivers and receivers are used to terminate the line. For the unbalanced case, “untwisting” the two wires gives the equivalent circuit of Fig. 30. The Faraday law-induced sources again tend to cancel. However, the induced current sources of the lower wire are short-circuited out but those attached to the upper wire do not cancel. Hence the inductive coupling portion of the crosstalk is canceled out and the capacitive coupling portion is approximately the same as before the wires were twisted together. For the balanced termination case, “untwisting the pair of receptor wires” gives the equivalent circuit in Fig. 31. Observe that the Faraday law-induced voltage sources are again canceled out by the twist but more importantly, the balancing of the terminations causes the capacitive-coupling-induced current sources to also cancel out. Hence, (1) a twisted pair eliminates inductive coupling by virtue of the twist but (2) the capacitive coupling can be eliminated only by using balanced terminations. See Ref. 1 for extensive experimental and computed data that confirm these observations about shielded wires and twisted pairs in the reduction of crosstalk.

Note: Grounded at only one end to avoid ground loops.

5. SUMMARY

Interference in electronic systems is increasing in importance because of the necessity to use higher clock speeds in digital systems and to use the GHz frequency spectrum for analog systems. For these reasons, the electromagnetic compatibility (EMC) of electronic systems is rapidly becoming an important design criterion. Susceptibility of electronic systems to electromagnetic emissions as well as the unintended generation of electromagnetic emissions by those electronic systems can create loss of consumer confidence if the operation of those devices is impaired.

Perhaps more importantly, virtually all countries throughout the world now limit the unintended electromagnetic emissions of digital devices, and some limit the susceptibility of digital devices to electromagnetic emissions. Hence EMC of digital devices has become a legal issue. It does little good to produce a novel digital device if it cannot be legally sold in a country because of its inability to comply with the legal requirements on its electromagnetic emissions and/or its susceptibility to them. Hence EMC will no doubt steadily increase as an important design criterion for digital products. The majority of electrical engineering curricula do not address this problem today, although the number of curricula that do is steadily increasing [2]. Hence the majority of those graduating engineers have little, if any, knowledge of this important aspect of design until they enter the job place. It has become imperative that universities begin to incorporate EMC into their curricula so that engineers will be better prepared to design future electronic products.

ELECTROMAGNETIC FERRITE TILE ABSORBER

CHRISTOPHER L. HOLLOWAY

 Boulder Laboratories
 Boulder, Colorado

Anechoic chambers have been used for over forty years to simulate different operating environments for a wide range of frequencies [1–3]. These chambers provide an accurate and convenient environment for electromagnetic compatibility (EMC) testing and are important cost-effective tools for achieving EMC compliance. To perform tests in anechoic chambers in the 30 MHz to 1000 MHz frequency range, good low-frequency electromagnetic absorbers are needed. Magnetic materials, such as ferrite tile absorbers, offer the type of low-frequency performance needed for EMC testing inside shielded rooms (or chambers).

The first anechoic chambers were constructed in the early 1950s for antenna measurements. These chambers were equipped with bats of loosely spun animal hair coated with carbon. This broadband “hair” absorber was 5.08 cm (2 in) thick and provided –20 dB of reflectivity (20 log [reflected wave/incident wave]) at normal incidence from 2.4 GHz to 10 GHz. Later in the decade, the hair absorber was replaced by a new generation of absorber that

offered -40 dB of reflectivity at normal incidence. Unlike the hair absorber, the new absorber was equipped with a shaped or convoluted front surface. Commercially manufactured absorbers emerged in the 1960s and boasted less than -60 dB of reflectivity at normal incidence. This low reflectivity was obtained at high microwave frequencies, however, where the thickness (tip-to-base dimension) of the pyramids was at least several wavelengths.

The multiple reflections between the electrically thick pyramids account for the excellent performance. Because the individual pyramids are relatively large compared with a wavelength, the sides of the pyramids reflect and re-reflect the incident wave many times. Upon each reflection, a portion of the wave is absorbed by the pyramid. Hence, an extremely small portion of the incident wave energy survives the many reflections that occur before it arrives at the solid absorber base located between the pyramids and the metal chamber wall. Then the remaining wave is absorbed further as it travels through the base until it is reflected by the chamber wall. The reflected wave is absorbed as it proceeds through the absorber base and again experiences the multiple reflections between adjacent pyramids before emerging from the plane defined by the pyramid tips.

Semi-anechoic chambers were first used for emission measurements during the 1970s as an alternative to an open area test site (OATS), a ground-plane facility for emission measurements performed from 30 MHz to 1000 MHz. These chambers were equipped with a conducting floor to simulate the large ground plane employed on the OATS. Because it obviously was impractical to construct a chamber with absorbers several wavelengths long at 30 MHz, the early chambers typically were equipped with 0.91 to 1.83 m (3 to 6 ft) thick absorber. Originally intended to be operated at higher frequencies, this absorber restricted the use of these chambers to approximately the 90 MHz to 1000 MHz frequency range [4].

With the promulgation of emission requirements during the late 1970s, absorber manufacturers were confronted with a growing demand for a compact wideband absorber to operate over the entire 30 to 1000 MHz frequency range. The evolution of compact wideband absorbers was catalyzed in the mid 1980s when techniques to calculate and measure its reflectivity were developed. The first computationally efficient, accurate calculation of absorber reflectivity became possible when the method of homogenization was used in a theoretical model [5–7]. Soon afterward, the reflectivity of compact, wideband absorbers was measured directly with large test fixtures [8–11].

To achieve small reflectivities over the entire 30 to 1000 MHz frequency range, compact wideband absorbers must use tapered structures (like pyramids or wedges) that not only operate at frequencies where they are electrically thick, but at the frequencies where they are electrically thin. When an incident wave encounters electrically thin absorbers, it does not “see” the fine structure of the pyramids or wedges. Instead, the incident wave behaves as though it encountered a solid medium whose effective conductivity and permittivity vary with the distance into the medium. These effective material properties differ from the conductivity and permittivity of the actual material used to construct the absorber.

An optimized electrically thin absorber provides a transition from the wave impedance of free space to the wave impedance of the absorber base. With the correct carbon loading, most of the incident wave penetrates the tapered structure (pyramids or wedges) and is absorbed as it travels through their solid base. Moreover, the carbon loading can be adjusted further to obtain cancellation between the portion of the incident wave reflected by the tapered structure and the wave that emerges from the absorber after reflection by the metal wall. This cancellation causes an extremely small reflectivity, albeit over a relatively narrow frequency range. In general, the carbon loading selected for electrically thin, tapered structures differs from the loading employed for electrically thick structures [7].

Although it is possible to achieve good low-frequency performance of carbon-loaded, tapered structures, they are physically large and require large metal enclosures to house them. An alternative to these large carbon-loaded, tapered structures is the ferrite-tile absorber. Electrically thin ferrite tiles were developed in Japan during the early 1960s [12–14] as an alternative to urethane pyramids and wedges. Because they have a wave impedance close to the impedance of free space, the tiles allow direct penetration of the incident wave without significant reflection at the air-to-tile interface. Furthermore, the tiles are magnetically lossy absorbing the penetrating wave almost completely as it travels through the tile. Subsequently, the wave is reflected by the metal wall behind the ferrite and travels toward the ferrite/air interface. As with the electrically thin urethane absorber, the thickness of the ferrite can be selected to achieve narrowband cancellation from the portion of the incident wave reflected at the air-to-tile interface and from the wave that emerges from the ferrite tile after reflection by the metal wall.

Recently, thin urethane pyramids or wedges that operate from about 200 MHz to 1000 MHz have been combined with ferrite tiles that are effective from 30 MHz to 600 MHz. The combination of these two absorbers, along with properly chosen dielectric layers, results in an ultra-compact wideband “hybrid” absorber that exhibits excellent performance from 30 MHz to 1000 MHz [15,16]. These “hybrid” absorbers are discussed in detail in [3].

In this chapter, we discuss the ferrite tile, ferrite grids, and hybrid combinations of urethane and ferrite absorbers typically used in electromagnetic test chambers for the 30 MHz to 1000 MHz frequency range. We present formulas and calculated reflectivities (or reflection coefficients). We also discuss how material properties and reflectivities are measured for the ferrite-tile absorbers.

1. MODELING FERRITE TILES

The performance of absorbers is determined by comparing the magnitudes of incident and reflected plane waves, where the absorber is assumed to be an infinite plane. One such comparison is the reflection coefficient Γ , defined as

$$\Gamma = \frac{E_r}{E_i} \quad (1)$$

where E_r is the reflected electric field and E_i is the incident electric field. Alternatively, absorber performance is expressed as reflectivity R in decibels as

$$R = 20 \cdot \log_{10}(|\Gamma|) [\text{dB}] \quad (2)$$

The smaller the value of R in dB, the better the performance of the absorber.

It is very straightforward to model a ferrite tile theoretically with the aid of classical transmission-line equations. The reflectivity of a solid ferrite tile backed by a metal wall is given by

$$\Gamma = \frac{Z_f - \eta}{Z_f + \eta} \quad (3)$$

where η is defined as

$$\eta = \sqrt{\frac{\mu}{\varepsilon}} \quad (4)$$

and

$$Z_f = \eta \frac{1 - e^{-2\gamma d}}{1 + e^{-2\gamma d}} \quad (5)$$

where d is the ferrite thickness and γ is the propagation constant defined by

$$\gamma = j\omega\sqrt{\mu\varepsilon} \quad (6)$$

In these expressions ε and μ are the complex permittivity and permeability of the ferrite tile. While Eq. (3) is for a normal incident plane wave, it can be modified to handle off-normal incidence by incorporating the angular dependence into the impedance and propagation constant (for details, see [3,6,17]).

Figure 1 shows the reflectivity of a solid ferrite tile and the material properties are given in Table 1. The figure shows that the tile performs very well below 600 MHz, but above 600 MHz, the tile performance deteriorates.

The higher frequency (>600 MHz) performance is improved by using so-called "ferrite grids." A ferrite grid (or waffle) is shown in Fig. 2. The grid is a two-dimensional array of square air sections cut into a ferrite-tile matrix. This structure is modeled with an averaging technique known as homogenization and the transverse material properties are approximated by the following expressions [3]:

$$\varepsilon_t = \varepsilon_a + \frac{1 - g}{\frac{1}{\varepsilon_0 - \varepsilon_a} + \frac{g}{2\varepsilon_a}}$$

and

$$\mu_t = \mu_a + \frac{1 - g}{\frac{1}{\mu_0 - \mu_a} + \frac{g}{2\mu_a}} \quad (7)$$

The longitudinal permittivity and permeability are known exactly [18] as

$$\varepsilon_z = (1 - g)\varepsilon_0 + g\varepsilon_a$$

Figure 1. Reflectivity of a 6.38 mm (0.25 in) solid ferrite tile at 0° and 45° incident angles.

and

$$\mu_z = (1 - g)\mu_0 + g\mu_a \quad (8)$$

In these expressions, $g = a^2/p^2$ is the fraction of space occupied by the absorber, and ε_a and μ_a are complex parameters of the bulk ferrite. These material properties then are substituted into Eq. (5) to obtain the reflectivity of the ferrite grid.

The reflectivity of the ferrite grid strongly depends on the filling factor g . One of the advantages of this ferrite

Table 1. Data on Ferrite Tiles

Figure 2. Illustration of the grid or waffle ferrite tile geometry.

grid geometry over the standard solid tile is that there is an additional parameter, the filling factor g , that can be varied to place the nulls (or minimum) of the reflectivity at a desired frequency. The ferrite grid can be designed for wider frequency band performance over that of the standard solid tiles by appropriately choosing the tile thickness, filling factor g , and the material properties of the ferrite. Figure 3 shows results of the reflectivity of a ferrite grid for various values of the filling factor g . The optimum reflectivity of an 18-mm thick ferrite grid with a filling factor of $g = 0.725$ was calculated using the material properties in [19]. The results are shown in Fig. 4 for normally and obliquely incident waves.

Small, tapered, electric-absorbing structures boast very low reflectivities above about 200 MHz [3], whereas ferrite tiles perform best below 600 MHz. Hence, compact wideband absorbers can be designed by combining tapered electrical absorbers with ferrite tiles. The reflectivity in the 600 MHz to 1000 MHz range is also reduced by simply adding a dielectric layer between the ferrite and the metal chamber wall. The performance advantages of these so-called “hybrids” are presented in [3].

Figure 3. Reflectivity of a 16 mm ferrite grid for various values of the volume fraction g for an incident angle of 0° .

Figure 4. Reflectivity of a ferrite grid at 0° and 45° incident angles for filling factor $g = 0.725$ and a thickness of $d = 18$ mm (0.71 in).

In the following sections, we discuss how the material properties and the reflectivities of the ferrite tiles are measured.

2. MEASUREMENTS OF MATERIAL PROPERTIES

Accurate measurements of the high-frequency dispersive magnetic properties of ferrite materials are important for optimally designing a ferrite tile absorber. Magnetic loss mechanisms are strongly frequency-dependent and generally behave nonlinearly. At very low frequencies hysteretic effects (or braking forces acting on Bloch walls in motion) dominantly influence magnetic loss. Eddy currents also produce an *apparent* reduction of permeability and an *apparent* increase of magnetic loss tangent associated with attenuation of the magnetic field inside a ferrite material at low frequencies. However this remains small in most ferrite materials with low dielectric loss.

At RF and microwave frequencies, domain wall movement and domain rotation contribute to magnetic loss. The initial permeability spectrum is usually considered to be that part of the permeability spectrum due to domain wall motion. As the RF excitation frequency increases, domain wall rotation no longer fully responds to the excitation. At this point, magnetization does not move in phase with the excitation, and losses occur. Then the real part μ' of the magnetic permeability decreases with increased frequency. The imaginary part, or magnetic loss index μ'' , goes through a broad absorptive relaxation.

One characteristic constant of ferrites is the product $f_0 = |\mu_d^*|f_c$, where $\mu_d^* = \mu'_d - j\mu''_d$ is the demagnetized scalar initial permeability and f_c is the corner frequency above which $|\mu_d^*|$ falls off with frequency as $1/f$. For some polycrystalline ferrites, this product represents the frequency at which the relative permeability becomes 1 [20]. This rule is only a first-order approximation that depends on the spectral overlap of domain wall and domain rotation relaxation phenomena in the ferrite under test. Another characteristic

of ferrite materials is that the peak in the magnetic loss index usually occurs at the frequency where the real permeability has decreased to one-half its static value [21].

Generally, the absorptive window applications of ferrite materials are at frequencies below natural gyromagnetic resonance $\gamma_{gr}M_s$, where M_s is saturation magnetization (T) and γ_{gr} is the gyromagnetic ratio (28 GHz/T or 35.19 MHz · m/kA). At frequencies less than $\gamma_{gr}M_s$, magnetic losses in ferrite materials are high, whereas at frequencies greater than natural gyromagnetic resonance, magnetic losses rapidly decrease. With increasing saturation magnetization, (1) natural gyromagnetic resonance shifts to higher frequencies, (2) f_c increases, and (3) the low-frequency static initial permeability decreases. The absorptive window, similarly, shifts to higher frequencies.

With an applied static magnetic field in the z direction, ferrite materials become uniaxially anisotropic and non-reciprocal, and the magnetic permeability is described by the well-known nondiagonalized tensor

$$\bar{\mu} = \mu_0 \begin{bmatrix} \mu^* & j\kappa^* & 0 \\ -j\kappa^* & \mu^* & 0 \\ 0 & 0 & \mu_z^* \end{bmatrix} \quad (9)$$

where $\mu^* = \mu' - j\mu''$ is the principal direction transverse component of the magnetic permeability, $\mu_z^* = \mu'_z - j\mu''_z$ is the parallel component, and $\kappa^* = \kappa' - j\kappa''$ is the off-diagonal transverse component. All components of the magnetic permeability tensor are complex because of ferrite magnetic losses. Particular tensor components depend on ferrite composition, porosity, grain size, saturation magnetization, and RF frequency, temperature, and applied static magnetic field strength. Near ferromagnetic resonance (with an applied static field) saturated ferrite losses are expressed by the resonance line width. Without an applied static field, the ferrite in the demagnetized state is isotropic and reciprocal. In this case the permeability tensor reduces to the scalar frequency-dependent permeability, $\mu_d^* = \mu'_d - j\mu''_d$.

Regardless of general spectral characteristics, the magnetic properties of ferrite materials must be measured at microwave frequencies. Experimental procedures for accurate magnetic permeability measurements on demagnetized ferrites, therefore, depend spectrally on which side of the natural gyromagnetic resonance the magnetic characterization is desired. At frequencies lower than $\gamma_{gr}M_s$, one-port permeameter and two-port coaxial transmission line measurements provide accurate magnetic permeability characterization of ferrite materials. At microwave frequencies above $\gamma_{gr}M_s$, resonant cavity or dielectric resonator techniques must be used.

2.1. Transmission Line Measurement

The goal of this section is to present transmission line measuring methods for permeability [22]. In the measurement, a sample is inserted into a waveguide or a coaxial line, and the sample is subjected to an incident electromagnetic field. In developing the scattering equations, usually only the fundamental waveguide mode is assumed

to exist. At low frequencies, the impedance of the sample is measured. At microwave frequencies, the two-port scattering matrix is measured. Reflection coefficient and scattering equations are found from an analysis of the magnetic field in the sample holder. Both high- and low-frequency measurements are considered. The first technique, the permeameter, is a low-frequency technique. When lumped circuit parameters (LCR) are used as data, this method is limited to frequencies below 50 MHz. The method is extended to a higher frequency by using reflection coefficient data from a network analyzer. As the operating frequency increases to the point where there is an appreciable electric field in the sample, however, then knowledge of the permittivity is required. The second technique is the transmission line scattering parameter technique. This technique is limited to microwave frequencies, because the measured phase change across the sample becomes inaccurate below 1 MHz. Previous work using the coaxial line for magnetic measurements has been done, for example, by Von Hippel [23], Bussey [24], Geyer and Baker-Jarvis [25], and Hoer [26].

2.1.1. Permeameters. The permeameter consists of a short-circuited coaxial sample holder (see Fig. 5) with a sample on the inner conductor of a coaxial line terminated in a short circuit. The advantages of this approach are the ease of sample installation and the broad frequency capability. An air-gap correction is not necessary for permeability measurements because the magnetic field is tangential to air gaps. In this technique, a LCR meter is used to measure admittance Y in the frequency range of 100 Hz to 1 MHz. Then this admittance is converted to a reflection coefficient by $\Gamma = (Y_0 - Y)/(Y_0 + Y)$, where Y_0 is the admittance without the sample. The reflection coefficient for a sample positioned next to a short-circuited termination is given by

$$\Gamma = \exp[-2(\gamma_a L_a + \gamma_t L_t)] \frac{\tanh(\gamma L) - \frac{\mu_0 \gamma}{\mu \gamma_0}}{\tanh(\gamma L) + \frac{\mu_0 \gamma}{\mu \gamma_0}} \quad (10)$$

where γ is the propagative constant in the material given by

$$\gamma = j \sqrt{\frac{\omega^2 \mu_r^* \epsilon_r^*}{c_{vac}^2} - \left(\frac{2\pi}{\lambda_c}\right)^2} \quad (11)$$

Figure 5. Measurement setup for one-port coaxial line permeameter. Sample resides adjacent to the short circuit.

Also, c_{vac} is the speed of light in a vacuum; L is the sample length, the subscripts a and t denote air-line section in the connector and support bead; λ_c is the cutoff wavelength; and ϵ_0 and μ_0 are the permittivity and permeability of vacuum, respectively, $\epsilon_r^* = \epsilon_r' - j\epsilon_r''$ and $\mu_r^* = \mu_r' - j\mu_r''$ are the complex permittivity and permeability relative to a vacuum, respectively. This equation is useful for both microwave and low-frequency measurements. At low frequencies the permittivity of the sample does not contribute to the determination of permeability. We have shown the frequency limitation for applying the permeability technique is given by

$$f \ll \frac{c}{4\pi\mu L} \quad (12)$$

where c is the speed of light in a vacuum.

2.1.2. Two-Port Permeability and Permittivity Determination. The two-port scattering parameter technique is used from approximately 50 MHz to microwave frequencies and yields both permittivity and permeability (see Fig. 6). The scattering parameters are defined in terms of the reflection coefficient Γ and the transmission coefficient z by

$$S_{11} = R_1^2 \left[\frac{\Gamma(1 - z^2)}{1 - \Gamma^2 z^2} \right] \quad (13)$$

$$S_{22} = R_2^2 \left[\frac{\Gamma(1 - z^2)}{1 - \Gamma^2 z^2} \right] \quad (14)$$

$$S_{21} = R_1 R_2 \left[\frac{z(1 - \Gamma^2)}{1 - \Gamma^2 z^2} \right] \quad (15)$$

and

$$\gamma_0 = j \sqrt{\left(\frac{\omega}{c_{lab}} \right)^2 - \left(\frac{2\pi}{\lambda_{nc}} \right)^2} \quad (16)$$

where γ_0 is the propagation constant in a vacuum, c_{lab} is the speed of light, and ω is the radian frequency.

$$R_1 = \exp(-\gamma_0 L_1) \quad (17)$$

and

$$R_2 = \exp(-\gamma_0 L_2) \quad (18)$$

are the respective reference plane transformations. Equations (13) through (15) are derived in detail by Hoer and

Figure 6. A dielectric sample in a transmission line. Port 1 and Port 2 denote positions of calibration reference planes.

Rasmussen [26]. The transmission coefficient z is expressed as

$$z = \exp(-\gamma L) \quad (19)$$

and the reflection coefficient is defined as

$$\Gamma = \frac{\frac{\mu}{\gamma} - \frac{\mu_0}{\gamma_0}}{\frac{\mu}{\gamma} + \frac{\mu_0}{\gamma_0}} \quad (20)$$

For a coaxial line, the cutoff frequency approaches 0 ($\omega_c \rightarrow 0$).

To obtain both the permittivity and the permeability from the scattering parameter relationships, at least two independent measurements are necessary. In the full scattering parameter solution, a solution of the equations is obtained that is invariant to reference planes for ϵ_r^* and μ_r^* . A set of equations for single-sample magnetic measurements for an air line of length L_{air} is

$$S_{11}S_{22} - S_{21}S_{12} = \exp(-2\gamma_0(L_{air} - L)) \frac{\Gamma^2 - z^2}{1 - \Gamma^2 z^2} \quad (21)$$

and

$$(S_{21} + S_{12})/2 = \exp(-\gamma_0(L_{air} - L)) \frac{z(1 - \Gamma^2)}{1 - \Gamma^2 z^2} \quad (22)$$

It is possible to obtain an explicit solution to Eqs. (21) and (22). If $x = (S_{21}S_{12} - S_{11}S_{22}) \exp[2\gamma_0(L_{air} - L)]$ and $y = [(S_{21} + S_{12})/2] \exp[\gamma_0(L_{air} - L)]$, then the physical roots for the transmission coefficient are given by

$$Z = \frac{x+1}{2y} \pm \sqrt{\left(\frac{x+1}{2y} \right)^2 - 1} \quad (23)$$

and the reflection coefficient is expressed as

$$\Gamma_2 = \pm \sqrt{\frac{x - Z^2}{xZ^2 - 1}} \quad (24)$$

The ambiguity in the \pm sign in Eq. (24) is resolved by considering the reflection coefficient calculated from S_{11} alone:

$$\Gamma_3 = \frac{\alpha(Z^2 - 1) \pm \sqrt{\alpha^2 Z^4 + 2Z^2(2S_{11} - \alpha^2) + \alpha^2}}{2S_{11}Z^2} \quad (25)$$

where $\alpha = \exp(-2\gamma_0 L_1)$. The correct root for Γ_3 is chosen by requiring that $|\Gamma_3| \leq 1$. An estimate of L_1 is needed in Eq. (25). If Γ_2 is compared with Γ_3 , then the \pm sign ambiguity is resolved and therefore Γ_2 is determined. Then the permeability and permittivity are

$$\mu_r^* = -\frac{1 + \Gamma_2}{1 - \Gamma_2} \frac{1}{\gamma_0 L} (\ln Z + 2\pi j n) \quad (26)$$

and

$$\varepsilon_r^* = \frac{c^2}{\omega^2} \left[\left(\frac{2\pi}{\lambda_c} \right)^2 - \frac{1}{L^2} (\ln Z + 2\pi jn)^2 \right] / \mu_r^* \quad (27)$$

where $n = 0, \pm 1, \pm 2, \dots$. The correct value of n is chosen by using a group-delay comparison test. At low frequencies, the correct roots are identified more easily because they are more widely spaced.

Equations (26) and (27) have an infinite number of roots for magnetic materials, because the logarithm of a complex number is multivalued. To choose the correct root, it is necessary to compare the measured group delay with the calculated group delay. The calculated group delay is related to the change of the wave number k with respect to the angular frequency by

$$\tau_{\text{calc.group}} = -L \frac{d}{df} \sqrt{\frac{\varepsilon_r^* \mu_r^* f^2}{c^2} - \frac{1}{\lambda_c^2}} \quad (28)$$

$$= -\frac{1}{c^2} \frac{f \varepsilon_r^* \mu_r^* + f^2 \frac{1}{2} \frac{d(\varepsilon_r^* \mu_r^*)}{df}}{\sqrt{\frac{\varepsilon_r^* \mu_r^* f^2}{c^2} - \frac{1}{\lambda_c^2}}} L \quad (29)$$

The measured group delay is given by

$$\tau_{\text{meas.group}} = \frac{1}{2\pi} \frac{d\phi}{df} \quad (30)$$

where ϕ is the phase of Z . To determine the correct root, the calculated group delays are found from Eq. (29) for various values of n in the logarithm term, where $\ln Z = \ln |Z| + j(\theta + 2\pi n)$. The calculated and measured group delays are compared to yield the correct value of n . When there is no loss in the sample under test, the solution is divergent at integral multiples of one-half wavelength in the sample. This occurs because the phase of S_{11} cannot be measured accurately for small $|S_{11}|$. In the low loss limit, both of the scattering equations reduce to the relationship $Z^2 \rightarrow 1$, which is a relationship only for the phase velocity, and therefore solutions for ε_r^* and μ_r^* are not separable. This singular behavior is minimized in cases where permeability is known a priori, as shown in previous work performed by Baker-Jarvis [22].

A measurement on a ferrite material is given in Fig. 7 using both the permeameter and two-port techniques. This figure indicates that the permeameter method breaks down around 50 MHz.

Figure 7. The measured real part of the permeability using both the permeameter and scattering techniques.

2.2. Dielectric-Resonator Measurements

At frequencies above $\gamma_{gr} M_s$, resonant-cavity [27–31] or dielectric-resonator techniques [32–36] must be used to accurately characterize ferrite magnetic properties. Commonly used fixtures for determining the demagnetized scalar permeability μ_d^* are either a H_{011} mode cavity for measuring one cylindrical sample or a rectangular cavity operating in the TE_{102} mode with a small spherical sample placed at the center [37]. Both of these techniques generally employ perturbation theory, which restricts sample size and, accordingly, allowable magnetic energy partial filling factors and sensitivity to measure small changes in the Q -factor. More recently, Latrach, Le Roux, and Jecko [31] have used a TM_{mn0} cavity for permeability measurements of ferrite disk samples from 2 GHz to 8 GHz. By dielectrically loading the TM_{mn0} cavity, the measured resonant frequency was changed. The method presented here, discussed in more detail in [34–36], uses low-loss H_{011} dielectric resonators, containing the ferrite sample under test, whose complex permittivity is given by $\varepsilon_f^* = \varepsilon_f' - j\varepsilon_f''$. The aspect ratios and permittivities of the dielectric resonators are chosen to spectrally characterize a *single* sample over a broad frequency range. The H_{011} resonant system used in these measurements is illustrated in Fig. 8. The resonators are coupled to the external microwave source through two loop-terminated coaxial cables,

Figure 8. Parallel-plate H_{011} resonant configuration used to measure magnetic permeability.

and these are adjusted so that the measured loaded Q -factor is equal to the unloaded Q -factor within any prescribed accuracy.

Formulations for the electromagnetic fields in a ferrite rod and in coaxial cylindrical dielectric layers surrounding the rod are found in several papers and textbooks [38–52]. At the boundaries between the cylindrical interfaces, the well-known continuity conditions between tangential electric and magnetic field components must be satisfied. At the conductive ground planes, tangential electric fields must vanish. These well-known boundary conditions create a system of linear equations with respect to the constant coefficients in the field expressions, which have nontrivial solutions only if the corresponding determinant vanishes. For fixed values of dimensions and material properties of the resonant system, it is possible to find eigenvalues as roots of the determinant equation. Material properties are determined by measuring resonant frequencies and unloaded Q factors of the dielectric ring resonators with and without the ferrite sample.

The H_{011} resonant frequencies of a ring resonator with a ferrite sample are determined by ϵ'_{rr} , ϵ'_f , and μ'_d , where ϵ'_{rr} is the relative permittivity of the dielectric ring resonator. For ferrite sample diameters less than one-quarter of the external ring resonator diameter, these resonant frequencies are primarily determined by ϵ'_{rr} and μ'_d .

The first step in the measurement process is to verify the complex permittivity of the ferrite sample under test with a TM_{0n0} cavity. Second, the complex permittivities of each dielectric ring resonator are found from measurements of the resonant frequencies and unloaded Q factors of the empty ring resonators operating in the H_{011} mode, given the geometrical dimensions of the resonators and taking into account conductive microwave losses of the upper and lower ground planes. Then values of the imaginary parts of ϵ_f^* and ϵ_r^* are calculated, assuming a linear increase with frequency. Next, the scalar permeability μ'_{db} computed from measurements of the resonant frequency of these resonators, which contain a completely demagnetized sample and operate in the H_{011} mode, is evaluated from the H_{011} eigenvalue equation in determinant form:

$$F(\epsilon'_f, \mu'_d, f_0) = 0 \quad (31)$$

where f_0 is the measured resonant frequency of the H_{011} mode for a resonator containing the demagnetized ferrite sample.

After μ'_d is determined, the imaginary part of the permeability, $\mu''_f = \mu'_f \tan \delta_{m,f}$, is found as a solution to the equation

$$Q^{-1} = Q_c^{-1} + p_{e,r} \tan \delta_{e,r} + p_{e,f} \tan \delta_{e,f} + p_{\mu'_d} \tan \delta_{m,f} \quad (32)$$

where Q is the unloaded Q factor for the H_{011} mode; Q_c is the Q factor representing conductor losses in the metal plates for the H_{011} mode; $p_{e,r}$ is the electric-energy-filling factor for the dielectric ring resonator; $p_{e,f}$, $p_{\mu'_d}$ are the ferrite sample electric- and magnetic-energy-filling factors; $\tan \delta_{e,r}$ and $\tan \delta_{e,f}$ are the dielectric loss tangents of the

Figure 9. Measured relative permeability μ'_d of several aluminum-doped, calcium-vanadium, and yttrium garnet ferrites with $9 \text{ kA/m} \leq M_s \leq 147 \text{ kA/m}$ as a function of frequency.

ring resonator and the ferrite sample under test; and $\tan \delta_{m,f}$ is the magnetic loss tangent of the ferrite.

Typical measurement data for bulk ceramic ferrites by this technique are given in Figs. 9 and 10. Uncertainties in μ'_d for typical dimensional uncertainties in the geometric parameters of the dielectric ring resonators and the ferrite sample under test are estimated to be $\pm 0.8\%$, that is, μ'_d is $\pm 1 \times 10^{-5}$. Combined complex permeability data of two ferrites with differing saturation magnetizations over greater than four frequency decades, where both

Figure 10. Measured relative magnetic loss index μ''_d of several aluminum-doped, calcium-vanadium, and yttrium garnets with $95 \text{ kA/m} \leq M_s \leq 147 \text{ kA/m}$ as a function of frequency.

Figure 11. Combined two-port coaxial transmission line and dielectric resonator relative permeability measurements for yttrium and calcium-vanadium garnet ferrites from 1 MHz to 10 GHz.

two-port coaxial transmission line and dielectric resonator data have been combined, are shown in Figs. 11 and 12. The rapid increase in magnetic loss, as natural gyromagnetic resonance is approached, is clearly seen. In addition, the large differences in nonlinear magnetic loss behavior over a broad frequency range are apparent.

The total attenuative losses of ferrite-tile absorbers should include both the dielectric and magnetic properties of the ferrite materials under examination. For a

Figure 12. Combined two-port coaxial transmission line and dielectric resonator measurements of relative magnetic loss index for yttrium and calcium-vanadium garnet ferrites from 1 MHz to 10 GHz.

plane-wave TEM field, the attenuative loss α is given by

$$\alpha = \frac{\sqrt{2\omega}}{2c} \sqrt{\epsilon_f \mu_f' [(1 + \tan^2 \delta_{e,f})^{1/2} (1 + \tan^2 \delta_{m,f})^{1/2} + \tan \delta_{e,f} \tan \delta_{m,f}]}$$
(33)

where c is the speed of light.

3. REFLECTIVITY MEASUREMENTS

In designing a ferrite absorber that performs well over a selected frequency range, it is important to measure the reflectivity of the absorber for normal and oblique incidence. However, the large test fixtures currently used to characterize an absorber from 30 MHz to 1000 MHz allow measuring reflectivities only at normal incidence [8–11]. Although an arch is used to measure reflectivities at oblique angles, it is useful only at frequencies above approximately 600 MHz [53,54]. An alternative to these techniques is a method under development at the National Institute of Standards and Technology (NIST) in Boulder, CO. This alternative technique uses time-frequency methods to measure reflectivity at arbitrary angles and polarization [55–57].

A block diagram of the bistatic free-space reflectivity measurement system at NIST is depicted in Fig. 13. The measurement system consists of a time- or frequency-domain network analyzer, two TEM horn antennas, and interconnecting RF/microwave cables with a 50 Ω characteristic impedance. More detailed descriptions of time- and frequency-domain versions of this measurement system are given in [55–59]. A rectangular ferrite-tile sample (or metal plate reference) is placed in the plane of the two TEM horn antennas at a distance of 1 to 4 m. The level of the sample center is adjusted to match the antenna aperture centers, and the normal to the sample surface bisects the angle between the two horn antenna apertures. The measurements are performed in an ordinary room (laboratory, warehouse, etc.) or in an absorber-lined chamber (semi- or fully anechoic). To minimize the effects of floor,

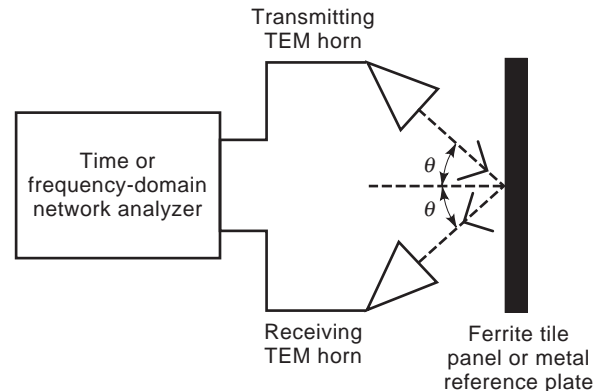

Figure 13. Bistatic free-space RF absorber reflectivity measurement system.

ceiling, and wall reflections, the sample under test should be situated centrally within the room volume.

Obtaining the scattering characteristics of the ferrite tile sample under test requires the following steps:

1. A time-domain waveform is obtained for the ferrite-tile sample under test by placing it close to the TEM horn antennas (typically from 1 to 4 m from the antenna apertures).
2. The sample is removed and a background time-domain waveform is obtained.
3. The waveform of step (2) is subtracted from that of step (1). The resulting waveform consisted of the ferrite-tile sample response plus a component that emanates from the shadow region behind the sample. This process removes significant systematic effects due to antenna-to-antenna coupling and spurious environmental reflections.
4. The shadow-region waveform component is readily eliminated by time-gating, which deletes the undesired waveform component(s). Time-gating works only if there is sufficient separation between the sample and the wall directly behind it, which allows the absorber response to die out before the shadow-region component arrives.
5. Steps (1)–(4) are repeated for a rectangular (or square) metal reference plate. The NIST system employs a 3 m × 3 m metal plate.
6. The time-gated absorber and metal reference plate waveforms obtained in steps (5) and (6) are each Fourier transformed to obtain scattering amplitude spectra.
7. Then the amplitude spectra are divided to obtain the backscatter coefficient which is given by

$$BC(f, \theta) = \frac{|FT(\text{gated absorber waveform})|}{|FT(\text{gated reference waveform})|} \quad (34)$$

where f is the frequency, θ is the angle of incidence, FT denotes the Fourier transform, and BC is the

Figure 14. Gated time-domain metal reference plate waveform.

Figure 15. Gated time-domain ferrite-tile waveform.

backscatter coefficient. The backscatter coefficient is a real, frequency-domain quantity that directly compares the reflection characteristics of the ferrite-tile absorber system under test with that of the metal plate reference signal. The smaller the backscatter coefficient, the better the performance of the ferrite-tile system.

Examples of gated time-domain reference and ferrite-tile-panel waveforms are shown in Figs. 14 and 15, respectively. These waveforms are obtained from a bistatic measurement at a 30° angle of incidence with both the receiving and transmitting antennas horizontally polarized. A synthetic time-domain method is used [59] in which the acquired frequency-domain data are Fourier transformed into time-domain waveforms. The reference waveform of Fig. 14 is obtained from a 3 m × 3 m

Figure 16. Backscatter coefficient results obtained from the waveforms of Figs. 14 and 15 in conjunction with Eq. (34).

metal reference plate, located 3.0 m from the antenna aperture centers. It is interesting to note that the reference waveform is nearly a perfect doublet, a result of the differentiating properties of TEM horns in the transmitting mode [60]. The corresponding waveform obtained for a 2.4 m × 2.4 m ferrite-tile panel backed by a plywood layer and metallic ground plate is depicted in Fig. 15. Reflections from the front and back surfaces of the ferrite tiles produce the initial triplet (5 ns to 7 ns). Wavefront curvature and finite sample size are responsible for the portion of the waveform that occurs after 7 ns. The frequency-domain back-scatter coefficient characteristics from these gated waveforms are depicted in Fig. 16 for a frequency range of 3 MHz to 500 MHz. The characteristic notch that occurs slightly above 300 MHz is a phenomenon typical for ferrite tile systems backed by a ground plane.

4. CONCLUSION

In this article, ferrite tile electromagnetic absorbing materials were discussed. Methods to model performance, measure material properties, and measure the reflectivity of this type of absorbing material were presented. The advantages of the ferrite-tile absorber are that they are small and offer very low reflectivity in the frequency range of 30 MHz to 600 MHz. However, above 600 MHz the performance of these ferrite tiles begins to degrade. Dielectric layers behind the ferrite tiles and tapered electric absorbing structures in front of the tiles are used to improve the high-frequency performance of the ferrites. A discussion on how well these hybrid absorbers work is found in [3]. The next generation of ferrite-tile absorbers, consisting of thin magnetic layers [61–64] and a combination of ferrite layers with chiral materials [3], is currently being developed.

ELECTROMAGNETIC FIELD COMPUTATION IN PLANAR MULTILAYERS

KRZYSZTOF ARKADIUSZ
MICHALSKI
Texas A&M University
College Station, Texas

1. INTRODUCTION

In a variety of applications, such as geophysical prospecting, remote sensing, detection of landmines and unexploded ordnance, noninvasive testing, planning of hyperthermia, modeling of wave propagation in wireless communication, design of microstrip circuits and antennas, modeling of integrated circuit interconnects, characterization of silicon wafer defects, interpretation of near-field scanning optical microscopy, modeling of nano- and extreme-ultraviolet (EUV) lithography, and other emerging technologies, it is necessary to compute electromagnetic fields in planar, layered media. The purpose of this article is to present a succinct yet reasonably complete introduction to this topic. The emphasis is on the development of dyadic Green functions (DGFs), which make it possible to compute the fields due to any configuration of sources. In particular, a complete set of electric and magnetic DGFs is derived for planar, multilayered media, in an efficient and convenient-to-use form, based on a transmission-line equivalent circuit along the axis normal to the stratification. Attention is limited to media with at most uniaxial anisotropy, which, although important in practice, still allow the simple transmission-line representation of the electromagnetic fields. Also, the analysis is restricted to multilayers of infinite lateral extent, although a large part of the presented material can also be adapted for laterally shielded geometries.

2. STATEMENT OF THE PROBLEM

Consider a plane-stratified medium excited by arbitrary electric and magnetic currents (\mathbf{J} , \mathbf{M})¹ occupying a volume V , as illustrated in Fig. 1a. It is desired to determine the resulting electric and magnetic fields (\mathbf{E} , \mathbf{H}) at an arbitrary location \mathbf{r} . Of interest are also the far-zone radiation fields and the fields excited in the multilayer by an obliquely incident plane wave.

We assume that the stratification is perpendicular to the z axis and of infinite lateral extent along x and y . The layers are numbered from 1 to N in the direction of increasing z , where the number of layers N is arbitrary. The n th layer, with interfaces at $z = z_n$ and $z = z_{n+1}$, is filled with a homogeneous, linear, uniaxial medium [1, p. 5], characterized by permittivity and permeability dyadics,²

¹Throughout this article, vectors are denoted by boldface letters, unit vectors are distinguished by carets, and dyadics (i.e., second-rank Cartesian tensors) are denoted by doubly underlined boldface letters.

²A symbol \mathbf{ab} is called a *dyad*, and a sum of dyads is called a *dyadic* [2, App. 3]. A dot product of a dyad and a vector is defined as follows: $\mathbf{ab} \cdot \mathbf{c} = \mathbf{a}(\mathbf{b} \cdot \mathbf{c})$, $\mathbf{c} \cdot \mathbf{ab} = (\mathbf{c} \cdot \mathbf{a})\mathbf{b}$.

$\underline{\underline{\epsilon}}_n$ and $\underline{\underline{\mu}}_n$, respectively. The optical axis of the medium is assumed to be normal to the interfaces. The multilayer may be shielded from below and/or above by plates that present three possible boundary conditions: (1) $\hat{\mathbf{n}} \times \mathbf{E} = Z_s \hat{\mathbf{n}} \times (\hat{\mathbf{n}} \times \mathbf{H})$, where $\hat{\mathbf{n}}$ is the interface normal vector and Z_s is a specified surface impedance; (2) $\hat{\mathbf{n}} \times \mathbf{E} = 0$, which defines a perfect electric conductor (PEC); and (3) $\hat{\mathbf{n}} \times \mathbf{H} = 0$, which defines a perfect magnetic conductor (PMC).

We approach this problem in the frequency domain, which means that all field quantities are phasors evaluated at an implicitly understood radian frequency ω . Once a phasor [e.g., $\mathbf{E}(\mathbf{r})$] is found, the corresponding physical, time-domain field can be obtained by the inverse Fourier transform [3, p. 9]³

$$\begin{aligned} \mathbf{E}(\mathbf{r}, t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathbf{E}(\mathbf{r}) e^{j\omega t} dt \\ &= \Re e \frac{1}{\pi} \int_0^{\infty} \mathbf{E}(\mathbf{r}) e^{j\omega t} dt \end{aligned} \quad (1)$$

Also, we will initially assume that the medium properties may vary along the z direction, which will obviate the use of layer subscripts. Only at a later stage will we restrict the medium to have piecewise-constant parameters along the z axis. Under these assumptions, the fields are governed by Maxwell's equations [4, p. 745]

$$\nabla \times \mathbf{E} = -j\omega \underline{\underline{\mu}}_0 \underline{\underline{\mu}} \cdot \mathbf{H} - \mathbf{M}, \quad (2)$$

$$\nabla \times \mathbf{H} = j\omega \underline{\underline{\epsilon}}_0 \underline{\underline{\epsilon}} \cdot \mathbf{E} + \mathbf{J}$$

where ϵ_0 and μ_0 are the free-space permittivity and permeability, respectively, and where

$$\underline{\underline{\epsilon}} = \underline{\underline{I}}_t \epsilon + \hat{\mathbf{z}} \hat{\mathbf{z}} \epsilon_z, \quad \underline{\underline{\mu}} = \underline{\underline{I}}_t \mu + \hat{\mathbf{z}} \hat{\mathbf{z}} \mu_z \quad (3)$$

In the above, $\underline{\underline{I}}_t = \hat{\mathbf{x}} \hat{\mathbf{x}} + \hat{\mathbf{y}} \hat{\mathbf{y}}$ is the transverse unit dyadic and ϵ and μ denote the transverse, and ϵ_z and μ_z the longitudinal permittivities and permeabilities, respectively, all relative to free space. For lossy media, the dyadics $\underline{\underline{\epsilon}}$ and $\underline{\underline{\mu}}$ become complex-valued.

To solve the problem before us, it will be helpful to introduce the concept of a dyadic Green function (DGF),⁴ as follows. Consider a Hertzian dipole with moment $\mathbf{I}\ell$ placed at \mathbf{r}_0 in a layered medium, as illustrated in Fig. 2. The current density of this point source is given as

$$\mathbf{J}(\mathbf{r}) = \mathbf{I}\ell \delta(\mathbf{r} - \mathbf{r}_0) \quad (4)$$

where δ denotes the Dirac delta function [3, p. 568]. The electric field due to this dipole at any point \mathbf{r} can be

³The $e^{j\omega t}$ time convention adopted here is prevalent in engineering disciplines. In physics, the alternative $e^{-i\omega t}$ convention is almost exclusively employed. The formulas presented here can be converted to that convention by the substitution $j \rightarrow -i$.

⁴Also referred to as *Green's tensor*.

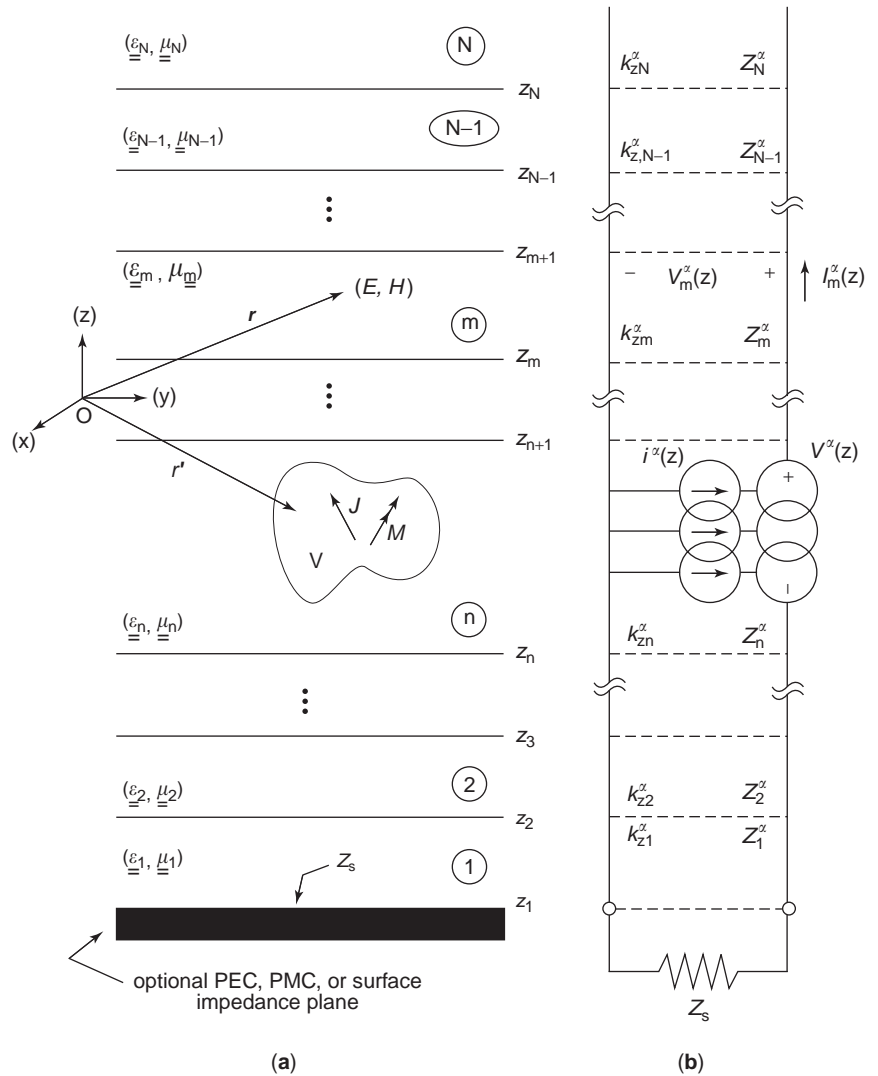

Figure 1. Electric and magnetic currents in a layered medium: (a) physical configuration; (b) transmission-line analog.

Figure 2. Hertzian dipole with moment $I\ell$ located at \mathbf{r}_0 in a layered medium. The field at \mathbf{r} is determined by the dyadic Green function $\underline{\underline{\mathbf{G}}}(\mathbf{r}|\mathbf{r}_0)$ and the orientation and amplitude of the dipole.

expressed as⁵

$$\mathbf{E}(\mathbf{r}) = \underline{\underline{\mathbf{G}}}(\mathbf{r}|\mathbf{r}_0) \cdot I\ell = \langle \underline{\underline{\mathbf{G}}}(\mathbf{r}|\mathbf{r}'); \mathbf{J}(\mathbf{r}') \rangle \quad (5)$$

⁵The notation \langle , \rangle is used for integrals of products of two functions separated by the comma over their common spatial support, with a dot over the comma indicating a dot product. Source coordinates are distinguished by primes.

where $\underline{\underline{\mathbf{G}}}(\mathbf{r}|\mathbf{r}')$ is the (electric) DGF of the layered medium. When expressed in Cartesian coordinates, $\underline{\underline{\mathbf{G}}}(\mathbf{r}|\mathbf{r}')$ can be thought of as a 3×3 matrix, whose columns render the x , y , and z components of the electric field at \mathbf{r} , due to an x -, y -, and z -oriented unit-strength dipole at \mathbf{r}' [2, p. 17]. For example, the x component of $\mathbf{E}(\mathbf{r})$, due to a unit-strength y -oriented dipole at \mathbf{r}' , is given as $G_{xy}(\mathbf{r}|\mathbf{r}') = \hat{\mathbf{x}} \cdot \underline{\underline{\mathbf{G}}}(\mathbf{r}|\mathbf{r}') \cdot \hat{\mathbf{y}}$. The DGF fully characterizes the influence of the layered medium on the field of the dipole. Hence, it rigorously includes all physical effects, such as multiple reflections and transmissions at the interfaces [5].

The DGF concept can be extended in an obvious way to magnetic fields and also to magnetic currents. The magnetic current concept is useful in the modeling of small coils [6], coaxial antenna feeds [7,8], as well as via holes and slots in printed-circuit boards (PCBs) [9,10]. Since we consider linear media, superposition applies,⁶ and the electric and magnetic fields due to arbitrary current

⁶The superposition principle states that, in a linear system, the effect due to an aggregate of causes is the sum of the effects due to all causes taken individually [11, p. 481].

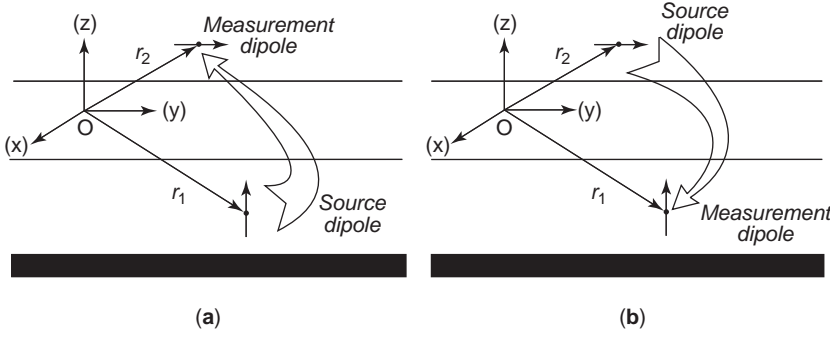

Figure 3. Illustration of reciprocity. The field measurements in situations (a) and (b) are identical.

distributions (\mathbf{J} , \mathbf{M}) may be expressed as

$$\mathbf{E}(\mathbf{r}) = \langle \underline{\underline{\mathbf{G}}}^{EJ}(\mathbf{r}|\mathbf{r}'); \mathbf{J}(\mathbf{r}') \rangle + \langle \underline{\underline{\mathbf{G}}}^{EM}(\mathbf{r}|\mathbf{r}'); \mathbf{M}(\mathbf{r}') \rangle \quad (6)$$

$$\mathbf{H}(\mathbf{r}) = \langle \underline{\underline{\mathbf{G}}}^{HJ}(\mathbf{r}|\mathbf{r}'); \mathbf{J}(\mathbf{r}') \rangle + \langle \underline{\underline{\mathbf{G}}}^{HM}(\mathbf{r}|\mathbf{r}'); \mathbf{M}(\mathbf{r}') \rangle \quad (7)$$

where $\underline{\underline{\mathbf{G}}}^{PQ}(\mathbf{r}|\mathbf{r}')$ is the DGF relating P -type fields at \mathbf{r} and Q -type currents at \mathbf{r}' . In view of the translational symmetry of the medium with respect to the transverse coordinates, these DGFs can also be expressed as

$$\underline{\underline{\mathbf{G}}}^{PQ}(\mathbf{r}|\mathbf{r}') \equiv \underline{\underline{\mathbf{G}}}^{PQ}(\boldsymbol{\rho} - \boldsymbol{\rho}'; z|z') \quad (8)$$

where $\boldsymbol{\rho}$ is the projection of \mathbf{r} on the xy plane. Note that this property does not hold in laterally shielded environments.

Let $(\mathbf{J}_a, \mathbf{M}_a)$ and $(\mathbf{J}_b, \mathbf{M}_b)$ be two separate source distributions, which give rise to the fields $(\mathbf{E}_a, \mathbf{H}_a)$ and $(\mathbf{E}_b, \mathbf{H}_b)$, respectively. From the Maxwell's equations (2), the following reciprocity theorem can be established⁷ [12, p. 50; 13, p. 22]:

$$\langle \mathbf{M}_a; \mathbf{H}_b \rangle - \langle \mathbf{J}_a; \mathbf{E}_b \rangle = \langle \mathbf{M}_b; \mathbf{H}_a \rangle - \langle \mathbf{J}_b; \mathbf{E}_a \rangle \quad (9)$$

By substituting various combinations of dipole sources and their corresponding responses (6) and (7) into the above, the reciprocity properties of the DGFs can be derived. For example, if we postulate $\mathbf{M}_a = \mathbf{J}_b = 0$, $\mathbf{M}_b = \hat{\mathbf{y}} \delta(\mathbf{r} - \mathbf{r}_1)$, and $\mathbf{J}_a = \hat{\mathbf{x}} \delta(\mathbf{r} - \mathbf{r}_2)$, we obtain $G_{xy}^{EM}(\mathbf{r}_2|\mathbf{r}_1) = -G_{yx}^{HJ}(\mathbf{r}_1|\mathbf{r}_2)$. Proceeding in a similar fashion, we can show that

$$\underline{\underline{\mathbf{G}}}^{EJ}(\mathbf{r}|\mathbf{r}') = [\underline{\underline{\mathbf{G}}}^{EJ}(\mathbf{r}'|\mathbf{r})]^T \quad (10)$$

$$\underline{\underline{\mathbf{G}}}^{HM}(\mathbf{r}|\mathbf{r}') = [\underline{\underline{\mathbf{G}}}^{HM}(\mathbf{r}'|\mathbf{r})]^T \quad (11)$$

$$\underline{\underline{\mathbf{G}}}^{EM}(\mathbf{r}|\mathbf{r}') = -[\underline{\underline{\mathbf{G}}}^{HJ}(\mathbf{r}'|\mathbf{r})]^T \quad (12)$$

One important use of reciprocity in electromagnetics is as a check of equations and their computer implementation. For example, from (10) we obtain $G_{yz}^{EJ}(\mathbf{r}_2|\mathbf{r}_1) = G_{zy}^{EJ}(\mathbf{r}_1|\mathbf{r}_2)$,

⁷This holds provided the permittivity and permeability dyadics are symmetric, $\underline{\underline{\boldsymbol{\epsilon}}} = \underline{\underline{\boldsymbol{\epsilon}}}^T$ and $\underline{\underline{\boldsymbol{\mu}}} = \underline{\underline{\boldsymbol{\mu}}}^T$, where the superscript "T" indicates a transposed dyadic. This condition is clearly satisfied for the uniaxial media considered here.

which means that the y component of the electric field "measured" at \mathbf{r}_2 , due to a unit-strength z -oriented dipole at \mathbf{r}_1 , is equal to the z component of the electric field "measured" at \mathbf{r}_1 , due to a y -oriented unit-strength dipole at \mathbf{r}_2 (see Fig. 3). Reciprocity can also be used to obviate some derivations and to reduce the programming effort. For example, we note that in view of (12), $\underline{\underline{\mathbf{G}}}^{EM}$ can be computed from $\underline{\underline{\mathbf{G}}}^{HJ}$.

It should now be clear that the problem stated at the beginning of this section, and illustrated in Fig. 1a, can be reduced to that of finding the four DGFs of the layered medium. In what follows, we will show that these DGFs can be conveniently expressed in terms of the scalar Green functions of the transmission line analogue of the medium, illustrated in Fig. 1b, whose parameters will be defined in due course. This transmission-line equivalent circuit will also prove useful in the derivation of the far-zone radiated fields, as well as the fields excited in the multilayer by an incident plane wave.

3. TRANSMISSION-LINE ANALOG

Let the currents (\mathbf{J}, \mathbf{M}) radiate in a region filled with a medium characterized by z -dependent parameters $\underline{\underline{\boldsymbol{\epsilon}}} = \underline{\underline{\boldsymbol{\epsilon}}}(z)$ and $\underline{\underline{\boldsymbol{\mu}}} = \underline{\underline{\boldsymbol{\mu}}}(z)$, as illustrated in Fig. 4a. For this problem, we will derive a transmission-line equivalent circuit depicted in Fig. 4b. Since the medium is homogeneous and of infinite extent in any transverse (to z) plane, the analysis is facilitated by the Fourier transformation of all fields with respect to the transverse coordinates, defined as follows

$$\mathcal{F}f(\mathbf{r}) \equiv \tilde{f}(\mathbf{k}_\rho; z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(\mathbf{r}) e^{j\mathbf{k}_\rho \cdot \boldsymbol{\rho}} dx dy \quad (13)$$

$$\mathcal{F}^{-1}\tilde{f}(\mathbf{k}_\rho; z) \equiv f(\mathbf{r}) = \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \tilde{f}(\mathbf{k}_\rho; z) e^{-j\mathbf{k}_\rho \cdot \boldsymbol{\rho}} dk_x dk_y \quad (14)$$

where

$$\boldsymbol{\rho} = \hat{\mathbf{x}}x + \hat{\mathbf{y}}y, \quad \mathbf{k}_\rho = \hat{\mathbf{x}}k_x + \hat{\mathbf{y}}k_y \quad (15)$$

Hence, we apply (13) to Maxwell's equations (2), noting that the operator nabla transforms as $\nabla \rightarrow -j\mathbf{k}_\rho + \hat{\mathbf{z}}d/dz$. Furthermore, we separate the transverse and longitudinal

Figure 4. Currents in a uniaxial medium with z -dependent parameters: (a) physical configuration; (b) transmission-line analog.

parts of the resulting equations, to obtain [14]

$$\begin{aligned} \frac{d}{dz} \tilde{\mathbf{E}}_t &= \frac{1}{j\omega\epsilon_0\epsilon} \left(k^2 - \frac{1}{v^e} \mathbf{k}_\rho \mathbf{k}_\rho \cdot \right) (\tilde{\mathbf{H}}_t \times \hat{\mathbf{z}}) \\ &+ \mathbf{k}_\rho \frac{\tilde{\mathbf{J}}_z}{\omega\epsilon_0\epsilon_z} - \tilde{\mathbf{M}}_t \times \hat{\mathbf{z}} \end{aligned} \quad (16)$$

$$\begin{aligned} \frac{d}{dz} \tilde{\mathbf{H}}_t &= \frac{1}{j\omega\mu_0\mu} \left(k^2 - \frac{1}{v^h} \mathbf{k}_\rho \mathbf{k}_\rho \cdot \right) (\hat{\mathbf{z}} \times \tilde{\mathbf{E}}_t) \\ &+ \mathbf{k}_\rho \frac{\tilde{\mathbf{M}}_z}{\omega\mu_0\mu_z} - z \times \tilde{\mathbf{J}}_t \end{aligned} \quad (17)$$

$$-j\omega\epsilon_0\epsilon_z \tilde{\mathbf{E}}_z = j\mathbf{k}_\rho \cdot (\tilde{\mathbf{H}}_t \times \hat{\mathbf{z}}) + \tilde{\mathbf{J}}_z \quad (18)$$

$$-j\omega\mu_0\mu_z \tilde{\mathbf{H}}_z = j\mathbf{k}_\rho \cdot (\hat{\mathbf{z}} \times \tilde{\mathbf{E}}_t) + \tilde{\mathbf{M}}_z \quad (19)$$

where

$$\begin{aligned} k &= k_0 \sqrt{\epsilon\mu}, \\ v^e &= \frac{\epsilon_z}{\epsilon}, \\ v^h &= \frac{\mu_z}{\mu} \end{aligned} \quad (20)$$

and where $k_0 = \omega\sqrt{\mu_0\epsilon_0}$ is the free-space wavenumber, k is the medium wavenumber, and v^e and v^h are the electric and magnetic anisotropy ratios, respectively. It is understood that all media parameters may be z -dependent.

The subsequent analysis is greatly simplified if one defines a spectral-domain coordinate system based on

Figure 5. Spectral-domain coordinate system.

$(\mathbf{k}_\rho, \hat{\mathbf{z}} \times \mathbf{k}_\rho)$, as illustrated in Fig. 5, with the unit vectors $(\hat{\mathbf{u}}, \hat{\mathbf{v}})$ given by [15]

$$\begin{aligned} \hat{\mathbf{u}} &= \frac{\mathbf{k}_\rho}{k_\rho} = \hat{\mathbf{x}} \cos \xi + \hat{\mathbf{y}} \sin \xi, \\ \hat{\mathbf{v}} &= \frac{\hat{\mathbf{z}} \times \mathbf{k}_\rho}{k_\rho} = -\hat{\mathbf{x}} \sin \xi + \hat{\mathbf{y}} \cos \xi \end{aligned} \quad (21)$$

where ξ is the angle the vector \mathbf{k}_ρ makes with the positive x axis and $k_\rho = \sqrt{k_x^2 + k_y^2}$. In this system, the transverse electric and magnetic fields can be expressed as [16,17]

$$\tilde{\mathbf{E}}_t = \hat{\mathbf{u}} V^e + \hat{\mathbf{v}} V^h, \quad \hat{\mathbf{z}} \times \tilde{\mathbf{E}}_t = -\hat{\mathbf{u}} V^h + \hat{\mathbf{v}} V^e \quad (22)$$

$$\tilde{\mathbf{H}}_t \times \hat{\mathbf{z}} = \hat{\mathbf{u}} I^e + \hat{\mathbf{v}} I^h, \quad \tilde{\mathbf{H}}_t = -\hat{\mathbf{u}} I^h + \hat{\mathbf{v}} I^e \quad (23)$$

On substituting this into (16), (17) and projecting the resulting equations on $\hat{\mathbf{u}}$ and $\hat{\mathbf{v}}$, we obtain two sets of transmission-line (TL) equations of the form

$$\begin{aligned} \frac{dV^\alpha}{dz} &= -jk_z^\alpha Z^\alpha I^\alpha + v^\alpha, \\ \frac{dI^\alpha}{dz} &= -jk_z^\alpha Y^\alpha V^\alpha + i^\alpha, \quad \alpha = (e, h) \end{aligned} \quad (24)$$

where

$$k_z^\alpha = \sqrt{k^2 - k_\rho^2 / v^\alpha} \quad (25)$$

$$Z^e = \frac{1}{Y^e} = \frac{k_z^e}{\omega\epsilon_0\epsilon}, \quad Z^h = \frac{1}{Y^h} = \frac{\omega\mu_0\mu}{k_z^h} \quad (26)$$

and where the source functions v^α and i^α are as given in Table 1. Hence, as anticipated by the notation introduced in (22), (23), the components of $\tilde{\mathbf{E}}_t$ and $\tilde{\mathbf{H}}_t$ in the spectral uv plane may be interpreted as voltages and currents⁸ on a transmission-line analog of the medium along the z axis, as illustrated in Fig. 4b. This analog comprises two transmission lines, with z -dependent propagation “constants” k_z^α and characteristic impedances Z^α , where $\alpha = (e, h)$. Since

⁸Note, however, that these “voltages” and “currents” have the units of V/m and A/m, respectively.

Table 1. Transmission-Line Sources in Terms of Field Sources

	$\alpha = e$ (TM)	$\alpha = h$ (TE)
v^x	$\frac{k_\rho}{\omega\epsilon_0\epsilon_z} \tilde{\mathbf{J}}_z - \tilde{\mathbf{M}}_v$	$\tilde{\mathbf{M}}_u$
i^x	$-\tilde{\mathbf{J}}_u$	$-\frac{k_\rho}{\omega\mu_0\mu_z} \tilde{\mathbf{M}}_z - \tilde{\mathbf{J}}_v$

the longitudinal field components may be found from the transverse components and the field sources by means of (18), (19), the original vector problem of Fig. 4a has in effect been reduced to the scalar TL problem of Fig. 4b. In fact, combining (22), (23) and (18), (19), we obtain the complete spectral domain fields as

$$\begin{aligned} \tilde{\mathbf{E}}(\mathbf{k}_\rho; z) = & \hat{\mathbf{u}}V^e(z) + \hat{\mathbf{v}}V^h(z) - \hat{\mathbf{z}} \frac{1}{j\omega\epsilon_0\epsilon_z(z)} \\ & \times [jk_\rho I^e(z) + \tilde{\mathbf{J}}_z(\mathbf{k}_\rho; z)] \end{aligned} \quad (27)$$

$$\begin{aligned} \tilde{\mathbf{H}}(\mathbf{k}_\rho; z) = & -\hat{\mathbf{u}}I^h(z) + \hat{\mathbf{v}}I^e(z) + \hat{\mathbf{z}} \frac{1}{j\omega\mu_0\mu_z(z)} \\ & \times [jk_\rho V^h(z) - \tilde{\mathbf{M}}_z(\mathbf{k}_\rho; z)] \end{aligned} \quad (28)$$

where $V^x(z)$ and $I^x(z)$ implicitly depend on k_ρ (but not on ξ). We observe that, outside the source region, (V^e, I^e) and (V^h, I^h) represent fields that are transverse magnetic (TM) and transverse electric (TE) to z , respectively. We also note from Table 1 that transverse x - or y -directed electric and magnetic currents, always excite both the TM and TE transmission lines, whereas longitudinal z -directed electric (magnetic) currents excite only the TM (TE) transmission line.

The preceding three-dimensional (3D) analysis can be specialized to the two-dimensional (2D) case, where there is a translational symmetry along one of the transverse axes—say, the y axis, and it may be assumed that the scalar components of all fields and sources have the form⁹

$$f(\mathbf{r}) = f_{2D}(x, \beta, z) e^{-j\beta y} \quad (29)$$

where β is a known or sought-after propagation constant [18–22 (Chap. 6 in Ref. 20)]. When (29) is substituted into (13), (14), one obtains

$$\mathcal{F}f(\mathbf{r}) = 2\pi\delta(k_y - \beta) \tilde{f}_{2D}(\mathbf{k}_\rho; z) \quad (30)$$

where

$$\tilde{f}_{2D}(\mathbf{k}_\rho; z) = \int_{-\infty}^{\infty} f_{2D}(x, k_y, z) e^{jk_x x} dx \quad (31)$$

⁹The term 2.5D is occasionally used in this context, with the 2D designation reserved for the $\beta=0$ case.

and

$$f_{2D}(x, k_y, z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{f}_{2D}(\mathbf{k}_\rho; z) e^{-jk_x x} dk_x \quad (32)$$

Hence, the transmission-line analog derived here is still applicable in 2D, with the understanding that the two-dimensional Fourier transform pair should be replaced by the one-dimensional transforms (31), (32), with $k_y = \beta$.

4. TRANSMISSION-LINE GREEN FUNCTIONS

To find the transmission-line voltages and currents appearing in (27), (28), it will be helpful to introduce transmission-line Green functions (TLGFs) as the voltages and currents excited by unit-strength impulsive sources. Hence, let $V_i(z|z')$ and $I_i(z|z')$ denote, respectively, the voltage and current at z , due to a 1-A shunt current source at z' , and let $V_v(z|z')$ and $I_v(z|z')$ denote, respectively, the voltage and current at z , due to a 1-V series voltage source at z' , as illustrated in Fig. 6.¹⁰ It then follows from (24) that the so-defined TLGFs satisfy the equations

$$\frac{dV_i}{dz} = -jk_z Z I_i, \quad \frac{dI_i}{dz} = -jk_z Y V_i + \delta(z - z') \quad (33)$$

$$\frac{dV_v}{dz} = -jk_z Z I_v + \delta(z - z'), \quad \frac{dI_v}{dz} = -jk_z Y V_v \quad (34)$$

In view of the linearity of the TL equations (24), we can use superposition¹¹ to express V and I at any point z as

$$V(z) = \langle V_i(z|z'), i(z') \rangle + \langle V_v(z|z'), v(z') \rangle \quad (35)$$

$$I(z) = \langle I_i(z|z'), i(z') \rangle + \langle I_v(z|z'), v(z') \rangle \quad (36)$$

The complete analogy with (6), (7) should be noted.

Let (v_a, i_a) and (v_b, i_b) be two separate TL source distributions, which give rise to (V_a, I_a) and (V_b, I_b) , respectively. Since both sets satisfy the TL equations (24) subject to the same boundary conditions, it can be shown that [4; p. 194; 24, p. 147]

$$\langle v_a, I_b \rangle - \langle i_a, V_b \rangle = \langle v_b, I_a \rangle - \langle i_b, V_a \rangle \quad (37)$$

which is the transmission-line counterpart of the reciprocity theorem (9). By substituting various combinations of point sources and their corresponding responses (35), (36) into the above, it is found that the TLGFs possess the re-

¹⁰Here and throughout this article, we omit the superscript α , whenever the equations apply to both the TM and TE transmission lines.

¹¹The principle of superposition for linear networks can be stated as follows. The response due to several independent voltage and current sources is equal to the sum of the responses due to each independent source acting alone, that is, with all other independent sources made inoperative. In the case of distributed sources, the sums become integrals [23, p. 63].

Figure 6. Network problems for determination of transmission-line Green functions: (a) current source excitation; (b) voltage source excitation.

reciprocity properties

$$\begin{aligned} V_i(z|z') &= V_i(z'|z), \quad I_v(z|z') = I_v(z'|z), \\ V_v(z|z') &= -I_i(z'|z) \end{aligned} \quad (38)$$

which are the transmission-line counterparts of (10)–(12).

The TL equations (33), (34) give rise to second-order differential equations of the Sturm–Liouville type [4, p. 278; 25, p. 53; 26, p. 291]. For example, equations (33) imply

$$\left[\frac{d}{dz} \mathcal{P}(z) \frac{d}{dz} - \mathcal{Q}(z) \right] V_i(z|z') = -\delta(z - z') \quad (39)$$

with

$$I_i(z|z') = -\mathcal{P} \frac{d}{dz} V_i(z|z') \quad (40)$$

where we have introduced the notation

$$\mathcal{P} = \frac{1}{jk_z Z}, \quad \mathcal{Q} = \frac{jk_z}{Z} \quad (41)$$

Assuming that the solution domain is restricted to $z_n \leq z \leq z_{n+1}$, to correspond to the n th layer in Fig. 1, we impose the boundary conditions

$$\left(\frac{V_i}{I_i} \right)_{z=z_n} = -\overleftarrow{Z}_n, \quad \left(\frac{V_i}{I_i} \right)_{z=z_{n+1}} = \overrightarrow{Z}_n \quad (42)$$

where \overleftarrow{Z}_n and \overrightarrow{Z}_n denote the “left-looking” and “right-looking” impedances at z_n and z_{n+1} , respectively. Let $\overleftarrow{V}(z)$ and $\overrightarrow{V}(z)$ be two homogeneous solutions of (39) that satisfy the boundary conditions at the left and at the right ends of the solution domain, respectively. Then, the solution of (39), subject to (42), can be found as

$$V_i(z|z') = \frac{\overleftarrow{V}(z_<) \overrightarrow{V}(z_>)}{-\mathcal{P} W(\overleftarrow{V}, \overrightarrow{V})} \quad (43)$$

where $z_< = \min(z, z')$, $z_> = \max(z, z')$, and where

$$W(\overleftarrow{V}, \overrightarrow{V}) = \overleftarrow{V} \frac{d\overrightarrow{V}}{dz} - \overrightarrow{V} \frac{d\overleftarrow{V}}{dz} \quad (44)$$

is the Wronskian determinant. It can be shown that the denominator in (43), which is referred to as the *conjugant*, is

independent of z . The solution of (34) follows by a dual procedure, in which voltages are replaced by currents, impedances by admittances, and vice versa.¹²

The simple and elegant result (43) clearly depends on the availability of the homogeneous solutions $\overleftarrow{V}(z)$ and $\overrightarrow{V}(z)$ in an analytical closed form. In Section 7, we derive such solutions for the most practically important case of piecewise homogeneous media.

5. SPECTRAL-DOMAIN DYADIC GREEN FUNCTIONS

On substituting (35), (36) into (27), (28) and referring to Table 1, one obtains, after some simple transformations, the spectral domain counterparts of (6), (7), specifically

$$\begin{aligned} \tilde{\underline{\underline{E}}}(\mathbf{k}_\rho; z) &= \langle \tilde{\underline{\underline{G}}}^{EJ}(\mathbf{k}_\rho; z|z'); \tilde{\underline{\underline{J}}}(\mathbf{k}_\rho; z') \rangle \\ &+ \langle \tilde{\underline{\underline{G}}}^{EM}(\mathbf{k}_\rho; z|z'); \tilde{\underline{\underline{M}}}(\mathbf{k}_\rho; z') \rangle \end{aligned} \quad (45)$$

$$\begin{aligned} \tilde{\underline{\underline{H}}}(\mathbf{k}_\rho; z) &= \langle \tilde{\underline{\underline{G}}}^{HJ}(\mathbf{k}_\rho; z|z'); \tilde{\underline{\underline{J}}}(\mathbf{k}_\rho; z') \rangle \\ &+ \langle \tilde{\underline{\underline{G}}}^{HM}(\mathbf{k}_\rho; z|z'); \tilde{\underline{\underline{M}}}(\mathbf{k}_\rho; z') \rangle \end{aligned} \quad (46)$$

with the spectral DGFs given as¹³

$$\begin{aligned} \tilde{\underline{\underline{G}}}^{EJ}(\mathbf{k}_\rho; z|z') &= -\hat{\mathbf{u}}\hat{\mathbf{u}}V_i^e - \hat{\mathbf{v}}\hat{\mathbf{v}}V_i^h + \hat{\mathbf{z}}\hat{\mathbf{u}} \frac{k_\rho}{\omega\epsilon_0\epsilon_z} I_i^e \\ &+ \hat{\mathbf{u}}\hat{\mathbf{z}} \frac{k_\rho}{\omega\epsilon_0\epsilon'_z} V_v^e + \hat{\mathbf{z}}\hat{\mathbf{z}} \frac{1}{j\omega\epsilon_0\epsilon'_z} \\ &\times \left[\frac{k_\rho^2}{j\omega\epsilon_0\epsilon_z} I_v^e - \delta(z - z') \right] \end{aligned} \quad (47)$$

$$\begin{aligned} \tilde{\underline{\underline{G}}}^{EM}(\mathbf{k}_\rho; z|z') &= -\hat{\mathbf{u}}\hat{\mathbf{v}}V_v^e + \hat{\mathbf{v}}\hat{\mathbf{u}}V_v^h + \hat{\mathbf{z}}\hat{\mathbf{v}} \frac{k_\rho}{\omega\epsilon_0\epsilon_z} I_v^e \\ &- \hat{\mathbf{v}}\hat{\mathbf{z}} \frac{k_\rho}{\omega\mu_0\mu'_z} V_i^h \end{aligned} \quad (48)$$

¹²Two equations of the same mathematical form are called *dual equations*, and quantities occupying the same position in dual equations are called *dual quantities*. When two equations are duals of each other, a systematic interchange of symbols changes the first equation into the second, and vice versa [27, p. 98].

¹³It is understood that the TLGFs in these equations depend on z and z' , such as $V_i^e = V_i^e(z|z')$, and also (implicitly) on k_ρ .

Figure 7. Coax-excited half-space medium: (a) computational model showing an equivalent magnetic surface current over a shorted-circuited annular aperture; (b) spectral-domain transmission-line equivalent circuit.

$$\begin{aligned} \underline{\tilde{\mathbf{G}}}^{HJ}(\mathbf{k}_\rho; z|z') &= \hat{\mathbf{u}}\hat{\mathbf{u}}I_i^h - \hat{\mathbf{v}}\hat{\mathbf{v}}I_i^e \\ &\quad - \hat{\mathbf{z}}\hat{\mathbf{v}}\frac{k_\rho}{\omega\mu_0\mu_z}V_i^h + \hat{\mathbf{v}}\hat{\mathbf{z}}\frac{k_\rho}{\omega\epsilon_0\epsilon'_z}I_v^e \end{aligned} \quad (49)$$

$$\begin{aligned} \underline{\tilde{\mathbf{G}}}^{HM}(\mathbf{k}_\rho; z|z') &= -\hat{\mathbf{u}}\hat{\mathbf{u}}I_v^h - \hat{\mathbf{v}}\hat{\mathbf{v}}I_v^e + \hat{\mathbf{z}}\hat{\mathbf{u}}\frac{k_\rho}{\omega\mu_0\mu_z}V_v^h \\ &\quad + \hat{\mathbf{u}}\hat{\mathbf{z}}\frac{k_\rho}{\omega\mu_0\mu'_z}I_i^h + \hat{\mathbf{z}}\hat{\mathbf{v}}\frac{1}{j\omega\mu_0\mu'_z} \\ &\quad \times \left[\frac{k_\rho^2}{j\omega\mu_0\mu_z}V_i^h - \delta(z-z') \right] \end{aligned} \quad (50)$$

where the primed and unprimed media parameters are evaluated at z' and z , respectively. It can readily be confirmed, using (38), that these DGFs possess the reciprocity properties

$$\underline{\tilde{\mathbf{G}}}^{EJ}(\mathbf{k}_\rho; z|z') = [\underline{\tilde{\mathbf{G}}}^{EJ}(-\mathbf{k}_\rho; z'|z)]^T \quad (51)$$

$$\underline{\tilde{\mathbf{G}}}^{HM}(\mathbf{k}_\rho; z|z') = [\underline{\tilde{\mathbf{G}}}^{HM}(-\mathbf{k}_\rho; z'|z)]^T \quad (52)$$

$$\underline{\tilde{\mathbf{G}}}^{EM}(\mathbf{k}_\rho; z|z') = -[\underline{\tilde{\mathbf{G}}}^{HJ}(-\mathbf{k}_\rho; z'|z)]^T \quad (53)$$

which are the counterparts of the spatial-domain relations (10)–(12).

The spectral-domain electric DGF (47) has been widely used in the analysis of planar microstrip antennas, resonators, and transmission lines by the spectral-domain approach (SDA) [16,28–33]. For planar circuits with infinitesimal metallization thickness, only the transverse part of $\underline{\tilde{\mathbf{G}}}^{EJ}$ is needed. This transverse dyadic, which has a

particularly simple form, can also be expressed as [34]

$$\begin{aligned} -\underline{\tilde{\mathbf{G}}}^{EJ}(\mathbf{k}_\rho; z|z') &= \underline{\mathbf{I}}_{\underline{\mathbf{t}}}V_i^h + \hat{\mathbf{u}}\hat{\mathbf{u}}(V_i^e - V_i^h) \\ &= \frac{1}{2}\underline{\mathbf{I}}_{\underline{\mathbf{t}}}(V_i^e + V_i^h) + \frac{1}{2}(2\hat{\mathbf{u}}\hat{\mathbf{u}} - \underline{\mathbf{I}}_{\underline{\mathbf{t}}})(V_i^e - V_i^h) \end{aligned} \quad (54)$$

where we have used the fact that $\underline{\mathbf{I}}_{\underline{\mathbf{t}}} = \hat{\mathbf{u}}\hat{\mathbf{u}} + \hat{\mathbf{v}}\hat{\mathbf{v}}$.

To demonstrate the application of the SDA, consider a half-space medium excited by a coaxial transmission line opening into a PEC flange at $z = z_1$, as illustrated in Fig. 7. The medium may be uniaxial, with z -dependent permittivity and permeability dyadics. It is desired to find the electric and magnetic fields in the half-space, assuming that the coax (coaxial TL) propagates the dominant TEM mode. This problem, which is relevant to coaxial feeds for microstrip antennas, PCB vias, and noninvasive testing, will also serve to introduce some results and notation needed in the subsequent development. We assume, without loss of generality, that the coax is concentric with the z axis. The field for $z > z_1$ can be found from the equivalent problem depicted in Fig. 7a, where the annular coax aperture has been short-circuited and covered by an equivalent magnetic surface current $\mathbf{M}_S = \mathbf{E}^a \times \hat{\mathbf{z}}$, where \mathbf{E}^a is the aperture electric field in the original problem. Although \mathbf{E}^a is not known, its distribution may be approximated by that existing in the cross section of an infinite coax, which results in the azimuthally oriented “frill current” [27, p. 112]

$$\mathbf{M}_S(\rho) = \hat{\boldsymbol{\phi}}\frac{K}{\rho}, \quad a < \rho < b, \quad z = z_1 \quad (55)$$

with $K = -V_c/\log(b/a)$, where V_c is the voltage at the mouth of the coax.¹⁴ Noting that the corresponding volume current density is $\mathbf{M}(\mathbf{r}) = \mathbf{M}_S(\rho)\delta(z - z_1)$, we may use

¹⁴We will assume that V_c is known, although this seldom is the case. In general, one must resort to numerical techniques to determine the aperture field [35].

(6) and (8) to express the electric field in the half-space as

$$\begin{aligned} \mathbf{E}(\mathbf{r}) &= \langle \underline{\mathbf{G}}^{EM}(\boldsymbol{\rho} - \boldsymbol{\rho}'; z|z_1); \mathbf{M}_S(\boldsymbol{\rho}') \rangle \\ &= \mathcal{F}^{-1} \{ \underline{\tilde{\mathbf{G}}}^{EM}(\mathbf{k}_\rho; z|z_1) \cdot \tilde{\mathbf{M}}_S(\mathbf{k}_\rho) \} \end{aligned} \quad (56)$$

where the second equality on the right side is the result of the well-known fact that a spatial-domain convolution of two functions corresponds to a product of their transforms in the spectral domain [36, p. 23]. Similarly, the magnetic field may be expressed as

$$\begin{aligned} \mathbf{H}(\mathbf{r}) &= \langle \underline{\mathbf{G}}^{HM}(\boldsymbol{\rho} - \boldsymbol{\rho}'; z|z_1); \mathbf{M}_S(\boldsymbol{\rho}') \rangle \\ &= \mathcal{F}^{-1} \{ \underline{\tilde{\mathbf{G}}}^{HM}(\mathbf{k}_\rho; z|z_1) \cdot \tilde{\mathbf{M}}_S(\mathbf{k}_\rho) \} \end{aligned} \quad (57)$$

To find the spectral-domain magnetic current density $\tilde{\mathbf{M}}_S$, we apply the Fourier transformation (13) to (55). The integration is facilitated by changing to polar coordinates in both domains, namely, $(x, y) \rightarrow (\rho, \varphi)$ and $(k_x, k_y) \rightarrow (k_\rho, \zeta)$, and invoking an integral representation of the Bessel function of order n

$$J_n(z) = \frac{(\pm j)^n}{2\pi} \int_{-\pi}^{\pi} e^{\mp j[z \cos(\varphi - \vartheta) + n(\varphi - \vartheta)]} d\varphi \quad (58)$$

where ϑ is an arbitrary angle [37, p. 106].¹⁵ From (58), we derive the formula

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{\cos}{\sin} n\varphi e^{jk_\rho \rho \cos(\varphi - \zeta)} d\varphi = j^n J_n(k_\rho \rho) \frac{\cos}{\sin} n\zeta \quad (59)$$

and apply it to evaluate the φ integral in a closed form. The ρ integration is also evaluated in a closed form,¹⁶ with the final result

$$\tilde{\mathbf{M}}_S(\mathbf{k}_\rho) = \hat{\mathbf{v}} 2\pi j \frac{K}{k_\rho} \underbrace{[J_0(k_\rho a) - J_0(k_\rho b)]}_{\varpi(k_\rho)} \equiv \hat{\mathbf{v}} \tilde{\mathbf{M}}_S(k_\rho) \quad (60)$$

where $\hat{\mathbf{v}}$ is the unit vector defined in (21). Note that, as evident from Table 1, this source excites only the TM transmission line, as illustrated in Fig. 7b, where $v^e = -\tilde{\mathbf{M}}_S$. Finally, we substitute (60) together with (48) and (50) into (56), (57) and apply the inverse Fourier transformation (14) to obtain the desired electric and magnetic fields. The ζ integrals are evaluated in closed forms by means of the formula

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{\cos}{\sin} n\zeta e^{-jk_\rho \rho \cos(\zeta - \varphi)} d\zeta = (-j)^n J_n(k_\rho \rho) \frac{\cos}{\sin} n\varphi \quad (61)$$

¹⁵This formula is also valid with n in the exponent of the integrand changed to $-n$, which can be confirmed by using the relationship $J_{-n}(z) = (-1)^n J_n(z)$ [38, p. 358]. Also, in view of the periodicity of the integrand, the limits of integration can be changed to any 2π range.

¹⁶This is done by invoking the formula $J_1(z) = -J_0'(z)$ [38, p. 361].

which can also be derived from (58). As a result, the non-zero field components are found as [8]

$$E_\rho(\mathbf{r}) = -2\pi K \mathcal{S}_1 \left\{ \frac{\varpi(k_\rho)}{k_\rho} V_v^e(z|z_1) \right\} \quad (62)$$

$$E_z(\mathbf{r}) = 2\pi K \frac{jn_1}{k_1 v_1^e} \mathcal{S}_0 \{ \varpi(k_\rho) I_v^e(z|z_1) \} \quad (63)$$

$$H_\varphi(\mathbf{r}) = -2\pi K \mathcal{S}_1 \left\{ \frac{\varpi(k_\rho)}{k_\rho} I_v^e(z|z_1) \right\} \quad (64)$$

with the notation

$$\begin{aligned} \mathcal{S}_n \{ \tilde{f}(k_\rho) \} &= \frac{1}{2\pi} \int_0^\infty \tilde{f}(k_\rho) J_n(k_\rho \rho) k_\rho dk_\rho \\ &= \frac{1}{4\pi} \int_{\infty e^{-j\pi}}^{\infty} \tilde{f}(k_\rho) H_n^{(2)}(k_\rho \rho) k_\rho dk_\rho \end{aligned} \quad (65)$$

where $H_n^{(2)}$ is the Hankel function of the second kind and order n .¹⁷ The integrals in (65) are recognized as Hankel (or Fourier-Bessel) transforms, but in the electromagnetics community they are generally known as *Sommerfeld integrals* [40,41]. The real-axis integration paths in (65) must be properly indented around the singularities of $\tilde{f}(k_\rho)$, as discussed in Section 8. Note that (62)–(64) can be used, in particular, when the upper half-space in Fig. 7 is a layered medium with piecewise constant parameters. The TLGFs for this case are derived in Section 7.

6. SPATIAL-DOMAIN DYADIC GREEN FUNCTIONS

The spatial-domain counterparts of (47)–(50) are obtained by the Fourier inversion

$$\underline{\mathbf{G}}^{PQ}(\boldsymbol{\rho}; z|z') = \mathcal{F}^{-1} \underline{\tilde{\mathbf{G}}}^{PQ}(\mathbf{k}_\rho; z|z') \quad (66)$$

which is performed by first projecting the unit vectors $(\hat{\mathbf{u}}, \hat{\mathbf{v}})$ on the xy coordinate system via (21) and then applying the transformation (14). Since all spectral integrands are of the form $\sin(n\zeta)\tilde{f}(k_\rho)$ or $\cos(n\zeta)\tilde{f}(k_\rho)$, with $n = 0, 1, \text{ or } 2$, the integration is facilitated by changing to polar coordinates in both domains and using the formula

$$\mathcal{F}^{-1} \left\{ \frac{\cos}{\sin} n\zeta \tilde{f}(k_\rho) \right\} = (-j)^n \frac{\cos}{\sin} n\varphi \mathcal{S}_n \{ \tilde{f}(k_\rho) \} \quad (67)$$

which follows from (61) and (65). We note that the second-order Hankel transforms in (67) can be expressed as

$$\mathcal{S}_2 \{ \tilde{f}(k_\rho) \} = \frac{2}{\rho} \mathcal{S}_1 \left\{ \frac{\tilde{f}(k_\rho)}{k_\rho} \right\} - \mathcal{S}_0 \{ \tilde{f}(k_\rho) \} \quad (68)$$

¹⁷The second integral form in [65] can be derived from the first by using the formulas $J_n(z) = \frac{1}{2}[H_n^{(1)}(z) + H_n^{(2)}(z)]$ and $H_n^{(1)}(ze^{j\pi}) = -e^{-jn\pi} H_n^{(2)}(z)$ [3, p. 453; 39, p. 231], under the assumption that the integrand functions $\tilde{f}(k_\rho)$ are even (odd) in k_ρ for even (odd) n .

Hence only the Hankel transforms of orders 0 and 1 are needed.¹⁸ Using (67), (68) in (66), we obtain the non-zero Cartesian components of the space-domain DGFs as

$$G_{xx}^{EJ}(\rho; z|z') = -\cos^2 \varphi \mathcal{S}_0\{V_i^e\} - \sin^2 \varphi \mathcal{S}_0\{V_i^h\} + \frac{\cos 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{V_i^e - V_i^h}{k_\rho}\right\} \quad (69)$$

$$G_{xx}^{EJ}(\rho; z|z') = G_{yx}^{EJ}(\rho; z|z') = -\frac{\sin 2\varphi}{2} \mathcal{S}_0\{V_i^e - V_i^h\} + \frac{\sin 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{V_i^e - V_i^h}{k_\rho}\right\} \quad (70)$$

$$G_{xz}^{EJ}(\rho; z|z') = \frac{\eta_0}{jk_0 \epsilon'_z} \cos \varphi \mathcal{S}_1\{k_\rho V_v^e\} \quad (71)$$

$$G_{yy}^{EJ}(\rho; z|z') = -\sin^2 \varphi \mathcal{S}_0\{V_i^e\} - \cos^2 \varphi \mathcal{S}_0\{V_i^h\} - \frac{\cos 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{V_i^e - V_i^h}{k_\rho}\right\} \quad (72)$$

$$G_{yz}^{EJ}(\rho; z|z') = \frac{\eta_0}{jk_0 \epsilon'_z} \sin \varphi \mathcal{S}_1\{k_\rho V_v^e\} \quad (73)$$

$$G_{zx}^{EJ}(\rho; z|z') = \frac{\eta_0}{jk_0 \epsilon_z} \cos \varphi \mathcal{S}_1\{k_\rho I_i^e\} \quad (74)$$

$$G_{zy}^{EJ}(\rho; z|z') = \frac{\eta_0}{jk_0 \epsilon_z} \sin \varphi \mathcal{S}_1\{k_\rho I_i^e\} \quad (75)$$

$$G_{zz}^{EJ}(\rho; z|z') = -\frac{\eta_0^2}{k_0^2 \epsilon_z \epsilon'_z} \mathcal{S}_0\{k_\rho^2 I_v^e\} - \frac{\eta_0}{jk_0 \epsilon_z} \delta(\rho) \delta(z - z') \quad (76)$$

$$G_{xx}^{EM}(\rho; z|z') = -G_{yy}^{EM}(\rho; z|z') = \frac{\sin 2\varphi}{2} \mathcal{S}_0\{V_v^e - V_v^h\} - \frac{\sin 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{V_v^e - V_v^h}{k_\rho}\right\} \quad (77)$$

$$G_{xy}^{EM}(\rho; z|z') = -\cos^2 \varphi \mathcal{S}_0\{V_v^e\} - \sin^2 \varphi \mathcal{S}_0\{V_v^h\} + \frac{\cos 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{V_v^e - V_v^h}{k_\rho}\right\} \quad (78)$$

$$G_{xz}^{EM}(\rho; z|z') = \frac{1}{jk_0 \eta_0 \mu'_z} \sin \varphi \mathcal{S}_1\{k_\rho V_i^h\} \quad (79)$$

$$G_{yx}^{EM}(\rho; z|z') = \sin^2 \varphi \mathcal{S}_0\{V_v^e\} + \cos^2 \varphi \mathcal{S}_0\{V_v^h\} + \frac{\cos 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{V_v^e - V_v^h}{k_\rho}\right\} \quad (80)$$

$$G_{yz}^{EM}(\rho; z|z') = -\frac{1}{jk_0 \eta_0 \mu'_z} \cos \varphi \mathcal{S}_1\{k_\rho V_i^h\} \quad (81)$$

$$G_{zx}^{EM}(\rho; z|z') = -\frac{\eta_0}{jk_0 \epsilon_z} \sin \varphi \mathcal{S}_1\{k_\rho I_v^e\} \quad (82)$$

$$G_{zy}^{EM}(\rho; z|z') = \frac{\eta_0}{jk_0 \epsilon_z} \cos \varphi \mathcal{S}_1\{k_\rho I_v^e\} \quad (83)$$

$$G_{xx}^{HJ}(\rho; z|z') = -G_{yy}^{HJ}(\rho; z|z') = -\frac{\sin 2\varphi}{2} \mathcal{S}_0\{I_i^h - I_i^e\} + \frac{\sin 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{I_i^h - I_i^e}{k_\rho}\right\} \quad (84)$$

$$G_{xy}^{HJ}(\rho; z|z') = \cos^2 \varphi \mathcal{S}_0\{I_i^h\} + \sin^2 \varphi \mathcal{S}_0\{I_i^e\} - \frac{\cos 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{I_i^h - I_i^e}{k_\rho}\right\} \quad (85)$$

$$G_{xz}^{HJ}(\rho; z|z') = -\frac{\eta_0}{jk_0 \epsilon'_z} \sin \varphi \mathcal{S}_1\{k_\rho I_v^e\} \quad (86)$$

$$G_{yx}^{HJ}(\rho; z|z') = -\sin^2 \varphi \mathcal{S}_0\{I_i^h\} - \cos^2 \varphi \mathcal{S}_0\{I_i^e\} - \frac{\cos 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{I_i^h - I_i^e}{k_\rho}\right\} \quad (87)$$

$$G_{yz}^{HJ}(\rho; z|z') = \frac{\eta_0}{jk_0 \epsilon'_z} \cos \varphi \mathcal{S}_1\{k_\rho I_v^e\} \quad (88)$$

$$G_{zx}^{HJ}(\rho; z|z') = \frac{1}{jk_0 \eta_0 \mu_z} \sin \varphi \mathcal{S}_1\{k_\rho V_i^h\} \quad (89)$$

$$G_{zy}^{HJ}(\rho; z|z') = -\frac{1}{jk_0 \eta_0 \mu_z} \cos \varphi \mathcal{S}_1\{k_\rho V_i^h\} \quad (90)$$

$$G_{xx}^{HM}(\rho; z|z') = -\cos^2 \varphi \mathcal{S}_0\{I_v^h\} - \sin^2 \varphi \mathcal{S}_0\{I_v^e\} + \frac{\cos 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{I_v^h - I_v^e}{k_\rho}\right\} \quad (91)$$

$$G_{xy}^{HM}(\rho; z|z') = G_{yx}^{HM}(\rho; z|z') = -\frac{\sin 2\varphi}{2} \mathcal{S}_0\{I_v^h - I_v^e\} + \frac{\sin 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{I_v^h - I_v^e}{k_\rho}\right\} \quad (92)$$

$$G_{xz}^{HM}(\rho; z|z') = \frac{1}{jk_0 \eta_0 \mu'_z} \cos \varphi \mathcal{S}_1\{k_\rho I_i^h\} \quad (93)$$

$$G_{yx}^{HM}(\rho; z|z') = -\sin^2 \varphi \mathcal{S}_0\{I_v^h\} - \cos^2 \varphi \mathcal{S}_0\{I_v^e\} - \frac{\cos 2\varphi}{\rho} \mathcal{S}_1\left\{\frac{I_v^h - I_v^e}{k_\rho}\right\} \quad (94)$$

$$G_{yz}^{HM}(\rho; z|z') = \frac{1}{jk_0 \eta_0 \mu'_z} \sin \varphi \mathcal{S}_1\{k_\rho I_i^h\} \quad (95)$$

$$G_{zx}^{HM}(\rho; z|z') = \frac{1}{jk_0 \eta_0 \mu_z} \cos \varphi \mathcal{S}_1\{k_\rho V_i^h\} \quad (96)$$

¹⁸This follows from the recurrence relation $J_{n+1}(z) = (2n/z)J_n(z) - J_{n-1}(z)$ [38, p. 361].

$$G_{zy}^{HM}(\rho; z|z') = \frac{1}{jk_0\eta_0\mu_z} \sin \varphi \mathcal{S}_1\{k_\rho V_v^h\} \quad (97)$$

$$G_{zz}^{HM}(\rho; z|z') = -\frac{1}{k_0^2\eta_0^2\mu_z\mu'_z} \mathcal{S}_0\{k_\rho^2 V_i^h\} - \frac{1}{jk_0\eta_0\mu_z} \delta(\rho)\delta(z-z') \quad (98)$$

where $\eta_0 = \sqrt{\mu_0/\epsilon_0}$ denotes the intrinsic impedance of free space. Although these expressions are given for source points on the z axis, they are readily generalized by the substitutions $x \rightarrow (x-x')$, $y \rightarrow (y-y')$, and

$$\rho \rightarrow \varrho = \sqrt{(x-x')^2 + (y-y')^2}, \quad (99)$$

$$\varphi \rightarrow \phi = \arctan \frac{y-y'}{x-x'}$$

where the quadrant of the argument must be noted when the inverse tangent is evaluated.¹⁹ The new cylindrical coordinates (ϱ, ϕ) are illustrated in Fig. 8. It may be directly verified, using (38), that the resulting DGFs satisfy the reciprocity relations (10)–(12).²⁰

It will be instructive to briefly revisit the problem of Fig. 7 using the space-domain approach. In view of (55), the electric and magnetic fields in the half-space can be expressed as

$$\mathbf{E}(\mathbf{r}) = K \int_a^b d\rho' \int_{-\pi}^{\pi} d\varphi' \underline{\mathbf{G}}^{EM}(\rho - \rho'; z|z_1) \cdot \hat{\boldsymbol{\varphi}}' \quad (100)$$

$$\mathbf{H}(\mathbf{r}) = K \int_a^b d\rho' \int_{-\pi}^{\pi} d\varphi' \underline{\mathbf{G}}^{HM}(\rho - \rho'; z|z_1) \cdot \hat{\boldsymbol{\varphi}}' \quad (101)$$

where $\underline{\mathbf{G}}^{EM}$ and $\underline{\mathbf{G}}^{HM}$ are as given by (77)–(83) and (91)–(98), respectively. Note that the integrals above must be evaluated by numerical quadratures. These equations can provide an excellent check for the DGFs and the numerical procedures used to evaluate the Sommerfeld integrals, since the results must agree with those computed from the spectral-domain formulas (62)–(64) [43]. It is also possible to demonstrate analytically the equivalence between (100), (101) and (62)–(64); consider H_x , for example. From (101), we obtain

$$H_x(\mathbf{r}) = K \int_a^b d\rho' \int_{-\pi}^{\pi} d\varphi' [-\sin \varphi' G_{xx}^{HM}(\rho - \rho'; z|z_1) + \cos \varphi' G_{xy}^{HM}(\rho - \rho'; z|z_1)] \quad (102)$$

$$= 2\pi K \int_a^b d\rho' \int_{-\pi}^{\pi} d\varphi' \frac{1}{4\pi} [\sin \varphi' \mathcal{S}_0\{I_v^e + I_v^h\} - \sin(2\phi - \varphi') \mathcal{S}_2\{I_v^e - I_v^h\}]$$

¹⁹The intrinsic FORTRAN function ATAN2 does this automatically and returns a result in the range $(-\pi, \pi)$ [42, p. 178]. Note that under this transformation $\delta(\rho)\delta(z-z') \rightarrow \delta(\mathbf{r}-\mathbf{r}')$.

²⁰Note that $\phi \rightarrow \pi + \phi$ when the locations of the source and field points in Fig. 8 are swapped, whereas ϱ is unaffected.

Figure 8. Cylindrical coordinates for off-axis source points.

where the Hankel transforms \mathcal{S}_0 and \mathcal{S}_2 are as given by (65) with ρ replaced by ϱ , and where we have omitted the arguments $(z|z_1)$ of the TLGFs for notational simplicity. Note that we have used (68) to simplify the second integral expression above. If we now change the order of the spatial and spectral integrals in the last equation, we obtain

$$H_x(\mathbf{r}) = 2\pi K \frac{1}{2\pi} \int_0^\infty dk_\rho k_\rho \int_a^b d\rho' \int_{-\pi}^{\pi} d\varphi' \times \frac{1}{4\pi} [\sin \varphi' J_0(k_\rho \varrho) \{I_v^e + I_v^h\} - \sin(2\phi - \varphi') J_2(k_\rho \varrho) \{I_v^e - I_v^h\}] \quad (103)$$

Next, we expand the Bessel functions in (103) using Graf's addition theorem [38, p. 363]

$$J_n(k_\rho \varrho) \begin{matrix} \cos \\ \sin \end{matrix} n\chi = \sum_{k=-\infty}^{\infty} J_k(k_\rho \rho) J_{n+k}(k_\rho \rho') \begin{matrix} \cos \\ \sin \end{matrix} k\alpha \quad (104)$$

where the angles $\chi = \pi - (\phi - \varphi')$ and $\alpha = (\phi - \varphi')$ are indicated in Fig. 8, which makes it possible to evaluate the spatial integrals in a closed form. As a result of the orthogonality of the trigonometric functions over the 2π range, many cancellations occur, leading to the remarkably simple final result

$$H_x(\mathbf{r}) = 2\pi K \sin \varphi \mathcal{S}_1 \left\{ \frac{\varpi(k_\rho)}{k_\rho} I_v^e(z|z_1) \right\} \quad (105)$$

where $\varpi(k_\rho)$ has been defined in (60). The other field components in (100), (101) can be transformed in a similar fashion, to arrive at (62)–(64).

The discussion above pertains to the general, 3D case. In 2D, where all field components have the form of (29), the space-domain DGFs can be obtained by applying the one-dimensional inverse transform (32) to (47)–(50), with k_y set to β and x replaced by $(x-x')$. Hence, the spectral integrals that arise in the 2D DGFs are ordinary Fourier transforms, rather than Sommerfeld integrals, with the

integrands expressed in terms of the TLGFs, exactly as in the 3D case [44].

We note that our Fourier representation of the DGFs is tantamount to a two-dimensional eigenfunction expansion in the transverse to z plane, with a closed-form solution in the z direction [45]. The appearance of the delta function terms in (76) and (98) is consistent with such “ z -propagating” eigenfunction representations [46–48].²¹ However, these terms do not represent the total source region singularity of the DGFs, since the remaining terms are still highly singular when $R = |\mathbf{r} - \mathbf{r}'| \rightarrow 0$ [50]. The level of these singularities is the same in layered media as in a homogeneous space (see the Appendix at the end of this article). In layered media, however, the DGFs are given in terms of the Sommerfeld integrals, and there is a direct relationship between the large- k_ρ divergence of the spectral integrands and the space-domain singularity, as discussed in the next section. It is found that in the source region $\underline{\mathbf{G}}^{EM}$ and $\underline{\mathbf{G}}^{HJ}$ behave as R^{-2} , while $\underline{\mathbf{G}}^{EJ}$ and $\underline{\mathbf{G}}^{HM}$ exhibit more severe R^{-3} singularities. Since such singularities are not generally integrable over a volume, special care has to be taken when the integrals (6), (7) are evaluated with $\mathbf{r} \in V$ [51]. The classical approach is to exclude from V an infinitesimal volume V_δ surrounding the field point [52–54], [12, p. 101]. The integral over $V - V_\delta$, which is referred to as the *principal value* (PV) integral, is then convergent, and the integral over V_δ gives rise to the so-called depolarization dyadic. Although both the PV integral and the depolarization dyadic depend on the shape of the exclusion volume, the sum of the two contributions is unique.²² The depolarization dyadic for several simple shapes, such as spherical, cubical, and cylindrical (with a needle shape and a disk as special cases), have been evaluated for both isotropic [54] and uniaxial [57] media.²³ An alternative approach is regularization, which uses the static form of the kernel to compensate for the singularity [59–62].

Still another way to “regularize” the integral representations with hypersingular DGF kernels is to convert them into the so-called mixed-potential forms, which express the fields in terms of the vector and scalar potentials [14,43,63–71]. Such potential representations, although not unique, have the advantage of being less singular (in space domain) and faster convergent (in spectral domain) than the field forms. The mixed-potential integral equations (MPIEs) have been frequently used in the analysis of antennas, printed-circuit boards, arbitrarily shaped scatterers, and other structures embedded in layered media.

²¹The occurrence of the Dirac deltas in $\underline{\mathbf{G}}^{EJ}$ and $\underline{\mathbf{G}}^{HM}$ indicates that these DGFs belong to the class of distributions (or generalized functions) [49, Chap. 1]. In the present context, a distribution may be defined as a function, which has meaning only when integrated against another, well-behaved function.

²²It should be mentioned here that in the special case of a uniform current and a cylindrical volume with the axis parallel to the direction of current flow, it is possible to evaluate the electric field inside the source region without invoking the concepts of exclusion volume or principal value [55,56].

²³It is interesting to note that the delta function terms in (76) and (98) give rise to depolarization dyadics corresponding to a disk-shaped exclusion volume perpendicular to the z axis [58].

Space limitations do not allow us to develop this important topic further here.

6.1. Comparison with Other Approaches

Before leaving this section, we wish to point out some salient features of the formulation presented here and to comment on other approaches. First, we note that the DGFs have been “scalarized”; that is, they are expressed in terms of the scalar Green functions of the transmission-line analog of the layered medium along the axis normal to the stratification [16,72–74]. The TLGFs are associated with the transverse field components, whose continuity at the media interfaces naturally translates into the continuity of the voltages and currents on the transmission-line network representation of the layered medium. As indicated in Fig. 1b, two transmission-line networks arise that represent the TM ($\alpha=e$) and TE ($\alpha=h$) partial fields. However, since the TM and TE networks have identical configurations and differ only in the propagation constants and characteristic impedances, it suffices to work out the solution for just one of them. The advantage of the TL representation is that it enhances the engineering insight and is amenable to the familiar network analysis techniques. By using these techniques, the TLGFs for any number of layers can easily be found, as discussed in the next section. Hence, the DGF expressions (69)–(98) are general, applicable to arbitrary source configurations and any number of layers. They are also in a convenient “ready to use” form, which cannot be further simplified—except, possibly, by invoking (68).²⁴

The transmission-line analogue employed here is based on the transverse field components and it treats the longitudinal components as dependent variables [4, p. 745]. However, it is also possible to scalarize the Maxwell equations in layered media by taking the longitudinal field components, (E_z, H_z) , as the independent variables (or “wave potentials”), from which the transverse components are derived [75–77]. A closely related approach is based on the longitudinal components of either the magnetic and electric vector potentials (A_z, F_z) , or the Hertz vectors (Π_x, Π_z) [29,78, p. 242; 79–82]. Although such representations achieve the TM-TE decomposition of the fields, they do not naturally lead to transmission-line equivalent circuits, because the chosen wave potentials are not continuous across the boundaries between dissimilar media. Perhaps to overcome this drawback, a formulation based on the longitudinal components of the electric and magnetic displacement vectors (D_z, B_z) has also been introduced [83].

Some authors have adopted Sommerfeld’s original approach [40,84,85], based on the horizontal and vertical components of the Hertz vector (Π_x, Π_z) ²⁵ [88–91]. However, the extension of this method, or its variant based on

²⁴However, using \mathcal{S}_2 to simplify equations does not necessarily lead to a more efficient formulation, because J_2 is usually computed from J_0 and J_1 .

²⁵It has been realized that Sommerfeld’s choice of Hertz potentials is nonunique, and that one could also use, for example, (Π_x, Π_y) [86,87](86), (87).

(A_x, A_z), to multilayered media is cumbersome, because the chosen wave potentials are coupled in the boundary conditions at the interfaces [55,92–96].

Another approach is based on the eigenfunction expansion of the DGFs in terms of vector wavefunctions [39, Chap. 11]. This method, although elegant and historically important, leads to representations that require much processing to render them tractable [89,97,98].

Still another formalism begins with a 3D Fourier transform representation of the DGF for a homogeneous medium [99, p. 38; 100–105]. The integration over the spectral variable associated with the z direction is then performed in closed form by the calculus of residues [12, p. 823]. This results in a 2D Fourier representation, which makes evident the TM and TE dyadic components and is suitable for application of the “scattering superposition method,” in which the spectral representation of the primary, whole-space DGF is augmented by homogeneous solutions, to account for the presence of the stratified medium. The augmented terms constitute upward- and downward-propagating waves, with coefficients that obey certain recurrence relations, which are determined by imposing the continuity of the transverse DGF components at the media interfaces. Finally, in the 3D case, the resulting two-dimensional spectral integrals are converted to Sommerfeld integrals.

In conclusion, the alternative techniques do not appear to offer any substantial advantages over the method espoused here.

7. TRANSMISSION-LINE ANALYSIS FOR PIECEWISE HOMOGENEOUS MEDIA

Although the theory presented thus far is applicable to media with parameters that have arbitrarily z dependence, only for a very few special media profiles can the transmission-line solution be found in an analytical closed form [106]. Therefore, we next focus attention on a multilayered medium with piecewise constant parameters, as illustrated in Fig. 1a, which is the most important and most frequently encountered case in practice. The transmission-line equivalent circuit now consists of a tandem connection of uniform transmission-line sections, where section n , with terminals at z_n and z_{n+1} , has propagation constant k_{zn}^z and characteristic impedance Z_n^z , as illustrated in Fig. 1b.

In this section, we first analyze the situation where there are no sources on the TL network, except possibly at infinity. This case is important in its own right, and it prepares the ground for the derivation of the TLGFs, which is presented next. We close with a brief discussion of the asymptotic behavior of the TLGFs.

7.1. Source-Free Case

The voltage and current on the n th TL section, which is assumed to be source-free, satisfy the homogeneous forms

of the transmission-line equations (24), which lead to

$$\begin{pmatrix} \frac{d^2}{dz^2} + k_{zn}^2 \\ I_n(z) \end{pmatrix} \begin{pmatrix} V_n(z) \\ I_n(z) \end{pmatrix} = 0, \quad I_n(z) = -\frac{1}{jk_{zn}Z_n} \frac{d}{dz} V_n(z) \quad (106)$$

Hence, choosing $e^{\pm jk_{zn}z}$ as the fundamental solutions, we may write²⁶

$$\begin{bmatrix} V_n(z) \\ Z_n I_n(z) \end{bmatrix} = \underbrace{V_n^+ e^{-jk_{zn}(z-z_n)}}_{V_n^+(z)} \pm \underbrace{V_n^- e^{jk_{zn}(z-z_n)}}_{V_n^-(z)} \quad (107)$$

where $V_n^+(z)$ and $V_n^-(z)$ represent the forward- and backward-propagating voltage waves, respectively, and where V_n^+ and V_n^- are as yet undetermined complex coefficients. The plus/minus signs between the forward and backward waves correspond, respectively, to the upper/lower terms on the left side of the equation. Note that, for later convenience, we use $(z - z_n)$, rather than just z , in the exponents. Thus, the phase reference point for the traveling waves has been arbitrarily selected at the left terminals of the TL section. An exception must be made if section 1 in Fig. 1b is of infinite extent; in this case, we move the phase reference to the right terminals—specifically we use z_2 in place of z_1 in (107).

We can also express (107) as

$$\begin{bmatrix} V_n(z) \\ Z_n I_n(z) \end{bmatrix} = V_n^+(z) [1 \pm \vec{\Gamma}_n(z)] \quad (108)$$

where

$$\vec{\Gamma}_n(z) = \frac{V_n^-(z)}{V_n^+(z)} \quad (109)$$

is the right-looking voltage reflection coefficient at z on the n th TL section. If we also define the right-looking impedance at z as

$$\vec{Z}_n(z) = \frac{V_n(z)}{I_n(z)} = Z_n \frac{1 + \vec{\Gamma}_n(z)}{1 - \vec{\Gamma}_n(z)} \quad (110)$$

where the second equality follows from (108), we obtain

$$\vec{\Gamma}_n(z) = \frac{\vec{Z}_n(z) - Z_n}{\vec{Z}_n(z) + Z_n} \quad (111)$$

Hence, the reflection coefficient at any location may be computed from the impedance, and vice versa. From (109)

²⁶The present choice of fundamental solutions leads to a traveling-wave representation of the voltages and currents. Another possible choice, $\sin(k_{zn}z)$ and $\cos(k_{zn}z)$, leads to a standing-wave representation [4, p. 203].

and (107), it follows that

$$\vec{\Gamma}_n(z_n) = \vec{\Gamma}_n e^{-j2\theta_n} \quad (112)$$

where

$$\theta_n = k_{zn} d_n, \quad d_n = z_{n+1} - z_n \quad (113)$$

and where $\vec{\Gamma}_n \equiv \vec{\Gamma}_n(z_{n+1})$. It should be noted that the terminal reflection coefficients shown above are evaluated on the inner sides of the TL section. This distinction is important, because unlike the impedances, the reflection coefficients are discontinuous across the TL terminals.²⁷ Using (110)–(112) and applying fact that $Z_n(z_{n+1}) \equiv Z_n = Z_{n+1}(z_{n+1})$, it is readily found that the right-looking reflection coefficients satisfy the recurrence relation

$$\vec{\Gamma}_n = \frac{\Gamma_{n+1,n} + \vec{\Gamma}_{n+1} e^{-j2\theta_{n+1}}}{1 + \Gamma_{n+1,n} \vec{\Gamma}_{n+1} e^{-j2\theta_{n+1}}} \quad (114)$$

where

$$\Gamma_{i,j} = \frac{Z_i - Z_j}{Z_i + Z_j} \quad (115)$$

Note that $\Gamma_{i,j}$ is analogous to the Fresnel reflection coefficient across an interface between two half-spaces filled with media i and j , looking from medium j [107, p. 62]. The recursion (114) is applied beginning with the rightmost TL section and it proceeds backward, toward the left end. If the N th layer is of infinite extent, as in Fig. 1, then it is reflectionless, and the starting value is $\vec{\Gamma}_N = 0$.

Using the translation formula [112] in (108), we can express the latter as

$$\begin{bmatrix} V_n(z) \\ Z_n I_n(z) \end{bmatrix} = V_n^+ e^{-jk_{zn}(z-z_n)} [1 \pm \vec{\Gamma}_n e^{-j2k_{zn}(z_{n+1}-z)}] \quad (116)$$

For simplicity, the terminal voltages will be denoted as $V_n \equiv V_n(z_n)$ and $V_{n+1} \equiv V_n(z_{n+1})$. Using the upper equation (116), we can eliminate the coefficient V_n^+ in favor of V_n , which results in

$$\begin{bmatrix} V_n(z) \\ Z_n I_n(z) \end{bmatrix} = \frac{V_n e^{-jk_{zn}(z-z_n)}}{1 + \vec{\Gamma}_n e^{-j2\theta_n}} [1 \pm \vec{\Gamma}_n e^{-j2k_{zn}(z_{n+1}-z)}] \quad (117)$$

Hence, the voltage and current at any location within a source-free TL section can be computed from the voltage at the left terminals. Evaluating the upper equation (117) at $z = z_{n+1}$, we find the right-looking voltage transmission

²⁷The continuity of the impedances is a consequence of the continuity of the voltages and currents when the sources are absent.

coefficient across the n th TL section as

$$\vec{\tau}_n \equiv \frac{V_{n+1}}{V_n} = \frac{(1 + \vec{\Gamma}_n) e^{-j\theta_n}}{1 + \vec{\Gamma}_n e^{-j2\theta_n}} \quad (118)$$

This formalism is useful if the excitation is to the left of the n th TL section. If the sources are to the right of the n th section, (107) is still applicable, except that V_n^- now plays the role of the ‘‘incident wave.’’ Hence, we define the left-looking reflection coefficient

$$\overleftarrow{\Gamma}_n(z) = \frac{V_n^+(z)}{V_n^-(z)} = \frac{\overleftarrow{Z}_n(z) - Z_n}{\overleftarrow{Z}_n(z) + Z_n} \quad (119)$$

and the left-looking impedance²⁸

$$\overleftarrow{\Gamma}_n(z) = -\frac{V_n(z)}{I_n(z)} = Z_n \frac{1 + \overleftarrow{\Gamma}_n(z)}{1 - \overleftarrow{\Gamma}_n(z)} \quad (120)$$

and from (119) and (107), we obtain

$$\overleftarrow{\Gamma}_n(z_{n+1}) = \overleftarrow{\Gamma}_n e^{-j2\theta_n} \quad (121)$$

where $\overleftarrow{\Gamma}_n \equiv \overleftarrow{\Gamma}_n(z_n)$. Applying (119)–(121) and the fact that $\overleftarrow{Z}_n(z_n) \equiv \overleftarrow{Z}_n = \overleftarrow{Z}_{n-1}(z_n)$, we readily derive the recurrence relation

$$\overleftarrow{\Gamma}_n = \frac{\Gamma_{n-1,n} + \overleftarrow{\Gamma}_{n-1} e^{-j2\theta_{n-1}}}{1 + \Gamma_{n-1,n} \overleftarrow{\Gamma}_{n-1} e^{-j2\theta_{n-1}}} \quad (122)$$

From this recursion, the left-looking reflection coefficients can be computed by the same procedure as that used for the right-looking coefficients, except now we begin in section 1 and progress forward, toward the right end of the TL network. The starting value, $\overleftarrow{\Gamma}_1$, is easily found. For example, if the first layer is backed by a plate with surface impedance Z_s , as illustrated in Fig. 1, then

$$\overleftarrow{\Gamma}_1 = \frac{Z_s - Z_1}{Z_s + Z_1} \quad (123)$$

which becomes -1 if the plate is PEC, and $+1$ if it is PMC. For a good, but not perfect, electrical conductor of conductivity σ , Z_s can be found as

$$Z_s = \frac{1+j}{\sigma\delta}, \quad \delta = \sqrt{\frac{2}{\omega\mu_0\sigma}} \quad (124)$$

where δ is the skin depth (not to be confused with the Dirac delta) [12, p. 201; [108]].

²⁸The minus sign arises because we maintain the positive- z direction as the reference direction for the current.

Using the translation formula [121] in (107), the latter can be expressed as

$$\begin{bmatrix} V_n(z) \\ -Z_n I_n(z) \end{bmatrix} = V_n^- e^{jk_{zn}(z-z_n)} [1 \pm \overleftarrow{\Gamma}_n e^{-j2k_{zn}(z-z_n)}] \quad (125)$$

where the coefficient V_n^- can be eliminated in favor of V_{n+1} , resulting in

$$\begin{bmatrix} V_n(z) \\ -Z_n I_n(z) \end{bmatrix} = \frac{V_{n+1} e^{-jk_{zn}(z_{n+1}-z)}}{1 + \overleftarrow{\Gamma}_n e^{-j2\theta_n}} [1 \pm \overleftarrow{\Gamma}_n e^{-j2k_{zn}(z-z_n)}] \quad (126)$$

Hence, the voltage and current at any point z within a source-free TL section can also be computed from the voltage at the right terminals. Finally, evaluating (126) at $z = z_n$, we find the left-looking voltage transmission coefficient for section n as

$$\overleftarrow{\tau}_n \equiv \frac{V_n}{V_{n+1}} = \frac{(1 + \overleftarrow{\Gamma}_n) e^{-j\theta_n}}{1 + \overleftarrow{\Gamma}_n e^{-j2\theta_n}} \quad (127)$$

To illustrate the application of this formalism, consider a TL network corresponding to an unshielded multilayer excited in the upper half-space (layer N). Let the incident field be represented by a voltage wave with the amplitude V_N^- . The resulting total voltage and current in the top layer are given by (125) with $n = N$, where $\overleftarrow{\Gamma}_N$ represents the overall reflection coefficient looking into the stack from the upper half-space, which can be computed from (122). Note that the voltage at the left terminals of section N is

$$V_N = (1 + \overleftarrow{\Gamma}_N) V_N^- \quad (128)$$

In layer 1 there is no reflection; hence

$$V_1(z) = V_1^- e^{jk_{z1}(z-z_2)} \quad (129)$$

and $V_2 = V_1^-$. The overall transmission coefficient of the stack can now be found as

$$\begin{aligned} \overleftarrow{T} &= \frac{V_1^-}{V_N^-} = (1 + \overleftarrow{\Gamma}_N) \frac{V_2}{V_N^-}, \\ \frac{V_2}{V_N^-} &= \frac{V_2}{V_3} \frac{V_3}{V_4} \cdots \frac{V_{N-1}}{V_N^-} = \prod_{n=2}^{N-1} \overleftarrow{\tau}_n \end{aligned} \quad (130)$$

where it is understood that the product is equal to one if the lower limit exceeds the upper.

As another interesting application, consider an arbitrary distribution of electric and magnetic currents radiating near a planar interface between a uniaxial medium (layer 1) and an isotropic medium (layer 2). The issue is whether it is possible to adjust the uniaxial medium parameters so that there is no reflection at the interface for any frequency and any configuration of the sources. Since the fields of arbitrary sources in layered media are expressible as Sommerfeld integrals whose integrands

comprise both TM and TE TLGFs, these requirements will be satisfied if the TM and TE Fresnel reflection coefficients given in (115) vanish for all values of k_ρ , that is, if $\Gamma_{1,2}^e = 0$ and $\Gamma_{1,2}^h = 0$, and thus $Z_1^e = Z_2^e$ and $Z_1^h = Z_2^h$. In view of (25), (26), these conditions imply

$$\frac{1}{\varepsilon_1} \sqrt{k_0^2 \varepsilon_1 \mu_1 - \frac{\varepsilon_1}{\varepsilon_2} k_\rho^2} = \frac{1}{\varepsilon_2} \sqrt{k_0^2 \varepsilon_2 \mu_2 - k_\rho^2} \quad (131)$$

and

$$\frac{1}{\mu_1} \sqrt{k_0^2 \varepsilon_1 \mu_1 - \frac{\mu_1}{\mu_2} k_\rho^2} = \frac{1}{\mu_2} \sqrt{k_0^2 \varepsilon_2 \mu_2 - k_\rho^2} \quad (132)$$

which will be simultaneously satisfied for all k_ρ if

$$\varepsilon_{z1} = \frac{\varepsilon_2^2}{\varepsilon_1}, \quad \mu_1 = \frac{\varepsilon_1 \mu_2}{\varepsilon_2}, \quad \mu_{z1} = \frac{\varepsilon_2 \mu_2}{\varepsilon_1} \quad (133)$$

where ε_1 may be selected arbitrarily. Hence, we may postulate a lossy medium with

$$\varepsilon_1 = \varepsilon_{r1} - j \frac{\sigma_1}{\omega \varepsilon_0} \quad (134)$$

where the dielectric constant ε_{r1} and conductivity σ_1 are arbitrary. It is interesting to note that, since ε_{z1} and μ_{z1} are inversely proportional to ε_1 , the resulting effective electric and magnetic conductivities along the optic axis are negative. Even though such media may be not realizable in practice, they have played an important role in the design of the so-called perfectly matched layers (PMLs) for reflectionless truncation of finite-difference and finite-element meshes [109–111]. Since such PMLs must be surrounded by impenetrable enclosures to be practical, let us consider the effect of terminating the perfectly absorbing medium characterized by (133), (134) with a PEC ground plane at a distance d_1 below the interface. The reflection coefficient looking into the uniaxial layer can be found using (122) with $n = 2$. Since in the present case $\Gamma_{1,2}^z = 0$ and $\overleftarrow{\Gamma}_1 = -1$, we obtain

$$\overleftarrow{\Gamma}_2^z = -e^{-j2k_{z1}d_1}, \quad k_{z1}^e = k_{z1}^h = \frac{\varepsilon_1}{\varepsilon_2} \sqrt{k_2^2 - k_\rho^2} \quad (135)$$

Using (134) here and making the substitutions $k_\rho = k_2 \sin \vartheta$, the reflectivity of this PML is found as²⁹

$$R^z(\theta) = e^{-4\eta_2 \sigma_1 d_1 \cos \vartheta} \quad (136)$$

where it is assumed that k_2 , η_2 (the intrinsic impedance of medium 2) and ϑ are real-valued. Here, ϑ can be interpreted as the angle of incidence, measured from the interface normal, of the continuous spectrum of plane waves representing the field radiated by the finite sources. We note that the reflectivity, which is the same for the TM and TE waves, can be made arbitrarily small by properly

²⁹Reflectivity is defined as the magnitude-squared reflection coefficient.

choosing the product $\sigma_1 d_1$. However, this PML works best for normal incidence and loses its effectiveness for waves incident at grazing angles ($\vartheta = 90^\circ$) and for evanescent waves (in which case ϑ is complex-valued [112, p. 231]).

For completeness, we also mention two alternative methods that have been extensively used in multilayer analysis [113–116]. The first is based on the relationship [3, p. 44; 12, p. 192]

$$\begin{bmatrix} V_n \\ I_n \end{bmatrix} = \begin{bmatrix} \cos \theta_n & jZ_n \sin \theta_n \\ \frac{j}{Z_n} \sin \theta_n & \cos \theta_n \end{bmatrix} \begin{bmatrix} V_{n+1} \\ I_{n+1} \end{bmatrix} \quad (137)$$

which can be derived from (107) by eliminating the traveling-wave coefficients V_n^\pm in favor of the terminal voltages and currents. The matrix in (137) is unimodular, that is, it has a unity determinant.³⁰ This property can be exploited in the analysis of periodic multilayers [117, p. 60], which have many important applications, such as gain-enhancing superstrates for microstrip antennas [118], or multilayer reflective coatings for EUV lithography [119]. The second method is based on the formula [12, p. 189; 120]

$$\begin{aligned} \begin{bmatrix} V_n^+ \\ V_n^- \end{bmatrix} &= \frac{1}{T_{n-1,n}} \begin{bmatrix} 1 & \Gamma_{n-1,n} \\ \Gamma_{n-1,n} & 1 \end{bmatrix} \begin{bmatrix} e^{-j\theta_{n-1}} & 0 \\ 0 & e^{+j\theta_{n-1}} \end{bmatrix} \\ &\times \begin{bmatrix} V_{n-1}^+ \\ V_{n-1}^- \end{bmatrix} \equiv Q_{n-1} \begin{bmatrix} V_{n-1}^+ \\ V_{n-1}^- \end{bmatrix} \end{aligned} \quad (138)$$

where $T_{i,j} = 1 + \Gamma_{i,j}$ is the Fresnel transmission coefficient from medium j to medium i . This equation can also be derived from (107), this time by eliminating the terminal voltages and currents in favor of the traveling-wave coefficients in adjacent layers. If layer 1 is of infinite extent, (138) is used with $\theta_1 = 0$.

Both matrix methods outlined above are useful in computation of the guided-wave poles of a multilayer, which correspond to the source-free solutions of the Maxwell equations, or waveguide modes. We will illustrate this for the second method, assuming an N -layer stack, as illustrated in Fig. 1. In this case, a repeated application of (138) leads to the relationship

$$\begin{aligned} \begin{bmatrix} V_N^+ \\ V_N^- \end{bmatrix} &= Q_{N-1} Q_{N-2} \cdots Q_1 \begin{bmatrix} V_1^+ \\ V_1^- \end{bmatrix} \\ &\equiv \begin{bmatrix} q_{11} & q_{12} \\ q_{21} & q_{22} \end{bmatrix} \begin{bmatrix} V_1^+ \\ V_1^- \end{bmatrix} \end{aligned} \quad (139)$$

which links the amplitudes of the forward- and backward-propagating voltage waves in the top and bottom layers. If layer 1 is shielded from below, the positive- and negative-propagating wave amplitudes can be expressed as $V_1^\pm = \frac{1}{2}(V_1 \pm Z_1 I_1)$, with the total voltage and current at

z_1 constrained by the impedance boundary condition $V_1 = -Z_0 I_1$. In layer N , assuming a stack open above, there should be no backward-propagating wave, thus $V_N^- = 0$. Using these constraints in (139), we obtain

$$\begin{bmatrix} 1 & (q_{11} \overleftarrow{\Gamma}_1 + q_{12}) \\ 0 & (q_{21} \overleftarrow{\Gamma}_1 + q_{22}) \end{bmatrix} \begin{bmatrix} V_N^+ \\ I_1 \end{bmatrix} = 0 \quad (140)$$

with $\overleftarrow{\Gamma}_1$ given by (123). Nontrivial solutions to this homogeneous system only exist for those values of k_ρ , which make the determinant vanish. This leads to the modal dispersion relation

$$q_{21} \overleftarrow{\Gamma}_1 + q_{22} = 0 \quad (141)$$

which also includes the cases of PEC backing ($\overleftarrow{\Gamma}_1 = -1$), PMC backing ($\overleftarrow{\Gamma}_1 = +1$), and no backing ($\overleftarrow{\Gamma}_1 = 0$). The zeros of (141) in the complex k_ρ plane determine the propagation constants of the guided-wave modes of the multilayer and are also the poles of the spectral integrands appearing in (69)–(98) [121,122]. A similar dispersion relation can be derived for a multilayer shielded from above.

The advantage of the matrix formulations is that they lead to analytic modal dispersion functions, which are amenable to the root finding methods based on Cauchy's theorem [123,124]. However, they are not well suited for use in the DGFs, because of the occurrence of growing exponentials when $k_\rho \rightarrow \infty$, which may cause numerical overflows in a computer implementation [6,125].

Finally, we mention that it is also possible to develop explicit recursive relationships between the coefficients of the forward- and backward-propagating waves in different layers, without using the matrix technique [13, p. 49; 126].

7.2. Source-Excited Case

Consider next a source-excited TL section n , as illustrated in Fig. 9, where $\overleftarrow{\Gamma}_n$ and $\overrightarrow{\Gamma}_n$ are the voltage reflection coefficients and Z_n and \overline{Z}_n are the total impedances, looking out of the left and right terminals, respectively. It will suffice to treat in detail only the current excitation case; the solution for the voltage source will follow by duality.

First, we note that the Sturm–Liouville theory of Section 4 can be directly applied to this problem. The homogeneous solutions satisfying the boundary conditions at the left and right terminals of TL section n have already been constructed in (125) and (116). Hence, we can choose

$$\overleftarrow{V}_n(z) = e^{jk_{zn}(z-z_n)} [1 + \overleftarrow{\Gamma}_n e^{-j2k_{zn}(z-z_n)}] \quad (142)$$

$$\overrightarrow{V}_n(z) = e^{-jk_{zn}(z-z_n)} [1 + \overrightarrow{\Gamma}_n e^{-j2k_{zn}(z_{n+1}-z)}] \quad (143)$$

The corresponding conjunct is readily found as

$$-\mathcal{P}W(\overleftarrow{V}_n, \overrightarrow{V}_n) = \frac{2}{Z_n} D_n \quad (144)$$

³⁰This matrix is sometimes referred to as the *ABCD matrix*.

Figure 9. Voltage and current sources in a transmission-line section.

where we have introduced the notation

$$D_n = 1 - \overleftarrow{\Gamma}_n \overrightarrow{\Gamma}_n e^{-j2\theta_n} \quad (145)$$

Using these equations in (43), we finally obtain

$$V_i(z|z') = \frac{Z_n}{2D_n} \overleftarrow{V}_n(z_<) \overrightarrow{V}_n(z_>) \quad (146)$$

and $I_i(z|z')$ then follows from (40). However, this product form of solution can be cumbersome when used in the DGFs, where it may be necessary to combine terms arising from different TLGFs. Therefore, we derive below a more convenient TLGF form, which also offers more physical insight.

Assume at first that the TL section in Fig. 9 is either of infinite extent, or is matched at both ends, so that there are no reflections. Let this TL be driven by a unit-strength current generator at z' . Note that the voltage V_i must be continuous at the source location z' and must have the form of outgoing waves. Furthermore, the current source is in effect loaded by two impedances Z_n connected in parallel. Hence, the solution must have the form [4, p. 206]

$$V_i(z|z') = \frac{Z_n}{2} e^{-jk_{zn}|z-z'|}, \quad I_i(z|z') = \pm \frac{1}{2} e^{-jk_{zn}|z-z'|} \quad (147)$$

where the upper and lower signs correspond to $z > z'$ and $z < z'$, respectively. Next, to account for the presence of the terminations, as in Fig. 9, we augment the particular solution given above by a homogeneous solution, as follows

$$V_i(z|z') = \frac{Z_n}{2} (e^{-jk_{zn}|z-z'|} + A_n e^{-jk_{zn}z} + B_n e^{jk_{zn}z}) \quad (148)$$

$$I_i(z|z') = \frac{1}{2} (\pm e^{-jk_{zn}|z-z'|} + A_n e^{-jk_{zn}z} - B_n e^{jk_{zn}z}) \quad (149)$$

where the coefficients A_n and B_n can be found by enforcing the boundary conditions (42). This last step is straightforward, and we omit the details.³¹ Substituting the so-obtained coefficients A_n and B_n back into (148), (149) completes the solution procedure. The final result can be

³¹Note that we are in effect using the scattering superposition method at the transmission-line level.

expressed compactly as

$$V_i(z|z') = \frac{Z_n}{2} \left[e^{-jk_{zn}|z-z'|} + \frac{1}{D_n} \sum_{s=1}^4 R_n^{(s)} e^{-jk_{zn}\zeta_n^{(s)}} \right] \quad (150)$$

$$I_i(z|z') = \frac{1}{2} \left[\pm e^{-jk_{zn}|z-z'|} - \frac{1}{D_n} \sum_{s=1}^4 (-1)^s R_n^{(s)} e^{-jk_{zn}\zeta_n^{(s)}} \right] \quad (151)$$

where we have introduced the notation

$$R_n^{(1)} = \overleftarrow{\Gamma}_n, \quad \zeta_n^{(1)} = (z + z') - 2z_n, \quad (152)$$

$$R_n^{(2)} = \overrightarrow{\Gamma}_n, \quad \zeta_n^{(2)} = 2z_{n+1} - (z + z'), \quad (153)$$

$$R_n^{(3)} = \overleftarrow{\Gamma}_n \overrightarrow{\Gamma}_n, \quad \zeta_n^{(3)} = 2d_n + (z - z'), \quad (154)$$

$$R_n^{(4)} = \overleftarrow{\Gamma}_n \overrightarrow{\Gamma}_n, \quad \zeta_n^{(4)} = 2d_n - (z - z'), \quad (155)$$

Of course, Eqs. (146) and (150) are equivalent, and the former can be directly manipulated into the form of the latter.

The TLGF representation (150), (151) can be given an interesting ray (geometric optical) interpretation [127], as illustrated in Fig. 10. Hence, the first terms in the brackets represent the direct ray between the source and the field point (ray 0), whereas the second terms represent four categories of rays that undergo partial reflections at the upper and lower slab boundaries before reaching the observation point (rays 1 through 4). This ray interpretation is more evident if the inverse of the “resonant denominator” D_n is expanded as [127]

$$\frac{1}{D_n} = \sum_{k=0}^K \Omega^k + \frac{\Omega^{K+1}}{1 - \Omega}, \quad \Omega = \overleftarrow{\Gamma}_n \overrightarrow{\Gamma}_n e^{-j2\theta_n} \quad (156)$$

With finite K , this formula leads to a hybrid ray modal representation, whereas for $K \rightarrow \infty$, it gives a pure ray representation. However, the simple ray picture shown in Fig. 10 obtains for only a single layer, and it becomes unwieldy in a multilayer geometry [127].

The remaining TLGFs, I_v and V_v , are governed by equations (34), which are dual to equations (33) satisfied by V_i and I_i . Hence, the expressions for I_v and V_v can be obtained from those for V_i and I_i , respectively, by simply replacing the characteristic impedances by admittances, and

Figure 10. Ray interpretation of the TLGFs.

vice versa, which has also the effect of changing the signs of the reflection coefficients. We should mention here the important fact that all TLGFs can be derived from either V_i or I_v [4, p. 194]. For, suppose we have found V_i , as given by (150) above. Then, I_i follows from the first equation in (33), which in turn implies knowledge of V_v , in view of the last reciprocity relation in (38). Finally, V_v determines I_v via the first equation in (34). Thus, all the required information is contained in V_i ; an alternative statement applies to I_v . Because, as is evident from (18), (19), the E_z and H_z field components are specified by, respectively, the current on the TM transmission line and the voltage on the TE transmission line, it is convenient to use V_v^e and V_i^h as the basic TLGFs.³² As we show later in this section, I_v^e and V_i^h are also the least singular of all the TLGFs on conversion to the space domain.

Although the formulas given above assume observation points within the source TL section, they can easily be extended to arbitrary observation points outside section n , by using the results derived earlier for the source-free case. Hence, if z is within section $m < n$, we use the source section formulas to compute the voltage V_n at the left terminals of section n , and then invoke (126) with $n = m$ and

$$V_{m+1} = V_n \prod_{k=m+1}^{n-1} \overleftarrow{\tau}_k \quad (157)$$

Similarly, if z is within section $m > n$, we compute the voltage V_{n+1} at the right terminals of the source section, and then use (117) with $n = m$ and

$$V_m = V_{n+1} \prod_{k=n+1}^{m-1} \overrightarrow{\tau}_k \quad (158)$$

We note that it would suffice to implement only one of these cases and to handle the other case by using the reciprocity relations (38). However, if both cases are implemented, the reciprocity relations can provide a useful check of the formulation and the computer program.

The formulation adopted here easily specializes to the case where the source or observation layer is a half-space, and thus either the left- or right-looking reflection coefficient becomes zero; one simply omits the terms involving the vanishing reflection coefficients. Also, an important feature of this formulation is that all exponentials that occur are nongrowing as $k_\rho \rightarrow \infty$, which greatly reduces the danger of overflows in the computation of Sommerfeld integrals (see Section 8).

Finally, an important property of the TLGFs should be mentioned, which also has important consequences for the evaluation of the Sommerfeld integrals. Namely, the TLGFs are even functions of k_{zn} , if n corresponds to a finite-thickness layer. This can be directly confirmed by noting that (150), (151) are unaffected by the replacement $k_{zn} \rightarrow -k_{zn}$, which also causes the replacements $Z_n \rightarrow -Z_n$,

³²Some authors [45] prefer to express I_v^e in terms of the *current* reflection coefficients, which are just the negatives of the voltage reflection coefficients used here.

$\overleftarrow{\Gamma}_n \rightarrow 1/\overleftarrow{\Gamma}_n$, and $\overrightarrow{\Gamma}_n \rightarrow 1/\overrightarrow{\Gamma}_n$. Hence, the choice of the square-root branch in k_{zn} is arbitrary, which means that there are no branchpoints in the k_ρ plane associated with any of the finite layers [13, p. 112]. However, this observation applies only to the full TLGFs, including the direct-ray terms.

7.3. Asymptotic Behavior

It is important to understand the asymptotic, large- k_ρ behavior of the TLGFs, because it affects the convergence of the Sommerfeld integrals and determines the source-region singularity of the DGFs in the space domain.³³ This knowledge is needed, for example, in extrapolation methods [128], or to extract the quasistatic parts from the spectral kernels, both as a measure to accelerate the Sommerfeld integrals and to isolate the singular parts of the kernels [80, p. 36; 129]. As is evident from (150), (151), the TLGFs decay exponentially as $k_\rho \rightarrow \infty$, unless $z = z'$, which represents the worst-case situation. We therefore focus attention on the case where z lies within the source layer. The large- k_ρ quasistatic forms of V_i^z and I_i^z are readily found from (150) and (151) by expanding the inverse resonant denominator in the geometric series (156) and replacing the reflection coefficients by their asymptotic values. Each term of the series then represents a quasistatic image of the source in the lower or upper interface. Hence, keeping only the direct components and two dominant image terms, we find that, as $k_\rho \rightarrow \infty$

$$V_i^z \sim \frac{Z_n^z}{2} \left[e^{-jk_{zn}^z |z-z'|} + \chi_{n-1,n}^z e^{-jk_{zn}^z \zeta_n^{(1)}} + \chi_{n+1,n}^z e^{-jk_{zn}^z \zeta_n^{(2)}} \right] \quad (159)$$

$$I_i^z \sim \frac{1}{2} \left[\pm e^{-jk_{zn}^z |z-z'|} + \chi_{n-1,n}^z e^{-jk_{zn}^z \zeta_n^{(1)}} - \chi_{n+1,n}^z e^{-jk_{zn}^z \zeta_n^{(2)}} \right] \quad (160)$$

where we have used the asymptotic forms

$$\Gamma_{i,j}^e \sim \chi_{i,j}^e = -\frac{\kappa_i^e - \kappa_j^e}{\kappa_i^e + \kappa_j^e}, \quad \kappa_n^e = \sqrt{\epsilon_n \epsilon_{zn}} \quad (161)$$

$$\Gamma_{i,j}^h \sim \chi_{i,j}^h = \frac{\kappa_i^h - \kappa_j^h}{\kappa_i^h + \kappa_j^h}, \quad \kappa_n^h = \sqrt{\mu_n \mu_{zn}} \quad (162)$$

which follow from (115) on noting that the characteristic impedances (26) behave as

$$Z_n^e \sim \frac{k_\rho}{j\omega\epsilon_0\kappa_n^e}, \quad Z_n^h \sim \frac{j\omega\mu_0\kappa_n^h}{k_\rho} \quad (163)$$

The asymptotic behavior of I_v^z and V_v^z can be deduced from (159) and (160) by invoking duality, as explained earlier. We summarize these findings in Table 2, where we also indicate the small- R behavior of the corresponding

³³This follows from the final value theorem for Fourier transforms [12, p. 826]. It can be seen from [25] that the case $k_\rho \rightarrow \infty$ corresponds to $\omega \rightarrow 0$, that is, the static case. If the $k_\rho \rightarrow \infty$ limit is applied only to the reflection coefficients, the resulting expressions are referred to as the *quasistatic forms*.

Table 2. Worst-Case Asymptotic Behavior of Transmission-Line Green Functions and Corresponding Spatial-Domain Singularities

TL Green Function	Asymptotic Behavior	Space-Domain Singularity
$V_{i,v}^e, I_v^h$	$\mathcal{O}(k_\rho^{+1})$	$\mathcal{O}(R^{-3})$
$V_{v,i}^e, I_i^h, V_{v,i}^h, I_v^e$	$\mathcal{O}(k_\rho^0)$	$\mathcal{O}(R^{-2})$
$V_{i,v}^h, I_v^e$	$\mathcal{O}(k_\rho^{-1})$	$\mathcal{O}(R^{-1})$

Sommerfeld integrals.³⁴ By referring to this table, one can easily ascertain the asymptotic behavior of the spectral integrands, as well as the source region singularities of the DGF components (69)–(98). It should be noted that not only can singularities arise as a result of the direct ray [the first terms in brackets in (159), (160)]; one of the dominant images (the second and third terms) can also give rise to a singularity when z and z' are both on the same interface between adjacent layers.

8. SPECTRAL INTEGRALS AND THEIR COMPUTATION

Consider the formula [131, p. 455]

$$\mathcal{S}_0 \left\{ \frac{e^{-jk_z^z |z|}}{2jk_z^z} \right\} = v^\alpha \frac{e^{-jkr^\alpha}}{4\pi r^\alpha}, \quad r^\alpha = \sqrt{v^\alpha \rho^2 + z^2} \quad (164)$$

which is the Sommerfeld identity [40] extended to uniaxial media. From (164), another important identity can be derived [132, p. 164; 133, p. 428; 134, p. 264]:

$$\mathcal{S}_1 \left\{ \frac{e^{-jk_z^z |z|}}{2jk_z^z k_\rho} \right\} = \frac{e^{-jk|z|} - e^{-jkr^\alpha}}{4\pi jk\rho} \quad (165)$$

In the case of infinite, homogeneous media, these identities and their derivatives can be used to obtain closed-form expressions for the Sommerfeld integrals that arise in (69)–(98) [133, p. 376; 135; 136, p. 136]. We include the resulting whole-space DGFs in the Appendix. In layered media, however, such closed forms do not exist and one must resort to numerical quadrature.

The spectral integrands appearing in (69)–(98) are in general multivalued, as a result of the branchpoints introduced by the square-root definition of k_{zn}^z [137, p. 238]. However, as pointed out earlier, these integrands are even functions of the k_{zn}^z corresponding to finite layers,³⁵ and thus the only branchpoints that appear are those associated with the half-space media. If the multilayer is sandwiched between two isotropic half-spaces (which represent the substrate and cladding in optical applications), the branchpoints occur at $\pm k_1$ and $\pm k_N$, and the complex k_ρ plane consists of four overlying Riemann sheets (or two sheets, if the multilayer is shielded on one side, or if the media of the substrate and cladding are the same, i.e., $k_1 = k_N$), joined at the branchcuts emanating from the

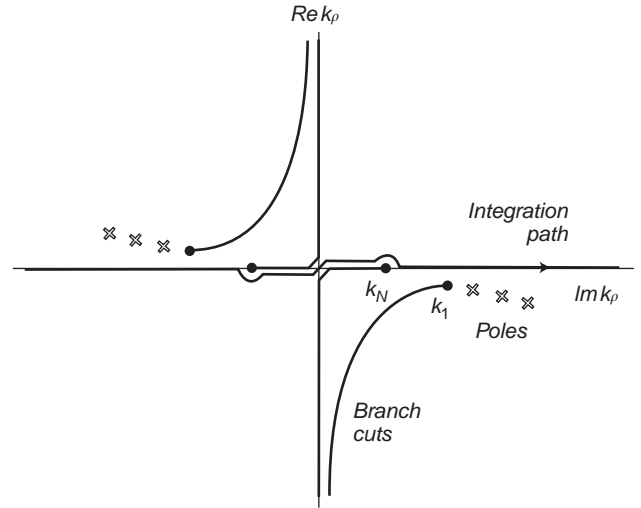

Figure 11. Integration path in the complex k_ρ plane.

branchpoints [13, p. 66; 85, p. 56; 137, p. 241]. Although the exact shape of these cuts is arbitrary, it is often convenient to specify them by the condition $\mathcal{I}m(k_{zn}^z) = 0$, which ensures that $\mathcal{I}m(k_{zn}^z)$ is of the same sign everywhere on a given sheet.³⁶ It is then customary to define the “proper” (also referred to as the “top” or “upper”) sheet as the one for which $-\pi < \arg\{k_{zn}^z\} \leq 0$. The spectral integrands also in general exhibit pole singularities in the complex k_ρ plane, contributed by the zeros of the resonant denominator and/or the reflection coefficients appearing in the TLGFs. For the layered medium geometry of Fig. 1, the poles can be found as the roots of the dispersion relation (141), as explained in the previous section. If the condition $-\pi < \arg\{k_{zN}^z\} \leq 0$ is imposed in the cladding, the roots of (141) are the proper poles, which are located on the top Riemann sheet and correspond to the bound modes of the structure. Otherwise, they are the “leaky-wave poles” located on the lower sheet [113].

The integration paths in the integrals (65) must be properly indented around the poles and branchpoints and must approach infinity on the proper Riemann sheet, to ensure that the fields are bounded as $z \rightarrow \pm \infty$ [105, 138]. An example path satisfying these requirements, referred to as the *Sommerfeld integration path* (SIP), is illustrated in Fig. 11, where only the right half of the path applies to the first integral form in (65). Note that the poles and branchpoints occur in pairs in the second and fourth quadrants of the k_ρ plane [4, p. 465].³⁷ In the limit of vanishing losses, all singular points move to the real axis. The Hankel function in the second integral in (65) introduces a logarithmic branchpoint [139] at the origin (not shown), and the path of integration must be indented around it into the

³⁶The so-defined branchcuts are referred to as the *Sommerfeld*, or *fundamental*, branchcuts.

³⁷Figure 11 corresponds to the situation where the media filling the lower and upper half-spaces are lossy and lossless, respectively. In the $e^{-i\omega t}$ convention, the singular points are complex conjugates of those shown here. Also, the SIP and the branchcuts are reflected in the real axis and $H_n^{(1)}$ replaces $H_n^{(2)}$ in [65] [4, p. 466].

³⁴The “big oh” symbol means “order of magnitude” [130, p. 9].

³⁵Provided that the whole-space terms are not extracted.

lower half of the k_ρ plane, which is emphasized in the notation by writing the lower integration limit as $\infty e^{-j\pi}$. If the SIP is used to compute the Sommerfeld integrals, the pole and branchpoint singularities that occur nearby must be avoided or, preferably, extracted and handled analytically [41,83, p. 161; 140–143]. Since the Bessel and Hankel functions are oscillatory on the real axis and the integrands are divergent, the integration is inefficient, unless extrapolation techniques (sequence accelerators) are employed. One proven and effective procedure is the “integration then summation” method [128,144–146]. In this approach, the Gauss–Kronrod or Patterson quadrature [147] is applied between consecutive zeros of the Bessel function and the resulting sequence of partial sums is accelerated by one of the extrapolation methods [148,149].

The integration may be more efficient if the SIP is deformed to another path, on which the integrand is rapidly convergent [41,88,150,151]. The contour deformation, which is based on Cauchy’s integral theorem [1, p. 294], is performed in a way, such that the conditions of Jordan’s lemma [12, p. 823; 139] are satisfied and no contribution results from any part of the path of integration at infinity. The residues of the poles “captured” by the deformation, as well as contributions from any branchcuts “swept” in this process, must be properly accounted for [152–155]. If the integration contour is restricted to the proper Riemann sheet, the pole contributions represent the guided-wave modes (or “discrete spectrum”) of the multilayer, and the branchcut integrals represent the radiation modes (“continuous spectrum”) [13, p. 333]. Near the surface of a layered medium, the latter assume the characteristics of “lateral waves” that propagate along the top and bottom interfaces [3, p. 484]. If the multilayer is shielded from below and above, the branchcuts are absent, but an infinite number of poles appear on the top (and, in this case, only) sheet. Hence, the spectrum is purely discrete, and the Sommerfeld integrals can be converted into series of pole residues [156].

One particularly attractive integration contour is the steepest-descent path (SDP), on which the integrand is most rapidly convergent [3, p. 462; 13, p. 107; 152,157]. However, this contour veers into a lower Riemann sheet, and thus there is a possibility of capturing some improper poles during the path deformation. The contribution from these leaky-wave poles, as well as any captured proper poles and branchcuts, must not be overlooked. In fact, the difficulty of tracking the location of these singularities vis-à-vis the SDP is a major obstacle in the practical implementation of the SDP integration. The SDP, which passes through the saddle point, also directly leads to the asymptotic techniques for the approximate evaluation of the integrals [4, Chap. 4; 13, p. 106]. These approximations are often performed in the complex angular spectrum plane, which is related to the k_ρ plane by $k_\rho = k_1 \sin w$ or $k_\rho = k_N \sin w$ [3, Sect. 15–7; 4, p. 541; 130, Sect. 1–7; 137, p. 241]. Either of these transformations “unfolds” one pair of branchcuts in the k_ρ plane and maps the associated two Riemann sheets onto a single sheet in the w plane. Another interesting transformation has been proposed, which unfolds all four sheets of the Riemann surface [158].

Other techniques that should be mentioned are the fast Hankel transform (FHT) method³⁸ [159,160] and the discrete complex image method (DCIM) [161–165]. In the FHT method the Sommerfeld integral is converted to a discrete convolution by a logarithmic transformation of the variables and the approximation of the transformed integrand [i.e., the $\tilde{f}(k_\rho)$ function in (65)] as a sum of sinc functions. This convolution has a form of a linear digital filter, which processes the “input function” [i.e., $\tilde{f}(k_\rho)$] to produce the “output function,” namely, the Sommerfeld integral. The coefficients of digital filters of various lengths, corresponding to Hankel transforms of orders 0 and 1, have been computed and are available in the literature [166,167]. The FHT method is effective only when there are no singularities near the real axis, as in the case of highly lossy media, or these singularities can be extracted and handled analytically. Also, the integrand envelope must be strictly decreasing as $k_\rho \rightarrow \infty$.

The basic idea of the DCIM is to approximate the spectral kernel on a suitable path in the complex k_ρ plane by a sum of complex exponentials, using an established system identification procedure [168], and then to use an identity, such as (164), to evaluate the Sommerfeld integrals in closed form.³⁹ The lateral range of applicability of DCIM is limited, unless the guided-wave poles are extracted from the integrands prior to the exponential fit. More recently, a related technique has been proposed, based on rational, rather than exponential, function fitting, which does not suffer from this limitation [169].

A remarkable property of both the FHT method and the DCIM is that no numerical integration is required and no evaluation of Bessel (or Hankel) functions is involved. As a result, these techniques are much faster than the most efficient numerical quadrature methods. However, they also share a significant drawback that they have no built-in convergence measures, and thus the accuracy of the result is usually difficult to ascertain.

Before any of the techniques discussed here is applied, a recommended and sometimes necessary practice is to improve the convergence of the Sommerfeld integrals by the subtraction of the large- k_ρ , quasi-static terms, which have closed-form space-domain counterparts [34,170]. The added benefit of this procedure is that it helps identify and isolate the singular parts of the space-domain Green functions. In the important special case where the source and observation points are on the same interface in a multilayer medium, the Sommerfeld integrals can be accelerated by the extraction of the half-space portion of the integrand, which makes the remainder exponentially convergent [171,172]. The extracted half-space part can be efficiently evaluated by SDP integration [152].

It should also be pointed out that the techniques described here are in practice usually applied to Sommerfeld integrals associated with electromagnetic potentials, rather than fields [41,129,173]. Since fields are related to potentials through differential operators, the potential forms

³⁸Also known as the “linear digital filter method.”

³⁹The layered media Green functions computed this way are often referred to, somewhat inappropriately, as “closed-form Green’s functions.”

are less singular (in spatial domain) and more rapidly convergent (in spectral domain), and thus more tractable, than the field forms. If repeated evaluation of Sommerfeld integrals is required, as is the case when integral equation techniques are used for objects in layered media, a viable alternative to the “on demand” computation is interpolation from a grid of precomputed and tabulated values [88,138,150,174]. The interpolation is in general over the three-dimensional (ρ, z, z') space. However, if the source and observation points are within the same layer, only two-dimensional interpolation is required, because, as is evident from (150), (151), the DGFs can always be split into parts that depend on either $(\rho, z - z')$ or $(\rho, z + z')$.

In the 2D case, the spectral integrals have the form of (32), where the integration can be limited to the positive real k_x axis, with the exponential function replaced by $-2j \sin(k_x x)$ or $2 \cos(k_x x)$, depending on whether the integrand \tilde{f}_{2D} is even or odd in k_x , respectively. Most of the techniques available for the Sommerfeld integrals can be adapted for this case. The singularities in the k_x plane are related to their k_ρ -plane counterparts by the mapping $k_x = \pm \sqrt{k_\rho^2 - \beta^2}$, where the propagation constant β may be complex-valued. Hence, the location of the poles and branchpoints changes with β , which may require a corresponding deformation of the integration path [18,175]. Finally, we note that the 2D counterpart of the Sommerfeld identity (164) is

$$\frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{e^{-jk_z^2 |z|}}{2jk_z^2} e^{-jk_x x} dk_x = \frac{\sqrt{v^2}}{4j} H_0^{(2)}(\gamma^2 \sqrt{v^2 x^2 + z^2}) \quad (166)$$

where $\gamma^2 = \sqrt{k^2 - \beta^2}/v^2$, with $-\pi < \arg\{\gamma^2\} \leq 0$ [176; 177, p. 48].

9. FAR-ZONE RADIATION FIELDS

In some important applications, such as antenna engineering, the far-zone (radiation) fields due to arbitrary source distributions in layered media are of interest. In this section we demonstrate that these fields can be easily computed using the formalism developed in the previous sections.

Hence, let (\mathbf{J}, \mathbf{M}) be known currents occupying a volume V anywhere in a layered medium, which is not shielded from above, as illustrated in Fig. 1a. We assume, for simplicity, that the medium of the upper half-space is isotropic. Let z_0 be a point on the z axis, such that the layered medium and the volume V are confined to the region $z \leq z_0$, as illustrated in Fig. 12. Our goal is to derive leading-order asymptotic expressions for the fields radiated by (\mathbf{J}, \mathbf{M}) , valid when the field point is far from V in the half-space region $z > z_0$.

It should be clear from (47)–(50) and the TLGFs derived in Section 7 that, in the region $z > z_0$, the spectral DGFs may be expressed as

$$\begin{aligned} \tilde{\mathbf{G}}^{PQ}(\mathbf{k}_\rho; z|z') &= \tilde{\mathbf{G}}^{PQ}(\mathbf{k}_\rho; z_0|z') e^{-jk_{zN}(z-z_0)}, \\ k_{zN} &= \sqrt{k_N^2 - k_\rho^2} \end{aligned} \quad (167)$$

Figure 12. Geometry for the evaluation of the far-zone field.

In view of (8)–(66), the space-domain counterpart of (167) may be written as [178, Sect. 13]

$$\begin{aligned} \underline{\underline{\mathbf{G}}}^{PQ}(\mathbf{r}|\mathbf{r}') &= \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} 2jk_{zN} \tilde{\mathbf{G}}^{PQ}(\mathbf{k}_\rho; z_0|z') \\ &\times e^{j\mathbf{k}_\rho \cdot \mathbf{r}'_0} \left\{ \frac{e^{-j\mathbf{k} \cdot \mathbf{r}}}{2jk_{zN}} \right\} dk_x dk_y \end{aligned} \quad (168)$$

where we have introduced the notation

$$\mathbf{k} = \mathbf{k}_\rho + \hat{\mathbf{z}}k_{zN}, \quad \mathbf{r}'_0 = \rho' + \hat{\mathbf{z}}z_0 \quad (169)$$

The integrand in (168) has been factorized into a slowly varying part and a part, enclosed in curly braces, that varies rapidly as $r = |\mathbf{r}| \rightarrow \infty$.⁴⁰ The integrals of the form (168) are amenable to the stationary phase method, or its equivalent, the steepest descent method [3, p. 594; 4, p. 386]. The stationary phase point is given by the conditions

$$\frac{\partial}{\partial k_x}(\mathbf{k} \cdot \mathbf{r}) = 0, \quad \frac{\partial}{\partial k_y}(\mathbf{k} \cdot \mathbf{r}) = 0 \quad (170)$$

which yield the solution

$$k_x^s = k_N \frac{x}{r}, \quad k_y^s = k_N \frac{y}{r}, \quad k_{zN}^s = k_N \frac{z}{r} \quad (171)$$

where the superscript “s” has been introduced to distinguish the stationary phase point values. This result has a clear physical interpretation; the stationary phase point corresponds to a plane wave with its propagation vector \mathbf{k} pointing to the far-zone field point [179]. Hence, we can write

$$\mathbf{k}_\rho^s = k_N \sin \vartheta (\hat{\mathbf{x}} \cos \phi + \hat{\mathbf{y}} \sin \phi), \quad k_{zN}^s = k_N \cos \vartheta \quad (172)$$

where the spherical angles (ϑ, ϕ) specify the observation direction. If we now replace the slowly varying part of the integrand in (168) by its value at the stationary phase point and perform the spectral integration in cylindrical

⁴⁰The reason for arbitrarily including the denominator $2jk_{zN}$ in the rapidly varying part will become evident in due course.

coordinates, we arrive at

$$\underline{\underline{\mathbf{G}}}^{PQ}(\mathbf{r}|\mathbf{r}') \sim 2jk_{zN}^s \underline{\underline{\mathbf{G}}}^{PQ}(\mathbf{k}_\rho^s; z_0|z') e^{i\mathbf{k}_\rho^s \cdot \mathbf{r}'_0} \mathcal{S}_0 \left\{ \frac{e^{-jk_{zN}z}}{2jk_{zN}} \right\}, \quad (173)$$

$$r \rightarrow \infty$$

where \mathcal{S}_0 is the zero-order Hankel transform defined in (65). Finally, we invoke the Sommerfeld identity (164), to obtain

$$\underline{\underline{\mathbf{G}}}^{PQ}(\mathbf{r}|\mathbf{r}') \sim -\frac{e^{-jk_N r}}{2\pi j r} e^{ik_{zN}^s z_0} k_{zN}^s \underline{\underline{\mathbf{G}}}^{PQ}(\mathbf{k}_\rho^s; z_0|z') e^{i\mathbf{k}_\rho^s \cdot \rho'}, \quad (174)$$

$$r \rightarrow \infty$$

The far-zone electric field can now be computed from (6), with the DGFs transformed according to (174). Note that at the stationary phase point $\hat{\mathbf{u}} = \hat{\rho}$ and $\hat{\mathbf{v}} = \hat{\phi}$, where the directions of the unit vectors $\hat{\rho}$ and $\hat{\phi} = \hat{\mathbf{z}} \times \hat{\rho}$ are fixed by the observation angle φ . Furthermore, since there are no reflected waves for $z > z_0$, the spectral-domain DGFs can be simplified by using the transmission line relationships (33),(34). As a result, we obtain the far-zone electric field components as [180,181]

$$E_{\vartheta,\varphi} \sim \frac{e^{-jk_N r}}{2\pi j r} e^{ik_{zN}^s z_0} k_N \left[\left\langle \mathbf{f}_{\vartheta,\varphi}^{EJ} e^{i\mathbf{k}_\rho^s \cdot \rho'}; \mathbf{J} \right\rangle + \eta_N \left\langle \mathbf{f}_{\vartheta,\varphi}^{EM} e^{i\mathbf{k}_\rho^s \cdot \rho'}; \mathbf{M} \right\rangle \right], \quad (175)$$

$$r \rightarrow \infty$$

where

$$\mathbf{f}_{\vartheta}^{EJ} = V_i^e(z_0|z') \hat{\rho} - \frac{\eta_0^2 \mu_N}{\epsilon_z'} \sin \vartheta \cos \vartheta I_v^e(z_0|z') \hat{\mathbf{z}} \quad (176)$$

$$\mathbf{f}_{\varphi}^{EJ} = \cos \vartheta V_i^h(z_0|z') \hat{\phi} \quad (177)$$

$$\mathbf{f}_{\vartheta}^{EM} = \cos \vartheta I_v^e(z_0|z') \hat{\phi} \quad (178)$$

$$\mathbf{f}_{\varphi}^{EM} = -I_v^h(z_0|z') \hat{\rho} + \frac{\epsilon_N}{\eta_0^2 \mu_z'} \sin \vartheta \cos \vartheta V_i^h(z_0|z') \hat{\mathbf{z}} \quad (179)$$

It is understood here that the TLGFs, which can be computed as explained in Section 7, are evaluated with $k_\rho = k_\rho^s = k_N \sin \vartheta$. Finally, the far-zone magnetic field components corresponding to (175) can be found as [27, p. 133]

$$H_\varphi = \frac{E_\vartheta}{\eta_N}, \quad H_\vartheta = -\frac{E_\varphi}{\eta_N} \quad (180)$$

The simple far-zone approximations derived here are not applicable when the observation point approaches the surface of the multilayer. In that case, there are singularities near the stationary phase point and a modified saddle-point technique must be used [3, p. 461; 12, p. 830].

10. PLANE-WAVE EXCITED FIELDS

In this section we show how the transmission-line formalism can be used to compute the electromagnetic field in any layer of a multilayer stack with piecewise constant parameters, due to a plane wave incident in the upper half-space (layer N). We assume, for simplicity, that the medium of the top layer is isotropic. The direction of arrival of the plane wave is specified by the angles (ϑ_i, φ_i) , and its polarization by the angle ψ_i , as illustrated in Fig. 13. Hence, the propagation vector of this wave can be expressed as $\mathbf{k}^i = \mathbf{k}_\rho^i + \hat{\mathbf{z}} k_{zN}$, where

$$\mathbf{k}_\rho^i = k_N \sin \vartheta_i (\hat{\mathbf{x}} \cos \varphi_i + \hat{\mathbf{y}} \sin \varphi_i), \quad k_{zN} = k_N \cos \vartheta_i \quad (181)$$

and the electric field as

$$\mathbf{E}^i = E_0 [(\hat{\rho}_i \cos \vartheta_i + \hat{\mathbf{z}} \sin \vartheta_i) \cos \psi_i + \hat{\phi}_i \sin \psi_i] \times e^{jk_{zN}(z-z_N)} e^{-j\mathbf{k}_\rho^i \cdot \rho} \quad (182)$$

where E_0 is the specified field amplitude and z_N is the phase reference point, selected to coincide with the upper interface of the multilayer. Note that the directions of the unit vectors $\hat{\rho}_i$ and $\hat{\phi}_i$ are fixed by the angle φ_i , which specifies the plane of incidence. Our goal is to find the total field $(\mathbf{E}_n, \mathbf{H}_n)$ established at any point of any layer n , as a result of the plane wave (182) incident in the upper half-space.

For the fields to match at the interfaces, the dependence of $(\mathbf{E}_n, \mathbf{H}_n)$ on the transverse coordinates must be the same in all layers and must match that of the incident plane wave (182). Furthermore, both the incident field and the total field must satisfy the source-free forms of (16)–(19), with $\mathbf{k}_\rho = \mathbf{k}_\rho^i$. Consequently, the transmission-line analog of the layered medium developed in Section 7 may be employed to find $(\mathbf{E}_n, \mathbf{H}_n)$. With (22) in mind,

Figure 13. Geometry for the evaluation of the plane-wave incident field.

where now $(\tilde{\mathbf{u}}, \tilde{\mathbf{v}}) = (\hat{\rho}_i, \hat{\phi}_i)$, we express the transverse part of (182) as [180,181]

$$\mathbf{E}_i^e(\mathbf{r}) = [\hat{\rho}_i V_N^{e-}(z) + \hat{\phi}_i V_N^{h-}(z)] e^{-jk_\rho^i \cdot \rho} \quad (183)$$

where

$$\begin{aligned} V_N^{e-}(z) &= \underbrace{E_0 \cos \psi_i \cos \vartheta_i}_{V_N^{e-}} e^{jk_{zN}(z-z_N)}, \\ V_N^{h-}(z) &= \underbrace{E_0 \sin \psi_i}_{V_N^{h-}} e^{jk_{zN}(z-z_N)} \end{aligned} \quad (184)$$

We may interpret $V_N^{e-}(z)$ and $V_N^{h-}(z)$ are the leftward-propagating incident voltage waves exciting the TM and TE transmission line networks, respectively, in the TL section corresponding to the upper-half-space (layer N). In view of (27),(28), the total electric and magnetic fields in any layer n can be found as

$$\mathbf{E}_n(\mathbf{r}) = \left[\hat{\rho}_i V_n^e(z) + \hat{\phi}_i V_n^h(z) - \hat{\mathbf{z}} \frac{\eta_N^e \epsilon_N}{\epsilon_{zn}} \sin \vartheta_i I_n^e(z) \right] e^{-jk_\rho^i \cdot \rho} \quad (185)$$

$$\begin{aligned} \mathbf{H}_n(\mathbf{r}) &= \left[-\hat{\rho}_i I_n^h(z) + \hat{\phi}_i I_n^e(z) + \hat{\mathbf{z}} \frac{\mu_N}{\eta_N \mu_{zn}} \sin \vartheta_i V_n^h(z) \right] \\ &\times e^{-jk_\rho^i \cdot \rho} \end{aligned} \quad (186)$$

where $V_n^\alpha(z)$ and $I_n^\alpha(z)$, with $\alpha = (e, h)$, are the total voltage and current at a point z in layer n of the TL network. These voltages and currents can be found as explained in Section 7. Hence, in the upper layer they are given by (125), with $n = N$. In any other layer n , they can be found from (126), where

$$V_{n+1}^\alpha = V_N^{\alpha-} (1 + \overleftarrow{\Gamma}_N^\alpha) \prod_{k=n+1}^{N-1} \overleftarrow{\tau}_k^\alpha \quad (187)$$

with $V_N^{\alpha-}$ given in (184). Note that in deriving this equation, use has been made of (127) and (128). It is understood in the above that all transmission-line voltages and currents are evaluated with $k_\rho = k_\rho^i = k_N \sin \theta_i$.

With reference to Fig. 13, observe that the polarization of the incident plane wave is parallel for $\psi_i = 0$, and perpendicular for $\psi_i = \pi/2$. From (184) we see that the parallel- and perpendicularly polarized waves only excite the TM and TE transmission lines, respectively, and that both lines are excited by an arbitrarily polarized wave. In the case of normal incidence, the field is TEM and the plane of incidence, and thus also φ_i and ψ_i , are undefined. However, this situation may be treated as a limiting case of parallel or perpendicular polarization, as $\vartheta_i \rightarrow 0$.

11. SUMMARY AND CONCLUSION

A complete set of electric- and magnetic-type dyadic Green functions (DGFs) is derived for plane-stratified, multilay-

ered, uniaxial media, based on the transmission-line network analog along the axis normal to the stratification. The DGFs are expressed in terms of transmission-line Green functions (TLGFs), which are the voltages and currents on the transmission-line network excited by unit-strength voltage or current sources. A practical algorithm is given for the efficient computation of the TLGFs. Also, various state-of-the-art techniques for computation of the Sommerfeld integrals are reviewed. Finally, the transmission-line analog is applied to derive the far-zone fields and the plane-wave-excited fields in the layered medium. The unified formulation presented here is compact, convenient to implement, and computationally efficient. It also affords much insight into the layered medium Green functions, because the behavior of the transmission-line voltages and currents is well understood.

12. APPENDIX: WHOLE-SPACE DGFs

In this appendix we give closed forms of the whole-space, three-dimensional DGFs for a uniaxial medium with the parameters of layer n . These expressions have been obtained by retaining only the direct ray terms of the TLGFs (corresponding to ray 0 in Fig. 10) in (69)–(98) and using the identities (164),(165) and their derivatives to evaluate the resulting Sommerfeld integrals.⁴¹ Equivalent forms of these DGFs were derived previously [135] using a different approach.

First, to simplify the equations, we define

$$\Psi_n^\alpha = v_n^\alpha \frac{e^{-jk_n R_n^z}}{4\pi R_n^\alpha}, \quad D_n^\alpha = \frac{e^{-jk_n R_n^z}}{4\pi j k_n \varrho^2}, \quad (A.1)$$

$$R_n^\alpha = \sqrt{v_n^\alpha \varrho^2 + (z - z')^2}$$

$$S_n^\alpha = \frac{\varrho}{R_n^\alpha}, \quad C_n^\alpha = \frac{z - z'}{R_n^\alpha} \quad (A.2)$$

$$\Lambda_n^\alpha = \frac{j}{k_n R_n^\alpha} + \frac{1}{(k_n R_n^\alpha)^2}, \quad \Upsilon_n^\alpha = 1 - \frac{j}{k_n R_n^\alpha} \quad (A.3)$$

Using this notation, the whole-space terms of (69)–(76) can be written as

$$\begin{aligned} G_{xx}^{E,I}(\mathbf{r}|\mathbf{r}') &= -jk_n \eta_n \{ [(1 - \Lambda_n^e) + \cos^2 \phi v_n^e (S_n^e)^2 (3\Lambda_n^e - 1)] \Psi_n^e \\ &\quad - \sin^2 \phi (\Psi_n^e - \Psi_n^h) + \cos(2\phi) (D_n^e - D_n^h) \} \end{aligned} \quad (A.4)$$

⁴¹The delta function terms in [76] and [98] are canceled in this process; however, the z derivatives must be taken in the sense of distributions [182].

$$G_{xy}^{EJ}(\mathbf{r}|\mathbf{r}') = G_{yx}^{EJ}(\mathbf{r}|\mathbf{r}') = -jk_n\eta_n\{\sin\phi\cos\phi v_n^e(S_n^e)^2(3\Lambda_n^e - 1)\Psi_n^e + \sin\phi\cos\phi(\Psi_n^e - \Psi_n^h) + \sin(2\phi)(D_n^e - D_n^h)\} \quad (\text{A.5})$$

$$G_{yy}^{EJ}(\mathbf{r}|\mathbf{r}') = -jk_n\eta_n\{[(1 - \Lambda_n^e) + \sin^2\phi v_n^e(S_n^e)^2(3\Lambda_n^e - 1)]\Psi_n^e - \cos^2\phi(\Psi_n^e - \Psi_n^h) - \cos(2\phi)(D_n^e - D_n^h)\} \quad (\text{A.6})$$

$$G_{xz}^{EJ}(\mathbf{r}|\mathbf{r}') = G_{zx}^{EJ}(\mathbf{r}|\mathbf{r}') = -jk_n\eta_n\cos\phi S_n^e C_n^e \times (3\Lambda_n^e - 1)\Psi_n^e \quad (\text{A.7})$$

$$G_{yz}^{EJ}(\mathbf{r}|\mathbf{r}') = G_{zy}^{EJ}(\mathbf{r}|\mathbf{r}') = -jk_n\eta_n\sin\phi S_n^e C_n^e \times (3\Lambda_n^e - 1)\Psi_n^e \quad (\text{A.8})$$

$$G_{zz}^{EJ}(\mathbf{r}|\mathbf{r}') = -jk_n\eta_n[(1 - \Lambda_n^e) + (C_n^e)^2(3\Lambda_n^e - 1)]\frac{\Psi_n^e}{v_n^e} \quad (\text{A.9})$$

Similarly, the whole-space parts of (84)–(90) are found as

$$G_{xx}^{HJ}(\mathbf{r}|\mathbf{r}') = -G_{yy}^{HJ}(\mathbf{r}|\mathbf{r}') = jk_n[\sin\phi\cos\phi(C_n^e\Upsilon_n^e\Psi_n^e - C_n^h\Upsilon_n^h\Psi_n^h) + \sin(2\phi)(C_n^e D_n^e - C_n^h D_n^h)] \quad (\text{A.10})$$

$$G_{xy}^{HJ}(\mathbf{r}|\mathbf{r}') = jk_n[\sin^2\phi C_n^e\Upsilon_n^e\Psi_n^e + \cos^2\phi C_n^h\Upsilon_n^h\Psi_n^h - \cos(2\phi)(C_n^e D_n^e - C_n^h D_n^h)] \quad (\text{A.11})$$

$$G_{yx}^{HJ}(\mathbf{r}|\mathbf{r}') = -jk_n[\cos^2\phi C_n^e\Upsilon_n^e\Psi_n^e + \sin^2\phi C_n^h\Upsilon_n^h\Psi_n^h + \cos(2\phi)(C_n^e D_n^e - C_n^h D_n^h)] \quad (\text{A.12})$$

$$G_{xz}^{HJ}(\mathbf{r}|\mathbf{r}') = -jk_n\sin\phi S_n^e\Upsilon_n^e\Psi_n^e \quad (\text{A.13})$$

$$G_{zx}^{HJ}(\mathbf{r}|\mathbf{r}') = jk_n\sin\phi S_n^h\Upsilon_n^h\Psi_n^h \quad (\text{A.14})$$

$$G_{yz}^{HJ}(\mathbf{r}|\mathbf{r}') = jk_n\cos\phi S_n^e\Upsilon_n^e\Psi_n^e \quad (\text{A.15})$$

$$G_{zy}^{HJ}(\mathbf{r}|\mathbf{r}') = -jk_n\cos\phi S_n^h\Upsilon_n^h\Psi_n^h \quad (\text{A.16})$$

It is noted that the whole-space $\underline{\underline{G}}^{EJ}$ is symmetric. One also observes that considerable simplifications in both $\underline{\underline{G}}^{EJ}$ and $\underline{\underline{G}}^{HJ}$ occur for isotropic media, in which case $R_n^e = \bar{R}_n^h \equiv R$, $\Psi_n^e = \Psi_n^h$, $D_n^e = D_n^h$, $S_n^e = \rho/R \equiv \sin\Theta$ and $C_n^e = (z - z')/R \equiv \cos\Theta$. In particular, $\underline{\underline{G}}^{EJ}$ properly reduces to its isotropic form [2, p. 221] and $\underline{\underline{G}}^{HJ}$ becomes skew-symmetric (i.e., it is equal to the negative of its transpose, with zero diagonal).

In view of the duality between $\underline{\underline{G}}^{EJ}$ and $\underline{\underline{G}}^{HM}$, the whole-space components of the latter can be derived from by making the substitution of symbols $\varepsilon \rightarrow \mu$ and $\mu \rightarrow \varepsilon$, which also entails the superscript replacement $e \rightarrow h$ and $h \rightarrow e$. Finally, the components of the whole-space $\underline{\underline{G}}^{EM}$ can be obtained from (A.10)–(A.16) by using the recipro-

city relation (12), which in the present case (infinite, homogeneous medium) simplifies to $G_{ij}^{EM}(\mathbf{r}|\mathbf{r}') = G_{ji}^{HJ}(\mathbf{r}|\mathbf{r}')$, i.e., $\underline{\underline{G}}^{EM}$ is simply the transpose of $\underline{\underline{G}}^{HJ}$.

The above expressions make evident the source region singularities of the DGFs. Namely, $\underline{\underline{G}}^{EJ}$ and $\underline{\underline{G}}^{HM}$ behave as R^{-3} , and $\underline{\underline{G}}^{HJ}$ and $\underline{\underline{G}}^{EM}$ behave as R^{-2} , where R represents either R^e or R^h .

ELECTROMAGNETIC FIELD MEASUREMENT

MOTOHISA KANDA
National Institute of Standards
and Technology

To establish standards for conducting electromagnetic (EM) field measurements, measurements must be made (1) in anechoic chambers, (2) at open-area test sites, and (3) within guided-wave structures; and a means to transfer these measurements from one situation to another must be developed. The underlying principles of these measurement and transfer standards are (1) measurements and (2) theoretical modeling. Thus, a parameter or a set of parameters is measured, or a parameter is calculated by established physical and mathematical principles.

Various electromagnetic field sensors for measuring radiofrequency (RF) electric and magnetic fields are discussed below. For electric field measurements, electrically short dipole antennas with a high-input-impedance load, such as a field-effect transistor (FET) and a high-frequency diode detector, are discussed. Since the input impedance of an electrically short dipole antenna is predominantly a capacitive reactance, very broadband frequency responses can be achieved with a high-impedance capacitive load. However, because conventional dipole antennas support a standing-wave current distribution, the useful frequency range of these dipole antennas is usually limited by their natural resonant frequencies. In order to suppress these resonances, a resistively loaded dipole antenna has been developed. To obtain a standard antenna with increased sensitivity at a specific frequency, a half-wave tuned dipole antenna with a diode is used, to measure the induced open-circuit voltage. Also used was a tuned receiver with a half-wave tuned dipole antenna, to further improve antenna sensitivity.

For magnetic field measurements, this article discusses an electrically small, resistively loaded loop antenna to achieve a broadband response. Resistive loading is achieved either with the loading resistance at the loop terminal or by uniform resistive loading along the loop antenna. This short-circuit current loop configuration gives a very flat frequency response over a wide frequency range.

In the region near a transmitting antenna or a scatterer, the electric and magnetic field vectors are not necessarily (spatially) orthogonal or in phase. For time-harmonic fields, the endpoints of the field vectors trace out polarization ellipses, and the Poynting vectors lie on the surface of a cone with its endpoint on an ellipse. In these cases, the electric and magnetic fields may be measured separately, or, using the single-loop antenna element described in this article, they may be measured simultaneously.

Photonic sensors are also discussed; they provide the wide bandwidth and low dispersion necessary to maintain the fidelity of time-domain signals. Since they consist of electro-optic modulators and optical fibers, they are free from electromagnetic interference, and there is minimal perturbation of the field being measured.

Throughout the discussion, the interplay between measured quantities and predicted (modeled) quantities is emphasized. The ability of measurements and the restrictions imposed by rigorous theoretical analysis of given models are discussed for the frequencies from 10 kHz to 40 GHz and upward.

1. ELECTRIC FIELD SENSORS

1.1. An Electrically Short Dipole Antenna with a Capacitive Load

Most electric field sensors consist of dipole antennas. The induced open-circuit voltage V_{oc} at the dipole antenna terminal is given by

$$V_{oc} = E_{inc}L_{eff} \quad (1)$$

where E_{inc} is the normal incident electric field strength and L_{eff} is the effective length of the dipole antenna. For an electrically short dipole antenna whose physical length is much shorter than the wavelength, the effective length L_{eff} and driving point capacitance C_a are approximately [1]

$$L_{eff} = \frac{L(\Omega - 1)}{4(\Omega - 2 - \ln 4)} \quad (2)$$

and

$$C_a = \frac{4\pi\epsilon_0 L}{2(\Omega - 2 - \ln 4)} \quad (3)$$

where L is the physical length of the dipole antenna, ϵ_0 is the free-space permittivity, Ω is the antenna thickness factor $\Omega = 2 \ln(L/a)$, and a is the antenna radius.

For an electrically short dipole antenna with a capacitive load C , the transfer function is given by [1]

$$S(f) = \frac{V_o(f)}{E_{inc}(f)} = \frac{h\kappa/2}{1 + C/C_a} \quad (4)$$

where

$$C_a = \frac{4\pi h}{c\zeta_0(\Omega - 2 - \ln 4)} \quad (5)$$

$$\kappa = \frac{\Omega - 1}{\Omega - 2 + \ln 4} \quad (6)$$

and where

- a = antenna radius
- C = capacitance of load
- C_a = capacitance of antenna
- E_{inc} = incident electric field
- h = half of the physical length of the dipole antenna
- V_o = output voltage of the antenna
- ζ_0 = free-space impedance
- c = speed of light in free space
- Ω = antenna thickness factor, $\Omega = 2 \ln(2h/a)$

Since the input impedance of an electrically short dipole antenna is almost purely capacitive, it is possible to achieve a frequency-independent transfer function with a capacitive load, as indicated in Eq. (4). In practice, the load impedance is seldom purely capacitive, but also may have a resistive component. This resistive component will cause a 6-dB/octave rolloff at the low end of the frequency range.

1.2. An Electrically Short Dipole Antenna with a Diode

A common standard sensor used for EM field measurements is an electrically short dipole antenna with a diode load connected to a DC metering unit by an RF filter transmission line. The main advantage of including a diode is to make the frequency response of the sensor very flat, even at higher frequencies where an FET amplifier is not readily available. When used with a high-input-impedance detector, the sensor can serve as a portable and compact transfer standard.

Figure 1 represents a dipole antenna, which can be used to determine the signal from the transmission line for a given incident electric field [2]. This circuit is valid for the frequency range to be considered (DC and $f > 1$ MHz). In Fig. 1, the small antenna resistance has been neglected. The stray gap capacitance of the filter line from the antenna terminal connections has been included in the effective shunt capacitance C_d . The antenna capacitance is given by C_a .

When a first-order, nonlinear differential equation associated with the Thevenin's equivalent nonlinear circuit

Figure 1. Thevenin's equivalent circuit of an electrically short dipole antenna with a shunt diode detector.

(shown in Fig. 1) is solved for the detected DC voltage V_o , for a small induced RF voltage V_i [2] we obtain

$$V_o = -\frac{\alpha}{4} \left(\frac{V_i}{1 + C_d/C_a} \right)^2 \quad (7)$$

where α ($\approx 38 \text{ V}^{-1}$) is derived from the diode characteristics, while for large V_i

$$V_o \cong -\frac{V_i}{1 + C_d/C_a} \quad (8)$$

Equation (7) indicates that for a small induced RF voltage V_i , the output DC voltage V_o is a square-law function of the induced voltage. On the other hand, Eq. (8) indicates that, for a large induced voltage V_i , the output DC voltage V_o is directly proportional to the induced voltage.

1.3. A Resistively Loaded Dipole Antenna with a Diode

A conventional dipole antenna essentially supports a standing-wave current distribution and is, therefore, highly frequency-sensitive. For the antenna to have a flat frequency response beyond any natural resonant frequency, a traveling-wave dipole antenna was realized by use of continuously tapered resistive loading [3,4]. If the internal impedance per unit length $Z^i(z)$ as a function of the axial coordinate z is expressed as

$$Z^i(z) = \frac{60\Psi}{h - |z|} \quad (9)$$

then the current distribution $I_z(z)$ along the linear antenna is that of a traveling wave

$$I_z(z) = \frac{V_i}{60\Psi(1 - j/kh)} \left[1 - \frac{|z|}{h} \right] e^{-jk|z|} \quad (10)$$

where $2h$ is the dipole antenna's total physical length, k is the wavenumber, V_i is the driving voltage, and Ψ is given by

$$\Psi = 2 \left[\sinh^{-1} \frac{h}{a} - C(2ka, 2kh) - jS(2ka, 2kh) \right] + \frac{j}{kh} (1 - e^{-j2kh}) \quad (11)$$

where a is the radius of the dipole and $C(x,y)$ and $S(x,y)$ are the generalized cosine and sine integrals. The main advantage of a resistively loaded dipole antenna with a diode is the very flat frequency response of the sensor system. A shortcoming of this sensor system is the relatively low sensitivity. To overcome this problem, a standard half-wave tuned dipole antenna should be used.

1.4. A Tuned Half-Wave Dipole Antenna

The magnitude of the electric field component at a given point in an electromagnetic field is determined from the open-circuit voltage V_{oc} induced in a standard half-wave

receiving dipole antenna as obtained from Eq. (1). The induced voltage is measured across the center gap of the dipole antenna, which is oriented parallel to the electric field vector of the incident field.

The RF voltage induced in the half-wave standard dipole antenna is rectified by a high-impedance Schottky barrier diode connected in shunt across the center gap of the antenna. The diode output is filtered by a balanced RC network, and this DC voltage is measured with a high-impedance DC voltmeter.

The effective length h_e of a thin dipole antenna near resonance and the required total length L for resonance are given by [1]

$$h_e = \frac{\lambda}{\pi} \tan\left(\frac{\pi h}{\lambda}\right) \quad (12)$$

and

$$L = \frac{\lambda}{2} \left[1 - \frac{0.2257}{\ln(\lambda/D) - 1} \right] \quad (13)$$

where D is the diameter of the standard dipole antenna.

To further increase the sensitivity of a standard antenna, a half-wave tuned dipole antenna with a narrowband receiver should be used. In this case, the transfer function $S(f)$ is given by

$$S(f) = \frac{V_L(f)}{E_{\text{inc}}(f)} = \frac{h_e Z_a}{Z_a + Z_r} \quad (14)$$

where V_L is the voltage across the receiver load, E_{inc} is the incident electric field, h_e is the effective length of the tuned dipole, Z_a is the antenna impedance, and Z_r is the receiver input impedance ($\sim 50 \Omega$). The input impedance of the antenna Z_a is complicated and is given in Ref. 1. When the cable losses are significant, they should be included in Z_a .

2. MAGNETIC FIELD SENSORS

2.1. An Electrically Small Loop Antenna with a Loading Resistance

A magnetic field sensor consists of an electrically small, balanced loop antenna. The voltage V_i induced in an electrically small loop antenna by an electromagnetic wave incident on the loop antenna is determined from Maxwell's equations and Stokes' theorem, and is given by [1]

$$V_i = \int E_i d\ell = j\omega\mu H_i NS \quad (15)$$

where E_i is the tangential electric field induced around the loop antenna, l is the circumference of the loop antenna, ω is the angular frequency of E_i , μ is the permeability of the loop antenna core, H_i is the component of the magnetic field normal to the plane of the loop antenna, N is the number of loop antenna turns, and S is the area of the loop antenna. The induced voltage V_i of an electrically small

loop antenna is proportional to frequency, the number of loop turns, and the area of the loop antenna.

To make the response of a loop antenna flat over the frequency range of interest, the Q of the antenna has to be reduced through a loading resistance. The resonance of a loop antenna is the result of the combined effect of the distributed capacitance of the loop antenna, the gap capacitance, and the capacitance of the amplifier along with the inductance of the loop antenna. The equivalent circuit for an electrically small loop antenna is shown in Fig. 2. Here V_i is the induced voltage, L is the loop inductance, C is the capacitance, R is the loading resistance, and V_o is the voltage across the loading resistance. Then the response of an electrically small loop antenna is given by [1]

$$\frac{V_o}{V_i} = \frac{-j\frac{1}{\delta}}{\frac{1}{Q} + j\left(\delta - \frac{1}{\delta}\right)} \quad (16)$$

where

$$Q = \frac{R}{X_0}, \quad X_0 = \omega_0 L = \frac{1}{\omega_0 C}, \quad \delta = \frac{\omega}{\omega_0}, \quad \omega_0 = \frac{1}{\sqrt{LC}} \quad (17)$$

The inductance L and the capacitance C of a loop antenna can be given by

$$L = \mu b \ln\left(\frac{b}{a}\right) \quad (18)$$

and

$$C = \frac{2\epsilon b}{\ln\left(\frac{b}{a}\right)} \quad (19)$$

where μ is the permeability of the medium, b is the loop antenna radius, and a is the radius of the loop wire.

The transfer function of $S(f)$ of an electrically small loop antenna can be obtained by combining Eqs. (15) and (16):

$$S(f) = \frac{V_o}{H_i} = \omega_0 \mu NS \frac{1}{\frac{1}{Q} + j\left(\delta - \frac{1}{\delta}\right)} \quad (20)$$

Figure 2. Thevenin's equivalent circuit of an electrically small loop antenna with a loading resistance.

The normalized transfer function $S_n(f)$ of a loop antenna with a loading resistor is given by

$$S_n(f) = \frac{1}{\frac{1}{Q} + j\left(\delta - \frac{1}{\delta}\right)} \tag{21}$$

as a function of the normalized frequency $\delta = \omega/\omega_0$ and is given in Fig. 3 for various $Q < 1$. Figure 3 shows that the upper frequency end ω_h of the 3-dB rolloff point is given by $\delta_h Q = 1$ and, similarly, the corresponding low frequency ω_l of the 3-dB rolloff point is given by $\delta_l/Q = 1$. Thus, from these conditions, we obtain

$$\delta_h \delta_l = \frac{\omega_h \omega_l}{\omega_0^2} = 1 \tag{22}$$

or

$$\omega_0 = \sqrt{\omega_h \omega_l} \tag{23}$$

The self-resonant frequency of a loop antenna is therefore the geometric mean of the highest and lowest cutoff frequencies.

3. AN ELECTROMAGNETIC FIELD SENSOR FOR SIMULTANEOUS ELECTRIC AND MAGNETIC FIELD MEASUREMENTS

The electric and magnetic field sensors discussed above measure either the electric or magnetic field only and, therefore, cannot measure complicated EM fields such as those with reactive near-field components and multipath reflections. For this reason, a single sensor capable of performing simultaneous electric and magnetic field measurements was developed [5,6]. In this case, a loop antenna is loaded at diametrically opposite points with equal impedances. Across one load, the magnetic loop response adds to the electric dipole response, whereas across the other load, the magnetic loop response subtracts from the electric dipole response. Thus, by taking the sum and difference of currents across loads at diametrically opposite points, the magnetic loop response and electric dipole response can be separated. Thus, the sum current gives a measure of the magnetic field, whereas the difference current gives a measure of the electric field.

To explain the basic characteristics of a doubly loaded loop antenna, the currents I_1 and I_2 at each load are given

Figure 3. The normalized transfer function of a loop antenna as a function of normalized frequency for different values of Q .

by [5]

$$I_1 = 2\pi b E_{\text{inc}} \left(\frac{f_0 Y_0}{1 + 2Y_0 Z_L} + \frac{f_1 Y_1}{1 + 2Y_1 Z_L} \right) \quad (24)$$

and

$$I_2 = 2\pi b E_{\text{inc}} \left(\frac{f_0 Y_0}{1 + 2Y_0 Z_L} - \frac{f_1 Y_1}{1 + 2Y_1 Z_L} \right) \quad (25)$$

where b is the radius of the loop, E_{inc} is the incident electric field, Z_L is the load impedance, Y_0 is the admittance for the magnetic loop response, and Y_1 is the admittance for the electric dipole antenna response of a loop. In general, Y_0 is much larger than Y_1 . f_0 and f_1 are Fourier coefficients of the incident wave. For a loop antenna orientation of maximum electric and magnetic field response, $f_0 = j\beta b/2$ and $f_1 = \frac{1}{2}$. Taking the sum and difference of these currents yields [5]

$$I_\Sigma = \frac{1}{2} (I_1 + I_2) = 2\pi b E_{\text{inc}} \frac{f_0 Y_0}{1 + 2Y_0 Z_L} \quad (26)$$

and

$$I_\Delta = \frac{1}{2} (I_1 - I_2) = 2\pi b E_{\text{inc}} \frac{f_1 Y_1}{1 + 2Y_1 Z_L} \quad (27)$$

This indicates that the sum current can be used to measure the magnetic field and the difference current can be used to measure the electric field. In general, $2Y_0 Z_L > 1$ for the magnetic field loop antenna current. Therefore, when the antenna is oriented for maximum response, I_Σ can be approximated as

$$I_\Sigma \cong j \frac{E_{\text{inc}}}{2Z_L} \pi b^2 \beta \quad (28)$$

This indicates that the magnetic loop current is approximately proportional to the product of frequency and the area of the loop antenna, and is inversely proportional to the load impedance. Similarly, for the electric field dipole current, assuming that $2Y_1 Z_L \ll 1$, we have

$$I_\Delta \cong \pi b E_{\text{inc}} Y_1 \quad (29)$$

which is approximately proportional to the product of the circumference of the loop antenna and frequency, since Y_1 has a capacitive susceptance (positive) and increases with frequency. This device is intended to measure not only the polarization ellipses of the electric and magnetic field vectors in the near field region but also the time-dependent Poynting vector and thus describe the energy flow.

4. PHOTONIC ELECTROMAGNETIC FIELD SENSORS

Properly designed photonic EM field sensors provide the wide bandwidth and low dispersion necessary to maintain the fidelity of time-domain signals so that both amplitude and phase information can be retrieved [7]. They are free

from electromagnetic interference, and there is minimal perturbation of the field being measured.

A number of photonic passive sensors for EM field measurements have been reported in the literature [7]. These are systems in which the sensor head contains no active electronics or power supplies. Optical measurement systems of the typical photonic EM field sensors is shown schematically in Fig. 4. Light from a laser is launched into an optical fiber link and serves as an optical signal carrier. At the sensor head, the EM field induces a voltage across the modulator crystal and changes its index of refraction. The crystal index changes occur at the frequency of the impressed EM field and result in a modulation in the amplitude of the optical carrier. At the receiver end of the fiber the light is converted to an electrical signal by a photodiode and is suitably amplified for analysis with a spectrum analyzer, oscilloscope, or other signal processor. The electro-optic interaction is weak, and, except for very high fields, the gain of a small antenna is usually required to obtain adequate modulation.

For the measurement of a pulsed electric field, an antenna with a flat broadband response is most desirable. A resistively loaded dipole antenna gives a nonresonant frequency response and is, therefore, ideal for use in the time-domain measurement of electromagnetic fields [3,4]. Electro-optical modulators that are driven by antenna feeds are characterized as a function of the voltage applied to their electrodes. A convenient parameter for characterizing a modulator's performance is the voltage V_π that is needed across the electrode to drive a modulator between maximum and minimum optical power levels. In general, a modulator transfer function is nonlinear. However, in most cases of interest, the field-induced RF voltages on the modulator's electrodes are small compared to V_π , and a small-signal linear transfer function evaluated at the operating bias point is appropriate. The most desirable operating bias point is where the modulator's sensitivity and linear range are at maximum. The physical characteristics of four modulators used in photonic EM field sensors are given in Table 1.

4.1. Pockels Cell

Pockels cell modulators often are used in EM field sensors. The small signal transfer function takes the form given in Table 1, when the constant phase shift Φ_0 is set equal to $-\pi/2$ by introducing a quarter-wave retardation plate into the cell. This biases the modulator at its point of maximum sensitivity and linearity. The characteristic voltage of a bulk crystal modulator is limited by (1) the magnitude of the electro-optic coefficients for available materials, (2) the minimum dimensions of crystals that can be handled as discrete optical elements, and (3) the maximum crystal lengths acceptable for the highest desired operating frequency. For operation to 5 GHz, the lowest obtainable values for V_π are on the order of 100 V for LiNbO_3 . It is relatively easy to increase V_π and reduce the modulator's sensitivity in order to measure high fields. In one application of this technology for measuring fields from electromagnetic pulses, a crystal of $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ (BGO), which has cubic symmetry and reduced temperature sensitivity,

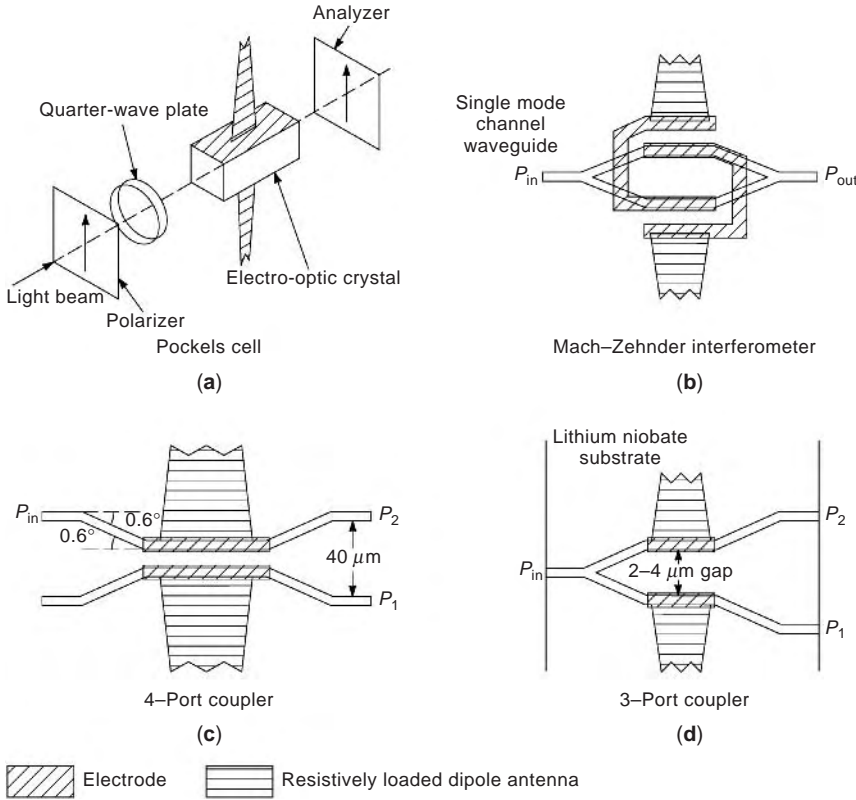

Figure 4. Measurement system of a photonic EM field sensor.

is used in a Pockels cell modulator and has a V_π of approximately 2100 V.

4.2. Mach-Zehnder Interferometer

Modulators based on Mach-Zehnder (MZ) interferometers and fabricated using optical guided wave (OGW) technologies have found widespread use in the fiberoptic communications industry. Their use as EM field sensors also has been investigated [7]. Photolithography is used to fabricate OGW modulators by defining the waveguide channels and then diffusing titanium into the surface of a LiNbO_3 crystal along these channels. The transfer function for an MZ interferometer is identical to that of the Pockels cell. The static phase shift Φ_0 is due to differences in the optical path length in the interferometer arms. Significantly, V_π for this device is typically two orders of magnitude smaller than that for a Pockels cell modulator of the same material and frequency response. The higher sensitivity is typical of most OGW modulators and arises from the higher fields created in the crystal with the closely spaced electrodes that are achievable using photo lithography. The principal problems to date with the MZ interferometer have been the difficulty in obtaining the correct value for Φ_0 during fabrication, and its temperature and wavelength dependence.

4.3. Directional Coupler

Directional couplers are also OGW devices that have been investigated for use as EM field sensors [7]. In the inter-

action region, the two waveguides lie close enough together that the evanescent field of the lightwave in one guide couples into the other guide. In such a coupled-mode system, the energy in one lightguide can be switched to the other guide by changing the relative propagation constants in the channels with the electro-optic effect. If the fabrication parameters are chosen correctly, the transfer function given in the literature [7] for the directional coupler can be written in the form given in Table 1.

5. ELECTROMAGNETIC FIELD STANDARDS

5.1. Transverse Electromagnetic Cell

Transverse electromagnetic (TEM) transmission-line cells are devices used for establishing standard EM fields in a

Table 1. Transfer Functions for Electro Optic Modulators

Modulator	General	Small Signal
Pockels cell	$\cos^2\left(\frac{\pi}{2}V_n + \frac{\phi_0}{2}\right)$	$\frac{\pi}{2V_\pi}$
Mach-Zehnder	$\cos^2\left(\frac{\pi}{2}V_n + \frac{\phi_0}{2}\right)$	$\frac{\pi}{2V_\pi}$
4-port coupler	$\frac{1}{1+3V_n^2} \sin^2\left(\frac{\pi}{2}\sqrt{1+3V_n^2}\right)$	$\approx \frac{1.6}{V_\pi}$
3-port coupler	$\frac{1}{2} - \frac{2V_n}{1+4V_n^2} \sin\left(\frac{\pi}{2\sqrt{2}}\sqrt{1+4V_n^2}\right)$	$\frac{2}{V_\pi} \sin \frac{\pi}{2\sqrt{2}} = \frac{1.79}{V_\pi}$

shielded environment [8]. Their application is becoming increasingly widespread because of their versatility, measurement accuracy, and ease of operation.

A TEM cell is essentially a 50-Ω triplate transmission line with the sides closed in, to prevent radiation of RF energy into the environment and to provide electrical isolation. A properly designed cell, terminated in its characteristic impedance, is capable of producing a calculable electric and magnetic field for calibrating an electrically small antenna or RF sensor. The cell consists of a section of rectangular coaxial transmission lines tapered at each end to adapt to standard coaxial connectors. The line and tapered transitions are designed to have a nominal characteristic impedance of 50 Ω along their length, to ensure minimum-voltage standing-wave ratio. A fairly uniform EM field is established between the plates inside the cell when RF energy is conducted in the line from a transmitter connected to the cell’s input port. A 50-Ω termination is connected to the cell’s output port. The expression for determining the electric field *E* in the cell is given by

$$E = \frac{V}{b} = \frac{\sqrt{PZ_0}}{b} \tag{30}$$

where *V* is the RMS voltage on the septum (center conductor), *b* is the separation distance between the septum and lower or upper walls, *P* is the net power flow to the cell, and *Z*₀ is the real part of the cell’s characteristic impedance $\cong 50 \Omega$.

A wave traveling through a cell has essentially the free-space impedance ($\cong 120\pi \Omega$), thus providing a close approximation to a far-field plane wave propagating in free space. The design of TEM cells can be based on an approximate equation for the characteristic impedance of a rectangular transmission line [8]

$$Z_0 \cong \frac{377}{4} \left\{ \left[\frac{p}{q} - \frac{2}{\pi} \ln \left(\sinh \frac{\pi g}{2q} \right) \right] - \frac{\Delta c}{\epsilon_0} \right\}^{-1} \tag{31}$$

where *p*, *q*, and *g* are as shown in Fig. 5 and $\Delta c/\epsilon_0$ is related to the fringing capacitance between the edges of the septum and the sidewalls. For large gaps ($g/p > 0.2$), this fringing term approaches zero [8].

The upper useful frequency for a cell is limited by distortion in the test field caused by multimoding and resonances that occur within the cell at frequencies above the

Figure 5. Cross-sectional view of a TEM cell.

cell’s multimode cutoff. Resonant frequencies associated with these modes can be found from the expression [8]

$$F_{\text{res}} = \sqrt{f_{mn}^2 + \left(\frac{cl}{2L} \right)^2} \tag{32}$$

where *f*_{*mn*} are the frequencies of the higher-order mode(s) excited inside the cell, *c* is the wave propagation velocity ($\cong 3.0 \times 10^8$ m/s), *L* is the resonant length of the cell in meters, and *l*, *m*, and *n* are integers corresponding to multiples of the resonant length and the particular waveguide mode. The influence of the first-order TE modes does not become significant until approaching their resonances. Since most cells are designed with the center plate (septum) centered symmetrically, the odd-order TE modes are not excited in an empty cell. The presence of a device placed in the cell will, however, excite these modes in varying degrees, depending on its size, shape, and placement.

5.2. Waveguide Chamber

For the frequency range of 300–1000 MHz, one can use a waveguide section with a rectangular cross section with a width-to-height (aspect) ratio of 2:1. The length of a guide “cell” must exceed two wavelengths over the specified frequency band, in order to create a fairly uniform field within the guide. Electromagnetic power is transmitted through the guide to a matched resistive load, and the maximum frequency is limited by the requirement that power propagates in the guide in the dominant TE₁₀ mode. In this well-known case, the direction of the electric field vector is across the narrow face of the guide.

Assuming good conductivity of the waveguide walls, an air dielectric, and sinusoidal excitation, the lowest cutoff frequency *f*_{co} is

$$f_{\text{co}} = \frac{c}{2a} \tag{33}$$

where *c* is the wave propagation velocity ($\cong 3.0 \times 10^8$ m/s) and *a* is the guide width.

The longest or cutoff wavelength is given by $\lambda_{\text{co}} = 2a$. The wavelength λ_{wg} inside the guide for these operating conditions is

$$\frac{1}{\lambda_{\text{wg}}} = \sqrt{\left(\frac{1}{\lambda_0} \right)^2 - \left(\frac{1}{\lambda_{\text{co}}} \right)^2} \tag{34}$$

where λ_0 is the free-space wavelength.

The transverse impedance *Z*_w of the wave traveling in the guide is

$$Z_w = \frac{-E_y}{H_z} = \zeta_0 \left(\frac{\lambda_{\text{wg}}}{\lambda_0} \right) = \frac{\zeta_0}{\sqrt{1 - (\lambda_0/2a)^2}} \tag{35}$$

where ζ_0 is the intrinsic impedance of free space ($\cong 120\pi$).

The direction of the electric field vector is across the narrow face of the guide, and its RMS magnitude at the

center of a rectangular waveguide is given by

$$E = \sqrt{\frac{2Z_w P_z}{ab}} \quad (36)$$

and, similarly, the RMS magnitude of the magnetic field in the guide center is given by

$$H = \sqrt{\frac{2P_z}{Z_w ab}} \quad (37)$$

where P_z is the total power flow in the guide and ab is the cross-sectional area of the waveguide ($= 0.5 a^2$).

5.3. Microwave Anechoic Chambers

Microwave anechoic chambers currently are used for a variety of indoor antenna measurements, electromagnetic field measurements, electromagnetic interference (EMI) measurements, and electromagnetic compatibility (EMC) measurements. The primary requirement is that a transmitting antenna at one location within a chamber or at a chamber wall generates a known field throughout a volume of the chamber, which has dimensions sufficient to perform EM field measurements. This volume is frequently called a *quiet zone*, and the level of reflected waves within it will determine the performance of the anechoic chamber.

Electromagnetic field measurements in an anechoic chamber usually are performed in the near-field region of a transmitting standard antenna. To establish the standard field, the radiated field intensity in the near-field region of the transmitting antenna is calculated. The antennas typically used for the anechoic chamber measurements consist of a series of open-ended waveguides at frequencies below 450 MHz, and a series of rectangular pyramidal horn antennas at frequencies above 450 MHz.

The electric field strength at a specific distance from the radiating antenna is calculated from measurements of the power delivered to the transmitting antenna and a knowledge of the gain of the antenna as a function of frequency and distance to the field point. The equation used to calculate the electric field E on the boresight axis of the transmitting antenna is

$$E = \frac{1}{d} \sqrt{\frac{\zeta_0 P_{\text{net}} G}{4\pi}} \approx \frac{\sqrt{30 P_{\text{net}} G}}{d} \quad (38)$$

where P_{net} is the net power delivered to the transmitting antenna, ζ_0 is the free-space impedance ($\approx 120\pi \Omega$), G is the near-field gain of the transmitting antenna at the given frequency and distance, and d is the distance from the center of the aperture of the transmitting antenna (horn or open-ended waveguide) to the on-axis field point.

The net power P_{net} delivered to the transmitting antenna is the difference between the incident P_{inc} and reflected P_{refl} powers as measured with a calibrated directional coupler (four ports) with calibrated power meters. In order for measurements to be accurate, an anechoic chamber must provide a truly free-space test

environment. The performance of a rectangular RF anechoic chamber can be determined by measuring the relative insertion loss versus separation distance between a source antenna and a receiving antenna.

Antenna insertion loss is the ratio of power received by a receiving antenna or probe to the power accepted by the transmitting antenna. If the anechoic chamber is a perfect free-space simulator, the relative insertion loss between two polarization-matched antennas will vary with distance according to the Friis transmission formula [9]

$$\frac{P_r}{P_t} = G_r G_t \left(\frac{\lambda}{4\pi d} \right)^2 \quad (39)$$

where P_t is the net power delivered to the transmitting antenna, P_r is the power received by the receiving antenna, G_t is the near-field gain of the transmitting antenna, G_r is the near-field gain of the receiving antenna, d is the separation distance between the two antennas, and λ is the wavelength. Experimental data can be compared with the calculated free-space transmission loss, using appropriate near-field transmitting antenna gains. The difference between the measured and calculated transmission loss is a measure of reflections from chamber surfaces.

5.4. Open-Area Test Sites

An open-area test site typically is used for the antenna calibration in the frequency range of 10 kHz–1000 MHz. A calibration consists of determining the antenna factor that permits a receiver (RF voltmeter) to be used with the calibrated antenna to conduct measurements of field strength.

At frequencies below about 50 MHz, loop antennas are calibrated in a quasi-static, near-zone, magnetic field produced by a balanced single-turn transmitting loop with a 10 cm radius. Above 25 MHz, dipole antennas are calibrated in a far-zone electric field, which is evaluated in terms of the open-circuit voltage induced in a self-resonant receiving dipole antenna. Between 30 kHz and 300 MHz, vertical monopole antennas and small probes are evaluated in an elliptically polarized electromagnetic field produced by a transmitting monopole antenna above a conducting ground screen.

Field strength can be evaluated using two independent techniques: (1) the standard field method and (2) the standard antenna method. For the standard field method, a transmitted field is calculated in terms of the type and dimensions of a transmitting antenna, its current distribution or net delivered power, the frequency of the transmitted signal, the distance from the transmitting antenna to the field point, and the effect of ground reflections (if present). For the standard antenna method, an unknown field is measured with a calculable receiving antenna. The voltage or current induced in a standard antenna by the component of field being evaluated is measured. The field strength is then calculated in terms of this induced voltage, the dimensions and form of the receiving antenna, and its orientation with respect to the field vector.

All the techniques described above for field strength standards are applicable only to steady-state RF fields with sinusoidal time variation. They are not intended for use with pulsed fields or other broadband applications.

5.5. Magnetic Field Strength Standards for Loop Antennas at 10 kHz–50 MHz (Standard Field Method)

The response of an electrically small receiving loop antenna is proportional to the average normal component of magnetic field strength incident on the antenna. A calculable quasi-static magnetic field can be produced to calibrate these antennas using a circular single-turn balanced transmitting loop. Up to 30 MHz, the current in a loop with a 10 cm radius is approximately constant in amplitude and phase around the loop. The receiving loop antenna being calibrated is positioned on the same axis as the transmitting loop at a distance of 1.5–3 m. The normal component of the magnetic field, averaged over the area of the receiving loop, is given by [10]

$$H = \frac{\beta I r_1}{r_2} \sum_{m=0}^{\infty} \frac{1}{(2m+1)!} \cdot \frac{1 \cdot 3 \cdots (2m+1)}{2 \cdot 4 \cdots (2m+2)} \left[\frac{\beta r_1 r_2}{R_0} \right]^{m+1} h_{2m+1}^{(2)}(\beta R_0) \tag{40}$$

where

- H = RMS value of magnetic field
- I = RMS current in transmitting loop
- r_1 = radius of transmitting loop
- r_2 = radius of receiving loop
- $R_0 = \sqrt{d^2 + r_1^2 + r_2^2}$
- d = axial distance between the two loops
- $\beta = 2\pi/\lambda_0$
- λ_0 = free-space wavelength
- $h_n^{(2)}$ = n th-order spherical Hankel function of second kind

The current in the transmitting loop antenna is measured with a vacuum thermocouple calibrated with direct current. The thermocouple is at the top of the loop winding.

While coaxial loop antennas normally are used for calibration purposes, the two-loop antennas also can be positioned in the same plane. Coplanar loop antennas are advantageous under certain conditions (e.g., with some ferrite core antennas in which the core length is large). In the coplanar loop antenna setup, the calibrating value of H would be half of that given by Eq. (41).

The calibration and subsequent measurement of magnetic field strength H often are expressed in terms of the electric field E that would exist if the measurement were made in free space, in which case $E/H \cong 120\pi \Omega$. When such a field strength meter is used to make measurements near the ground, the indicated value of the electric field is not necessarily valid. The same is true for measurements made in the near zone of a transmitting antenna. However, the value of the magnetic component H can still be measured correctly.

For calibrating loop antennas or magnetic field sensors at a higher field, it is possible to use the calculable magnetic field generated in a TEM cell, or a waveguide chamber, or at the center of a flat multiturn coil, or at the midpoint of a Helmholtz coil pair.

5.6. Electric Field Strength Standards for Dipole Antennas from 25 to 1000 MHz (Standard Antenna Method)

The magnitude of the electric field component at a given point in a locally generated field is determined from the open-circuit voltage V_{oc} induced in a standard (calculable) half-wave receiving dipole antenna. The induced voltage is measured across the center gap of the dipole antenna, which is oriented parallel to the electric field vector of the incident field. In using the standard antenna method, a plane-wave field can be generated by a suitable transmitting antenna, such as a log-periodic or half-wave dipole antenna. The magnitude of this incident field is measured with the standard dipole antenna by the relation

$$E_{inc} = \frac{V_{oc}}{L_{eff}} \tag{41}$$

where E_{inc} is the field strength of the locally generated field, V_{oc} is the open-circuit voltage induced in the standard dipole antenna, and L_{eff} is the effective length of the standard dipole antenna.

The RF voltage V_{oc} picked up by the $\lambda/2$ standard dipole is detected by a high-impedance Schottky barrier diode connected in shunt across the center gap of the antenna. The diode output is filtered by a balanced RC network, and this DC voltage is measured with a high-impedance DC voltmeter. The RF-to-DC-characteristic of the dipole antenna and its filter circuit is obtained experimentally. Assuming a cosinusoidal current distribution on an infinitesimally thin dipole, the effective length of a half-wave dipole antenna in free space is given by Eq. (12).

5.7. Electric Field Strength Standards for Vertical Monopole Antennas from 30 kHz to 300 MHz (Standard Field Method)

Several approaches were considered for generating a standard (calculable) field to calibrate vertically polarized antennas. The system chosen for this measurement consists of a thin cylindrical transmitting monopole antenna over a metallic ground plane. The field strength is calculated in terms of the magnitude and distribution of the monopole antenna current, and other factors such as (1) monopole height, (2) horizontal distance from the transmitting antenna to the field point, (3) vertical height of this point above the ground plane, and (4) electrical conductivity of the ground plane.

The height of the transmitting monopole antenna is adjustable, with a maximum height of about 3 m. The electrical height of this antenna is $\lambda/4$ (resonant) at 25 MHz, but only 0.0003λ at 30 kHz. At frequencies above 25 MHz, the antenna height is reduced to a $\lambda/4$ value. The base diameter of the monopole antenna is about 1 cm. The monopole antenna is excited through a coaxial cable from a transmitting room located beneath a concrete ground

slab that is covered by a conducting metal screen to form the electrical ground plane.

Equations (42), (43), and (44) give the magnitudes of the three field components E_z , E_ρ , and H_ϕ , respectively, of a transmitting $\lambda/4$ monopole antenna above a perfect ground plane of infinite extent:

$$E_z = 30I_0 \left(\frac{e^{-j\beta r_1}}{r_1} + \frac{e^{-j\beta r_2}}{r_2} \right) \quad (42)$$

$$E_\rho = \frac{30I_0}{r_0} \left[\left(\frac{e^{-j\beta r_1}}{r_1} \right) \left(z - \frac{\lambda}{4} \right) + \left(\frac{e^{-j\beta r_2}}{r_2} \right) \left(z + \frac{\lambda}{4} \right) \right] \quad (43)$$

$$H_\phi = \frac{I_0}{4\pi r_0} (e^{-j\beta r_1} + e^{-j\beta r_2}) \quad (44)$$

where

- E_z = vertical electric field component
- E_ρ = horizontal electric field component
- H_ϕ = magnetic field, encircling the monopole antenna
- I_0 = RMS base current of the monopole antenna
- $\beta = 2\pi/\lambda$ = the wavelength constant
- $r_1 = [d^2 + (z - l)^2]^{1/2}$
- $r_2 = [d^2 + (z + l)^2]^{1/2}$
- $r_0 = [d^2 + z^2]^{1/2}$
- l = monopole antenna length
- d = horizontal distance between the monopole antenna and the field point
- z = vertical distance from the ground plane to the field point

For frequencies near self-resonance, the monopole antenna base current is measured with an RF ammeter consisting of a thermoconverter that has been calibrated with known values of DC current. At lower frequencies, where the monopole antenna input impedance Z_{in} is a high-capacitance reactance, the base current is calculated from Ohm's law in terms of the base voltage measured with a high-input impedance voltmeter and the theoretical input impedance. At very low frequencies, Z_{in} may be calculated from the antenna capacitive reactance (11).

$$Z_{in} = \frac{1}{j\omega C_a} \quad (45)$$

where

$$C_a = \frac{5.56 \times 10^{-11} h}{\ln(h/a) - 1} \quad (46)$$

where C_a is the monopole antenna input capacitance (F), h is the monopole antenna height (m), and a is the monopole antenna radius (m).

The standard field equations are relatively simple for a ground plane with infinite extent and infinite conductivity. In addition, the current on a vertical monopole antenna with finite diameter departs from the sinusoidal current distribution of a filamentary monopole antenna. This does not seriously affect the calculated values of

current-related field components, such as the magnetic field or the far-zone electric field. However, the low-frequency near-zone quasi-static electric field components are more nearly charge-related and are given by the spatial derivative of the current distribution. Hence, there is greater uncertainty in calculating the electric field components at frequencies well below that of a $\lambda/4$ -resonant monopole antenna.

If a transmitting monopole antenna is electrically short—that is, if the height is less than $\lambda/4$ and the frequency is below resonance—the current distribution is triangular. The field equations are a little more complicated; only the vertical electric field is given below [11]:

$$E_z = \frac{-j30I_0}{\sin(\beta l)} \left[\frac{e^{-j\beta r_1}}{r_1} + \frac{e^{-j\beta r_2}}{r_2} - 2 \cos(\beta l) e^{-j\beta r_0} \right] \quad (47)$$

The EM field values in the half-space above a perfect ground are the same as those in each half-volume of a center-fed $\lambda/2$ dipole antenna in free space. The input impedance of a monopole antenna above perfect ground is half that of a dipole antenna in free space. The power required to generate a given field strength is half that required for a dipole antenna, but the radiated power goes into half the volume, so the field is the same. Measurements of Z_{in} with a commercial impedance meter are performed to check the theoretical values from 0.5 to 50 MHz. Measurements of the monopole antenna capacitance can be made at lower frequencies with a commercial Q meter.

6. FUTURE DIRECTIONS

Established techniques for EM field measurements will probably be extended to higher frequencies; however, such work would not involve fundamental changes in the instrumentation or measurement strategy. The measurement methods described earlier are suitable only for (1) measuring plane-wave sinusoidal fields of a given frequency and (2) calibrating the devices that measure such fields.

The challenge of the future resides in the development of standards for measurement of fields that are nonsinusoidal and/or nonplanar. The fundamental requirement for EM field sensors is that their outputs provide amplitude and phase information simultaneously over a broad spectrum for nonsinusoidal fields. For fields containing more than one frequency component, it is clear that such simultaneous measurement is necessary. Similarly, if phase information is preserved, then measurements of single-frequency nonplanar fields can be made in terms of true energy density or in terms of the Poynting vector.

The standard techniques of today rely on very high-resistance transmission lines to convey DC voltage and current to regions external to the field under measurement. Future standards of measurement employ optically sensed EM field sensors whose optical sensing signal paths will not perturb the EM field under measurement, but will also convey field amplitude and phase information to a region external to the field for measurement. Optically sensed sensors are being built today. However,

additional work is needed to transform these experimental devices into stable elements for standards applications. Also, standard fields need to be developed, in order to calibrate these probes of the future.

1. INTRODUCTION

1.1. Definition of Electromagnetic Inverse Problems

Electromagnetic inverse problems, also known as *electromagnetic inverse scattering problems*, aim to recover information on some inaccessible region from the scattered electromagnetic fields measured in the exterior region [1]. This region (hereafter referred to as “scatterers”) could be homogeneous or inhomogeneous, of any dimension, with

or without electromagnetic scatterers embedded. The information of interest is the location, shape, size, electrical properties (penetrable or impenetrable), and electromagnetic constitutive parameters. Most of the electromagnetic inverse problems can be considered as “active,” where a known incident field is artificially applied to illuminate the inaccessible unknown scatterers to give rise to scattered fields, which is measured at some accessible area. There are some cases, however, such as passive remote sensing, in which the scattered electromagnetic fields from the unknown scatterers are not due to such artificially applied incident electromagnetic fields. Usually, the scattered electromagnetic fields are measured over limited domain of aspect angle, frequency, and polarization, and are contaminated by noise and measurement error.

Electromagnetic inverse scattering is concerned with how we can obtain a large part of information about the world surrounding us. An everyday example of electromagnetic inverse problems is human vision; from the measurements of scattered light that reaches our retinas, our brains construct a detailed three-dimensional map of the world around us. This is a highly automated process, and most of us do not stop to reflect on how difficult this problem is. In fact, a large part of the human brain is devoted to such activities.

It should be pointed out that this definition of electromagnetic inverse problems is made in a narrow sense. In fact, all synthetic problems in electromagnetics, for example, the design of microwave filters and the synthesis of antennas, and many others, can be regarded as electromagnetic inverse problems. However, we will stick to this narrow definition of the electromagnetic inverse problems, unless otherwise stated.

Electromagnetic inverse problems and electromagnetic scattering problems come in pairs. For a given electromagnetic scattering problem, a priori information on the size, shape, and material constituents of the scatterers and the incident electromagnetic fields is provided, and the scattered field is calculated for a specific area and frequency domain. The electromagnetic community has embraced scattering problems with a warmth that is not generally extended to inverse problems. In fact, our training on electromagnetics is dominated by direct problems (in the general sense), while inverse problems continue to be regarded as very new and challenging research topics.

Note that electromagnetic inverse problems belong to a much wider class of inverse problems and are closely related to inverse problems in acoustic and elastic waves. It is also known that some techniques used in one field are identical, at least in principle, to those used in other, completely different fields. These interdisciplinary applications of the inversion techniques are drawing increasing attention. Hence, although we focus on electromagnetic inverse problems here, other fields of inverse problems will be touched on slightly where necessary.

1.2. Some Mathematical Challenges in Electromagnetic Inverse Problems

Electromagnetic inverse scattering problems and the associated electromagnetic scattering problems are highly

additional work is needed to transform these experimental devices into stable elements for standards applications. Also, standard fields need to be developed, in order to calibrate these probes of the future.

1. INTRODUCTION

1.1. Definition of Electromagnetic Inverse Problems

Electromagnetic inverse problems, also known as *electromagnetic inverse scattering problems*, aim to recover information on some inaccessible region from the scattered electromagnetic fields measured in the exterior region [1]. This region (hereafter referred to as “scatterers”) could be homogeneous or inhomogeneous, of any dimension, with

or without electromagnetic scatterers embedded. The information of interest is the location, shape, size, electrical properties (penetrable or impenetrable), and electromagnetic constitutive parameters. Most of the electromagnetic inverse problems can be considered as “active,” where a known incident field is artificially applied to illuminate the inaccessible unknown scatterers to give rise to scattered fields, which is measured at some accessible area. There are some cases, however, such as passive remote sensing, in which the scattered electromagnetic fields from the unknown scatterers are not due to such artificially applied incident electromagnetic fields. Usually, the scattered electromagnetic fields are measured over limited domain of aspect angle, frequency, and polarization, and are contaminated by noise and measurement error.

Electromagnetic inverse scattering is concerned with how we can obtain a large part of information about the world surrounding us. An everyday example of electromagnetic inverse problems is human vision; from the measurements of scattered light that reaches our retinas, our brains construct a detailed three-dimensional map of the world around us. This is a highly automated process, and most of us do not stop to reflect on how difficult this problem is. In fact, a large part of the human brain is devoted to such activities.

It should be pointed out that this definition of electromagnetic inverse problems is made in a narrow sense. In fact, all synthetic problems in electromagnetics, for example, the design of microwave filters and the synthesis of antennas, and many others, can be regarded as electromagnetic inverse problems. However, we will stick to this narrow definition of the electromagnetic inverse problems, unless otherwise stated.

Electromagnetic inverse problems and electromagnetic scattering problems come in pairs. For a given electromagnetic scattering problem, a priori information on the size, shape, and material constituents of the scatterers and the incident electromagnetic fields is provided, and the scattered field is calculated for a specific area and frequency domain. The electromagnetic community has embraced scattering problems with a warmth that is not generally extended to inverse problems. In fact, our training on electromagnetics is dominated by direct problems (in the general sense), while inverse problems continue to be regarded as very new and challenging research topics.

Note that electromagnetic inverse problems belong to a much wider class of inverse problems and are closely related to inverse problems in acoustic and elastic waves. It is also known that some techniques used in one field are identical, at least in principle, to those used in other, completely different fields. These interdisciplinary applications of the inversion techniques are drawing increasing attention. Hence, although we focus on electromagnetic inverse problems here, other fields of inverse problems will be touched on slightly where necessary.

1.2. Some Mathematical Challenges in Electromagnetic Inverse Problems

Electromagnetic inverse scattering problems and the associated electromagnetic scattering problems are highly

mathematical. This is an ideal area for applied mathematicians. Electromagnetic inverse problems provide a rich supply of challenging mathematical problems.

1.2.1. Electromagnetic Scattering. Studying an electromagnetic inverse problem always requires a solid knowledge of the corresponding direct scattering problem. Unfortunately, the study of electromagnetic scattering problems is very far from complete. For example, the current level of understanding on wave propagation in complex media and random media remains very poor.

1.2.2. Nonlinearity. The scattering problem is linear in the sense that for a known scatterer, the relationship between the incident field and scattered field is linear. However, for electromagnetic inverse problems, we are interested in the relationship between the scatterer and its action on the incident fields. This relationship is inherently nonlinear.

1.2.3. Ill-Posedness. According to Hadamard [2], a problem is well-posed if it has a unique solution that depends continuously on the given data. Problems that are not well-posed are known as ill-posed. In general, electromagnetic inverse problems are ill-posed. The ill-posedness of electromagnetic inverse problems comes from the incomplete and contaminated measurement data, and the existence of a nonradiating source.

For an ill-posed electromagnetic inverse problem, the following questions must be addressed:

Existence: Is there any solution?

Uniqueness: Is the solution unique?

Stability: Is the solution stable? In other words, do small perturbations of the measured scattered fields always result in small perturbation of the solution?

1.3. Applications of Electromagnetic Inverse Problems

Although the electromagnetic inverse problem is a relatively new area of applied mathematical research, it has been increasingly used in scientific, military, medical, industrial, agricultural, and many other civil areas. Since the mid-1980s we have witnessed an explosion in the applications of electromagnetic inverse problems.

1.3.1. Scientific Applications. Electromagnetic inverse problems have been enormously influential in the development of natural sciences, with great advances in science and technology made possible through their solutions. Electromagnetic inverse problems could lead to the establishment of physical laws via indirect observations. Their solutions provide us with a wealth of scientific information: the discovery of DNA structure through solving X-ray diffraction problems and the structure of the atom and its constituents from studies on the scattering phenomena when materials are bombarded with particles. Over the years, electromagnetic inverse problems have played an increasingly important role in many scientific areas, such

as archaeology, seismology, geophysics, optics, material science, and meteorology.

1.3.2. Military Applications. The area of electromagnetic inverse problems was strongly stimulated by the great success in military applications during World War II, which witnessed the invention of radar and sonar for detection and identification of both friendly and hostile objects. As the world is not devoid of violence and war, military demands on electromagnetic inverse problems continue to increase. As an example, for people living in countries under the threat of landmines left over from earlier wars, safe detection and removal of these landmines using electromagnetic waves is a lifesaving method. On the other hand, increasingly powerful radar, spy satellite networks, and missile defense systems are being built to defend against attacks from terrorists and hostile countries.

1.3.3. Medical Applications. So far, besides military applications, medical imaging is one of the most successful application areas of electromagnetic inverse problems. In fact, the X-ray radiography machine is used in almost every hospital to diagnosis tuberculosis and other anomalies in the human body. In 1972, G. N. Hounsfield introduced a new radiographic imaging procedure, X-ray computer-assisted tomography (CAT). A picture of the CAT apparatus in a hospital is shown in Fig. 1. It is replacing the conventional and obsolete X-ray radiography machines in many hospitals. More recently, even some CAT machines have been replaced by more advanced nuclear magnetic resonance imaging machines for more accurate diagnosis.

1.3.4. Industrial Applications. The electromagnetic inverse problems are of commercial value to the industries. Oil companies, for example, determine the location of oil through solving inverse scattering problems. A significant fraction of the computational workload is performed by the oil companies. In fact, much of the recent resurgence

Figure 1. CAT apparatus in a hospital.
(Source: <http://encyclopedia.thefreedictionary.com/Computer%20assisted%20tomography>.)

in the oil industry is due to improvements in mathematical algorithms that allow scientists to “see” through salt layers to detect the oil-bearing strata below.

Ground penetrating radar (GPR) is a highly commercialized solution for nondestructive evaluation (NDE) that produces a continuous cross-sectional profile or record of subsurface features, without drilling, probing, or digging. The GPR for a shallow survey is shown in Fig. 2. Ground penetrating radar profiles are used to evaluate the location and depth of buried objects such as pipes and cables, and to investigate the presence and continuity of natural subsurface conditions and features.

The commercial aviation industry has also benefited significantly from solving electromagnetic inverse problems. For example, it is now mandatory for passengers to receive security check, including metal detection, before boarding. Other industries taking advantage of electromagnetic inverse problems include nuclear energy, food, construction, and marine enterprises. For example, the nondestructive evaluation of steam generator tubes is a major issue in the nuclear industry.

1.3.5. Agricultural Applications. Electromagnetic inverse problems are also very important to agriculture. In China, a large amount of effort has been put into predicting the national crop harvest using remote sensing techniques and monitoring the coverage of plants within Chinese territory.

1.3.6. Other Civil Applications. Electromagnetic inverse problems are also applicable to many other civil areas. For example, the environment can be monitored using remote sensing techniques.

1.4. Some Outstanding Research Groups

Electromagnetic inverse problems have been one of the most challenging areas in electromagnetics. Many

Figure 2. Shallow ground-penetrating radar surveys. (Source: <http://www.geomodel.com/>)

research groups and researchers from both within and outside the electromagnetic community have devoted their efforts to study the fundamental theory of inverse problems, develop inversion algorithms for particular cases, produce real datasets to test the developed algorithms, develop prototypes for practical applications, and commercialize the developed prototypes. Because of the large number of researchers and groups involved in this area, it is not possible to list all of them. However, special tributes should be paid to the following researchers and organizations for their outstanding work in this field: Institut Fresnel (France), W. M. Boerner, R. E. Kleinman, K. J. Langenberg, Rome Laboratory (renamed as Air Force Research Laboratory in 1997), and A. N. Tikhonov.

Their well-established contributions to this field will be highlighted at the appropriate parts in this article.

1.5. Some Future Directions

The field of electromagnetic inverse problems is a relatively new area with apparent potential for applications. However, many problems remain to be solved. Besides the topics mentioned in this article, the following topics in electromagnetic inverse problems also require special attention.

1.5.1. Three-Dimensional Electromagnetic Inverse Problems. Researchers in the field of electromagnetic inverse problems typically simplify their work by concentrating on lower-dimensional problems. Electromagnetic inverse problems that have been extensively studied usually assume geometry of only one or two dimensions, with a half-space or layered medium. However, such an assumption is insufficient for many practical problems, leading to failure of the inversion algorithms to produce any meaningful results.

Increasing attention has been devoted to three-dimensional electromagnetic inverse problems. Researchers are attempting to extend well-established lower-dimensional inversion algorithms to three-dimensional cases, as well as to develop new inversion algorithms focusing on three-dimensional electromagnetic inverse problems.

1.5.2. Electromagnetic Inverse Problems of Complex Scatterers. Most of the existing inversion algorithms assume that the scatterers are simple, that is, isotropic and nondispersive. However, this assumption is not valid for many real scatterers, such as human brains and organs.

1.5.3. Electromagnetic Inverse Problems in Complex Media. Another important issue is the electromagnetic inverse problem of scatterers in complex media. Some examples of complex media are soil, foliage, sea ice, sea surface, and the human body.

2. AN OVERVIEW OF RESEARCHES ON ELECTROMAGNETIC INVERSE PROBLEMS

Because of the theoretical and practical significance of electromagnetic inverse problems, extensive studies have been performed on electromagnetic inverse problems.

These studies include fundamental theories of electromagnetic inverse problems, measurement of scattering data, development of inversion algorithms for specific electromagnetic inverse problems and testing them with synthetic and/or real measurement data, development of prototypes for practical applications, and commercialization of the developed prototypes. Numerous monographs, technical reports, and dissertations have been published. The number of journals specializing in inverse problems or with scope on inverse problems has increased significantly, with rapid growth in the number of special issues and papers on inverse problems. A large number of international conferences, workshops, and symposia (e.g., APS, MTTs, IGARSS, APMC, PIERS) on electromagnetic inverse problems have also been organized.

2.1. A Brief History

The study on electromagnetic inverse problems can be traced back to 1895 when X rays were discovered in the first body imaging tests conducted by Wilhelm Roentgen, the discoverer of X rays. The first major mathematical breakthrough took place in 1917 when the radon transform, the basic mathematical framework common to a large class of inverse problems, was proposed [3]; unfortunately, this work was not well appreciated in the application areas until the 1970s. The second stimulation to electromagnetic inverse problems occurred during World War II, when radar was invented by scientists and engineers to identify friendly and hostile aircraft. However, the field of electromagnetic inverse problems was not well recognized until A. N. Tikhonov established the fundamental theory of ill-posed problems in the mid-1960s [4]. In 1972, G. N. Hounsfield introduced CAT [5]. Since then, an extensive and intensive study on electromagnetic inverse problems and other related inverse problems has been carried out.

The first extensive survey covering many fields in which inverse problems were applied was presented in a NASA memorandum by Colin [6]. In 1981, the *IEEE Transactions on Antennas and Propagation* published a special issue on inverse methods in electromagnetics [7]. Subsequently, W. M. Boerner organized the NATO Advanced Research Workshop on Inverse Methods in Electromagnetic Imaging in 1983 [5]. Afterward, there was a burst in publication of research results scattered in many monographs [8], technical reports, dissertations, journals, and conference proceedings.

Nevertheless, the field of electromagnetic inverse problems remains one of the most challenging problems of applied electromagnetics. A review on the latest state of the art is presented in Ref. 1.

2.2. Mathematical Fundamentals of Electromagnetic Inverse Problems

Applied mathematicians such as D. Colton, R. Kress [8], and P. Monk studied the fundamental mathematical theories behind the electromagnetic inverse problems. Such studies strengthened our understanding of the electromagnetic inverse problems and gave confidence to developers of inversion algorithms. Apparently, these

fundamental mathematical theories are also directly applicable—or can be applied with minor modifications—to other fields of inverse problems.

2.2.1. Existence and Uniqueness. As mentioned before, in any realistic situation, the measured data are not exact. Hence, an exact solution to a real inverse problem seldom exists in its original solution space. However, existence can be forced by enlarging or reducing the solution space. Therefore, the common practice is to assume that an approximate solution does exist and is physically feasible. The existence of an inverse problem is rarely considered since it is of little theoretical and practical importance.

There are three famous uniqueness theorems in electromagnetic inverse problems [9]: Tikhonov's uniqueness theorem for a one-dimensional inverse problem, Weidelt's uniqueness theorem for a two-dimensional inverse problem with an electrical conductivity described by an analytic function, and Gusarov's uniqueness theorem for a two-dimensional inverse problem with a piecewise analytic function of electrical conductivity. Later, Colton, Kress [8], and P. Monk obtained the more general uniqueness theorems for electromagnetic inverse problems.

2.2.2. Stability and Regularization. We will now consider the issue of stability of inverse problems. This problem reflects the practical fact that although two sets of observation data may differ only in the noise level, the corresponding inversion results could be completely different. Negligence or improper remedy for the illness could have disastrous consequences. The common technique to restore stability of an inverse problem is to employ regularization methods, which are discussed in detail in the tutorial paper [10] as well as other topical review papers [11–14] and monographs [4,8,9,15].

Consider a general inverse problem

$$Au = f \quad (1)$$

where $A:u \in X \rightarrow f \in Y$ is an operator mapping space X into Y . The well-known Tikhonov regularization is designed to minimize the Tikhonov functional defined as

$$\|Au - f\|^2 + \gamma\|f\|^2 \quad (2)$$

2.3. Development of Inversion Algorithms

Development of inversion algorithms is always the key issue in the field of electromagnetic inverse problems. Extensive studies have been carried out on this subject, with many inversion algorithms developed.

As relevant literature are scattered over a large number of resources, a summary is given here for convenience for future study. However, the author makes no claim that this summary is exhaustive, since it is based only on the author's current knowledge.

As mentioned earlier, the field of inverse problems is interdisciplinary, as clearly demonstrated by the vast diversity of literature on electromagnetic inverse problems

and the background of researchers involved in the area. Some techniques used in one field are identical, at least in principle, to those used in completely different fields. Therefore, the inversion algorithm is considered here regardless of its origin, if it is applicable to electromagnetic inverse problems.

2.3.1. Linear Inversion Algorithms. The earliest attempts to solve the electromagnetic inverse problems simplified them by linearization through applying some approximations, such as the Born approximation, the Rytov approximation, and physical optics approximations (or Kirchhoff approximation). Generally speaking, such linear inversion algorithms are mathematically very elegant. For one-dimensional (1D) electromagnetic inverse problems, such linearization may lead to an analytical solution of the problem. Unfortunately, we seldom encounter 1D problems in practice. Moreover, the simplicity of the 1D case is rarely preserved in higher dimensions.

The most prominent inversion algorithms in this category include the layer-stripping algorithm, the method of characteristics, the Gelfand–Levitan–Marchenko integral equation method, the Born iterative method, and the linear diffraction tomography algorithm. K. J. Langenberg established his reputation in developing linear inversion algorithms. Readers are referred to Wirgin’s text [16] for detailed contributions by Langenberg to linear inversion algorithms.

2.3.2. Nonlinear Inversion Algorithms. As mentioned previously, nonlinearity is one of the distinct features of electromagnetic inverse problems. Developers of linear inversion algorithms usually ignore this basic feature of the inverse problems. In addition, the approximations made in linear inversion algorithms imposed too many restrictions, thereby limiting their applications.

The nonlinear inversion algorithms retain the nonlinearity of the electromagnetic inverse problems. Most of the nonlinear algorithms are mathematically more difficult and computationally more expensive, as nonlinear electromagnetic inverse problems are solved iteratively. On the other hand, such algorithms are usually more versatile and accurate, hence attracting more attention from practical applications.

In essence, electromagnetic inverse problems are optimization problems and can be solved by applying different optimization algorithms. Accordingly, nonlinear inversion algorithms can be further categorized in accordance with the optimization algorithms applied: the local inversion algorithms and the global inversion algorithm.

2.3.2.1. Local Inversion Algorithms. As the term implies, optimization algorithms involved in this category are local, or gradient-based. The prominent local algorithms include the distorted Born iterative method (or distorted wave Born iterative method, Newton–Kantorovitch algorithm), the conjugate-gradient method, the local shape function method, the modified gradient method, and the contrast source inversion method.

R. E. Kleinman and P. M. van den Berg proposed the modified gradient method and the contrast source inver-

sion method, which have been actively applied. The two algorithms have proved to be effective through experiment using two sets of real data to be discussed later in this article. Numerous papers have been published on their application in the field of electromagnetic inverse problems and other fields of inverse problems. For details of the two methods, please refer to their review paper [17].

2.3.2.2. Global Inversion Algorithms. The local algorithms rely critically on an initial solution to the electromagnetic inverse problem of interest. Under some strict hypotheses such as convexity, differentiability, and continuity of the object function, the solution can be obtained quickly from a good initial solution. Otherwise, the local algorithms will be trapped in local minima or may even diverge.

Global optimization algorithms have gained popularity in the optimization community for their simplicity, versatility and, most of all, strong ability in searching. The global optimization methods, including the genetic algorithms (GA), the evolution strategies, the Monte Carlo method, the neural network, the simulated annealing method, the memetic algorithm, and the particle swarm algorithm, are in general stochastic.

For developers of the inversion algorithm, interest in the global optimization algorithm has increased since the 1990s. Currently, S. Caorsi, C. C. Chiu, A. Massa, M. Pasatorino, and A. Qing are very active in this area.

2.3.2.3. Hybrid Inversion Algorithms. It is evident that local and global inversion algorithms are complementary to each other. It is therefore very logical to combine these two types of inversion algorithms in an attempt to obtain the global optimal solution within a shorter timeframe. The common practice of this approach is to use a preset threshold. Once the optimal objective function value obtained by the global inversion algorithm exceeds the threshold, the inversion is transferred to the local inversion algorithm. A smarter hybrid inversion algorithm combining the real-coded genetic algorithm (RGA) and the Newton–Kantorovitch algorithm (NKA) is presented in Ref. 18.

2.4. Verifications of Inversion Algorithms

Any developed inversion algorithm is subject to verification. Such verification includes tests on synthetic data (scattered field data obtained by numerical solution of the corresponding scattering problem from a known scatterer), tests on real data generated in controlled experiments, and practical testing in the real world, where possible.

2.4.1. Synthetic Test and Inverse Crime. It is acceptable and is almost a common practice to first verify an inversion algorithm on synthetic data. The inversion algorithm developer uses a synthetic test as a preliminary evaluation of the algorithm’s performance. The basic advantages of this test are that it is cost-effective and can be performed as and when required.

To ensure a reliable synthetic test of an inversion algorithm, inverse crime must be avoided. The inverse

crime, as defined by Colton and Kress [8], implies that the forward scattering solver used in generating the synthetic data is also used in the inversion algorithm, and/or the same discretization is used in both numerical procedures. Synthetic test committing inversion crime usually leads to surprisingly good results.

2.4.2. Test Using Controllable Experimental Data. As compared to the synthetic test, verifying an inversion algorithm based on laboratory-generated experimental data, especially the well-established data generated independently by other researchers, is more convincing. The algorithm developer can use such a test for an objective performance evaluation of the algorithm. It is also very beneficial for the developer to refine the algorithm on the basis of experience gained during such test.

The Ipswich dataset generated by Rome Laboratory in 1995 is well known in the community of electromagnetic inverse problems. Friendly contests among researchers based on this dataset have been conducted and presented in the *IEEE Antennas and Propagation Magazine* special sessions [19–22]. The tested algorithms include the Newton–Kantorovitch method, the modified gradient method, the conjugate-gradient method, the local shape function method, the backpropagation routine, the contrast source inversion method, and the variable metric method.

In 2001, Institut Fresnel provided a second set of real data for friendly contests among algorithm developers [23]. One interesting feature of this dataset comes from the wide frequency range. The tested inversion algorithms are the modified gradient method, the contrast source inversion method, the linear diffraction tomography algorithm, the real-coded genetic algorithm, the differential evolution strategy (DES), the distorted-wave Born iterative method, the linear spectral estimation technique, the iterative and distorted Born method, and some other inversion algorithms.

Of course, some other researchers from both within and outside the community of electromagnetic inverse problems have produced experimental data on their own. However, their works are more self-focused and their experimental setups are more specific to their own inversion algorithms.

2.5. Prototype Development and Commercialization

The ultimate objective in studying electromagnetic inverse problems is to apply the developed inversion algorithms and experimental setups in practical areas, and perhaps commercialization as well. Besides the successful commercialization of CAT and GPR, many researchers are building their own prototypes and testing them in different practical fields [1].

3. A STANDARD ELECTROMAGNETIC INVERSE PROBLEM

In this section, we consider a standard electromagnetic inverse problem, namely, the reconstruction of multiple perfectly conducting cylinders in free space.

Figure 3. Geometry of the problem.

The geometry of the problem is depicted in Fig. 3, where O is the origin, Ω is a circle with radius R^{meas} in the measuring domain in which the scattered electric fields are measured, the black dots on Ω are receivers, and D is the imaging domain, which is usually chosen to be circular or rectangular; K perfectly conducting cylinders within D are the objects to be reconstructed, and O_i is the local origin of the i th cylinder, which can be any point within the cylinder contour C_i .

A transverse magnetic (TM) incident field is assumed (time factor of $e^{j\omega t}$ assumed and suppressed)

$$\mathbf{E}^{\text{inc}}(\mathbf{r}) = \hat{z} E_z^{\text{inc}} = \hat{z} \exp(-jk_0 \hat{\mathbf{k}} \cdot \mathbf{r}) \quad (3)$$

where $\omega = 2\pi f$ is the angular frequency, $\mathbf{r} = x\hat{x} + y\hat{y}$, $k_0 = \omega/c$ is the wavenumber in free space, c is the speed of light, $\hat{\mathbf{k}} = \cos \varphi \hat{x} + \sin \varphi \hat{y}$ is the incident wave unit vector, and φ is the incident angle; \hat{x} , \hat{y} , and \hat{z} are the unit vectors in the x , y , and z directions, respectively.

3.1. Problem Formulation

3.1.1. Direct Problem. Electric surface currents $\mathbf{J}_j(\mathbf{r}) = \hat{z} J_{zj}(\mathbf{r})$, $j = 1, K$ are induced on the surface of cylinders, and the scattered electric field $\mathbf{E}^{\text{scat}}(\mathbf{r}) = \hat{z} E_z^{\text{scat}}(\mathbf{r})$ is subsequently computed as follows

$$E_z^{\text{scat}}(\mathbf{r}) = \sum_{j=1}^K -\frac{\omega \mu_0}{4} \oint_{C_j} J_{zj}(\mathbf{r}') H_0^{(2)}(k_0 |\mathbf{r} - \mathbf{r}'|) d\mathbf{r}' \quad (4)$$

where μ_0 is the permeability of free space and $H_0^{(2)}(\cdot)$ is the Hankel function of the second kind of zeroth order.

On the surface of the cylinders, the tangential component of the total electric field vanishes:

$$[\mathbf{E}^{\text{scat}}(\mathbf{r}) + \mathbf{E}^{\text{inc}}(\mathbf{r})] \cdot \hat{\mathbf{z}} = 0 \quad \mathbf{r} \in \bigcup_{i=1}^K C_i \quad (5)$$

Therefore

$$\begin{aligned} E_z^{\text{inc}}(\mathbf{r}) &= \sum_{j=1}^K \frac{\omega \mu_0}{4} \oint_{C_j} J_{zj}(\mathbf{r}') H_0^{(2)} \\ &\cdot (k_0 |\mathbf{r} - \mathbf{r}'|) d\mathbf{r}', \quad \mathbf{r} \in \bigcup_{i=1}^K C_i \end{aligned} \quad (6)$$

The distribution of surface current is obtained after solving (6) by the point-matching method [24] with pulse basis function and the Dirac delta testing function.

3.1.2. Inverse Problem. The inverse problem is to locate the unknown cylinders and reconstruct the cylinder contours, given the scattered electric fields measured on Ω , $\mathbf{E}_{\text{meas}}^{\text{scat}}(\mathbf{r} \in \Omega)$. Usually, $\mathbf{E}_{\text{meas}}^{\text{scat}}$ is measured at a finite number of frequency points (N_f) and a finite number of incident angles for the incident plane waves (N_a) by a finite number of receivers (N_r). Accordingly, $\mathbf{E}_{\text{meas}}^{\text{scat}}$ becomes an ($N_f \times N_a \times N_r$)-dimensional vector. Equations (4) and (6) are the data and object (or state) equations of the present electromagnetic inverse problem.

Mathematically, the inverse problem described above is not well defined. The locations and contours of the cylinders must be represented by some mathematical quantities or functions. Usually, the location of a cylinder is represented by any point (center) $O_i(d_i, \psi_i)$ within its contour, while the contour is represented by a local shape function (LSF) $\rho_i = F_i(\theta_i)$ in its local polar coordinate system, where d_i and ψ_i are the polar radius and angle of O_i and ρ_i and θ_i are the local polar radius and angle of a point on the i th cylinder's contour, respectively.

The inverse problem is cast into an optimization problem by minimizing the object functional with respect to the local origins and local shape functions as follows

$$\begin{aligned} f\left(\bigcup_{i=1}^K [d_i, \psi_i, F_i]\right) &= \frac{\|\mathbf{E}_{\text{meas}}^{\text{scat}} - \mathbf{E}_{\text{simul}}^{\text{scat}}\|}{\|\mathbf{E}_{\text{meas}}^{\text{scat}}\|} \\ &+ \alpha \sum_{i=1}^K \sum_{j=1, j \neq i}^K \oint_{C_i} F_i(\theta_i) U \\ &\cdot [F_j(\theta_j) - \rho_{ij}(\theta_j)] d\theta_i \end{aligned} \quad (7)$$

where $\mathbf{E}_{\text{simul}}^{\text{scat}}$ is an ($N_f \times N_a \times N_r$)-dimensional vector constituting the scattered electric field simulated with the latest reconstruction results of cylinder locations O_i and local shape functions F_i and α is the intensity of penalty imposed on infeasible reconstruction results with inter-

secting cylinders as shown in Fig. 4:

$$\begin{aligned} \|\mathbf{E}_{\text{meas}}^{\text{scat}}\| &= \sqrt{\sum_{j=1}^{N_f \times N_a \times N_r} |(\mathbf{E}_{\text{meas}}^{\text{scat}})_j|^2} \\ \|\mathbf{E}_{\text{meas}}^{\text{scat}} - \mathbf{E}_{\text{simul}}^{\text{scat}}\| &= \sqrt{\sum_{j=1}^{N_f \times N_a \times N_r} |(\mathbf{E}_{\text{meas}}^{\text{scat}})_j - (\mathbf{E}_{\text{simul}}^{\text{scat}})_j|^2} \\ U(t) &= \begin{cases} 0, & t < 0 \\ 1, & t \geq 0 \end{cases} \end{aligned}$$

The first term of the objective functional (7) is the relative reconstruction error that gives a measurement on how close the reconstruction results approach the true profile, while the second term is an artificial penalty applied only in the case of intersecting cylinders.

3.1.3. Local Shape Functions

3.1.3.1. Trigonometric Local Shape Function. Most researchers approximate the LSF by a trigonometric series of order $N/2$:

$$\begin{aligned} F_i(\theta_i) \approx F_i^T(\theta_i) &= \sum_{n=0}^{N/2} A_{in} \cos(n\theta_i) \\ &+ \sum_{n=1}^{N/2} B_{in} \sin(n\theta_i) \end{aligned} \quad (8)$$

Under such an approximation, the objective functional (7) becomes the following objective function

$$f\left(\bigcup_{i=1}^K [d_i, \psi_i, F_i]\right) \approx f_T(\mathbf{x}_T) \quad (9)$$

where $\mathbf{x}_T = [\mathbf{x}_1 \ \cdots \ \mathbf{x}_K]$, $\mathbf{x}_i = [d_i \ \psi_i \ A_{i0} \ \cdots \ A_{iN-1} \ B_{i1} \ \cdots \ B_{iN-1}]$.

A basic requirement on a LSF is that it be nonnegative. However, it is hardly possible to guarantee the nonnegative definiteness of the trigonometric local shape function (TLSF) when it is applied in the global inversion algorithms. The unrealistic initial profile shown in Fig. 5 is the

Figure 4. Intersecting cylinders.

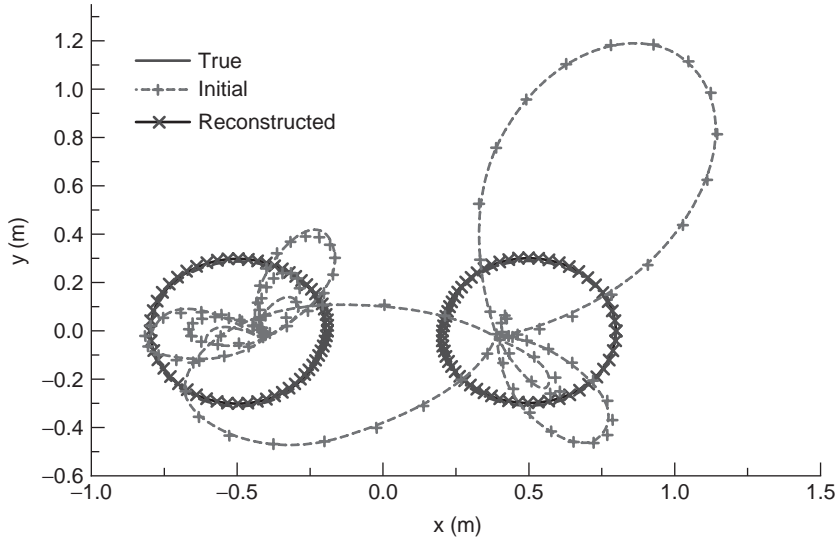

Figure 5. An unrealistic initial profile represented by trigonometric local shape functions. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

best profile in the initial population while reconstructing profile SP2, to be defined later in this article using RGA.

Some tricks can be used to guarantee the nonnegative definiteness of the TLSF, for example, by restricting the coefficient A_{i0} to be in a positive range with a big positive average value, and other coefficients in a much smaller range. However, for the present electromagnetic inverse problem, such tricks impose the unreasonable requirement of a priori knowledge of the cylinder's size.

3.1.3.2. Closed Cubic B-Spline Local Shape Function. The difficulty of the TLSF can be overcome by the closed cubic B-spline local shape function (BLSF) of N control points proposed by A. Qing [25]

$$F_i(\theta_i) \approx F_i^B(\theta_i) = R\left(\frac{N}{2\pi}\theta_i\right) \quad (10)$$

where

$$R(t') = \sum_{n=0}^{N-1} r_n(t' - n)$$

$$\begin{aligned} r_n(t) &= C_{\text{mod}(n-1,N)}Q_0(t) \\ &+ C_{\text{mod}(n,N)}Q_1(t) + C_{\text{mod}(n+1,N)}Q_2(t) \\ &+ C_{\text{mod}(n+2,N)}Q_3(t), \quad t \in [0, 1] \end{aligned}$$

$$Q_0(t) = \frac{1}{6}(1-t)^3$$

$$Q_1(t) = \frac{1}{2}t^3 - t^2 + \frac{2}{3}$$

$$Q_2(t) = -\frac{1}{2}t^3 + \frac{1}{2}t^2 + \frac{1}{2}t + \frac{1}{6}$$

$$Q_3(t) = \frac{1}{6}t^3$$

One promising feature of the BLSF is its boundedness, expressed mathematically as

$$\min_{0 \leq n \leq N-1} C_{\text{in}} \leq F_i^B(\theta_i) \leq \max_{0 \leq n \leq N-1} C_{\text{in}} \quad 0 \leq \theta_i \leq 2\pi \quad (11)$$

Therefore, the nonnegative definiteness of the BLSF can be guaranteed if all control points C_{in} are nonnegative. Such natural condition does not impose any artificial restrictions on the choice of the control points.

The corresponding objective function is

$$f\left(\bigcup_{i=1}^K [d_i, \psi_i, F_i]\right) \approx f_B(\mathbf{x}_B) \quad (12)$$

where $\mathbf{x}_B = [\mathbf{x}_1 \cdots \mathbf{x}_K]$, $\mathbf{x}_i = [d_i \ \psi_i \ C_{i0} \cdots C_{iN-1}]$

3.2. Applicable Inversion Algorithms

The present electromagnetic inverse problem has been solved using different inversion algorithms, including the linear diffraction tomography algorithm, the NKA, the GA, the DES, the differential evolution strategy with individuals in groups (GDES), and hybrid algorithms. Reconstruction using the linear diffraction tomography algorithm is conducted by K. J. Langenberg and his colleagues. Readers are referred to Ref. 23 for details, which will not be discussed here. In addition, since the hybrid algorithm is basically a combination of the NKA and one of the global inversion algorithms, it is also not included here. Interested readers are referred to Ref. 18 for more information.

3.2.1. Newton–Kantorovich Algorithm. The NKA, a generalization of the well-known Newton method, was proposed by Kantorovitch in 1948 and was applied to reconstruct the shape of a perfectly conducting cylinder in 1981 with a priori knowledge of the exact location of the cylinder [26]. The TLSF is used to approximate the cylinder contour. Although mathematically complicated, it is straightforward to generalize the formulation in Ref. 26 to reconstruct the locations and contours of multiple

perfectly conducting cylinders. The TLSF and the BLSF can be regarded as two special cases of a more general LSF in the form of expansion of basis functions.

The key idea in the NKA is to obtain the relationship between small variation in the measured scattered electric field, $\delta E_z^{\text{scat}}(\mathbf{r})$, and small variation in the cylinder's profile parameters $\delta \mathbf{x}$:

$$\delta E_z^{\text{scat}}(\mathbf{r}) = \mathbf{A} \cdot \delta \mathbf{x} \quad (13)$$

This equation is usually overdetermined and ill-posed. Different regularization measures can be applied to obtain an update of the cylinder's profile parameters $\delta \mathbf{x}$

$$\delta \mathbf{x} = \mathbf{A}^{-1} \cdot \delta E_z^{\text{scat}}(\mathbf{r}) \quad (14)$$

where \mathbf{A}^{-1} , the inverse of operator (matrix) \mathbf{A} , is in general obtained with regularization.

The cylinder's profile parameters are obtained iteratively as follows:

1. Select an initial solution \mathbf{X}^0 .
2. Solve the scattering problem for $\mathbf{E}_{\text{simul}}^{\text{scat},k}$ to obtain $\delta \mathbf{E}_z^{\text{scat},k} = \mathbf{E}_{\text{simul}}^{\text{scat},k} - \mathbf{E}_{\text{meas}}^{\text{scat}}$.
3. Update the cylinders' profile parameters $\mathbf{x}^{k+1} = \mathbf{x}^k + \delta \mathbf{x}^k = \mathbf{x}^k + \mathbf{A}_k^{-1} \cdot \delta E_z^{\text{scat},k}$.
4. Repeat steps 2 and 3 until the termination conditions are satisfied.

3.2.2. Genetic Algorithms. The concept of GA was first proposed by Holland [27]. It imitates the mechanism of natural selection and evolution, and aims to solve an optimization problem with object function $f(\mathbf{x})$ where \mathbf{x} is an N -dimensional vector of optimization parameters. Usually, the objective function $f(\mathbf{x})$ is scaled to a fitness function $\text{fit}(\mathbf{x})$.

Genes and chromosomes are the basic building blocks of GA. A gene can be the optimization parameter itself, or a code in a code string of the encoded optimization parameters. A chromosome is a concatenation of genes that takes the form

$$\text{Chromosome} = \underbrace{g_1^1 g_2^1 \cdots g_{L_1}^1}_{x_1} \underbrace{g_1^2 g_2^2 \cdots g_{L_2}^2}_{x_2} \cdots \underbrace{g_1^N g_2^N \cdots g_{L_N}^N}_{x_N} \quad (15)$$

where g_j^i is a gene and L_i is the length of the code string of the i th optimization parameter.

The GA operates on a population of N_{pop} individuals simultaneously. Each individual is related to a fitness value, an optimization parameter vector, and a chromosome. The GA starts with an initial population randomly generated within the search space. On completing the initialization, the population enters the main GA loop and performs a global optimization to search for the optimum solution of the problem. The GA loop continues until the termination conditions are fulfilled. A block diagram of the GA is shown in Fig. 6.

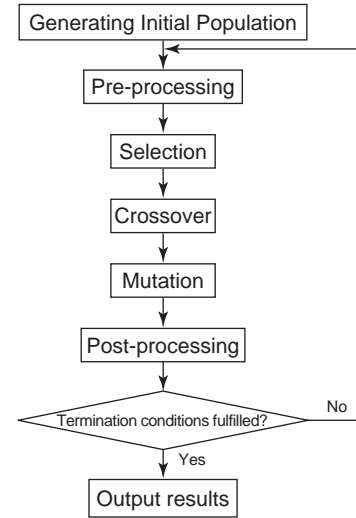

Figure 6. Block diagram of genetic algorithms.

In a GA loop, the three basic genetic operations—selection (or reproduction), crossover, and mutation—are executed sequentially. The selection operator selects good individuals on the basis of their fitness values and produces a temporary population, namely, the mating pool. This can be achieved by many different schemes, but the most common methods are the roulette wheel, ranking, and stochastic binary tournament selection. The selection operator is responsible for the convergence of GA. The crossover operator is the main search tool. It mates individuals in the mating pool by pairs and generates candidate offspring by crossing over the mated pairs with probability p_{cross} . Many crossover schemes, such as one-point crossover and continuous or random multipoint crossover, have been developed. After crossover, some of the genes in the candidate offspring are subjected to mutation with a probability p_{mut} . The mutation operator is included to prevent premature convergence by ensuring diversity in the population. There may be preprocessing operation(s) before selection and postprocessing operation(s) after mutation. However, these are not considered as basic genetic operations.

The promising advantages of GA are the robust global search ability, simplicity, and versatility, while the notorious disadvantage of GA is the long runtime.

The GA was appreciated by the electromagnetic community in 1990s and has gained popularity since then. Details of the genetic algorithms and its applications in electromagnetics are comprehensively summarized in the two tutorial papers [28,29] and a review paper [30].

3.2.2.1. Standard Genetic Algorithm. C. C. Chiu [31] applied the conventional standard (or simple) genetic algorithm (SGA, also known as binary genetic algorithm, BGA), to reconstruct the shape of a perfectly conducting cylinder in free space with an exact a priori knowledge of the cylinder location. Unfortunately, the results presented in this pioneering work are dubious.

The SGA encodes the optimization parameters into a string of binary codes. A gene in SGA is a binary code. The

correspondence between a chromosome and the optimization parameters is given by

$$x_i = x_i^{\min} + \frac{x_i^{\max} - x_i^{\min}}{2^{L_i} - 1} \sum_{j=1}^{L_i} g_j^i 2^{L_i - j} \quad i = 1, N \quad (16)$$

where $[x_i^{\min}, x_i^{\max}]$ is the search range for the i th optimization parameter, $g_j^i \in [0, 1]$.

3.2.2.2. Real-Coded Genetic Algorithm. The SGA does not operate directly on the optimization parameters but on a discretised representation of them. Discretization error will inevitably be introduced when encoding a real parameter. The encoding and decoding operations also make the algorithm more computationally expensive for problems with real optimization parameters. The RGA, a GA working directly on real optimization parameters, is more desirable.

In the RGA, a gene is the optimization parameter itself, and the chromosome of the i th individual in the n th population takes the form

$$\text{Chromosome}^{n,i} = \mathbf{x}^{n,i} = [x_1^{n,i} \quad x_2^{n,i} \quad \dots \quad x_N^{n,i}] \quad (17)$$

Consequently, the crossover and mutation operators used in the RGA are quite different from those in the SGA. Commonly used crossover schemes in RGA include one-point mixture, continuous or random multipoint mixture, and arithmetical one-point crossover. The mutation in RGA takes the form of random perturbation.

A. Qing has successfully applied the RGA to reconstruct the location and shape of multiple perfectly conducting cylinders [1,32,33]. It has also been verified by real data reconstruction [34].

3.2.3. Differential Evolution Strategy. It is evident that the genetic operators in the genetic algorithms could be destructive: (1) the selection operation discriminates those less-fit parents—hence, their chance to produce possibly better babies is deprived; and (2) for crossover and mutation operations, all parents are replaced by their baby children, even if their children are less fit.

The DES [35] is a very simple but very powerful global optimizer. Its apparent distinction from GA is in the order of execution of the genetic operations. In the DES, the three genetic operations are executed in the order of mutation, crossover, and selection (or mother-child competition). Each parent individual is given equal chance to have her child. Selection is conducted between the mother and her child for a survival chance. In this way, destructive genetic operations are avoided. The other key behind the success of the DES is a scheme for generating trial parameter vectors.

The DES was first applied to reconstruct the location and radius of buried circular conductors or tunnels [36]. It was later applied to the present standard electromagnetic inverse problem [37].

The block diagram of the DES is shown in Fig. 7. (Please refer to Refs. 35–37 for a detailed explanation.)

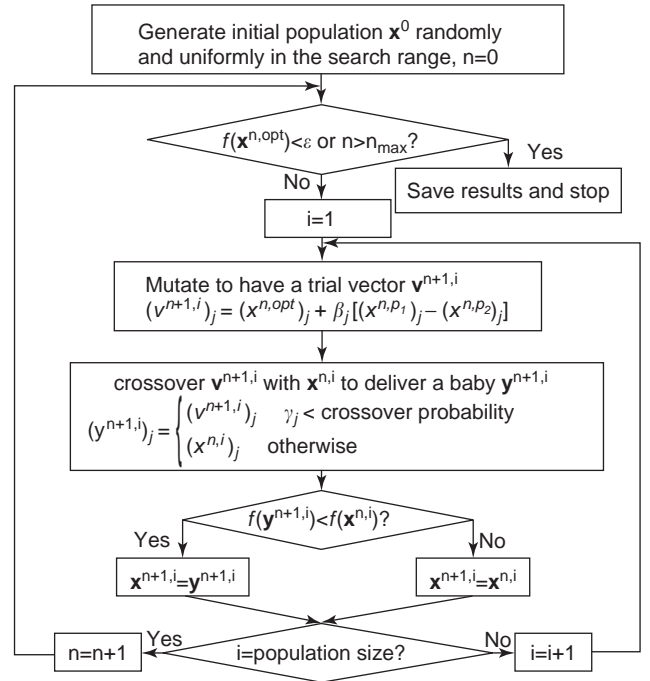

Figure 7. Block diagram of differential evolution strategy (ϵ —convergence threshold for minimization problem; β_j —random number uniformly distributed in $[0,1]$, γ_j —random number uniformly distributed in $[0,1]$; $1 \leq p_1 \neq p_2 \neq i \leq \text{population size}$).

3.2.4. Differential Evolution Strategy with Individuals in Groups. Although an inexact a priori knowledge of the number of cylinders in the imaging domain enables the execution of the NKA, the GA, and the DES, in terms of reconstruction time and quality of reconstruction results, an exact a priori knowledge of the number of cylinders in the imaging domain is crucial for these algorithms. Unfortunately, it is never easy to obtain such an exact a priori knowledge.

Such difficulty is overcome by the recently (in 2004) proposed GDES [38]. The number of cylinders is treated as an additional optimization parameter, to keep it flexible during the reconstruction. Therefore, no a priori knowledge on the number of cylinders is necessary. A crude guess on the maximum number of cylinders in the imaging domain is sufficient.

The key idea of the GDES is to organize the entire population into different groups according to the number of optimization parameters that they have; for instance, individuals in the same group have the same number of optimization parameters. This is possible since the maximum number of cylinders is limited and because individuals with the same number of cylinders have the same number of optimization parameters. The basic genetic operations of the DES (mutation, crossover, and mother-child competition) are performed within each group to determine the optimal profile in the group. An additional operator, the group competition, is introduced to adjust the group's size during evolution.

Since the number of cylinders of the reconstructed profile matches the exact number of cylinders of the true profile, the quality of the reconstruction results are therefore

Figure 8. Optimization of function $f(\mathbf{x}) = \sum_{k=1}^{14} (x_k - k)^2$, $x_k \in [-500, 500]$ using RGA.

much better, while the reconstruction time required is correspondingly reduced.

3.3. Numerical Results

3.3.1. Optimization of a Mathematical Function

3.3.1.1. Function for Optimization. The mathematical function to be optimized is

$$f(\mathbf{x}) = \sum_{k=1}^K (x_k - k)^2 \tag{18}$$

The optimal solution is $f(x_k = k) = 0$.

3.3.1.2. Search Range. The optimization parameters are searched within the range $[-500, 500]$, unless otherwise specified.

3.3.1.3. Termination Conditions. The two termination conditions are

1. Normal termination: $\min_{1 \leq i \leq N_{pop}} f^n(\mathbf{x}^{n,i}) \leq \varepsilon = 0.01$
2. Abnormal termination: $n > N_{max} = 1000$

3.3.1.4. SGA versus RGA. Here, $K = 14$ is considered, with $N_{pop} = 256$, $p_{cross} = 1.0$, $p_{mut} = 0.1$ for RGA. The one-point arithmetic crossover scheme is chosen as the crossover operator. The converging curves of RGA are shown in Fig. 8, in which the applied selection schemes are also shown.

For the SGA, $N_{pop} = 256$, $p_{cross} = 0.8$, $p_{mut} = 0.04$ are used. No test is successful for SGA within the same search range, which is subsequently narrowed to $[-20, 20]$ for SGA. The corresponding curves are shown in Fig. 9. The

Figure 9. Optimization of function $f(\mathbf{x}) = \sum_{k=1}^{14} (x_k - k)^2$, $x_k \in [-20, 20]$ using SGA.

convergence is not satisfactory even with the narrowed search range.

This comparison clearly shows the advantages of RGA over SGA.

3.3.1.5. RGA versus DES. Here, $K=20$ is considered, with $N_{\text{pop}}=256$, $p_{\text{cross}}=1.0$, $p_{\text{mut}}=0.1$ for RGA and $N_{\text{pop}}=100$, $p_{\text{cross}}=0.9$, $\beta=0.7$ for DES. The convergence performances are shown in Fig. 10.

The DES converges to the true solution with fewer generations and a smaller population size. It is apparent that the DES outperforms the RGA.

3.3.2. Synthetic Reconstruction

3.3.2.1. Synthetic Profiles. The following profiles are reconstructed using one or more of the abovementioned inversion algorithms:

SP1—a single cylinder: $d=0$, $\psi=0$, $F(\theta)=0.3+0.05\sin 2\theta$

SP2—two parallel circular cylinders: $d_1=0.5$, $\psi_1=0$, $F_1(\theta_1)=0.3$; $d_2=0.5$, $\psi_2=\pi$, $F_2(\theta_2)=0.3$

SP3—a single cylinder: $d=0$, $\psi=0$, $F(\theta)=0.3+0.06\cos\theta+0.03\sin\theta+0.025\cos 2\theta$

SP4—two parallel circular cylinders: $d_1=0.8$, $\psi_1=0$, $F_1(\theta_1)=0.3$; $d_2=0.8$, $\psi_2=180^\circ$, $F_2(\theta_2)=0.3$

SP5—a single circular cylinder: $d=0$, $\psi=0$, $F(\theta)=0.3$

3.3.2.2. Settings of Parameters. The incident frequency is 300 MHz ($\lambda=1$ m). It illuminates the unknown objects from eight incident directions, $\varphi_i=i\pi/4$, $i=1-8$; 32 receivers are located uniformly on Ω , with $R^{\text{meas}}=10\lambda$.

For SGA, $N_{\text{pop}}=256$, $p_{\text{cross}}=0.8$, $p_{\text{mut}}=0.04$ are used. For the RGA, $N_{\text{pop}}=256$, $p_{\text{cross}}=1.0$, $p_{\text{mut}}=0.1$ are chosen, and for DES, $p_{\text{cross}}=0.9$, $\beta=0.7$. The population size is 5 times that of the number of optimization parameters for DES. Finally, for the GDES, $N_{\text{pop}}=300$, $p_{\text{cross}}=0.9$,

$\beta=0.7$ are used. The local origins of the cylinders are searched in a circle around the origin with a radius of 1λ .

BLSF is used to approximate the cylinder's contours. The number of control points of a BLSF is 6. The search range of control points is $[0, \lambda]$

Settings that differ from the above specification will be pointed out explicitly.

3.3.2.3. Generation of Synthetic Data. The measured scattering data are obtained from simulation through solving the direct problem with finer subdivision of the cylinder contours. The synthetic data are assumed to be noise free.

3.3.2.4. Search Ability and Robustness

3.3.2.4.1. NKA versus RGA. The NKA and the RGA are applied to reconstruct SP1 and SP2. For SP1, an inexact a priori knowledge of the cylinder's location, $d=0.1$, $\psi=\pi/4$, is assumed. The contour of SP1 is approximated by a TLSF of order 4. The search ranges for the coefficients of the TLSF are $[0,2]$ for A_0 and $[-0.5,0.5]$ for A_i and B_i , $i=1-4$. Similarly, the locations of cylinders are known in advance for SP2, with $d_1=0.4$, $\psi_1=0$, $d_2=0.4$, and $\psi_2=\pi$. The order of the TLSF for SP2 is 3. The search ranges are set to be similar. The initial guess for the NKA is generated using the four schemes described in Ref. 1.

SP1 and SP2 are reconstructed successfully by the RGA. However, most of the trials with NKA fail to reconstruct the profiles. On the other hand, the few successful trials consume significantly less time.

3.3.2.4.2. SGA versus RGA. SP3, the profile considered in Ref. 31, is reconstructed using SGA and RGA. To be consistent with Ref. 31, the cylinder location is assumed to be known exactly in advance. The contour is approximated by a TLSF of order 4. The search range of A_0 is $[0,2]$. For A_i and B_i , $i=1-4$, the search ranges of $[-0.5,0.5]$ and $[0,2]$ are tested. RGA successfully obtained the profile with the narrow search range, while SGA can obtain only a

Figure 10. Optimization of function $f(\mathbf{x}) = \sum_{k=1}^{20} (x_k - k)^2$, $x_k \in [-500, 500]$ using DES (solid lines) and RGA (dotted lines). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

quasioptimal result ($\epsilon=0.03$) in affordable simulation time. The corresponding convergence performances are shown in Fig. 11. Both RGA and SGA failed to reconstruct the true profile with wide search range.

3.3.2.4.3. *RGA versus DES.* Profile SP4 is reconstructed using both RGA and DES. For the DES, $N_{pop} = 100$, $p_{cross} = 0.9$, $\beta = 0.7$ are used. A priori knowledge of the exact locations of the cylinders is assumed for RGA. The convergence performances are shown in Fig. 12.

3.3.2.5. *Effect of A Priori Knowledge of the Number of Cylinders.* A priori knowledge of the number of cylinders in the imaging domain is absolutely required for all algorithms considered, with the exception of the GDES. However, such a priori knowledge is rarely available. Here, its effect on the reconstruction will be studied.

SP4 and SP5 are the profiles of interest. The inversion algorithms studied are DES and GDES. The GDES requires a maximum number of cylinders in the imaging domain, which is set to be 3 here. This requirement does not impose too much inconvenience, since the maximum value is not necessarily exact and is usually restricted only by the available computational resources.

When reconstructing SP4 using DES, two cases of such a priori knowledge are considered. The first case is that the number (2) is exactly known. The other case is that the number is incorrectly assumed to be 3. The relationship between the optimal objective function value and generation is shown in Fig. 13. Apparently, the incorrect assumption on the number of cylinders significantly delays the reconstruction. However, the quality of the reconstruction result is not significantly affected.

It is worth noting that the difference in the reconstruction time for these two cases is more significant, since it takes much longer for the second case to complete one generation due to the larger population size and longer time required to evaluate an individual.

The GDES obtained the true profile within a much shorter time as shown in Fig. 14.

Similar results are observed for SP5 as shown in Fig. 15 and Fig. 16. However, in this case, the quality of the

Figure 13. Reconstruction of profile SP4 using DES with exact (black solid line) and inexact (red dashed line) a priori knowledge of the number of cylinders.

Figure 14. Reconstruction of profile SP4 using GDES (black solid line) and DES (red dashed line) with inexact a priori knowledge of the number of cylinders.

Figure 15. Reconstruction of profile SP5 using DES with exact (black solid line) and inexact a priori knowledge of the number of cylinders (red dashed line—2; blue dotted line—3).

reconstruction results using DES deteriorates with inexact assumption on the number of cylinders in the imaging domain, as shown in Fig. 17.

3.3.3. Reconstruction Using Fresnel Real Dataset

3.3.3.1. Experimental Setup. As mentioned earlier, the set of data was measured at Institut Fresnel, France [23]. The experimental setup is shown in Fig. 18. Please refer to Ref. 23 for more details.

3.3.3.2. Profiles Tested. The following two profiles are considered here:

RP1—centered 12.7×25.4 -mm rectangular cylinder (center position known before reconstruction)

RP2—decentered 12.7×25.4 -mm rectangular cylinder (center position unknown before reconstruction)

3.3.3.3. Measurement Noise. The data are very noisy, as shown in Table 1.

Figure 16. Reconstruction of profile SP5 using GDES (black solid line—2; red dashed line—3) and DES with inexact a priori knowledge of the number of cylinders (green dotted line—2, blue dashed-dotted line—3).

(a)

(b)

Figure 17. Reconstruction of profile SP5 using DES with inexact assumption of the number of cylinders: (a) assumed number of cylinders two; (b) assumed number of cylinders three.

3.3.3.4. Reconstruction Results. Both RGA and DES are applied to reconstruct the profiles.

The local origin is searched within a circle around the origin with radius 100 mm. Other parameters are identical as specified earlier. The reconstruction results are shown in Fig. 19 and 20. The cylinder is exactly located in all reconstructions. For RP1, excellent reconstruction results on the shape of RP1 are obtained at 8 and 16 GHz. The shape of RP1 at 4 and 12 GHz are a bit poorer but acceptable. The reconstructed shape of RP2 is good at 8, 10, 14, and 16 GHz, but a little bit poorer at 2, 4, 6, and 12 GHz. It is also observed that the reconstruction result of the centered case is in general better than those of the decentered case.

Figure 18. Fresnel experimental configuration.

It should be noted that the sample target, which is a rectangular cylinder, has four sharp corners. From the reconstruction results, it is noted that the cubic *B*-splines have difficulties in modeling these sharp corners.

Because of the strong noise in the experimental data, the reconstructed profile is quasioptimal. It is observed that the number of generations required to obtain the quasioptimal profile is comparable between the DES and the RGA. However, it is still reasonable to claim that the DES converges faster than the RGA, since the population size of the DES here (40) is much smaller than that of the RGA (256).

3.4. General Remarks

The abovementioned reconstructions and numerical experiences show that

1. The NKA is mathematically much more complicated. Its mathematical formulation is strongly related to the problem under consideration.
2. A good initial solution is very critical to the NKA. When such an initial solution is available, the NKA obtains the optimal solution very quickly.
3. In practice, the TLSF is applicable in the NKA since the NKA requires good a priori knowledge.
4. The BLSF applies equally well in all inversion algorithms considered.

Table 1. Measurement Error of RP1

Frequency (GHz)	Relative Error (%)
4	59.89
8	38.97
12	75.40
16	29.23

Figure 19. Reconstruction results of RP1. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

5. The SGA applies equally well to problems with any kinds of parameters (discrete, integer, real, or their mixture). However, its evolution mechanism needs to be improved.

(a)

(b)

Figure 20. Reconstruction results of RP2: (a) 2–8 GHz; (b) 10–16 GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

6. For problems involving real parameters only, the DES outperforms the RGA and the RGA outperforms the SGA.
7. The GDES is the first choice, if the number of cylinders in the imaging domain is unknown.

More recently, large-scale numerical experiments on the DES have been carried out. It is confirmed that the performance of the DES is dependent on the choice of genetic parameters. It is also noted that the required number of objective function evaluations is proportional to the population size, while the success probability is inversely proportional to the population size. Therefore, a tradeoff between success probability and time must be made.

We have developed a novel global inversion algorithm: the dynamic differential evolution strategy. Preliminary results show that the required number of objective function evaluations is independent of the population size. Detailed and complete results will be reported soon, when the simulation is completed.

4. CONCLUSIONS

This article addresses the electromagnetic inverse problem, beginning with a definition of this problem, followed by detailed discussion of the mathematical challenges involved and the application areas. We then attempt to predict some future directions in electromagnetic inverse problems and present a survey of the research in electromagnetic inverse problems. This survey includes a brief history of electromagnetic inverse problems, an overview of practical application fields, and a brief summary of the fundamental theories involved in the electromagnetic inverse problems and the inversion algorithms developed. The survey also covers the well-known real dataset and the tested inversion algorithms. Subsequently, a standard electromagnetic inverse problem—the reconstruction of multiple perfectly conducting cylinders—is considered. The inversion algorithms applicable to the cases presented in this article have been discussed. Comparisons between different algorithms have been made. Remarks on the advantages and disadvantages of each algorithm are given. The most recent advancements in this area are also briefly discussed.

Acknowledgment

The authors would like to thank Ms. Cassie Craig and Prof. Kai Chang for their kind invitation to make this contribution.

1. INTRODUCTION

Greek philosophers Plato and Socrates were aware of the polarities of lodestone, an iron ore, which could attract iron. Pierre de Marri-court used this property of lodestone to construct a compass to locate the North Pole. Gilbert (1540–1603) postulated that Earth is like a giant spherical magnet, and Kirchner (1601–1680) demonstrated that the magnetic poles of a magnet are of equal strength. Isaac Newton (1642–1727) made the first attempt to determine the law of force for a bar magnet, but the correct version (i.e., the inverse square law) was determined in 1750 by John Mitchell (1724–1793). In 1785 Charles de Coulomb (1736–1806) used the same inverse square law for determining the force between electric charges. Hans Christian Oersted (1777–1851) discovered in 1820 that a current-carrying wire could deflect a compass, and later on André Ampère (1775–1836) discovered that two current-carrying wires exert force on each other. Then Jean-Baptiste Biot (1774–1862) and Félix Savart (1791–1841) formulated their famous Biot–Savart law, which quantifies the force between the currents.

The inverse square law for magnetism was more or less established by the early nineteenth century. Benjamin Franklin (1706–1790) proposed an experiment to postulate the inverse square law for stationary electric charges, similar to the law of gravitation. In succeeding years considerable amount of work was carried on by Cavendish (in the early 1770s) and by Coulomb in 1785 to verify the inverse square law for electric charges. Karl Frederick Gauss (1777–1855) proposed the divergence theorem and presented the famous Gauss law of electrostatics, specifically, that the integral of the normal component of the electric flux over a closed surface is directly related to the net charge enclosed by that surface. In 1831 Michael Faraday (1791–1867) discovered that a time-varying magnetic field produces an electric field, and verified his law using the battery invented in 1800 by Alessandro Volta (1745–1827). In 1873, James Clerk Maxwell (1831–1879), a Scottish mathematician, published his famous treatise *Electricity and Magnetism*, which unified not only electricity and magnetism but also optics, and laid the foundation of electromagnetics through his four equations. Excellent descriptions of the groundwork of earlier researchers in connection with the foundation of electromagnetics are provided in Refs. 1–3.

On the application of electromagnetic (EM) fields, materials react in variety of ways. The applied electric field would influence both free and bound electrons, whereas the magnetic field would change the orientation of tiny

atomic moments. However, these responses are mostly linear (i.e., proportional to the applied field) over a specified range of the field. If the response to the field is independent of the orientation of material with respect to the direction of field; the material is isotropic. By applying time-varying EM fields to such linear, isotropic materials, their response would greatly depend on the frequency of the applied field. A few examples of such linear, isotropic materials are common dielectrics such as fused silica and glass, and common conductors such as copper and aluminum. Materials are classified as dielectric, conductor, and magnetic on the basis of their dominant response; for example, ferromagnetic materials are mostly highly conductive but are classified as magnetic materials because that property is most significant and useful. In practice, all materials have some response to magnetic fields but, except for ferromagnetic and ferrimagnetic, the response is usually small.

2. DIELECTRIC MATERIALS

Dielectric materials do not possess free electric charges and hence do not conduct electric current. The polar *dielectric materials* possess a dipole moment, but not the nonpolar ones. In an external electric field the molecules of dielectric materials are deformed and an induced electric moment appears. In some crystalline dielectric, spontaneous orientation of the dipole moments occurs even in the absence of electric field, and these substances are called *ferroelectric materials* (all fields are harmonic in time t).

For *lossy nonmagnetic dielectric materials*, permittivity can be represented as

$$\varepsilon = \varepsilon' - j\varepsilon'' \quad (1)$$

In this equation both ε' and ε'' are functions of frequency, and for solid, liquid, and gaseous states, the various physical phenomena contributing to ε' and ε'' essentially differ [4–6].

It can be shown that polarized atoms or molecules in a volume V present a *dipole moment density* defined as

$$\mathbf{P}_d = \lim_{\Delta v \rightarrow 0} \frac{\sum_i \mathbf{P}_i}{\Delta V}$$

Neglecting higher-order multipoles, this is identical to the so-called polarization, which exists in the relationship between \mathbf{D} and \mathbf{E} .

$$\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P} = \varepsilon_0 (1 + \chi_e) \mathbf{E} \quad (2)$$

where χ_e is the dielectric susceptibility. Here we have assumed that the polarization is *linearly* dependent on the field \mathbf{E} . If N represents the number of *like* molecules per unit volume, the induced polarization will have the form

$$\mathbf{P} = \varepsilon_0 \chi_e \mathbf{E} = N \alpha \mathbf{E}_l = N \alpha \Omega \mathbf{E} \quad (3)$$

where α is the *molecular* polarizability, Ω is the ratio between local field \mathbf{E}_l acting on the molecule and the applied

field \mathbf{E} . It should be noted at this point that the local field \mathbf{E}_l differs from applied electric field owing to the effect of molecules in the surrounding region. The displacement vector \mathbf{D} is related to the applied electric field \mathbf{E} as

$$\mathbf{D} = \varepsilon \mathbf{E} = \varepsilon_0 \varepsilon_r \mathbf{E} \quad (4)$$

Using Eqs. (2) and (4), the *relative permittivity* ($\varepsilon_r = \varepsilon / \varepsilon_0$) can be written as

$$\varepsilon_r = 1 + \frac{N \alpha g}{\varepsilon_0} = 1 + \chi_e \quad (5)$$

If the surrounding molecules have a spherically symmetric behavior, the factor g can then be written as

$$\frac{\varepsilon_r - 1}{\varepsilon_r + 2} = \frac{N \alpha}{3 \varepsilon_0} \quad (6)$$

This relationship is called the *Mossotti–Clausius equation*. If the effects of frequency on the *molecular polarizability* α are included, this relationship is known to be *Debye equation*.

Basically the molecular polarizability α consists of electronic and ionic effects of molecules. The electronic effect arises from the shift of the electron cloud (in each atom) from its positive molecules, and the ionic part is due to the displacement of positive and negative ions from their neutral positions. However, if the individual molecules have permanent dipole moments, these also contribute to the molecular polarizability, and the applied electric field tends to align these permanent dipoles. Thus the total molecular polarizability can be written as

$$\alpha_T = \alpha_e + \alpha_i + \alpha_d \quad (7)$$

with α_e , α_i and α_d denote electronic, ionic, and permanent dipole contributions, respectively.

According to the classical model of electronic polarization, any displacement of the charge cloud from its central ion produces a restoring force, and its interaction with the inertia of the moving charge cloud produces a resonance. This phenomenon is the same as discussed for a spring–mass system in mechanics. Similarly, the displacement of one ion from another produces resonances in the *ionic polarizability*. The *electronic polarizability* α_e is given as

$$\alpha_e = \frac{(e^2/m)}{(\omega_0^2 - \omega^2) + j\omega\Gamma} \quad (8)$$

where Γ is a *damping constant* and ω_0 is related to the restoring force. This equation can be generalized to represent all electronic and ionic resonant responses as

$$\alpha_j = \frac{F_j}{(\omega_j^2 - \omega^2) + j\omega\Gamma_j} \quad (9)$$

where F_j measures the strength of the j th resonance; real and imaginary parts of the equation contribute to $\varepsilon'(\omega)$ and

$\epsilon''(\omega)$, respectively. According to *Debye model*, $\epsilon'(\omega)$ can take negative as well as positive values. The relationships between $\epsilon'(\omega)$ and $\epsilon''(\omega)$ are known as *Kramers-Kronig relations* [7], and are given by

$$\epsilon'(\omega) = \epsilon_0 + \frac{2}{\pi} P \int_0^\infty \frac{\omega' \epsilon''(\omega')}{(\omega^2 - \omega'^2)} d\omega' \quad (10)$$

$$\epsilon''(\omega) = -\frac{2\omega}{\pi} P \int_0^\infty \frac{[\epsilon'(\omega') - \epsilon_0]}{(\omega^2 - \omega'^2)} d\omega' \quad (11)$$

where P denotes that the principal value of the integral that should be considered.

At optical frequencies one uses the refractive index rather than permittivity, and this is also a complex quantity for materials with absorption. With $\mu = \mu_0$, the complex refractive index is given as

$$n_c(\omega) = n_r(\omega) - jn_i(\omega) = \left\{ \frac{\epsilon'(\omega) - j\epsilon''(\omega)}{\epsilon_0} \right\}^{1/2} \quad (12)$$

3. CONDUCTORS, SEMICONDUCTORS, AND SUPERCONDUCTORS

Ohm’s law is truly obeyed in the case of good conductors. Also, for such materials the displacement current is negligible as compared to the conduction current, and therefore, the current and the electric field are in phase. The *displacement current* becomes increasingly important at higher frequencies. For example, at microwave frequencies semiconductors may have comparable conduction as well as displacement currents.

Let n_e be the density of free electrons in a medium with a background of fixed positive ions having the same density; this model may be considered for a conductor, semiconductor, or an ionized gas (plasma) with different values of parameters. It can be shown that the components of the *complex permittivity* defined by Eq. (1) will have the forms

$$\epsilon' = \epsilon_1 - \frac{n_e e^2}{m(v^2 + \omega^2)} \quad (13)$$

$$\epsilon'' = \frac{n_e e^2 v}{\omega m(v^2 + \omega^2)} \quad (14)$$

where ϵ_1 represents the effect of bound electrons of the positive ion background, v is the collision frequency, and e and m , respectively, are the electronic charge and mass. It is to be noted that $(n_e e^2 / m v)$ is the low-frequency conductivity σ . In the case of materials with moderate to low conductivities such as semiconductors, for microwave and millimeter-wave frequencies where $\omega^2 \gg v^2$, the second term in Eq. (13) is negligible. Thus, the complex permittivity ultimately becomes

$$\epsilon = \epsilon_1 - j \frac{\sigma}{\omega} \quad (15)$$

On the other hand, in the case of ionized gas with very low density and negligible collision frequency, we can have $\epsilon_1 = \epsilon_0$ and $\epsilon'' = 0$, and therefore, the permittivity takes the form

$$\epsilon = \epsilon_0 \left[1 - \left(\frac{\omega_p}{\omega} \right)^2 \right] \quad (16)$$

where ω_p is called the *plasma frequency*, and is given as

$$\omega_p = \left(\frac{n_e e^2}{\epsilon_0 m} \right)^{1/2} \quad (17)$$

Thus, we observe from Eq. (16) that the permittivity is negative for all frequencies below the plasma frequency. Therefore, for $\omega < \omega_p$, the intrinsic wave impedance $\eta (= \sqrt{(\mu/\epsilon)})$ becomes imaginary. As such, when a wave with $\omega < \omega_p$ incidents from free space on a region of ionized gas, the wave is reflected. The ω - β diagram for TEM waves propagating in an ionized gas is shown in Fig. 1.

For perfect conductors, there is no electric field at any frequency, and also, there is then no time-varying magnetic field. A truly static magnetic field is unaffected by conductivity of any value. For a metallic electrode, the “perfect conductor” approximation ensures uniform potential over its surface. A perfect conductor can be approximated as a conductor in which the collision frequency approaches zero, and this was considered to be the correct model for a superconductor in the period between its discovery (in 1911) by H. K. Onnes and the experiment (in 1933) by W. Meissner and Ochsenfeld [8]. A collision conductor can be modeled as a dense plasma, and for frequencies below the plasma frequency, the fields inside the conductor can exist only near the interface where they are excited. For extremely pure metallic crystals, very low collision frequencies may occur at temperature near the absolute zero. The ideal collisionless conductor excludes

Figure 1. The ω - β diagram for a plane wave propagating through an ionized gas.

time-varying fields from the interior. However, the experiments conducted by Meissner and Ochenfeld on a superconductor showed that constant magnetic fields are also excluded from the interior. In 1935 London showed that this result could be obtained if

$$\nabla \times \mathbf{J} = -\Lambda \mathbf{B} \quad (18)$$

with $\Lambda = n_e e^2 / m$ at $T = 0$. Substituting (18) in Maxwell's curl \mathbf{H} equation, and neglecting the displacement current, one finally obtains

$$\nabla^2 \mathbf{B} - \mu \Lambda \mathbf{B} = 0 \quad (19)$$

This last equation can be applied for the fields inside the surface of a superconductor by considering a half-space of superconductor filling $z \geq 0$ (Fig. 2). If we assume that only the x component of \mathbf{B} exists with its variation along the z direction only, then Eq. (19) finally becomes

$$\frac{d^2 B_x}{dz^2} - \frac{B_x}{\lambda_L^2} = 0 \quad (20)$$

where $\lambda_L = (m / \mu n_e e^2)^{1/2}$ at $T = 0$; λ_L is called the *London penetration depth*. The solution of Eq. (20) will be of the form

$$B_x = B_{x0} e^{-z/\lambda_L} \quad (21)$$

Experimentally determined values of penetration depths typically lie in the range 50–200 nm.

The phenomenon of superconductivity requires that the material be held at temperatures near absolute zero. Superconductors are mostly metallic elements,

Figure 2. Fields at the surface of a half-space of collisionless conductor or superconductor.

compounds, or alloys that make transitions into the superconducting state at critical temperatures below ~ 23 K. Among the others, niobium has the highest critical temperature about 9.2 K. Compounds of niobium with higher critical temperatures are widely used in many applications. A new family of oxide-based superconductors was discovered in 1986, which have much higher *critical temperatures* about 125 K [9]. However, the oxide-based superconductors are highly anisotropic as compared with metallic superconductors.

Superconductive transmission lines are nearly nondispersive in nature. Losses occur in superconductors at nonzero frequencies and nonzero temperatures (unlike the case for the ideal collisionless conductor) because the conduction electrons are not in the superconducting state and the penetrating fields can cause them to have collisions, resulting in heat dissipation. For frequencies throughout the microwave range, these losses are much smaller than in normal metals such as copper.

4. ANISOTROPIC DIELECTRICS

For isotropic dielectric materials, the quantities permittivity and permeability are scalar, and may be nonlinear and frequency-dependent. In fact, every permittivity is frequency-dependent because of the Kramers–Kronig relations. However, in some frequency bands, it may be possible to ignore the frequency dependence. Materials that respond differently to fields with different orientations are termed *anisotropic*, and the property of anisotropy may be in the response to either the electric or magnetic field. The anisotropy in the electric field response is represented by a matrix permittivity, which is an array of nine scalar quantities that may be nonlinear and frequency-dependent. Similarly, the anisotropy in the magnetic field response is represented by a matrix permeability [10,11]. Materials that have both the permittivity and the permeability are anisotropic, and are rarely found.

For *anisotropic dielectrics*, the relationship between \mathbf{D} and \mathbf{E} [12–14] is given as

$$D_x = \varepsilon_{11} E_x + \varepsilon_{12} E_y + \varepsilon_{13} E_z \quad (22a)$$

$$D_y = \varepsilon_{21} E_x + \varepsilon_{22} E_y + \varepsilon_{23} E_z \quad (22b)$$

$$D_z = \varepsilon_{31} E_x + \varepsilon_{32} E_y + \varepsilon_{33} E_z \quad (22c)$$

which may be presented in matrix form as

$$\begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix} = \begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{21} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{31} & \varepsilon_{32} & \varepsilon_{33} \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} \quad (23)$$

This equation can be written in a more compact form as

$$[\mathbf{D}] = [\boldsymbol{\varepsilon}][\mathbf{E}] \quad (24)$$

For physically real materials, the *permittivity matrix* is *Hermitian*, which is defined as

$$\epsilon_{ij} = \epsilon_{ji}^* \quad (25)$$

However, the permittivity is Hermitian only if a material is lossless (no physical material is lossless, by virtue of causality). For lossless crystals, Eq. (25) implies real and symmetric matrices, which can be diagonalized by a rotation of coordinates. Thus, Eqs. (22) reduce to the form

$$D_x = \epsilon_{11}E_x; \quad D_y = \epsilon_{22}E_y; \quad D_z = \epsilon_{33}E_z \quad (26)$$

where ϵ_{11} , ϵ_{22} , and ϵ_{33} are called as *principal permittivities*.

5. ELECTROOPTIC MATERIALS

Some certain materials show a change in permittivity on application of an electric field. If the change in permittivity is directly proportional to the applied electric field, this is known as *Pockels effect*. Certain noncentrosymmetric solids [13,15], such as lithium niobate and gallium arsenide, are examples of materials showing the Pockels effect. On the other hand, if the change in permittivity is directly proportional to the square of the applied electric field, this is known as *Kerr effect*. Some liquids such as carbon disulfide and nitrobenzene, and some centrosymmetric solids present the Kerr effect. Both the effects are, however, relatively small for practical values of externally applied electric field.

The electrooptic effect can be described by considering the change in permittivity element ϵ_{ij} on application of the electric field component E_k . However, the effect is defined in terms of the reciprocal matrix. Let us define the matrix

$$\left[\frac{1}{n^2} \right] = \left[\epsilon \right]^{-1} \quad (27)$$

Now, when the electric field is applied, the change in an element of this matrix is

$$\Delta \left(\frac{1}{n^2} \right)_{ij} = \sum_{k=1}^3 r_{ijk} E_k \quad (28)$$

where r is the distance from an arbitrary origin, where the subscripts i,j,k each range over the three spatial coordinates x,y,z , denoted by the integers 1,2,3, respectively. Since the matrices $[\epsilon]$, and hence $(1/n^2)$, are symmetric, one may implement contracted notations as $11 \rightarrow 1$, $22 \rightarrow 2$, $33 \rightarrow 3$, $23 = 32 \rightarrow 4$, $13 = 31 \rightarrow 5$, $12 = 21 \rightarrow 6$, so that Eq. (27) may be written in another form as

$$\Delta \left(\frac{1}{n^2} \right)_{ij} = \sum_{k=1}^3 r_{pk} E_k \quad (29)$$

Here the subscript k has values ranging from 1 to 3 and the subscript p ranges from 1 to 6. Table 1 shows the values of r_{pk} [as in Eq. (29)] for a few anisotropic crystals [15].

Table 1. Electrooptic Properties of a Few Materials

Materials	n_o ($\lambda_0 = 550$ nm)	N_e ($\lambda_0 = 550$ nm)	r_{pk} ($\times 10^{-12}$ mV $^{-1}$)
KDP	1.51	1.47	$r_{41} = 8.6$ $r_{63} = 10.6$
GaAs (10.6 μ m)	3.34		$r_{41} = 1.6$
LiNbO ₃	2.29	2.20	$r_{33} = 30.8$ $r_{13} = 8.6$ $r_{22} = 3.4$ $r_{42} = 28.0$
BaTiO ₃	2.437	2.365	$r_{33} = 23.0$ $r_{13} = 8.0$ $r_{42} = 820.0$

6. MAGNETIC MATERIALS

Under the influence of an external magnetic field the internal dipole moments align themselves. Also, a magnetic moment is induced in the magnetic material. As such, in the presence of a magnetic material, the resultant magnetic flux density will be different from its value in free space. The effect of magnetization can be studied by incorporating the equivalent volume current density, \mathbf{J}_m into the basic curl equation for the magnetic induction \mathbf{B} , given as

$$\nabla \times \mathbf{B} = \mu_0 \mathbf{J} \quad (30)$$

We thus have

$$\frac{1}{\mu_0} \nabla \times \mathbf{B} = \mathbf{J} + \mathbf{J}_m \quad (31)$$

where

$$\mathbf{J}_m = \nabla \times \mathbf{M} \quad (32)$$

It is assumed that an externally applied magnetic field causes the atomic circulating currents to align with it, thereby magnetizing the material. In Eq. (32) \mathbf{M} is the magnetization vector which measures the strength of magnetizing effect. From Eqs. (31) and (32), we finally get

$$\nabla \times \left(\frac{\mathbf{B}}{\mu_0} - \mathbf{M} \right) = \mathbf{J} \quad (33)$$

We now define the *magnetic field intensity* \mathbf{H} , which is a new fundamental field quantity, such that

$$\mathbf{H} = \frac{\mathbf{B}}{\mu_0} - \mathbf{M} \quad (34)$$

From Eqs. (33) and (34), we obtain the new equation

$$\nabla \times \mathbf{H} = \mathbf{J} \quad (35)$$

where \mathbf{J} is the volume density of free current. Equation (35) along with the equation $\nabla \cdot \mathbf{B} = 0$ (the divergence equation for the magnetic induction) form the two funda-

mental governing differential equations for magnetostatics [16–18]. Clearly, the factor permeability of the medium does not appear in both of these equations. For linear and isotropic materials the magnetization is directly proportional to the magnetic field intensity, and therefore

$$\mathbf{M} = \chi_m \mathbf{H} \quad (36)$$

where χ_m is a dimensionless quantity called the *magnetic susceptibility*. Using Eqs. (34) and (36), we obtain

$$\mathbf{B} = \mu_0(1 + \chi_m)\mathbf{H} = \mu_0\mu_r\mathbf{H} = \mu\mathbf{H} \quad (37)$$

or $\mathbf{H} = (1/\mu)\mathbf{B}$, where

$$\mu_r = 1 + \chi_m = \frac{\mu}{\mu_0} \quad (38)$$

μ_r is again a dimensionless quantity called as the *relative permeability* of the medium. The parameter $\mu = \mu_0\mu_r$ is said to be the *absolute permeability* (or the permeability) of the medium, and the unit of μ is henries per meter. Linear, isotropic, and homogeneous media have constant values of μ and χ_m . At this point, it is to be noted that the value of permeability for most materials is very close to that of free space, namely, μ_0 . For ferromagnetic materials such as Fe, Ni, and Co, the value of μ_r could be very large (e.g., 50–500 and $\geq 10^6$ for certain types of alloys). In fact, the value of permeability depends not only on the magnitude of magnetizing field \mathbf{H} but also on the previous history of the material.

6.1. Behavior of Magnetic Materials

The classification of magnetic materials can be roughly made according to their relative permeability μ_r . In general, magnetic materials are classified into three main groups; *diamagnetic* ($\mu_r \leq 1$; i.e., χ_m is a very small negative number), *paramagnetic* ($\mu_r \geq 1$; i.e., χ_m is a small positive number), and *ferromagnetic* ($\mu_r \gg 1$; i.e., χ_m is a large positive number) [19]. As such, the macroscopic magnetic property of a linear, isotropic medium can be described by defining the *magnetic susceptibility* χ_m . Generally, all materials have some response to magnetic fields. Except for ferromagnetic and *ferrimagnetic* (a special class of ferromagnetics) materials, the magnetic response is usually very weak. The magnetic response can either decrease or increase the flux density for a given magnetizing field \mathbf{H} . If \mathbf{B} is decreased, the material is said to be *diamagnetic*, and if it is increased, it is *paramagnetic*. However, a knowledge of quantum mechanics is essentially required in order to deal with the microscopic magnetic phenomena. A qualitative description of the behavior of various types of magnetic materials is given below, which is based on the classical atomic model.

The property of diamagnetism arises primarily from the orbital motion of electrons within an atom, and it is present in almost all materials. However, in most of the materials the effect of diamagnetism is too weak to be of any practical significance. In the absence of an externally applied magnetic field, the atoms of diamagnetic materials

have vanishing net magnetic moment (due to the orbital and spin motions of electrons). When an external magnetic field is applied to diamagnetic materials, it produces a force on the orbiting electrons, causing a perturbation in angular velocities, which results into a net magnetic moment. Now the induced magnetic moment always tends to oppose the externally applied field (according to *Lenz law*), and therefore, the magnetic flux density is ultimately reduced. The macroscopic effect of this process is analogous to that of a negative magnetization that can be described by a negative magnetic susceptibility χ_m . Thus, the diamagnetic response of atoms arises from the changes of electron orbits when an external magnetic field is applied. According to *Faraday's law*, an electric field can be produced by a changing magnetic field. That field induces currents which, in turn, produce a magnetic field that opposes the change. The response of electron orbits in an atom is of this kind. However, this kind of effect is generally extremely small. The effect produces fractional changes in μ from μ_0 by only 10^{-8} – 10^{-5} . The value of χ_m for most of the known diamagnetic materials (Bi, Cu, Pb, Hg, Ge, Au, silver, etc.) is of the order -10^{-5} . Diamagnetic materials do not exhibit permanent magnetism, and the induced magnetic moment disappears when the applied field is withdrawn.

On the other hand, in some materials the magnetic moments due to the orbiting and spinning electrons do not cancel each other completely, and therefore, the atoms and molecules possess a net magnetic moment. In such materials the diamagnetic response is usually obscured. When an external magnetic field is applied, tiny molecular magnetic moments tend to align in the direction of applied field, increasing the magnetic flux density. In addition, a very weak diamagnetic effect is also caused. The macroscopic effect of this process is equivalent to that of a positive magnetization that can be described by a positive magnetic susceptibility. Materials with this kind of behavior are said to be paramagnetic. Generally, such materials (Al, Mg, Ti, and W) have very small positive values of χ_m , of the order of 10^{-5} .

The property of paramagnetism primarily arises because of the magnetic dipole moments of spinning electrons. The externally applied field acts on molecular dipoles to align those, and the alignment forces are counteracted by the deranging effects of thermal agitation. The property of paramagnetism is temperature-dependent, unlike the case for diamagnetism (it is independent). Therefore, *paramagnetic effects* are stronger at lower temperatures because there is less thermal agitation.

If there are induced magnetic dipoles in the atoms or there is a nonzero average alignment of natural dipoles, in that case, the term *dipole density* can be defined as

$$\mathbf{M} = \lim_{\Delta v \rightarrow 0} \frac{\sum_i \mathbf{m}_{0i}}{\Delta V} \quad (39)$$

This is identical to the so-called magnetization that enters the relation between \mathbf{B} and \mathbf{H} as in Eq. (34). It can be shown that the magnitude of magnetization can be expressed in terms of molecular magnetic field \mathbf{H}_i acting on

the atomic dipoles and the absolute temperature T [20] as

$$M = Nm_0 \left(\coth \frac{m_0 \mu_0 H_i}{k_B T} - \frac{k_B T}{m_0 \mu_0 H_i} \right) \quad (40)$$

where k_B is Boltzmann’s constant, N is the number of dipoles per unit volume, and m_0 is the *natural dipole moment*. Equation (40) is derived considering the statistical distribution of the orientation of dipoles. In such materials, the direction of \mathbf{M} is the same as that of the molecular field \mathbf{H}_i ; that is, they are aligned parallel. If the external magnetic field \mathbf{H} is not too strong and the temperature is not too low, the terms in parentheses in Eq. (40) may be approximated by the first term only in its series expansion. In this case the magnetization is linearly related to the applied field:

$$\mathbf{M} = \chi_m \mathbf{H} \quad (41)$$

$$\chi_m \cong \frac{N \mu_0 m_0^2}{3k_B T} \quad (42)$$

At room temperature, the values of χ_m for a variety of materials are of the order of 10^{-5} .

6.2. Materials with Residual Magnetization

If the temperatures of paramagnetic substances are reduced below a certain value, which depends essentially on materials, the magnetization \mathbf{M} would be sufficient enough to produce the field necessary to hold the dipoles aligned even after the removal of the external field. The molecular field produced by the magnetization is given as [4]

$$\mathbf{H}_i = \kappa \mathbf{M} \quad \text{or} \quad \mathbf{M} = \frac{1}{\kappa} \mathbf{H}_i \quad (43)$$

where κ is the factor measuring the interaction of neighboring dipoles (it must be on the order of 1000). We see that there exists another relationship between \mathbf{H}_i and \mathbf{M} , as observed in Eq. (40). By equating the Eqs. (43) and (40), one may obtain the condition for *spontaneous magnetization*. The temperature below which a material exhibits spontaneous magnetization is called its *Curie temperature*.

For ferromagnetic materials, the effect of magnetization can be many orders of magnitude larger than that of paramagnetics. The effect of ferromagnetism can be explained on the basis of the model of magnetized domains, according to which ferromagnetic materials (e.g., Co, Ni, Fe) are composed of several tiny domains with their linear dimensions ranging from a few micrometers to ~ 1 mm. Each domain contains $\sim 10^{15}$ atoms, which are fully magnetized; that is, they contain aligned magnetic dipoles (even in the absence of an externally applied magnetic field) resulting from spinning electrons. In a molecular domain, strong coupling forces exist between the magnetic dipole moments (of the atoms). As a result, the different dipole moments are aligned parallel to each other. There exists a transition region between adjacent domains,

Figure 3. Domain structure of a polycrystalline ferromagnetic specimen.

which is about 100 atoms thick. This region is called the *domain wall* [21]. For ferromagnetic materials, when these are not magnetized, the magnetic moments of the adjacent domains have different directions (Fig. 3), and the random nature of orientations of these domains results in no net magnetization.

In ferromagnetic materials, under the influence of external magnetic field, the walls of domains having magnetic moments in the direction of applied field move in such a way that the volumes of those domains grow, resulting thereby an increase in magnetic flux density. When the applied field is weak (up to point P_1 in Fig. 4), the movements of domain walls are reversible. However, for stronger applied fields (i.e., after point P_1 is crossed), domain wall movements are no longer reversible. Also, domains rotate toward the direction of the externally applied field. If the applied strong field is reduced to zero at point P_2 , the B – H relationship will no longer follow the solid curve path P_2P_1O , but will decrease from P_2 to P'_2 instead, and the path followed will be along the broken lines as shown in Fig. 4. This phenomenon is called *hysteresis*, which is derived from a Greek word meaning “to

Figure 4. Hysteresis loop for ferromagnetic material.

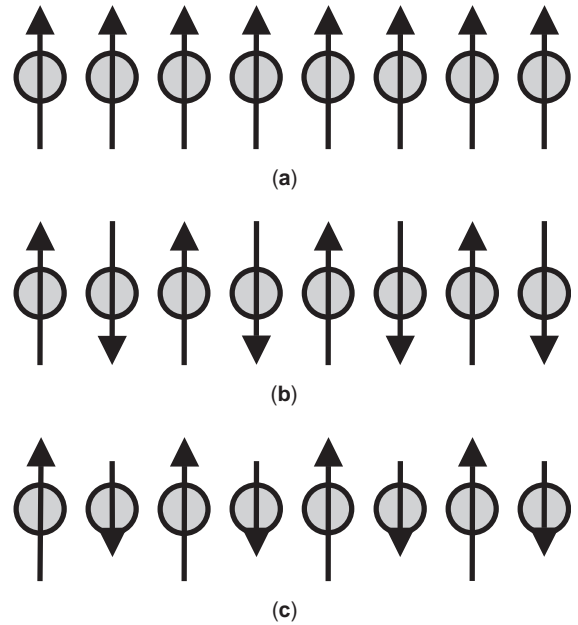

Table 2. Properties of a Few Hard Magnetic Materials

Materials	Composition (%)	Remanence B_r (T)	Coercive Force H_c (A/m)
Iron	Bonded powder	0.6	0.0765
Iron-cobalt	Bonded powder	1.08	0.0980
Alnico V	Ni 14%;Al 8%,Co 24%; Cu 3%,Fe 51%	1.27	0.0650
Ticonol II	Ni 15%;Al 7%;Co 34%; Cu 4%;Ti 5%;Fe 35%	1.18	0.1315

lag"; in this case we observe the lagging of magnetization behind the applied field. When the applied field strengthens (i.e., from point P_2 to P_3 in Fig. 4), domain rotation as well as domain wall motion will cause a complete alignment of the magnetic moments with the externally applied field. At this point, the ferromagnetic magnetic material is said to be saturated. The curve $OP_1P_2P_3$ (on the $B-H$ plane) is called the *normal magnetization curve*. If, after reaching point P_3 , the applied magnetic field is reduced to zero, the magnetic flux density does not fall to zero, but assumes the value at B_r , instead. This value of B is called as the residual flux density, and its unit is Webers per square meter (Wb/m^2). The value of B_r depends on the maximum intensity of the applied field. The property of the existence of a residual flux density in ferromagnetic materials is exploited in transforming them to permanent magnets.

In order to render the magnetic flux density of a ferromagnetic material zero, it is necessary to apply a magnetic field intensity H_c , called the *coercive force* (or the *coercive field intensity*), in the opposite direction. The unit of H_c is A/m, and its value also depends on the maximum value of the intensity of the applied field. It can be seen from the Fig. 4 that the relationship between B and H fields is nonlinear. Therefore, from the relationship $\mathbf{B} = \mu\mathbf{H}$, the permeability μ is not a constant, and it is a function of the magnitude of magnetizing field \mathbf{H} . The value of μ also depends on the history of magnetization of the material.

Some important applications of ferromagnetic materials include permanent magnets, signal recording tapes and disks, magnetic shielding, and cores for electromagnets, transformers, electric motors, and generators [21]. These materials can be roughly divided into two different categories called *hard* and *soft*; the designations refer to

**Figure 5.** Schematic atomic spin structures for (a) ferromagnetic, (b) antiferromagnetic, and (c) ferrimagnetic materials.

permanence of magnetization when the external applied field is removed, with hard materials retaining a strong magnetization. Ferromagnetic applications require that the material should acquire a large magnetization for a very small magnetic field. As such, these materials should have tall and narrow *hysteresis loops*. The properties of some technically important materials for permanent magnets are listed in Table 2 [22]. Generally, the coercive field intensity of hard ferromagnetic materials (such as Alnico alloys) would be about $\geq 10^5$ A/m, whereas that for soft ferromagnetic materials, it is usually around ≤ 50 A/m. The properties of some important soft materials are listed in Table 3 [22,23].

It may thus be inferred that ferromagnetism is the result of strong coupling effects between the magnetic dipole moments of atoms in a domain. The atomic spin structure of a ferromagnetic material is illustrated in Fig. 5a. If the temperature of a ferromagnetic material is raised to such a value that the thermal energy exceeds the coupling energy, the tiny magnetized domains lose their organized orientation, thus losing the property of magnetization. As

Table 3. Properties of a Few Soft Magnetic Materials

Materials	Composition (%)	Initial Permeability (μ_r) ₀	Maximum Permeability (μ_r) _{max}	Coercive Force ($\times 10^4$) (A/m)	Saturation Induction (T)
Iron	Commercial (Fe 99%)	2×10^2	6×10^3	0.9	2.16
Iron	Pure (Fe 99.9%)	2.5×10^4	3.5×10^5	0.01	2.16

such, a critical value of temperature can be defined, above which a ferromagnetic material behaves like a paramagnetic material; the critical temperature is known as the *Curie temperature*. For most of the ferromagnetic materials, the Curie temperature lies between a few hundred to a thousand degrees Celsius. For iron, the Curie temperature is about 770°C.

In the case of very small crystals, there are factors such as crystal shape, energetically preferred crystal directions, and the magnetic history of the sample that lead to nonzero net magnetization [24]. In the presence of an applied field the existence of domain walls in thin films is exploited for the so-called bubble memory devices for computer memories [25].

Some elements, such as chromium and manganese, also have strong coupling forces between the atomic dipole moments. However, their coupling forces produce antiparallel alignments of electron spins (Fig. 5b), and the spins alternate in direction from atom to atom, resulting in no net magnetic moment. Such materials are referred to as *antiferromagnetics*, and this property is also temperature-dependent. An antiferromagnetic material, on heating above its Curie temperature, exhibits random spin directions, and the materials ultimately become paramagnetic.

Another class of magnetic materials that exhibit behavior between ferromagnetism and antiferromagnetism are called as *ferrimagnetic materials*. Here quantum-mechanical effects cause the directions of magnetic moments in the ordered spin structure to alternate, and their magnitudes to be unequal. As a result, a nonzero magnetic moment exists for such materials (Fig. 5c). As such, in ferrimagnetic materials, the neighboring dipoles are aligned in an antiparallel arrangement, but different types of atoms are present and the dipoles do not cancel. As seen in Fig. 5c, because of the partial cancellation of magnetic moments, the maximum magnetic flux density for ferrimagnetic materials is much lower than that for ferromagnetics. Typically, its value is about 0.3 Wb/m², which is approximately one-tenth the value of that for ferromagnetic materials.

6.3. Ferrites

Ferrites are a subgroup of ferrimagnetic materials that have low loss and strong magnetic effects at microwave frequencies [26]. These materials have a particular type of solid crystal structure made up of oxygen, iron, and another element such as lithium, magnesium, or zinc. These mostly have the formula XO-Fe₂O₃, where X denotes a divalent metallic ion such as Fe, Co, Ni, Mn, Mg, Zn, or Cd. There are also some ceramiclike compounds with very low conductivity as well as magnetic garnets which are used as ferrites such as yttrium-iron-garnet (YIG; Y₃Fe₅O₁₂). Ferrites present relatively low losses at microwave frequencies. The dielectric constants of ferrites are relatively high, and the anisotropic behavior of permeability comes into existence when the material is subjected to a steady magnetic field [27].

In order to define the energy state of an atom, both the orbital and spin quantum numbers must be specified. As

mentioned above, the electron spin generates a strong magnetic moment. These magnetic moments are randomly oriented in paramagnetic substances. However, a strong coupling between spin magnetic moments of neighboring atoms exists in ferromagnetics, antiferromagnetics, and ferrites. This results in parallel or antiparallel alignment of spin magnetic moments. The model of a spinning electron is shown in Fig. 6. For a rotating body, the applied torque **T** is the rate of change of angular momentum **J**:

$$\frac{d\mathbf{J}}{dt} = \mathbf{T} \tag{44}$$

Since the magnetic moment **m** can be given as

$$\mathbf{m} = \gamma\mathbf{J} \tag{45}$$

γ being the gyromagnetic ratio, for a spinning electron, the magnetic moment **m** can be related to the applied torque. Now, the torque resulting from subjecting a magnetic moment **m** to a magnetic field **B_i** is

$$\mathbf{T} = \mathbf{m} \times \mathbf{B}_i \tag{46}$$

From Eq. (44), we would obtain

$$\frac{d\mathbf{m}}{dt} = \gamma \frac{d\mathbf{J}}{dt} = \gamma\mathbf{T} = \gamma(\mathbf{m} \times \mathbf{B}_i) \tag{47}$$

In a magnetic material, the magnetic field **B_i** acting on a molecule can be represented as

$$\mathbf{B}_i = \mu_0\mathbf{H} + \mathbf{M} \tag{48}$$

where μ_0 is the free-space permeability and **M** is the *magnetization vector*. The vector **M** may also be treated as magnetic dipole density, and can be given as $N_0\mathbf{m}$ with N_0 as the effective number density. The relationship between the intensity of magnetic field **H** and the external applied field **B** depends on the shape of the ferrite body. The matrices [**B**] and [**H**] are related as

$$[\mathbf{B}] = [\mu][\mathbf{H}] \tag{49}$$

Figure 6. Model of a spinning electron in a magnetic field.

or

$$\begin{bmatrix} B_x \\ B_y \\ B_z \end{bmatrix} = \begin{bmatrix} \mu_{11} & \mu_{12} & 0 \\ \mu_{21} & \mu_{22} & 0 \\ 0 & 0 & \mu_0 \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ H_z \end{bmatrix} \quad (50)$$

Here the permeability components are

$$\mu_{11} = \mu_{22} = \mu_0 \left(1 + \frac{\omega_0 \omega_M}{\omega_0^2 - \omega^2} \right) \quad (51)$$

$$\mu_{12} = \mu_{21}^* = j \frac{\mu_0 \omega_0 \omega_M}{\omega_0^2 - \omega^2} \quad (52)$$

with

$$\omega_M = -\mu_0 \gamma M_0 \quad \text{and} \quad \omega_0 = -\mu_0 \gamma H_0 \quad (53)$$

where M_0 is the *saturation magnetization* and H_0 is the strength of the DC magnetic field. It is to be noted that the value of magnetic intensity \mathbf{H} is averaged over the space of many molecules within the material, and therefore, the magnetic field within the ferrite differs from the applied field.

It can be shown that linearly polarized waves cannot propagate through ferrites, and therefore, it is not a normal mode of propagation for the medium. In reality, circularly polarized waves are normal modes for ferrites; media having this property are called *gyrotropic media*. In ferrite media, the propagation constants for clockwise- and counterclockwise- polarized waves are different.

In 1845, Michael Faraday observed that when optical waves are allowed to propagate through a dielectric with an applied magnetic field, there occurs a rotation of plane of polarization of the optical wave, and the angle of rotation θ can be given as

$$\theta \propto H_0 l \quad (54)$$

where H_0 is the DC magnetic field strength and l is the interaction length. The rotation of the plane of polarization of optical waves is called *Faraday rotation*, and this effect is very strong in ferrites. Equation (54) can be rewritten as

$$\theta = V H_0 l \quad (55)$$

where the constant of proportionality V is known as the *Verdet constant*.

Faraday rotation is also observed even in ordinary dielectrics (e.g., silica), but the angle of rotation θ is relatively small, and the value of V is about 0.014 min/Oe · cm at the operating wavelength 600 nm. In silica, the angle of rotation decreases at longer wavelengths approximately as λ^{-2} .

There are waveguides and stripline devices that employ ferrites, and these devices have found enormous use in microwave applications. Waveguide devices operate on the *Faraday effect* principle. The operation of stripline devices is based on the asymmetry caused by an applied

steady magnetic field. In waveguide devices, according to the principle of Faraday rotation, for both the positive and the negative traveling waves (as shown in Fig. 7), the linearly polarized wave is oriented in the same direction relative to the direction of the DC magnetic field. The *gyrator* [28] is the simplest microwave device that uses the effect of Faraday rotation, and it produces a phase shift of 180° in one direction but no shift in the opposite direction.

The *absorption isolator* is another Faraday rotation device where the wave traveling to one side is appreciably attenuated (about 30 dB) and that traveling to the other side suffers only a little attenuation (say, ~0.5 dB). *Circulators* also exploit the principle of Faraday rotation, and these devices transmit a wave from one guide to the other. These devices employ ferrite rods, and can also be used as switches or modulators (by controlling the field that magnetizes the ferrite rod). The dimensional structure of ferrite rods used in Faraday rotation devices is designed so that the required rotation is easily achieved with reasonable magnetic fields, and the wave reflections are minimized with maximum power-handling capacity. These devices are useful only for low power.

The *stripline Y-junction circulator* is one among stripline devices, and it can be used as a switch or isolator. Such a device employs ferrite disks, and a DC magnetic field is applied perpendicular to the disks. Standing-mode patterns are formed in ferrite disks; a detailed description [29,30] of the operating principle is beyond the scope of this article.

7. BIANISOTROPIC MATERIALS

Since the mid-1990s, intensive research on new artificially engineered physical systems has been reported

Figure 7. Rotation of waves in magnetized ferrite rods.

emphasizing the different aspects of nanostructure and mesoscopic physics as well as physics of microwave composite materials. A good example of an artificially engineered physical system would be a small ferrite disk with the magnetostatic wave oscillation spectrum. The magnetostatic wave oscillations in a small ferrite disk resonator are characterized by a discrete spectrum of energy levels. Reports have been made on the different mechanisms of excitation of magnetostatic wave oscillations in small ferrite specimens by external RF magnetic fields.

Since the mid-1990s, rapid advancements in materials science enabled the fabrication of complex materials in the form of thin films and particulate composites, thus rendering the term *bianisotropy* quite fashionable [31,32]. In bianisotropic materials the electromagnetic field vectors are coupled in a pattern more complex than that in the usual type of anisotropy. *Artificial bianisotropic materials*, because of their potential usefulness for a variety of applications, have attracted considerable attention of the R&D community devoted to research on the electromagnetics of bianisotropic materials [33]. Artificial, isotropic chiral materials have been made (although quite useless for RAM purposes). Artificial anisotropic materials with a wide variety of properties have also been made. Their properties are local when the long-wavelength approximation is valid. With the use of composites, a wide variety of novel response properties become achievable.

There are several bianisotropic materials that possess the property of chirality [34], specifically, optical activity or handedness. Also, many bianisotropic materials have the property of *nonreciprocity*, meaning that they exhibit direction-dependent responses. However, all materials with direction-dependent response properties are not non-reciprocal. Thus, bianisotropic materials have a wide variety of response properties owing to their complexity in structure, and have found many different applications in the areas of microwaves, electrical engineering, and optics. Sculptured thin films which present nanoengineered response properties, have been developed [35–40]. Many new composite materials with nonlinear optical applications are now emerging.

7.1. Linear Constitutive Equations

The reciprocity theorem due to Lorentz states that fields $\mathbf{E}_a, \mathbf{H}_a$ and $\mathbf{E}_b, \mathbf{H}_b$ from two different sources at the same frequency satisfy the condition

$$\nabla \cdot (\mathbf{E}_a \times \mathbf{H}_b - \mathbf{E}_b \times \mathbf{H}_a) = 0 \quad (56)$$

This theorem is easily verified for isotropic media by substituting Maxwell's equations in complex form. It can also be shown that this holds for an anisotropic medium provided the permittivity and permeability matrices are symmetric. The reciprocity theorem does not hold if the matrices are asymmetric.

The theory of reciprocal bianisotropic materials can be described on the basis of following equations [41]

$$\mathbf{D} = \bar{\bar{\epsilon}} \cdot \mathbf{E} + j\bar{\bar{\alpha}}^T \cdot \mathbf{H} \quad (57)$$

$$\mathbf{B} = \bar{\bar{\mu}} \cdot \mathbf{H} - j\bar{\bar{\alpha}}^T \cdot \mathbf{E} \quad (58)$$

where the electric and the magnetic fields are coupled. These equations are valid in both the time and the frequency domains, and are called *constitutive relations* as they contain information about the nature of the material under consideration. It is to be noted that the constitutive relations relate the matter-derived fields \mathbf{D} and \mathbf{H} to the basic fields \mathbf{E} and \mathbf{B} in any material medium. Both permittivity and permeability of a reciprocal material are symmetric.

In Eqs. (57) and (58), the tensor $\bar{\bar{\alpha}}$ measures the optical activity (or chirality) of the medium, the superscript "T" represents the transpose operation, and j stands for the imaginary part. The fundamental properties of the material tensors $\bar{\bar{\epsilon}}$ (the permittivity), $\bar{\bar{\mu}}$ (the permeability), and $\bar{\bar{\alpha}}$ have been determined [41–43]. Possible alternative constitutive relations have also appeared in the literature [44]. However, different constitutive equations are actually equivalent (after appropriate redefinition of the field vectors). Equations (57) and (58) provide the most rational and convenient way to describe the effects of chirality, especially in nonuniform media.

7.2. Electromagnetics of Bianisotropic Materials

Investigators have presented the study of spherical waves in chiral bianisotropic materials with the scalar dielectric permittivity and dyadic chirality parameter. The electromagnetic behavior of bianisotropic materials with uniaxial symmetry [45,46] have been discussed in the literature with the appropriate constitutive equations as [45]

$$\mathbf{D} = \bar{\bar{\epsilon}} \cdot \mathbf{E} + j(-\alpha \bar{\bar{I}}_t + \kappa \bar{\bar{J}}) \cdot \mathbf{H} \quad (59)$$

$$\mathbf{B} = \bar{\bar{\mu}} \cdot \mathbf{H} + j(\alpha \bar{\bar{I}}_t + \kappa \bar{\bar{J}}) \cdot \mathbf{E} \quad (60)$$

In these equations, the dielectric permittivity $\bar{\bar{\epsilon}}$ and the magnetic permeability $\bar{\bar{\mu}}$ are uniaxial diadics given as

$$\bar{\bar{\epsilon}} = \epsilon_t \bar{\bar{I}}_t + \epsilon_n \bar{z}_0 \bar{z}_0 \quad (61)$$

$$\bar{\bar{\mu}} = \mu_t \bar{\bar{I}}_t + \mu_n \bar{z}_0 \bar{z}_0 \quad (62)$$

where \bar{z}_0 represents the unit vector along the geometric axis and $\bar{\bar{I}}_t = \bar{x}_0 \bar{x}_0 + \bar{y}_0 \bar{y}_0$ is the transverse unit dyadic. Further, in Eqs. (59) and (60), $\bar{\bar{J}} (= \bar{z}_0 \times \bar{\bar{I}}_t = \bar{y}_0 \bar{x}_0 - \bar{x}_0 \bar{y}_0)$ is the 90° rotator in the transverse (x - y) plane, α is the chirality parameter as defined in Eqs. (57) and (58), and the parameter κ measures the coupling of orthogonal transverse electric and magnetic fields. Composite materials governed by the constitutive relations (59) and (60) can be fabricated by embedding small Ω -shaped metal elements in isotropic dielectric, together with chiral

elements. Such materials are useful in microwave applications.

Bianisotropic omega materials can be described by the constitutive relations [47]

$$\mathbf{D} = \bar{\bar{\epsilon}} \cdot \mathbf{E} + j\bar{\bar{\kappa}}_{em} \cdot \mathbf{H} \quad (63)$$

and

$$\mathbf{B} = \bar{\bar{\mu}} \cdot \mathbf{H} - j\bar{\bar{\kappa}}_{me} \cdot \mathbf{E} \quad (64)$$

In these equations, the dielectric permittivity $\bar{\bar{\epsilon}}$ and the magnetic permeability $\bar{\bar{\mu}}$ are diagonal dyadics given as

$$\bar{\bar{\epsilon}} = \epsilon_0(\epsilon_{xx}\bar{\mathbf{x}}_0\bar{\mathbf{x}}_0 + \epsilon_{yy}\bar{\mathbf{y}}_0\bar{\mathbf{y}}_0 + \epsilon_{zz}\bar{\mathbf{z}}_0\bar{\mathbf{z}}_0) \quad (65)$$

$$\bar{\bar{\mu}} = \mu_0(\mu_{xx}\bar{\mathbf{x}}_0\bar{\mathbf{x}}_0 + \mu_{yy}\bar{\mathbf{y}}_0\bar{\mathbf{y}}_0 + \mu_{zz}\bar{\mathbf{z}}_0\bar{\mathbf{z}}_0) \quad (66)$$

If the equivalent electric dipoles of molecules (or stems of the omega particles in composite materials) are all aligned with the z axis and the magnetic dipoles are in the y direction (the loops lie in the $(x-z)$ plane), then $\bar{\bar{\kappa}}_{em}$ and $\bar{\bar{\kappa}}_{me}$ can be given as

$$\bar{\bar{\kappa}}_{em} = \kappa\bar{\mathbf{z}}_0\bar{\mathbf{y}}_0 \quad (67)$$

$$\bar{\bar{\kappa}}_{me} = \kappa\bar{\mathbf{y}}_0\bar{\mathbf{z}}_0 \quad (68)$$

The combination of omega-shaped layers with biased ferrites provides good microwave applications. For optical applications, chiral bianisotropic materials can be manufactured as multilayered structures formed by anisotropic layers [48].

Apart from linear bianisotropic materials, there are *nonlinear* bianisotropic materials as well, the crystals of which combine the practical advantages of liquid crystals possessing spiral structures with those of nonlinear materials [49,50]. The property of chirality facilitates frequency-selective and polarization-sensitive reflection together with polarization rotation, whereas the nonlinearity makes the parametric interaction and frequency transformation effects possible.

8. MAGNETOSTRICTION

In the early 1840s James Prescott Joule observed that the magnetization of an iron sample induces a change in the length of the sample. Since then this phenomenon, known as the *Joule effect*, is often exploited in *magnetostrictive actuators*. The converse of this effect, in which the magnetization of the sample can be changed on application of stress, known as the *Villari effect*, and also at times referred to as the *magnetostrictive effect*, is usually exploited in magnetostrictive sensors. There also exists another pair – Wiedemann effect and its converse Matteucci effect, which correlate, respectively, twist in the sample to the generation of the helical magnetic field, and vice versa. Both of these effects are used in devices and torque sensors. The Joule, the Wiedemann, the Villari and the

Matteucci effects lead to two modes of operation of magnetostrictive transducers: transformation of magnetic energy into mechanical energy and of mechanical energy into magnetic energy. The former is exploited in actuators for generating motion or force, and also, in sensors for detecting the states of magnetic field; the latter is used in sensors to detect motion or force, passive damping devices, and devices for inducing change in the state of magnetic fields in materials.

Magnetoelasticity (or magnetostriction) is a phenomenon that describes the interaction between magnetism and elasticity in ferromagnetic materials. In magnetoelasticity, *Hooke's law* of elasticity is violated, since an additional expansion/contraction results from the reorientation of tiny magnetic domains. Thus in magnetostriction phenomenon strain is caused by the magnetic field. When an external stress is applied, the initially randomly oriented magnetic domains align themselves in the direction of the resultant strain, and produce an irreversible change in the dimension of the material. The total strain in the magnetic material is the sum of pure *elastic strain* and the strain produced by the displacement of domain walls. Although the elastic strain vanishes when the stress is removed, the *magnetostrictive strain* can be restored only by applying a compressive stress. Such a behavior of magnetic materials generates a hysteresis loop on the alternating stress–strain curve. The *saturation magnetostriction coefficient*, represented by λ_s , a dimensionless quantity, is defined as the ratio of the change of length to the original length, and is measured at the saturation flux density. If the magnetostriction is sufficiently large and the applied field is an alternating one (in the audible frequency range of 50–60 Hz), it creates noise (sound). It has been discovered that alloys of iron and rare-earth elements (Sm, Tb, Dy, Ho, Er, Tm, etc.) cause intense magnetostriction 100–1000 times greater than that generated by CoFeNi alloys (the conventional magnetostrictive materials). Thus, rare-earth alloys are designated as *supermagnetostrictive materials*. Magnetostrictive actuators, based on magnetostrictive effects, are driven by external magnetic fields.

In the beginning, the magnetostrictive materials were used in telephone receivers, hydrophones, magnetostrictive oscillators, torque meters, and scanning sonars, employing nickel and other magnetostrictive materials that exhibit bulk saturation strains up to 100 $\mu\text{m}/\text{m}$. Some of the current applications of magnetostrictive devices include ultrasonic cleaners, high-force linear motors, active vibration or noise control systems, medical and industrial ultrasonics, pumps, and sonars. Ultrasonic magnetostrictive transducers have been developed for chemical and material processing, surgical tools, and underwater sonars.

Applications of amorphous magnetoelastic materials for numerous tagging [51,52] and remote sensing applications are now prevalent [53,54]. In sensors, these materials exhibit sufficiently large magnetoelastic effect [55]; specifically, the material effectively converts magnetic energy into elastic energy and vice versa. Magnetoelastic sensors are magnetostrictive; therefore, they launch magnetic flux oscillations when they become mechanically

deformed. A magnetoelastic sensor, when coated uniformly with a layer of an elastic material, its characteristic resonant frequency changes owing to the loading of additional mass as well as the influence of elasticity in the coating [56]. Usually, in magnetoelastic sensors, the resonant frequency is observed by using a pickup coil [53]. For example, in case of a thin longitudinally vibrating bar, the frequency of magnetoelastic resonance coincides with the resonance of acoustic vibration, and therefore, the resonance (of the magnetoelastic sensor) can be described as the mechanical resonance of the vibrating bar.

Magnetic shape memory (MSM) alloys are also gaining importance as possible “smart” materials that can function as both actuators and sensors. The MSM effect is due to the magnetic field induced by the redistribution of twin variants in a martensitic phase, and it offers faster response compared to conventional temperature-driven shape memory alloys. In addition, the strains generated are much larger than in ordinary magnetostrictive materials [57].

8.1. Magnetoelastic Damping

Magnetoelastic (or magnetostrictive) materials are attractive materials for the purpose of damping and for the absorption of energy. Terfenol-D is an example of such a material, which, in a stress–strain cycle, will absorb up to 80% of the mechanical energy input to the system. However, pure Terfenol-D has low tensile strength, which limits its use in applications related to energy absorption. The damping mechanism in Terfenol-D arises from the *jumping* of the magnetization from one easy magnetic direction to another through the process of *magnetoelastic coupling*, which describes the relation between magnetic properties of ferromagnetic materials and the applied mechanical tension. The jumping requires a minimum amount of energy that corresponds to a critical value of the applied stress. When the material is returned to a lower level of stress, the magnetization may not return to the original state, and this indicates the absorption of energy. A simplified domain structure is illustrated in Fig. 8, which shows the “jump” from a vertical orientation under tension to a horizontal orientation under compression.

By incorporating Terfenol-D powder into a resin matrix, the composite may be loaded in tension in order to realize the damping properties. The mechanism of magnetoelastic damping is not related to the rate of loading, but it depends on the magnitude of loading. Thus, this type of mechanism is completely different from the typical damping mechanisms, which are highly rate-dependent. The aspect of magnetoelastic damping, along with the composite material approach, allows the possibility of nanoengineered hybrid dampers for certain applications similar to impedance matching in transducers.

As mentioned earlier, in magnetostrictive materials, vibrational energy is damped through the movement of magnetic domains. Consequently, the dissipation of vibrational energy generates heat. This effect is not diminished even at low temperatures, and therefore, magnetostrictive materials can be expected to be effective in damping vibrations at very low temperatures. In order to suppress

Figure 8. Domain structure of magnetoelastic material.

vibrations of large motors and transformers that operate at temperatures below 100 K, initially viscoelastic dampers were in use, which are based on the principle of *viscoelasticity*. Viscoelastic damping involves the movements of atoms and, at low temperatures, these movements become very small. Therefore, such viscoelastic dampers cannot work efficiently at low temperatures. As such, in order to operate at such low temperatures, for such applications, magnetoelastic dampers have also been proposed. This type of damper is usually made of magnetostrictive materials such Tb/Dy alloys [58,59]. At a temperature of ~ 77 K, a specimen of Tb/Dy alloy is found to dissipate about 30% of the vibrational energy per stress–strain cycle. It has been observed that the dissipation factor can be further enhanced by adding very small amounts of N, Ta, or some other elements to a Tb/Dy alloy, and also, by changing the processing conditions.

9. PIEZOELECTRICITY

Piezo is the Greek word for pressure. As such, *piezoelectricity* is also termed *pressure electricity*. The phenomenon of piezoelectricity was discovered in the 1880s by Pierre and Jacques Curie. They found that some crystalline materials, when compressed, produce a voltage proportional to the applied pressure, and that when an electric field is applied across the material, there occurs a corresponding change in shape. This characteristic is called *piezoelectricity*. Thus, piezoelectric materials are those that generate an electric charge when deformed mechanically. This is commonly referred to as the “generator effect.” Conversely, when an external electric field is applied to piezoelectric materials, they assume mechanical deformation or stress. This is commonly referred to as the “motor effect.”

Typical examples of the naturally occurring piezoelectric materials are quartz, tourmaline, human skin, and

human bone, although the latter two have very low coupling efficiencies. Some artificially produced piezoelectric crystals are Rochelle salt, lithium sulfate, and ammonium dihydrogen phosphate. Another class of materials possessing piezoelectric properties is polarized piezoelectric ceramic. They are typically referred to as *ferroelectric materials*. In contrast to the naturally occurring piezoelectric crystals, ferroelectric ceramics are polycrystalline in nature. The most commonly produced piezoelectric ceramics are barium titanate, lead titanate, lead metaniobate, and lead zirconate titanate (PZT). Although piezoelectricity is found in several types of natural materials, most modern devices use PZT. Piezoelectric ceramics respond rapidly to the changes in input voltage; noise due to the power supply is the only limiting factor in the positional resolution. Although high voltages are used to produce piezoelectric effect, the power consumption is low, and the energy consumption is minimal in maintaining a fixed position with a fixed load.

Production of all piezoelectric ceramic materials involves detailed processing, and the material properties may be altered by modifying the chemical composition and the manufacturing process. This essentially provides the designer with a means to tailor the material properties to the application. The processing involves different stages such as calcination, high firing, polling, and aging. To discuss the details of these processes is beyond the scope of the present article.

Piezoelectric ceramic materials possess electrical, mechanical, and electrochemical properties resulting from the chemical formulation and the manufacturing process. Typical electrical parameters are the dielectric constant and the dissipation. High dielectric constants of the materials are desirable as this property provides low impedance. Materials with low dissipations are required because they result in low electrical losses. Typical electromechanical parameters are the electromechanical coupling constant k and the piezoelectric constants g and d . High values of the electromechanical coupling result in a more efficient transfer of electrical energy to the mechanical energy. In fact, the constant k is a dimensionless number related to the ratio of the energy stored in the mechanical and electrical portion of the material. The constant d relates to mechanical strain and applied electrical field, and it is defined as the ratio of the strain to the field, with the unit meters per volt. The constant g relates the open-circuit voltage and mechanical stress, and it is defined as the ratio of the voltage to stress. The unit of g is voltmeters per newton. Typical mechanical parameters are the density and the elastic constants.

Depolarization of piezoelectric ceramics would result if these materials were exposed to excessive heat, electrical drive, or mechanical stress or any combination of these. The temperature at which piezoelectric ceramic is completely depoled is known as the *Curie point*. Piezoelectric ceramics also possess the properties of *pyroelectricity*, in which a change in ceramic temperature results in a change in mechanical dimensions, thereby producing stress within the ceramic and a corresponding electrical charge on the surface of electrodes.

An example of a piezoelectric device is ultrasonic probes (transducers) employed to create underwater Sonar. This area of exploitation of piezoelectric materials is quite mature, and nowadays ultrasonic probes work almost exclusively according to the piezoelectric effect. A series of powerful piezoelectric materials are now available to generate ultrasound in ultrasonic probes. These materials differ in their physical properties, and depending on the technical application and the required probe characteristics, an appropriate selection of the piezoelectric material can be made. Knowledge of the constructional details of the utilized piezoelectric materials, however, not only contributes toward a better technical understanding of the basic action of the probe but also helps us understand the behavior of the probe under certain operation conditions.

For the construction of ultrasonic probes, the diameter and the frequency of the piezoelectric element are the important parameters to be considered. However, it is essential to have a detailed knowledge of the physical and the acoustic properties of the piezoelectric material used; the relevant information will not only contribute to a better technical understanding of the basic working principle of probes but will also give an insight into the behavior of the probe under various operating conditions. Information about the piezoelectric materials will also be helpful in detecting the suitability of the type of probe under the given circumstances. As such, it would be worthwhile to introduce the different types of piezoelectric materials currently in use. We shall explain their strengths and weaknesses and to show how they can be exploited for various probe designs.

9.1. Piezoelectric Materials

In the early days of ultrasound technology, materials such as quartz, lithium sulfate, and barium titanate were used. However, such materials are rarely in use today; instead, new powerful piezoelectric materials are available, which have varieties of basic acoustic and electric characteristics. Table 4 lists the important physical characteristics of different piezoelectric materials used today to generate ultrasonic waves [60].

The acoustic impedances of *piezoceramic* materials are usually high and comparable to those of many metallic or ceramic solids. The coupling coefficient for radial (or transverse) vibrations indicates to what extent a piezoelectric element can convert energy into transverse modes, which are perpendicular to the thickness mode. Transverse modes should be suppressed as much as possible as they cause undesired signal distortions. These modes are developed at low frequencies, because they correspond to the lateral dimensions of the piezoelectric element. Lead titanate is the only piezoelectric material that has a negligibly small coupling coefficient k . The *electromechanical coupling coefficient* k_t is a measure of the fraction of electrical energy, which is converted into mechanical energy in the thickness mode. It determines the efficiency of generating ultrasonic waves in a particular vibrational mode utilized in probes. The values of k_t for piezoceramic materials are usually high. However, if ultrasonic waves prop-

Table 4. Characteristics of Piezoelectric Materials

Physical Properties	Lead Zirconate Titanate PZT-5	Lead Titanate PT	Lead Metaniobate PbNb ₂ O ₆	Polyvinylidene Fluoride PVDF (Copolymer)	1-3 Composite
Acoustic impedance Z ($10^6 \text{ kg m}^{-2} \text{ s}^{-1}$)	33.7	33	20.5	3.9	9
Resonant frequency f (MHz)	<25	<20	<30	160–10 (55–2)	<10
Coupling coefficient (thickness mode) k_t	0.45	0.51	0.30	0.2 (0.3)	0.6
Coupling coefficient (radial mode) k_p	0.58	<0.01	<0.1	0.12 (k_{31})	~0.1
Relative permittivity ϵ_r	1700	215	300	10	450
Maximum temperature ($^{\circ}\text{C}$)	365	350	570	80	100

agate into liquids or plastics, most of the acoustic energy generated by the piezoceramic element is reflected at the boundary between the piezoelectric material and the medium of propagation. Therefore, only a fraction of the acoustic energy is transferred into the medium of propagation. Such piezoceramics are used for up to a maximum of 30 MHz.

Piezoelectric plastics such as PVDF or related copolymers are better matched to the low acoustic impedance of liquids or plastics. In addition, they are mechanically flexible. It becomes possible to generate ultrasound at frequencies up to 160 MHz with very thin foils of PVDF. However, it becomes evident from the coupling coefficient k_t for the thickness mode that PVDF is less sensitive than ceramics.

The so-called 1–3 composite materials [61] appear more promising as they have high values of k_t and low values of k . Such composites perform better within the approximate temperature range of 100°C . Table 4 shows typical values for 1–3 piezocomposites. However, these values will vary in a wide range by varying the piezoceramic material as the design.

9.2. Applications of Piezoelectric Materials in Probes

Different properties of piezoelectric materials are very useful for the design of different types of probes. The most suitable material can be selected depending on the intended application of the probe. As we can see from Table 4, lead metaniobate has the lowest acoustic impedance of all the piezoceramics. This is better suited to design high-resolution shockwave probes (shockwaves have extremely short pulses). The relatively low impedance of lead metaniobates is also useful for the design of broadband angle probes and TR probes. Lead titanate has small values of k , and therefore, radial vibrational modes of this material are negligible. As such, lead titanate can be utilized to produce probes with especially small measurements. Lead zirconate titanate (PZT) is used where large measurements and high ultrasonic absorption are required. In such cases, it is important that the probe should generate ultrasound of higher intensity than usual, so that even echoes from the far end can still be detected. For receiver probes, it is better to use a bulk PZT element of appropriate thickness. This is because, at a given input pressure, the voltage across the

electrodes of a piezoelectric element is proportional to its thickness.

At high frequencies the use of piezoceramics is limited. Since the resonant frequency of piezoelectric disks vibrating in the thickness mode is inversely proportional to the thickness, piezoceramic disks become thinner than 0.1 mm above 20 MHz. Such piezoceramic disks are brittle and difficult to handle during the manufacturing process of the probe. However, at higher frequencies, thin foils of PVDF are easier to handle [62]. Because of their low acoustic impedance, an effective transfer of ultrasonic waves is possible only into water or plastic materials. Even at normal frequencies the high flexibility of PVDF and its low impedance, are useful for the design of special line-focused immersion probes. Such line-focused PVDF probes have been in use since 1990 in high-speed test systems for steel pipes. These are described in more detail in other publications [63,64].

Because of their relatively low acoustic impedance and high sensitivity, 1–3 composites are also suitable for generating ultrasound in liquids and plastics. However, the manufacturing of such probes is less complicated than the manufacturing process of the piezo element itself. 1–3 composites are also suitable for the manufacturing of line-focused immersion probes. However, PVDF foils are less expensive.

In conclusion, the currently available piezoelectric materials complement each other in their physical characteristics. PVDF is very flexible, and it is easy to handle and shape. Further, it exhibits good stability over time, and does not depolarize when subjected to very high alternating fields. But the coupling constant of PVDF is significantly lower than that of PZT. Shaping of PVDF can reduce the effective coupling of mechanical and electrical energies due to edge effects. In the design of ultrasonic probes, it is very important to use a material that has the best suitable characteristics. In addition, economy also plays a vital role for the user, as well as for the manufacturer. As a result, PZT has been considered as an economic piezoelectric material over the years.

Acknowledgment

The authors are immensely grateful to Prof. Akhlesh Lakhtakia of the Pennsylvania State University (USA) for reviewing and making constructive suggestions to improve the manuscript.

ELECTROMAGNETIC MODELING

R. VAHLDIECK
 Swiss Federal Institute of
 Technology Zürich (ETHZ)
 Zürich, Switzerland
 WOLFGANG J.R. HOEFER
 University of Victoria
 Victoria, BC, Canada

Numerical modeling of electromagnetic (EM) fields or *computational electromagnetics* is a combination of numerical methods and field theory—a discipline in its own right and of growing importance in such diverse areas as microwave and RF (radiofrequency) engineering, antenna design, EM field scattering, semiconductor physics, bioelectromagnetics, and electromagnetic compatibility and interference (EMC/EMI).

The starting point for modeling electromagnetic fields is Maxwell's equations considering a set of known boundary/initial conditions. In addition, certain theorems and principles, such as superposition, equivalence, and duality can be utilized. Entirely analytical solutions to Maxwell's equations are possible only for a narrow range of problems

and most of them were solved a long time ago. Classical analytical methods are the methods of separation of variables, conformal mapping, series expansion, and integral methods (if the integrals have analytical solutions).

Today's complexity of relevant EM field problems prevent entirely analytical (closed-form) solutions to Maxwell's equations. Rather, numerical approaches are necessary that approximate the exact solution with any desired degree of accuracy. Does this eliminate the need for analytical methods? Certainly not! In fact, analytical preprocessing is part of all numerical methods, and if the analytical content is high, the method is often described as semianalytical.

In general, the electromagnetic field problem can be conveniently formulated as a partial-differential equation while that of the source problem as an integral equation (operator equation). The objective of numerical methods is to transform an exact operator equation into a solvable (discrete) matrix equation. To achieve this, virtually all numerical methods follow the same principal steps:

1. To express the unknown function of the operator equation by a sum of linear independent functions with unknown expansion coefficients. This is often called a trial function which approximates the real function if the number of terms in the sums goes to infinity.
2. The continuous solution domain is represented by a set of discretized subdomains consisting of a finite number of elements or nodes.
3. To determine the unknown expansion coefficients in the trial function, some form of error minimization is chosen. Employing either variational principles or the method of weighted residuals, the operator equation is transformed into a matrix equation that must be solved by appropriate techniques.

Depending on the kind of operator used, numerical methods are in general categorized into domain methods and boundary methods. More recently a new category has been added, that of hybrid methods.

Domain methods solve the electromagnetic field problem described by partial differential equations. Examples are the finite difference method and the finite element method. Both methods are based on differential equations and on discretization of the entire computational domain. *Boundary methods* solve the electromagnetic source problem described by integral equations, either volume integral equations or boundary integral equations. Examples are the boundary element method or the method of moments. The latter can also be used to solve differential equations. *Hybrid methods* are a combination of two or more different methods. A hybrid numerical approach can be a two-step procedure or an implicit hybrid algorithm. In the two-step procedure, one part of the problem is solved with one method, the results of which become the input parameters for the next method. In the implicit hybrid algorithm two or more modeling approaches are combined into one new algorithm to exploit only the advantageous features of each method. Hybrid methods are very useful

for problems that can either not be solved within the framework of a single technique or in cases where a combination of methods results in a computationally more efficient algorithm to model the electromagnetic field.

Since the late 1970s the importance of modeling electromagnetic fields has increased manifold. This refers not only to the analysis of arbitrary electromagnetic field problems but also to the CAD (computer-aided design) of circuits and components. With rising operating frequency and higher circuit density, quasistatic analysis methods are replaced by full-wave analysis methods to account for near-field effects or higher-order mode interaction. Simplifying assumptions about material properties have been replaced by realistic material descriptions taking dispersion and losses into account. With the steady increase in computer power, research in electromagnetic modeling is still advancing at a rapid pace, introducing new techniques, expanding the capability of existing methods or simply improving their computational efficiency and accuracy. Only some of the multitude of electromagnetic modeling techniques available today can be outlined here.

This article will focus only on some mainstream techniques, most of which employ either the method of weighted residuals or variational principles. We will begin with modeling techniques in the frequency domain, most importantly the method of moments (MoM). This section is followed by time-domain methods and here in particular the finite-difference time-domain method (FDTD) and the transmission-line matrix (TLM) method. Finally, a brief overview with respect to hybrid methods concludes this article. A comparison between the various modeling approaches as well as their advantages and disadvantages is added where appropriate.

For a more detailed representation of the various methods, the interested reader is referred to the books by Sadiku [1] or Zhou [2]. Another excellent source of information is the book edited by Itoh [3], which discusses the various methods in the context of passive microwave circuit modeling.

1. FREQUENCY-DOMAIN METHODS

Most electromagnetic modeling techniques operate in the frequency domain; that is, the time derivative d/dt is replaced by $j\omega t$. Therefore, all calculations are performed at a single frequency only. In cases where the electromagnetic field is of interest over a frequency band, repeated calculations are necessary. This is in contrast to time-domain methods. Here a single run of the algorithm, after a proper impulse excitation, followed by a Fourier transform of the impulse response, provides the information over a wide frequency range. Which method to use depends on the problem at hand.

1.1. The Method of Moments

The *method of moments* (MoM) is a general form of weighted residuals to solve integral, differential, and integrodifferential equations. The method itself does not provide any information about the derivation of the gov-

erning equation, thereby allowing its applicability to a wide range of physical phenomena.

The equations solved by MoM are normally an electric field integral equation (EFIE) or a magnetic field integral equation (MFIE) of the following form

$$\text{EFIE : } \mathbf{E} = f_e(\mathbf{J})$$

$$\text{MFIE : } \mathbf{H} = f_m(\mathbf{J})$$

whereby \mathbf{E} and \mathbf{H} are the incident field quantities and \mathbf{J} is the induced current density. The form of integral equation (EFIE or MFIE) depends on the problem. In most cases these integrals are formulated in the frequency domain, although the MoM can also be applied to solve problems in the time domain.

The MoM as a mathematical technique was first introduced by Mikhlin [4] and later popularized in the area of numerical electromagnetics by Harrington [5]. The mathematical formulation of the MoM is simple and general. Consider a linear operator L such that

$$L\mathbf{J} = \mathbf{g} \quad (1)$$

The function \mathbf{J} (e.g., current density) is the response of the system represented by the operator L to the excitation \mathbf{g} (magnetic or electric field). When L and \mathbf{g} are known, Eq. (1) represents an analysis problem from which \mathbf{J} is determined. A synthesis problem is one in which both \mathbf{J} and \mathbf{g} are known but L is to be determined.

The MoM solution of Eq. (1) takes advantage of the linearity of the operator L to expand \mathbf{J} in a series of the form

$$\mathbf{J} = \sum_m a_m \mathbf{J}_m \quad (2)$$

The a_m 's are unknown expansion coefficients and the \mathbf{J}_m 's are known functions in the domain of the operator L . The functions \mathbf{J}_m , which are assumed to form a complete set, are called *basis functions*. Substituting the expansion of \mathbf{J} in Eq. (1) and using the linearity of L , we get

$$L\mathbf{J} = L \sum_m a_m \mathbf{J}_m = \sum_m a_m L\mathbf{J}_m = \mathbf{g} \quad (3)$$

The original problem is now reduced to determining the expansion coefficients from this last equation. In the MoM, both sides of the equation are projected onto the range of the operator L . Let \mathbf{T}_m denote a complete set of functions in the range of L . The \mathbf{T}_m 's are referred to as testing or weighting functions. Taking the inner product of Eq. (3) against the testing functions, yields

$$\sum_m a_m \langle \mathbf{T}_n, L\mathbf{J}_m \rangle = \langle \mathbf{T}_n, \mathbf{g} \rangle \quad n = 1, 2, \dots \quad (4)$$

Here, a suitable inner product (a linear form) is assumed to be known. Usually, the inner product is taken as the

integral of the product of the arguments

$$\langle \mathbf{J}, \mathbf{g} \rangle = \int \mathbf{J} \mathbf{g} \quad (5)$$

Equation (4) can be rewritten in a more convenient matrix form

$$[A][a] = [U] \quad (6)$$

where

$$[A]_{mn} = \langle \mathbf{T}_m, \mathbf{L} \mathbf{J}_n \rangle \quad (7)$$

$$[U]_m = \langle \mathbf{T}_m, \mathbf{g} \rangle \quad (8)$$

If the matrix $[A]$ is not singular, its inverse $[A]^{-1}$ exists. The expansion coefficients a_m are then given by

$$[a] = [A]^{-1}[U] \quad (9)$$

Once the expansion coefficients are known, the solution is given by Eq. (2). The MoM is most commonly implemented in the form of Galerkin’s method in which the testing functions are equal to the basis functions, $\mathbf{T}_m = \mathbf{J}_m$.

In practice, the infinite expansion Eq. (2) is truncated at some upper value of m . The approximate solution, given by Eq. (9), is then straightforwardly computed using a computer. The efficiency of the technique depends heavily on having basis functions which approximate well the exact solution with only a few terms. Therefore, MoM techniques are not very effective in the analysis of complex geometries or inhomogeneous dielectrics. On the other hand, MoM techniques are particularly efficient for the analysis of antennas and electromagnetic scattering problems.

1.2. The Mode-Matching Technique

The mode-matching technique (MMT), or modal analysis method, can be viewed as a special case of the method of moments and is a frequently used analysis tool for scattering of electromagnetic waves at metal waveguide discontinuities. In this method, the fields immediately left and right from the discontinuity are expanded in a series of weighted eigenfunctions. From the matching condition or continuity condition of the fields tangential to the discontinuity plane the coefficients of the series expansions can be determined. Details of the method can be found in Refs. 6 and 7. The MMT has been successfully applied to eigenvalue as well as to scattering problems both in homogeneous waveguides as well as partially dielectric loaded waveguides. Numerous application examples for eigenvalue problems are given, for example, in Refs. 8 and 9 and for scattering problems in Refs. 10 and 11.

The basic problem to be solved in the MMT is to find the coefficients of the field expansion to minimize the least square error between the exact EM field and the approximating series of eigenfunctions. If we postulate $g(x)$ as the exact field in the aperture between two subregions, the approximation by a series of orthogonal eigenfunctions

$f_i(x)$ is written

$$g(x) \cong \sum_i^N a_i f_i(x), \quad x \in x_1, x_2 \quad (10)$$

where a_i denote the weighting (expansion) coefficients. Multiplying both sides of Eq. (10) with a set of weighting functions $w_j(x)$ and integrating over the domain of x results in

$$\int_{x_1}^{x_2} w_j(x) g(x) dx = \sum_i^N a_i \int_{x_1}^{x_2} w_{ji}(x) f_i(x) dx \quad (11)$$

We solve Eq. (11) such that its weighted residual is zero:

$$\int_{x_1}^{x_2} w_j(x) \left[g(x) - \sum_i^N a_i f_i(x) \right] dx = 0, \quad (12)$$

$$j = 1, 2, \dots, N$$

If the weighting function is a set of delta functions

$$w_j(x) = \delta(x - x_j)$$

Eq. (10) becomes Eq. (13) which is known as *point matching* Eq. (11):

$$g(x_j) \cong \sum_i^N a_i f_i(x_j), \quad j = 1, 2, \dots, N \quad (13)$$

This equation is solved for a_i . If the weighting functions are the eigenfunctions themselves, we use the least-square error to select the expansion coefficients such as to minimize the integrated squared error

$$0 = \frac{\partial}{\partial a_i} \int \left[g(x) - \sum_i^N a_i f_i(x) \right]^2 dx$$

By using the orthogonality of the eigenfunctions $f_i(x)$ we find the individual coefficients

$$\frac{\int_{x_1}^{x_2} f_i(x) g(x) dx}{\int_{x_1}^{x_2} f_i(x)^2 dx} = a_i \quad (14)$$

It should be noted that the integral in the denominator of Eq. (14) is a normalization constant while the integral in the numerator (the coupling integral) can in most cases be solved analytically, except in cases where the geometry of the regions left and right of a discontinuity is described by different coordinate systems.

The MMT becomes a powerful analysis tool in conjunction with the generalized scattering matrix (GSM) approach. The GSM relates all reflected wave amplitudes of fundamental and higher-order modes at discontinuities to the incident wave amplitudes. Wave amplitudes are in this context the power normalized expansion coefficients in Eq. (10).

Figure 1. H -plane discontinuity in rectangular waveguide; (a) perspective view; (b) scattered wave amplitudes.

A simple example illustrates the MMT in conjunction with the GSM technique. A waveguide step discontinuity is shown in Fig. 1. We assume that in both waveguide sections only the fundamental TE_{10} mode can propagate.

The TE_{10} mode consists of three field components of which two, E_y and H_x , are tangential to the discontinuity plane at $z=0$ (Fig. 1b). In regions 1 and 2, the electric field component can be expressed as a series of eigenfunctions such as in Eq. (10). Applying the continuity condition at the discontinuity plane ($z=0$), $E_y^1 = E_y^2$, results in

$$\begin{aligned} & \sum_{m=1}^M T_m^1 \sin\left(\frac{m\pi}{a}x\right) (A_m^1 + B_m^1) \\ &= \sum_{n=1}^N T_n^2 \sin\left(\frac{n\pi}{a-x_1}(x-x_1)\right) (A_n^2 + B_n^2) \end{aligned} \quad (15)$$

The coefficients T in Eq. (15) ensure power normalization of the incident A and reflected B wave amplitudes for fundamental and higher-order modes. The products $T \cdot A$ or $T \cdot B$ are the expansion coefficients of Eq. (10). Multiplying both sides of Eq. (15) with $\sin(i\pi/a x)$ and integrating over the cross section $x=0-a$ yields

$$E_y : A_i^1 + B_i^1 = \frac{\sum_{n=1}^N T_n^2 \int_{x_1}^a \sin\left(\frac{n\pi}{a}x\right) \sin\left(\frac{i\pi}{a-x_1}(x-x_1)\right) dx}{\underbrace{\int_0^a \sin^2\left(\frac{i\pi}{a}x\right) dx}_{LE}} (A_n^2 + B_n^2) \quad (16)$$

The normal modes satisfy the orthogonality relation, and the integral in the denominator of Eq. (16) thus becomes

$$\int_0^a \sin^2\left(\frac{i\pi}{a}x\right) dx = \frac{a}{2} \quad (17)$$

A similar equation is obtained from the continuity condition of the H_x component

$$H_x : \frac{\sum_{m=1}^M T_m^2 Y_m \int_{x_1}^a \sin\left(\frac{m\pi}{a}x\right) \sin\left(\frac{i\pi}{a-x_1}(x-x_1)\right) dx}{\underbrace{\int_{x_1}^a \sin^2\left(\frac{i\pi}{a-x_1}x-x_1\right) dx}_{LH}} \quad (18)$$

$$A_i^1 - B_i^1 = A_m^2 - B_m^2$$

Both equations can be written in matrix notation:

$$\begin{aligned} E_y : & [A]^1 + [B]^1 = [L_E] \cdot ([A]^2 + [B]^2) \\ H_x : & [L_H] \cdot ([A]^1 - [B]^1) = [A]^2 - [B]^2 \end{aligned}$$

Rearranging these equations leads to the generalized scattering matrix of the waveguide discontinuity

$$\begin{bmatrix} [B]^1 \\ [A]^2 \end{bmatrix} = \begin{bmatrix} [S_{11}] & [S_{12}] \\ [S_{21}] & [S_{22}] \end{bmatrix} \begin{bmatrix} [A]^1 \\ [B]^2 \end{bmatrix} \quad (19)$$

A well-known problem in the MMT is the slow convergence rate and the relative convergence phenomenon. The latter can be alleviated to some degree by choosing the number of modes on both sides of the discontinuity in the same ratio as the waveguide dimensions left and right from the discontinuity. The MMT is also not well suited for problems in which the structure contains a mixed-coordinate system. Coupling integrals must then be solved numerically, which makes the algorithm slow and not very effective. In those cases the MMT can be combined with other techniques (hybrid methods discussed later) that are more appropriate for certain parts of the problem.

1.3. Coupled Integral Equation Technique

The problem of slow convergence in the MMT is due mainly to the fact that the eigenfunctions of the waveguides left and right from the discontinuity do not accommodate the boundary conditions of the fields in the discontinuity plane. This is not so in the coupled integral equation technique (CIET). A major advantage of the CIET is its ability to include a priori information, such as the edge conditions, at multiple discontinuities simultaneously. The salient features of the technique can be found in Refs. 12 and 13; here we only show how the edge condition at a single discontinuity is handled through the CIET. For this we refer again to the example of Fig. 1.

The tangential electric field within the discontinuity region (the gap region) is expanded in a series of basic functions that are chosen such that they include the edge condition of the electric field at $x=x_1$:

$$E_{\text{gap}}(x) = \sum_i^I c_i E_i(x) \begin{cases} E_{\text{gap}} = 0, & 0 \leq x \leq x_1 \\ E_{\text{gap}} \neq 0, & x_1 < x \leq a \end{cases} \quad (20)$$

A possible set of basic functions that satisfy the edge condition is the following:

$$E_i(x) = \frac{\sin\left[\frac{i\pi}{a-x_1}(x-x_1)\right]}{[(x-x_1)(2a-x_1-x)]^{1/3}}$$

Matching the tangential electric field of both regions (1 and 2) to the electric field in the discontinuity plane

E_{gap} yields

$$\begin{aligned} E_y^1(x) &= E_{\text{gap}}(x), & 0 \leq x \leq a \\ E_y^2(x) &= E_{\text{gap}}(x), & x_1 \leq x \leq a \end{aligned} \tag{21}$$

From Eq. (21), using Eq. (20), one obtains

$$\begin{aligned} B_i^1 &= -\delta_{i1} + \frac{2}{a} \int_{x_1}^a E_{\text{gap}}(x) \sin\left(\frac{i\pi}{a}x\right) dx \\ B_i^2 &= \frac{2}{a-x_1} \int_{x_1}^a E_{\text{gap}}(x) \sin\left(\frac{i\pi}{a-x_1}x-x_1\right) dx \end{aligned} \tag{22}$$

Utilizing the matching condition from the tangential magnetic field, $H_x^1 = H_x^2$, which is defined in the interval $x_1 \leq x \leq a$ and replacing the expansion coefficients therein by using Eq. (22), leads to the following integral equation

$$\begin{aligned} 2Y_1^1 \sin\left(\frac{\pi}{a}x\right) &= \sum_i Y_i^2 \frac{2}{a-x_1} \int_{x_1}^a E_{\text{gap}}(x) \sin\left(\frac{i\pi}{a-x_1}x'-x_1\right) \\ &\sin\left(\frac{i\pi}{a-x_1}x-x_1\right) dx' + \sum_n Y_n^1 \frac{2}{a} \int_{x_1}^a E_{\text{gap}}(x) \\ &\sin\left(\frac{n\pi}{a}x'\right) \sin\left(\frac{n\pi}{a}x\right) dx' \end{aligned} \tag{23}$$

The remaining step is to find the expansion coefficients c_i in Eq. (20). This is accomplished by substituting Eq. (20) in Eq. (23) and using the method of moments in the form of Galerkin’s method. The number of terms in Eq. (20), the value of I , is increased until convergence is achieved. Typically only a few terms are needed to accurately describe the discontinuity. Although the analytical content of the CIET is higher than for the MMT, the numerical efficiency is significantly better and no relative convergence problems are encountered.

1.4. The Spectral-Domain Method

The spectral-domain method (SDM) [14] utilizes the Fourier transformation to eliminate all but one space variable in the Helmholtz equation. The latter is then solved analytically for the remaining space variable. The SDM is a computationally very efficient analysis tool for microwave transmission lines. The method has found numerous applications, mainly in the analysis of electromagnetic fields in planar transmission line structures where the overall cross section can be divided into homogeneous dielectric subregions. Although the method was originally introduced for single conductor transmission lines with infinitely thin conductor [15], the SDM has been generalized [16,17] to include finite metallization thickness and multiple dielectric layers.

The method is best illustrated by considering the example of a microstrip line (Fig. 2). In regions with constant μ and ϵ the electromagnetic field, represented by a potential function $\phi^{e,h}$, satisfies the Helmholtz

equation

$$\left(\frac{\partial}{\partial x^2} + \frac{\partial}{\partial y^2} + \frac{\partial}{\partial z^2} + k^2\right)\phi^{e,h}(x,y,z) = 0$$

A two-dimensional Fourier transform on $\phi^{e,h}$ (e.g., on x and z)

$$\tilde{\phi}^{e,h}(\alpha,y,\beta) = \iint e^{-j(\alpha x + \beta z)} \phi^{e,h}(x,y,z) dx dz \tag{24}$$

transforms the Helmholtz equation into one that contains only one space variable

$$\frac{\partial^2 \tilde{\phi}^{e,h}}{\partial y^2} - (\alpha^2 + \beta^2 - k^2)\tilde{\phi}^{e,h} = 0 \tag{25}$$

A solution to this equation is known in the form of exponential functions or hyperbolic functions. In each homogeneous subregion, $\phi^{e,h}$ can thus be transformed from one boundary to the opposite. With respect to Fig. 2, this implies that the known boundary condition of the electromagnetic field at planes $y=0$ and $y=h$ can be transformed into plane $y=d$. The final step in the formulation of the SDM is then to satisfy the boundary condition of the tangential fields at the interface $y=d$, which are in the transformed domain

$$\tilde{E}_{z1} = \tilde{E}_{z2}; \tilde{E}_{x1} = \tilde{E}_{x2}; \tilde{H}_{x2} - \tilde{H}_{x1} = \tilde{J}_z; \tilde{H}_{z2} - \tilde{H}_{z1} = -\tilde{J}_x$$

\tilde{J}_x and \tilde{J}_z are the Fourier transforms of the unknown currents on the strip. From this, a matrix equation can be derived as follows

$$\begin{bmatrix} \tilde{E}_{z1} \\ \tilde{E}_{x1} \end{bmatrix} = \begin{bmatrix} \tilde{Z}_{zz} & \tilde{Z}_{zx} \\ \tilde{Z}_{xz} & \tilde{Z}_{xx} \end{bmatrix} \begin{bmatrix} \tilde{J}_z \\ \tilde{J}_x \end{bmatrix} \tag{26}$$

with $\tilde{J}_z = \sum_m^M c_m \tilde{J}_{zm}(\alpha)$ and $\tilde{J}_x = \sum_m^M d_m \tilde{J}_{xm}(\alpha)$.

Using Galerkin’s technique, \tilde{E}_x and \tilde{E}_z in Eq. (26) can be eliminated and a matrix equation for the expansion

Figure 2. Cross section of a microstrip transmission line.

coefficients c_m and d_m is found

$$\underbrace{\begin{bmatrix} \int_{\gamma} \tilde{\mathbf{J}}_z \tilde{\mathbf{Z}}_{zz} \tilde{\mathbf{J}}_z \int_{\gamma} \tilde{\mathbf{J}}_z \tilde{\mathbf{Z}}_{zx} \tilde{\mathbf{J}}_x \\ \int_{\gamma} \tilde{\mathbf{J}}_x \tilde{\mathbf{Z}}_{xz} \tilde{\mathbf{J}}_z \int_{\gamma} \tilde{\mathbf{J}}_1 \tilde{\mathbf{Z}}_{xx} \tilde{\mathbf{J}}_x \end{bmatrix}}_{[A]} \begin{bmatrix} c \\ d \end{bmatrix} = 0 \quad (27)$$

The propagation constant β is contained in the matrix elements of $\tilde{\mathbf{Z}}$. The transformed currents on the strip are found from an educated guess of the current distribution on the strip in the space domain. To describe the current in the space domain as accurate as possible, basis functions must be employed that are zero outside the strip area and also model the singular behavior of the magnetic field components normal to the strip edge. Equation (27) can then be solved for β by finding the zeros of the determinant of $[A]$ (i.e., $\det[A] = 0$).

A disadvantage of the SDM is that the algorithm is developed for very specific transmission-line geometries. If the geometry changes, for example, substrate regions become inhomogeneous, or conductor contours do not fit into a rectangular coordinate system, the SDM algorithm must be reformulated. This applies also to the previous methods and can be avoided only if more general methods are utilized that are based on finite-element or finite-difference discretization of Maxwell's equations or the Helmholtz equation.

1.5. The Generalized Multipole Method

The generalized multipole technique (GMT) is also based on the weighted residual technique. It is a unique form of the method of moments in that the expansion functions are analytic solutions of the fields generated by sources a distance away from the surface where the boundary condition is being enforced. The GMT is a frequency domain method for calculating electromagnetic fields both in 2D and in 3D. The method is also known as the *multiple-multipole method* (MMT) [19]. In the GMT the field domain is separated into a number of subdomains D_i , each with linear and homogeneous material. In each D_i , a separate expansion of the electromagnetic field is given as

$$\begin{pmatrix} E \\ H \end{pmatrix} = \begin{pmatrix} E_0 \\ H_0 \end{pmatrix} + \sum_{l=1}^{\infty} a_l \begin{pmatrix} E_l \\ H_l \end{pmatrix} \quad (28)$$

In static cases, either the electric or magnetic field is replaced by a potential. E_0, H_0 in Eq. (28) is a given excitation. Any choice of the unknown coefficients a_l results in a correct solution of Maxwell's equation, since E_l and H_l is such a solution. Thus, all degrees of freedom in this solution, that is, the set a_l , may be used to satisfy the boundary conditions. The GMT is often referred to as a *semianalytical* method since the differential equations (i.e., Maxwell's equations) in each subdomain D_i are solved analytically (= exactly), while the boundary conditions on the boundaries ∂D_{ij} between subdomains D_i and D_j are solved numerically (= approximately). In order to accelerate convergence and to keep the number of unknowns as low as possible, the expansion in each subdomain D_i is

chosen such that it fits best to the particular shape of D_i and the particular excitation.

The boundary conditions are fulfilled numerically (approximately), using the extended point-matching technique. This is numerically equivalent to both a projection technique using Galerkin's choice of test functions and a least-squares error minimization. All the boundary conditions concerning fields may be taken into account. As a special case, surface impedance boundary conditions are also possible. Also in the GMT/MMT, a system of linear equations is developed which is solved for the best coefficients of the expansion functions. In order to save computer memory and to improve the numerical stability, matrix solvers like Givens plane rotation may be used.

The difference between the GMT and the MoM is that the latter normally employs expansion functions that are located on the boundary representing quantities such as charge or current. The fields are then determined by integrating these quantities over the entire surface. This integration is not necessary in the GMT since the expansion functions are already field solutions corresponding to multiple poles.

Dielectric and conducting boundaries are treated with the same efficiency in the GMT because the same expansion functions are used. Therefore, GMT models are quite general and do not suffer from the limitations of most MoM models. On the other hand, MoM models that employ functions optimized for a particular problem, are generally more efficient than GMT models.

An overview article about GMT was published by Ludwig [18]. Details of the GMT and application examples are given in the text by Hafner [19] and Leuchtman [20].

1.6. The Method of Lines

The method of lines (MoL) is also a semianalytical method that was developed by Russian mathematicians [21,22] to solve partial-differential equations. In this scheme a set of coupled differential equations is transformed into a set of ordinary differential equations which can be solved analytically. As such the MoL can also be classified as a hybrid method since it combines an analytical approach with the finite-difference method. For the microwave domain, Pregla and coworkers were the first to adopt this method, mainly for the analysis of planar microwave circuits. A very detailed description of the method is given by Pregla and Pascher in Ref. 23. The MoL provides, in comparison to the MMT or the SDM, more flexibility in the analysis of transmission-line geometries with almost arbitrary cross section. The only restriction is that at least one space direction must be amenable to an analytical solution, which is always true for planar transmission lines.

To illustrate the MoL, it is best to choose a two-dimensional problem, although three-dimensional problems can be solved as well. An example of a cross section suitable for an MoL analysis is again the microstrip line as shown in Fig. 2, only this time we consider also the finite metallization thickness. The objective is to find the effective permittivity ϵ_{eff} . Assuming a symmetric structure, the domain is bounded with a magnetic wall at the symmetry plane, and with electric walls elsewhere. The discretization

Figure 3. Discretization scheme of the method of lines for a microstrip transmission line with metallic enclosure of dimensions $a \times b$.

of the cross section by lines is shown in Fig. 3 with three homogeneous subdomains. In each subregion the wave equation is discretized in x direction with stepsize h , and analytical solutions are sought in y direction along the solid and dashed lines shown in the figure. To be more precise, analytical solutions for the electric field components are defined on the solid lines ($x = kh, k = 0, 1, 2, \dots$) in order to fulfill the Dirichlet boundary condition at $x = 0$ by setting $E_{\text{tangential}} = 0$. The magnetic field will be defined on the dashed lines ($x = kh + h/2, k = 0, 1, 2, \dots$), where the Neumann boundary condition at $x = 0$ can be fulfilled to a first order [$H_{\text{tangential}}(+h/2) = H_{\text{tangential}}(-h/2)$]. Similar considerations apply to the magnetic wall boundary at $x = a/2$, as well as to subdomain 2 besides the strip. The discretization in x direction is done by a finite difference scheme, and the second-order derivative at line i can be written as

$$\left. \frac{\partial^2 \phi}{\partial x^2} \right|_i \approx \frac{\phi^{i-1} - 2\phi^i + \phi^{i+1}}{h^2}$$

The coupled differential equations in each subregion are then found in matrix form as

$$\frac{\partial^2 \phi}{\partial y^2} - \frac{1}{h^2} [P] \phi + k_c^2 \phi = 0 \tag{29}$$

whereby the vector ϕ represents either the longitudinal electric (E_z) or magnetic (H_z) field component. The second-order difference operator $[P]$ couples the differential equations of three neighboring lines. Because matrix $[P]$ is symmetric, decoupling of the differential equations above is possible by an orthogonal transformation matrix $[T]$ ($[T]^{-1} = [T]^t$) such that

$$\bar{\phi} = [T]^t \phi$$

The eigenvectors of $[P]$ are the columns of $[T]$. The discretized wave equations in the transformed domain is

decoupled and written as

$$\frac{\partial^2 \bar{\phi}}{\partial y^2} + \left(k_c^2 - \left(\frac{\lambda_k}{h} \right)^2 \right) \bar{\phi} = 0 \tag{30}$$

where λ_k^2 are the eigenvalues of $[P]$. Equation (30) can now be solved analytically along each line by using trigonometric functions. In other words, the EM fields in the transformed domain can be transformed from one boundary of a subregion to the opposite. At the interfaces between subregions (i.e., at $y = d$ and at $y = d + t$, Fig. 3), the tangential fields are matched at the points where the lines cross the interface planes. Depending on the problem at hand, field matching is done either in the transformed domain or in the space domain. The latter requires full matrix inversions, which complicates the algorithm. Regarding the example of the microstrip line, field matching in the space domain becomes necessary due to the finite thickness of the strip (i.e., the number of lines to match is different from one subregion to another). The assumption of an infinitely thin strip would make possible a field matching in the transformed domain and, therefore, lower the computational cost of the algorithm by avoiding several matrix inversions. In any case, an eigenvalue problem must be solved for k_c . The size of the eigenvalue matrix corresponds to the minimum number of lines in one layer: the number of lines in region 2 besides the strip. The effective permittivity of the microstrip line is then found from the wavenumber k_c .

A significant advantage of the MoL over other space discretization methods such as the finite-difference method or the finite-element method is that a two-dimensional problem requires only a one-dimensional space discretization. This feature can lower the computational requirements significantly at the cost of a higher analytical content.

1.7. The Finite-Difference Method

The finite-difference method (FDM) is an approximate method to solve partial-differential equations. In contrast to the method of lines, the computational domain is discretized in all three space directions. The derivative operations, for example, for the space variable x , $\partial \phi / \partial x$ and $\partial^2 \phi / \partial x^2$ are approximated by $\Delta \phi(x) / \Delta x$ and $\Delta^2 \phi(x) / \Delta x^2$, and thus the partial-differential equation is reduced to a set of algebraic equations. In electromagnetics as in other areas of engineering, the FDM is one of the most important methods to solve a wide range of problems. These include linear and nonlinear problems, time- and frequency-domain problems, wave propagation in homogeneous and inhomogeneous media and in media with different boundary conditions. An early example on the application of the FDM to waveguide problems is given in Refs. 25 and 26. Detailed chapters on the FDM can be found in books by Sadiku and Zhou [1,2].

To illustrate the FDM, we choose a problem that can be described by the two-dimensional Laplace equation

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0 \quad (31)$$

Sampling the continuous electromagnetic field in the computational domain by a mesh of regular points separated by a constant distance h (Fig. 4), Eq. (31) is approximated by the difference quotients at the adjacent mesh points. Depending on the choice of the difference and the difference quotient, different methods can be used to derive the discretization formulations. Using a Taylor expansion, the potentials surrounding the center node o (Fig. 4) can be expressed as

$$\begin{aligned} \phi_{x-h} &= \phi_o - h \left(\frac{\partial \phi}{\partial x} \right)_o + \frac{h^2}{2!} \left(\frac{\partial^2 \phi}{\partial x^2} \right)_o \\ &\quad - \frac{h^3}{3!} \left(\frac{\partial^3 \phi}{\partial x^3} \right)_o + \varepsilon(h^4) \\ \phi_{x+h} &= \phi_o + h \left(\frac{\partial \phi}{\partial x} \right)_o + \frac{h^2}{2!} \left(\frac{\partial^2 \phi}{\partial x^2} \right)_o \\ &\quad + \frac{h^3}{3!} \left(\frac{\partial^3 \phi}{\partial x^3} \right)_o + \varepsilon(h^4) \\ \phi_{y-h} &= \phi_o - h \left(\frac{\partial \phi}{\partial y} \right)_o + \frac{h^2}{2!} \left(\frac{\partial^2 \phi}{\partial y^2} \right)_o \\ &\quad - \frac{h^3}{3!} \left(\frac{\partial^3 \phi}{\partial y^3} \right)_o + \varepsilon(h^4) \\ \phi_{y+h} &= \phi_o + h \left(\frac{\partial \phi}{\partial y} \right)_o + \frac{h^2}{2!} \left(\frac{\partial^2 \phi}{\partial y^2} \right)_o \\ &\quad + \frac{h^3}{3!} \left(\frac{\partial^3 \phi}{\partial y^3} \right)_o + \varepsilon(h^4) \end{aligned} \quad (32)$$

Figure 4. Finite-difference discretization of a microstrip transmission line.

where $\varepsilon(h^4)$ is the remaining error. Adding these equations and considering that the resulting term

$$h^2 \left(\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} \right)_o = 0$$

the approximation of ϕ_o at node center o becomes

$$\frac{1}{4} (\phi_{x+h} + \phi_{x-h} + \phi_{y+h} + \phi_{y-h}) = \phi_o$$

whereby it is assumed that $\varepsilon(h^4)$ is negligible. This equation shows that the value of ϕ_o is the average of the potentials at the four neighboring points. The above equation for the 2D problem is also said to be the five-point difference equation of the Laplacian problem. For a 3D problem the above equation expands to a seven-star node

$$\frac{1}{6} (\phi_{x+h} + \phi_{x-h} + \phi_{y+h} + \phi_{y-h} + \phi_{z+h} + \phi_{z-h}) = \phi_o$$

Repeating this procedure over the whole computational domain and considering the boundary conditions on ϕ , leads to the following matrix equation

$$[A]\mathbf{f} = \mathbf{X}$$

Since the individual grid points are connected only to their neighboring points, the coefficient matrix $[A]$ contains a large number of zero elements (banded sparse matrix) and only the diagonal and nearby elements are filled. \mathbf{f} is a vector of all potentials on the interior nodes and \mathbf{X} contains the information about the boundary conditions (or sources). Matrix $[A]$ can be solved by the Gauss elimination method but due to the sparsity of the matrix, iterative methods such as the over-relaxation iteration are more economical in terms of computer resources.

1.8. Finite-Element Method

Although the finite-element method (FEM) was used by mechanical and civil engineers for many years [27], its application to the electromagnetics area was not before 1967 by Winslow [28] and in 1970 by Silvester and co-workers [29]. Since then, the FEM has become a widely used numerical simulation tool for electromagnetic fields in structures with arbitrary boundary shape [30,31]. In contrast to the finite-difference method, the finite element method discretizes the computational domain with a number of small interconnected subregions, called *elements* (Fig. 5). The shape of these elements is typically rectangular or triangular. This explains why there are virtually no restrictions on the shape of the structures that can be analyzed with the FEM. This feature is its main advantage over other methods.

The FEM is based on the fact that the potential function ϕ^e (superscript “e” denotes *element*) within each element, can be approximated by an (often linear) interpolation function which is zero outside the element. Summation of ϕ^e over all elements N gives an approximate

Figure 5. Finite-element discretization of a ridged waveguide.

solution for the total potential in the computational domain

$$\phi = \sum_p^N \phi^e(x,y) \tag{33}$$

The simplest form of approximation for ϕ^e within a triangular element (Fig. 5) is the following:

$$\phi^e = a + bx + cy \tag{34}$$

It is assumed that the field strength is uniform within a small element and that the potential varies linearly depending on the coordinates x and y . The unknown parameters a, b, c are found from the nodal parameters $\phi_p^e, x_p,$ and y_p ($p = 1, 2, 3$) as

$$\begin{bmatrix} a \\ b \\ c \end{bmatrix} = \begin{bmatrix} 1 & x_1 & y_1 \\ 1 & x_2 & y_2 \\ 1 & x_3 & y_3 \end{bmatrix}^{-1} \begin{bmatrix} \phi_1^e \\ \phi_2^e \\ \phi_3^e \end{bmatrix} \tag{35}$$

Substituting the functions obtained from Eq. (35) into Eq. (34) yields

$$\phi^e = \sum_p N_p^e \phi_p^e \tag{36}$$

N_p^e are the so-called shape functions. The potential ϕ^e within each element is thus a linear combination of the shape functions and the three nodal values of the triangle.

The next step in the FEM is to determine the potential at the corners of all elements. This is usually done by minimizing (or maximizing) a functional that is known to be stationary about the true solution (variational method). For a Laplacian problem, the equivalent functional for

each element is

$$I^e(\phi^e) = \int_{s^e} \frac{1}{2} \epsilon |\nabla \phi^e|^2 dx dy \tag{37}$$

The functional over all elements is then the sum over Eq. (37). From a physical point of view, I^e is the energy per unit length of the element e . Substituting the approximation for ϕ^e into Eq. (37) yields

$$I^e = \frac{1}{2} \sum_{p=1}^3 \sum_{k=1}^3 \epsilon \phi_p^e \underbrace{\left[\int_{s^e} \nabla N_p^e \cdot \nabla N_k^e dx dy \right]}_{C_{pk}} \phi_k^e \tag{38}$$

or in matrix form

$$I^e = \frac{1}{2} \epsilon [\phi^e]^T [C^e] [\phi^e] \tag{39}$$

$[C^e]$ is the element coefficient matrix (stiffness matrix in structural analysis). The matrix elements represent the coupling between the nodes. Summation of Eq. (39) over all the elements and applying the extremum condition of the functional

$$\frac{\partial I(\phi)}{\partial \phi_i} = 0$$

yields the system matrix equation

$$[C][\phi] = 0 \tag{40}$$

$[C]$ is a sparse, symmetric, and banded matrix of size $M \times M$ (M =total number of nodes). Equation (40) can be solved for the potentials of all nodes in the computational domain.

The FEM is one of the most flexible numerical modeling approaches which can be applied to nonlinear problems and also can be formulated in time and frequency domain. Although its formulation is more involved than the finite-difference method the advantage of the FEM is that it can be applied to almost arbitrarily shaped boundaries. Application to open boundaries is difficult except if the FEM is combined with other methods which are more suitable for open boundary problems.

1.9. The Boundary-Element Method

The boundary-element method (BEM) or boundary integral element method is similar to the finite-element method applied to the boundary only. As such the BEM is also known as a form of weighted residual technique that falls under the category of moment methods. The main advantage of the BEM over the FEM is that it reduces the dimension of the problem by one. For example, in a three-dimensional problem only the surface of the computational domain needs to be discretized and not the entire volume, which leads to a much smaller number of algebraic equations. For two-dimensional problems the boundary elements are taken as straight line segments,

whereas for three-dimensional problems triangular elements are taken. Disadvantages of the BEM are that the number of integrations required are great and that singularities must be considered. The calculation of the coefficient matrix may require more time than in the FEM.

A very detailed account of the BEM may be found in Ref. 2. In the BEM the quantity of interest ϕ anywhere within the computational domain is expressed in terms of a functional, except that this functional now depends only on the value of ϕ at the boundary and its normal derivative thereon. Again, for the Laplace equation in a source free volume Ω bounded by a surface Γ , for example, the potential ϕ_i inside the volume is given by the integral equation

$$\phi_i = \frac{1}{4\pi} \int_{\Gamma} \left[\frac{1}{r} \frac{\partial \phi}{\partial n} - \phi \frac{\partial}{\partial n} \left(\frac{1}{r} \right) \right] d\Gamma$$

In most of the relevant EM problems, the governing equation is not Laplacian and ϕ on the boundary is unknown. Then the boundary contour is discretized and ϕ for each boundary element is derived using the method of weighted residuals where the expansion and weighting functions are only defined within the boundary cell. The integral equation is thus transformed into a set of algebraic equations at the nodes of the boundary, and the value for ϕ and its derivatives are found simultaneously by solving a matrix equation [2].

2. TIME-DOMAIN METHODS

Time-domain methods are important if the time-domain response of an electromagnetic structure is required. Lately, time-domain methods have also gained momentum over frequency-domain methods since they deliver, depending on the excitation, all frequencies of interest with one computation run without the need for large matrix inversions. This feature is attractive if a wide band frequency response is required. One might also add that a variety of problems are more naturally formulated in the time domain than in the frequency domain. This is in particular the case for nonlinear problems.

Some of the frequency-domain methods discussed before can be formulated also in the time domain. This is a great advantage if one is already familiar with a particular method. Extending the formulation from one domain into the other without leaving the framework of one method not only minimizes the development effort but also expands the application range of that method. Among the many different techniques that can be formulated in both domains, the finite-difference time-domain (FDTD) method and the time-domain transmission-line matrix (TDTLM) method are the most prominent ones. While the finite-difference method in the frequency domain, the FDM or FDFDM, has been discussed in a previous section, the frequency-domain version of the TLM method, the FDTLM method [32], is not discussed here. However, as in the framework of the finite-difference methods the duality between frequency- and time-domain methods exists also in the framework of the TLM method.

In the FDTD and TDTLM methods of electromagnetic modeling the continuous field functions that satisfy Maxwell's equations are approximated by samples of these functions defined only at discrete points in space and time. In the most general sense, FDTD and TLM belong to the method-of-moments (MoM) family. In FDTD the electromagnetic field is approximated by a set of local pulse functions in space and time, while in TLM it is expressed as a superposition of impulse waves traveling forward and backward along the coordinate directions, their sum yielding the electric and their difference the magnetic field values, respectively. Thus, FDTD is formulated in terms of total electric and magnetic field samples in discretized space, whereas the TLM formulation employs elementary incident and reflected waves traveling on a mesh of transmission lines (scattering formulation).

While both methods can be derived rigorously from Maxwell's equations using MoM formalism [33], a more intuitive approach that is also historically authentic will be used to formulate the basic FDTD and TLM algorithms. Their properties and associated errors will be discussed, and some more recent variations will be mentioned.

2.1. Finite-Difference Time-Domain Method

The finite-difference time-domain (FDTD) scheme is obtained by replacing the partial derivatives (space *and* time) in Maxwell's curl equations by finite differences. The best approximation is obtained by central differencing (trapezoidal rule), resulting in an error that is proportional to the square of the space and time step (second-order accuracy).

The first FDTD formulation was proposed by Yee in 1966 [34] and subsequently applied and developed further by Taflov and Brodwin [35]. Yee simply replaced the partial derivatives in Maxwell's curl equations by central finite differences. Weiland [36] derived an equivalent discretization approach using finite integration of Maxwell's equations in 1977. Fig. 6 shows a unit FDTD cell (Yee cell) of a Cartesian space grid. Continuous space and time coordinates (x,y,z,t) are replaced by discrete coordinates $l \Delta x, m \Delta y, n \Delta z, k \Delta t$, where l,m,n,k are integers and

Figure 6. Topology of the elementary FDTD cell (Yee cell). Electric and magnetic field components are interleaved in space and time.

Δx , Δy , Δz , and Δt are the space/timesteps. Note that the three electric field components are defined along the edges of the cell, while the magnetic field components are normal to the cell faces. The staggering of the field components by one-half of the cell dimensions is due to the central-difference approximation of the differential operators. For the same reason, electric and magnetic field components are also staggered in time, the electric field components being defined at time points $k \Delta t$ and the magnetic field components at $(k + \frac{1}{2}) \Delta t$.

If we assume that $\Delta x = p \Delta l$; $\Delta x = q \Delta l$; $\Delta x = r \Delta l$, where Δl is the unit reference length, and the scaling coefficients p , q , and r are all smaller or equal to unity, then the finite difference equations for the electric and magnetic field components in each cell are given by

$$\begin{aligned} {}_{k+1}E_x(l + \frac{1}{2}, m, n) &= {}_kE_x(l + \frac{1}{2}, m, n) \\ &+ sx \{ [{}_{k+1/2}H_z(l + \frac{1}{2}, m + \frac{1}{2}, n) \\ &- {}_{k+1/2}H_z(l + \frac{1}{2}, m - \frac{1}{2}, n)]/q \\ &+ [{}_{k+1/2}H_y(l + \frac{1}{2}, m, n - \frac{1}{2}) \\ &- {}_{k+1/2}H_y(l + \frac{1}{2}, m, n + \frac{1}{2})]/r \} \end{aligned}$$

$$\begin{aligned} {}_{k+1}E_y(l, m + \frac{1}{2}, n) &= {}_kE_y(l, m + \frac{1}{2}, n) \\ &+ sy \{ [{}_{k+1/2}H_x(l, m + \frac{1}{2}, n + \frac{1}{2}) \\ &- {}_{k+1/2}H_x(l, m + \frac{1}{2}, n - \frac{1}{2})]/r \\ &+ [{}_{k+1/2}H_z(l - \frac{1}{2}, m, n + \frac{1}{2}, n) \\ &- {}_{k+1/2}H_z(l + \frac{1}{2}, m + \frac{1}{2}, n)]/p \} \end{aligned}$$

$$\begin{aligned} {}_{k+1}E_z(l, m, n + \frac{1}{2}) &= {}_kE_z(l, m, n + \frac{1}{2}) \\ &+ sz \{ [{}_{k+1/2}H_x(l, m - \frac{1}{2}, n + \frac{1}{2}) \\ &- {}_{k+1/2}H_x(l, m + \frac{1}{2}, n + \frac{1}{2})]/q \\ &+ [{}_{k+1/2}H_y(l + \frac{1}{2}, m, n + \frac{1}{2}) \\ &- {}_{k+1/2}H_y(l - \frac{1}{2}, m, n + \frac{1}{2})]/p \} \end{aligned}$$

$$\begin{aligned} {}_{k+1/2}H_x(l, m + \frac{1}{2}, n + \frac{1}{2}) &= {}_{k-1/2}H_x(l, m + \frac{1}{2}, n + \frac{1}{2}) \\ &+ sx' \{ [{}_kE_y(l, m + \frac{1}{2}, n + 1) \\ &- {}_kE_y(l, m + \frac{1}{2}, n)]/p \\ &+ [{}_kE_z(l, m, n + \frac{1}{2}) \\ &- {}_kE_z(l, m + 1, n + \frac{1}{2})]/q \} \end{aligned}$$

$$\begin{aligned} {}_{k+1/2}H_y(l + \frac{1}{2}, m, n + \frac{1}{2}) &= {}_{k-1/2}H_y(l + \frac{1}{2}, m, n + \frac{1}{2}) \\ &+ sy' \{ [{}_kE_x(l + \frac{1}{2}, m, n) \\ &- {}_kE_x(l + \frac{1}{2}, m, n + 1)]/r \\ &+ [{}_kE_z(l + 1, m, n + \frac{1}{2}) \\ &- {}_kE_z(l, m, n + \frac{1}{2})]/p \} \\ {}_{k+1/2}H_z(l + \frac{1}{2}, m + \frac{1}{2}, n) &= {}_{k-1/2}H_z(l + \frac{1}{2}, m + \frac{1}{2}, n) \\ &+ sz' \{ [{}_kE_x(l + \frac{1}{2}, m + 1, n) \\ &- {}_kE_x(l + \frac{1}{2}, m, n)]/q \\ &+ [{}_kE_y(l, m + \frac{1}{2}, n) \\ &- {}_kE_y(l + 1, m + \frac{1}{2}, n)]/r \} \end{aligned} \quad (41)$$

where

$$\begin{aligned} sx &= Z_0 c \Delta t / (\epsilon_{rx} \Delta l) \\ sy &= Z_0 c \Delta t / (\epsilon_{ry} \Delta l) \\ sz &= Z_0 c \Delta t / (\epsilon_{rz} \Delta l) \\ sx' &= c \Delta t / (\mu_{rx} Z_0 \Delta l) \\ sy' &= c \Delta t / (\mu_{ry} Z_0 \Delta l) \\ sz' &= c \Delta t / (\mu_{rz} Z_0 \Delta l) \end{aligned} \quad (42)$$

In these expressions, c and Z_0 are the velocity of light and the wave impedance in vacuo, and ϵ_{rx} , ϵ_{ry} , ϵ_{rz} and μ_{rx} , μ_{ry} , μ_{rz} are the diagonal elements of the relative permittivity and permeability tensors of the medium, respectively. This algorithm explicitly updates each field component in a leapfrog timestepping process. The change in each E -field component is computed from the four H -field components circulating around it, and vice versa.

2.1.1. Stability. The process is stable as long as the timestep is smaller than a maximum value known as the so-called Courant stability limit. For electrically and magnetically isotropic media characterized by ϵ_r and μ_r the stability criterion is

$$\Delta t \leq \frac{\Delta l \sqrt{\mu_r \epsilon_r}}{c \sqrt{\frac{1}{p^2} + \frac{1}{q^2} + \frac{1}{r^2}}} \quad (43)$$

Since in anisotropic media the wave velocity depends on the (generally unknown) polarization, it is prudent to enter the smallest of the three μ and ϵ values of the diagonal tensors into the stability condition. For free space discretized into cubic cells ($\mu_r = \epsilon_r = p = q = r = 1$), it

becomes

$$\Delta t \leq \frac{\Delta l}{c\sqrt{3}} \quad (44)$$

2.1.2. Initial and Boundary Conditions. At the start of a computation the initial values of all electric and/or magnetic field components in the computational domain are specified before the updating process can begin. By enforcing the field values in certain regions at each timestep, source functions with arbitrary time and space dependence can be modeled.

Boundary conditions must be enforced at each timestep as well. Electric and magnetic walls are modeled by extending the discretized space one cell beyond the boundary and imposing appropriate symmetry conditions on the field values on each side of the boundary. For example, the tangential electric field components must be identical on either side of a magnetic wall (ideal open circuit) and equal and opposite on either side of an electric wall (ideal short circuit). A dual condition applies to the tangential magnetic field components. Lossy resistive boundary conditions call for a fixed ratio between the tangential electric and magnetic field components at the boundary. More complex boundary conditions such as wide band absorbing walls or frequency dispersive boundaries call for special algorithms, such as one-way absorbing boundary conditions [37,38] or Berenger's perfectly matched layer [39]. A detailed discussion of absorbing boundary conditions in FDTD and TLM can be found in Ref. 40. Similar approaches are required for the modeling of complex materials and devices.

The books by Kunz and Luebbers [41] and Taflové [42] are excellent sources of information on all aspects of FDTD modeling and contain extensive bibliographies on the theory, implementation, and application of the FDTD method. Together with Yee's seminal paper [34] they are good starting points for exploring the extensive literature on FDTD theory and applications.

2.2. Transmission-Line Matrix Method

2.2.1. The Expanded Node. The transmission-line matrix (TLM) formulation of Maxwell's equations was first proposed in 1971 by Johns and Beurle [43]. In their seminal paper they describe a novel numerical technique for solving two-dimensional scattering problems. Inspired by earlier network simulation techniques [44], they employ a Cartesian mesh of shunt-connected two-wire transmission lines as a discretized 2D propagation medium. The nodes of this mesh act as scattering centers for short voltage impulses. Johns and Akhtarzad [45] extended the method to three space dimensions (the expanded node TLM model) in 1974, by creating an intricate 3D lattice of shunt- and series-connected transmission lines, as shown in Fig. 7. This model is, in many respects, similar to the Yee cell in Fig. 6 since it yields identical solutions for the six field components when the time step in the Yee algorithm is set to $\Delta t = \Delta l/(2c)$ (free space, cubic cell). However, in contrast to the strictly mathematical formulation of FDTD, the TLM model is a "hardwired" network

Figure 7. Topology of the expanded TLM node. Electric field components are modeled by the voltage across shunt connections, while magnetic field components are modeled by the loop current in series connections of transmission lines. The positions of the field components in space and time are identical to those in the Yee cell.

(albeit conceptual rather than material) to which all known techniques of circuit and transmission line analysis can be applied in both frequency and time domains.

2.2.2. The Symmetric Condensed Node. One of the shortcomings of these algorithms resides in the complicated topology of their unit cells and in the separate locations of electric and magnetic field components in space and time. This makes the modeling of complex boundary conditions and interfaces between materials more difficult and may introduce errors. To overcome these drawbacks, Johns [46,47] introduced the symmetrical condensed TLM node in 1986. This spawned the development of several new TLM formulations, from the hybrid and supercondensed nodes to the alternating and rotated alternating [48] TLM models. In the following, the basic formulation proposed by Johns will be outlined. However, the port numbering scheme proposed by Russer [48] will be used since it allows a simpler and more compact representation of the TLM algorithm than Johns' original numbering scheme.

2.2.3. The Symmetric Condensed Node TLM Algorithm. A unit cell of the symmetric condensed TLM model is shown in Fig. 8. It contains a hybrid junction of 12 transmission lines (the node) that is characterized by a 12×12 scattering matrix. The time-domain TLM algorithm is executed in two steps. First, 12 short voltage pulses are simultaneously injected into the node ports 1–12. The pulses are scattered and give rise to 12 reflected voltage pulses. Second, the reflected pulses are transferred to the neighboring nodes where they become incident pulses at the subsequent timestep, and the process is repeated. This series of events can be described in symbolic form as follows

$$[{}_k v^r] = S \cdot [{}_k v^i], \quad [{}_{k+1} v^i] = C \cdot [{}_k v^r] \quad (45)$$

Figure 8. Topology of the symmetric condensed TLM node. All six electric and magnetic field components are defined in the center of the node, and tangential field components are defined in the cell boundaries as well.

where $[{}_k v^r]$ and $[{}_k v^i]$ are the vectors of reflected and incident pulses at the k th timestep, \mathbf{S} is the impulse scattering matrix of the node, and \mathbf{C} is a connection matrix describing the topology of the network. It governs the transfer of the reflected pulses to the connected ports of the neighboring cells and/or the reflection from boundaries. The subscripts k and $k + 1$ denote the discrete time points at which the pulses are scattered at the nodes.

For a homogeneous, lossless, and isotropic medium, all transmission lines of a cubic cell have the same characteristic impedance. The 12×12 scattering matrix \mathbf{S} is then

$$\mathbf{S} = \begin{bmatrix} 0 & \mathbf{S}_0 & \mathbf{S}_0^T \\ \mathbf{S}_0^T & 0 & \mathbf{S}_0 \\ \mathbf{S}_0 & \mathbf{S}_0^T & 0 \end{bmatrix} \quad (46)$$

where the submatrix \mathbf{S}_0 is given by

$$\mathbf{S}_0 = \begin{bmatrix} 0 & 0 & \frac{1}{2} & -\frac{1}{2} \\ 0 & 0 & -\frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} & 0 & 0 \\ \frac{1}{2} & \frac{1}{2} & 0 & 0 \end{bmatrix} \quad (47)$$

Since the transit time Δt of the pulses is linked to the space step Δl by the pulse propagation velocity along the transmission lines, the TLM process is unconditionally stable. The time step is automatically set to $\Delta t = \Delta l / (2c)$.

2.2.4. Inhomogeneous Materials and Losses. Dielectric or magnetic materials can be modeled by loading the nodes

situated inside these materials with reactive shunt stubs of appropriate normalized characteristic admittance and a length $\Delta l / 2$ [46]. An open-circuited shunt stub will produce the effect of additional capacitance at the node, while a short-circuited series stub creates additional inductance. The resulting storage of reactive energy reduces the phase velocity and alters the intrinsic impedance in the structure. The interface conditions at the boundary between different materials are automatically fulfilled. Each cell can have a different set of stubs (three permittivity and three permeability stubs), thus allowing the modeling of inhomogeneous anisotropic materials with diagonal permittivity and permeability tensors. The six stubs add six more ports to the node, and as a result, the \mathbf{S} becomes an 18×18 matrix. Losses can be modeled by connecting so-called loss stubs to the nodes. The loss stubs are matched transmission line sections that extract a fraction of the energy scattered at the node at each time step. Since no pulses travel back into the nodes on these stubs, they only modify the elements of \mathbf{S} without increasing its size.

2.2.5. Initial and Boundary Conditions. At the start of a computation the initial values of all pulses incident on all field components are uniquely determined in the center of the nodes by a linear combination of these pulses at the moment of scattering (47). When the pulses transit from one cell to the next ($t / \Delta t = k + 1/2$) the tangential components of the fields are obtained in the cell boundaries as well. By enforcing the pulse values (and hence the corresponding electric and magnetic field values) in certain regions at each timestep, source functions with arbitrary time and space dependence can be modeled.

Boundary conditions can be imposed either in the center of the nodes or in the cell boundaries. In the latter case, boundaries are represented by means of impulse reflection coefficients. Electric walls reflect pulses with “ $a - 1$ ” reflection coefficient, while magnetic walls have “ $a + 1$ ” reflection coefficient. Lossy resistive boundaries have impulse reflection coefficients less than unity in magnitude. More complex boundary conditions such as wide-band absorbing walls or frequency dispersive boundaries are treated in the same way as FDTD boundaries with the difference that the boundary operators are applied to the incident pulses rather than to the field quantities at the boundaries. It is straightforward to implement nonrecursive and recursive convolution techniques for the modeling of frequency dispersive boundaries and for partitioning large computational domains using time-domain diakoptics [49]. Similar approaches are required for the modeling of complex materials and devices [50].

Johns’ seminal papers [43,45–47] are good starting points for exploring the world of TLM modeling, as are an introductory chapter on TLM by Hoefer [51] and a book by Christopoulos [52]. They contain many references and describe the implementation and applications of TLM in detail.

3. HYBRID METHODS

None of the previous methods is capable of solving all electromagnetic modeling problems. The methods are

either limited by the available computer memory and/or by computer runtime, or the numerical model can simply not be applied to the structure at hand. For example, the method of moments is not applicable to structures with inhomogeneous or nonlinear dielectrics. The finite difference method is difficult to implement when fine circuit details must be resolved within a structure of large dimensions. The discretization size chosen for the smallest circuit detail determines the total number of discretization cells and thus the total matrix size to be handled may become too large. This problem is even more pronounced for the time-domain version of the finite-difference method, the FDTD, since here also the time is discretized. Similarly, the finite-element method cannot efficiently model large radiation problems because of the large computational space that must be discretized.

In practice, many of these—and more—complicating factors are encountered. Not all appear in the same problem and at the same time, thus making it possible to choose one electromagnetic modeling approach over the other. But there is a significant number of problems (and others are emerging) that cannot be solved within the framework of any of the previous methods.

A solution to those problems is possible by combining two or more techniques. The task is to apply each method to the problem domain for which it is best suited. There are two possible approaches. A two or more step procedure is utilized in which one part of the problem is solved by one method and the results are used as input data to solve remaining parts of the problem with other techniques. That requires that boundary conditions are established that must be enforced at the interfaces between the different regions. This approach is called an explicit hybrid approach. An implicit hybrid approach is one in which the advantageous features of one technique are combined with those of another technique to form a new standalone algorithm.

Several successful implementations of hybrid methods have been reported in the literature. Although this research direction does not replace the effort to improve existing single methods, hybrid methods offer electromagnetic modeling of a whole new class of problems and may in particular be important in the area of CAD.

3.1. Combinations of Frequency-Domain Methods

3.1.1. GTD and MoM. The first combinations of electromagnetic modeling approaches appeared in the analysis of antenna problems and radar cross sections. The geometric theory of diffraction (GTD) and the method of moments were used to analyze antenna problems in Ref. 53. The GTD is an extension to geometric optics, which includes the effect of diffraction. This method is only accurate if the dimensions of the object being analyzed is large compared to the wavelength of the field. For that reason this method is also called a *high-frequency method*. In the combination of the GTD and the MoM, the latter is used to solve the region close to the antenna, while the GTD is used for the free space surrounding the antenna.

3.1.2. FEM and GSM Technique. A combination of the finite-element method (FEM) and the generalized scattering matrix (GSM) technique was utilized in the study of scattering from jet engines [54]. The FEM was applied to the complex part of the scatterer to generate the GSM at its boundary which can then be interfaced with high-frequency techniques for computation of the engine's scattered fields without reference to the geometry of the jet engine. One of the methods alone would not have been able to solve this complex problem.

3.1.3. FEM/FDM and MMT. For the analysis of micro-wave circuits the combination of the FEM and the mode-matching technique (MMT) has been proposed to study large cavities [55]. In Ref. 56 the FEM was applied to analyze waveguide discontinuities with arbitrary boundary shape. In Ref. 57 the FDM was employed instead of the FEM to analyze segments of waveguide structures that are not suitable for a MMT analysis, for example a circular stub in a rectangular waveguide. In all these papers the MMT was used to characterize the uniform sections of the waveguide while the FEM or FDM was employed to analyze rounded corners or discontinuity shapes that do not fit into the coordinate system of the MMT. The latter was then used to derive the scattering parameters of the overall circuit.

3.1.4. Method of Lines and SDM. For the 3D analysis of planar waveguide problems a combination of the method of lines and the spectral-domain method was introduced in Ref. 58. The purpose of this combination was to eliminate some of the problems associated with the 2D MoL and the 2D SDM. The problem in the latter was the difficulty to find 2D basis functions that converge easily, while for the 2D MoL a 2D discretization may not always be able to satisfy all boundary conditions simultaneously with effortable computer memory. The combination of the computationally very efficient 1D SDM in transverse direction of the propagating wave with the equally efficient 1D MoL in propagation direction eliminates these problems.

3.2. Combinations of Time- and Frequency-Domain Methods

3.2.1. Hybrid Finite-Difference–Time-Domain Method. The hybrid finite-difference–time-domain (HFDTD) method is a combination of frequency-domain and time-domain concepts. In its widest sense, the technique utilizes a standard FDTD mesh in the areas of structure inhomogeneity and expansion into a known set of modes in transversely homogeneous regions of the structure. This provides substantial savings both in terms of computer memory and CPU time as was first demonstrated in the eigenvalue analysis of planar transmission lines [60]. A conventional FDTD analysis of such a structure requires a 3D mesh, which, depending on the space resolution required, needs several thousand time iterations before a Fourier transform can provide the results for the propagation constant. By replacing the space discretization in propagation direction (z) by a simple phase shift (note that the field at location l_z is different from that at location $l_z + z$ by only a factor $e^{-j\beta z}$), results in a 2D FDTD mesh

[59]. Multiplying the field equations furthermore by a factor j such that

$$\begin{aligned} E_x, E_y, H_z &= j(E_x, E_y, H_z)e^{-j\beta z} \\ H_x, H_y, E_z &= (H_x, H_y, E_z)e^{-j\beta z} \end{aligned}$$

leads to discretized Maxwell's equations without complex quantities. This feature accelerates the computation considerably. Exciting the 2D mesh with a time domain impulse requires much less time iterations for the impulse to settle than in the case of a 3D mesh. A Fourier transform provides the frequency at which the assumed value of β is valid.

The same principle can be applied to the time domain TLM method, and also here significant savings in computer resources are possible if only the propagation constant and related quantities (characteristic impedance, losses) are of interest.

3.2.2. TD TLM and MMT. In the TD TLM analysis of complex cascaded discontinuity problems, diakoptics is used to subdivide the problem into simpler subsections that are then modeled individually. Interconnecting the individual solutions requires a node to node convolution at the interface. This approach tends to be computationally quite demanding since the number of convolutions increases with N^2 (N is the number of branches of interest). To reduce the computational effort, it was suggested in Ref. 61 that the uniform sections of the problem domain are modeled by modal functions treated in the time domain (time-domain Green function), while the discontinuity region is represented by the TD TLM method for which the incident fields are superpositions of those modes. The response of that subvolume to an excitation is obtained by convolution of the excitation with the time-domain Green function. This approach leads to a significant reduction of the computational resources as compared to the analysis with only the TD TLM. Furthermore, the complex discontinuity region is now represented by its generalized scattering matrix (GSM), which makes it easy to cascade discontinuities.

3.3. Combinations of Time-Domain Methods

3.3.1. FDTD and FEM. The FDTD method is well suited for applications in Cartesian coordinates. However, as soon as mixed coordinates are necessary to describe the problem contour, a staircase approximation must be utilized. For example, a round structure within a rectangular mesh layout can be described accurately only by a fine staircase approximation. This leads to a very fine mesh and consequently a small timestep to satisfy the stability condition. The computational effort to calculate such a structure with acceptable accuracy becomes prohibitive. An alternative solution is to model the arbitrary boundary with the finite-element method and incorporate this approach in the FDTD method which is applied elsewhere in the problem domain [62].

The list of methods that have been combined can be continued and new combinations appear every month in

the various periodicals. A good starting point to find out more about hybrid methods and the rationale behind their combinations is in Ref. 63.

4. SUMMARY

The tremendous increase of computer power since the late 1980s has inspired a new era in the field of electromagnetic modeling or computational electromagnetics. Numerical codes that ran only on supercomputers yesterday are running on workstation computers today. This development will not stop here, and the electromagnetic modeling problem that appears to be inaccessible by any of today's available codes (because the required computer resources are just too large) will be solvable with tomorrow's computers and the then available (unlimited?) computer memory.

Because of this rapid development in computer hardware, electromagnetic modeling has become commonplace in the world of electrical engineers. Many of the methods that we have briefly described are already implemented in commercial simulation tools used in practice to analyze a wide variety of problems and to design (CAD) a wide range of circuits and components that would not function otherwise.

We have divided the methods into frequency-domain, time-domain, and hybrid methods. They all have advantages and disadvantages depending on the problem range they are applied to. The aim of this article was not to provide extensive information on all of these methods but to introduce the reader to those numerical methods that have a broad enough application as well as to provide key references for further reading.

5. LITERATURE

The literature on electromagnetic field modeling is quite extensive, and only a few key references could be cited here. For more information on the subject the reader is referred to the books by R. Sorrentino [65] and E. Miller et al. [66], who have assembled a collection of reprints of key papers on the subject, and the book by E. Yamashita [64]. Furthermore, various journals and conferences are devoted to the topic of numerical modeling of electromagnetic fields.

ELECTROMAGNETIC SHIELDING

SALVATORE CELOZZI
 RODOLFO ARANEO
 University of Rome "La
 Sapienza"
 Rome, Italy

1. GENERAL ASPECTS

Electromagnetic shielding is an important constraint in the design of RF and microwave devices consisting in the mitigation of the emission levels of electromagnetic (EM) sources and/or in the protection of people or electrical and electronic apparatus and systems against possible effects due to external EM fields. Very often the need for electromagnetic shielding depends not only on functioning motivations but also on the compliance with standards fixing the limits of emission or immunity for various classes of apparatus and systems. Such a limitation or protection is generally obtained by means of a structure that is often, but not necessarily, metallic called a *shield*. Shield performance depends on its geometric and electrical parameters and on the characteristics of the unperturbed EM field (i.e., the EM field that would exist without any shielding structure, often referred to as *incident*). Various constructive peculiarities affect the performance of the overall shielding system. The most important factors in determining the performance of a shielding structure are the geometric configuration and the thickness of the shield and its materials, generally characterized by the values of conductivity σ , permeability μ , and permittivity ϵ . Also very important are the so-called discontinuities of the shield such as junctions, seams, gaps, and apertures, which are always present in practical configurations and considerably affect the performance in the radio frequency range.

The performance of a shield configuration is often expressed synthetically in terms of *shielding effectiveness* (SE), which is defined by the IEEE as the ratio of electric or magnetic field strength (modulus of the vector) at a point before (E^i or H^i) and after (E or H) the placement of the shield between a given external source and the observation point considered. In terms of Cartesian coordinates x_0, y_0, z_0 , the following expressions apply:

$$SE_E = \frac{E^i(x_0, y_0, z_0)}{E(x_0, y_0, z_0)} \quad (1a)$$

$$SE_H = \frac{H^i(x_0, y_0, z_0)}{H(x_0, y_0, z_0)} \quad (1b)$$

These two figures of merit are usually expressed in decibels, as

$$SE_{E(\text{dB})} = 20 \log_{10} \frac{E^i(x_0, y_0, z_0)}{E(x_0, y_0, z_0)} \quad (2a)$$

$$SE_{H(\text{dB})} = 20 \log_{10} \frac{H^i(x_0, y_0, z_0)}{H(x_0, y_0, z_0)} \quad (2b)$$

In case of sinusoidal sources the electric and the magnetic fields, expressed as root mean-square (RMS) values in the expressions above, do not account for polarization and are local quantities.

Also very important is the evaluation of SE performance in terms of EM power (incident) P^i and transmitted power P :

$$SE_{(dB)} = 10 \log_{10} \frac{P^i(x_0, y_0, z_0)}{P(x_0, y_0, z_0)} \quad (3)$$

Figure 1 shows the configuration leading to the evaluation of SE.

2. SHIELDING THEORY AND PREDICTION OF PERFORMANCE

Shielding theory, including analytical formulations, has been well developed in order to obtain guidance in practical problems and to firmly grasp the key factors on which the theory of electromagnetic shielding is based. The initial studies are due to Maxwell, although King presented perhaps the first work specifically oriented to the radio-frequency range [1]. For difficulty in handling real configurations by means of exact analytical expressions, approximate formulations have been developed and im-

Figure 1. System configurations for the evaluation of the shielding effectiveness (SE).

proved over the years, while the analysis of the SE of closed structures, often referred to as *enclosures*, is generally performed, in either the frequency or the time domain, by using numerical techniques, and can require significant computational effort, depending on the geometric configuration, the characteristics of the shield material, and the source type; the latter aspect is the starting point of every shielding study.

Among the analytical methods used to solve shielding problems, the most relevant and successful are the direct solution of the Maxwell equations governing the system and the so-called transmission-line approach, proposed by Schelkunoff [2].

2.1. Direct Solution of Maxwell Equations

The direct solution of the equations governing the shielding problem is available only in a few simple configurations. However, some relevant cases with reasonable assumptions may be studied in this way. Moreover, such exact solutions may serve as reference for the validation of other methods and thus represent a fundamental tool in shielding analyses. The system configurations for which an analytical solution of the Maxwell equations has been found include those characterized by planar shields of infinite extent in the presence of straight or circular filamental wire current sources [3–6]. The ideal configuration of a planar shield of infinite extension and illuminated by a plane wave provides an exact solution, which is described in detail below.

2.2. Transmission-Line Approach

This method was initially introduced with reference to a plane wave impinging with a normal angle of incidence on an infinite planar shield and successively extended to accommodate other source and shield configurations. The method is based on the analogy existing between the equations governing voltage and current in a transmission line and those describing the electric and the magnetic field propagation inside a planar shield subjected to a plane wave, as shown in Fig. 2. Assuming a sinusoidal field source, the problem may be solved in the frequency domain, provided the shield material is linear. For a normal angle of incidence of a plane wave having only the y component of the electric field and the z component of the magnetic field, Maxwell curl equations governing the field propagation through the shield become

$$\frac{dE_y}{dx} = -j\omega\mu H_z \quad (4a)$$

$$\frac{dH_z}{dx} = -(\sigma + j\omega\epsilon)E_y \quad (4b)$$

It is readily recognized that this equation system describes the electric and magnetic field propagation as well as the voltage and current propagation in a transmission line, when expressing voltage and current instead of E_y and H_z , respectively, and substituting $j\omega\mu$ and $(\sigma + j\omega\epsilon)$ with the per unit length impedance and admittance of the line, respectively. The electric and magnetic

Figure 2. Shielding of a plane-wave electromagnetic field by means of a planar shield and analogy with the transmission-line configuration.

fields inside the shield material, $E_y(x)$ and $H_z(x)$, at the generic distance x from the first interface between air and shield, are expressed as functions of the corresponding quantities at $x = 0$

$$E_y(x) = E_y(0) \cosh(\gamma x) + \eta H_z(0) \sinh(\gamma x) \quad (5a)$$

$$H_z(x) = \frac{1}{\eta} E_y(0) \sinh(\gamma x) + H_z(0) \cosh(\gamma x) \quad (5b)$$

where η is the intrinsic impedance of the shield given by

$$\eta = \left(\frac{j\omega\mu}{\sigma + j\omega\epsilon} \right)^{1/2} \quad (6)$$

and γ is the propagation constant of the electromagnetic field inside the shield:

$$\gamma = [j\omega\mu(\sigma + j\omega\epsilon)]^{1/2} \quad (7)$$

The system is solved by applying the boundary conditions at the interfaces. Usually, such boundary conditions are applied considering the continuity of the tangential components of the electric and magnetic fields incident on the shield surfaces, which are also the only components propagating through the shield by virtue of the Poynting theorem. In the configuration considered, they are

expressed as

$$E_y^i + E_y^r = E_y^t \quad \text{at } x = 0 \quad (8a)$$

$$H_z^i - H_z^r = H_z^t \quad \text{at } x = 0 \quad (8b)$$

$$E_y^t = E_y^o \quad \text{at } x = d \quad (8c)$$

$$H_z^t = H_z^o \quad \text{at } x = d \quad (8d)$$

where superscripts i, r, t, and o respectively denote the incident, reflected, transmitted, and outgoing fields and $x = d$ is the abscissa of the second interface. The incident field is due to the source alone, the reflected field is due to the contribution of the induced currents on the shield surface, the transmitted field is the field propagating through the shield medium, and the outgoing field is the field that passes behind the shield.

2.2.1. Uniform Plane-Wave Field Source. A uniform plane wave is, by definition, a wave in which the electric and magnetic fields are perpendicular to each other, their direction of propagation does not vary in time, and their amplitude is constant in space and in time. This is, of course, an idealization because the EM field produced by real sources must decay in space, but if the observation point is very far from the real source, that is, if its distance is much greater than the wavelength of the electromagnetic field, the uniform plane-wave assumption is quite realistic. In a plane wave both incident and reflected electric and magnetic fields remain in a fixed ratio, which is

defined as the wave impedance Z_w of the EM field, and its value in vacuum is

$$Z_w = \frac{E_y^i}{H_z^i} = \frac{E_y^r}{H_z^r} = \frac{E_y^o}{H_z^o} = \sqrt{\frac{\mu_0}{\epsilon_0}} = 120 \pi \Omega \cong 377 \Omega \quad (9)$$

Equations (8b) and (8d), expressing the continuity of the tangential components of the magnetic field, are multiplied by Z_w , and the results are added to Eqs. (8a) and (8c), respectively, in order to find the relationships between the incident and the transmitted fields at the two shield interfaces:

$$2E_y^i = E_y^t + Z_w H_z^t \quad \text{at } x=0 \quad (10a)$$

$$0 = E_y^t - Z_w H_z^t \quad \text{at } x=d \quad (10b)$$

In this way the reflected fields, which are generally unknown and not always easy to evaluate, do not appear in the boundary conditions. It is evident that Eqs. (10) are formally identical to those valid for a real voltage source and a simple load impedance, allowing the use of the analogy with a transmission line also with respect to the boundary conditions, as shown in Fig. 2. In case of a uniform plane wave presenting an oblique angle of incidence on a shield surface, the problem may be solved considering that an arbitrarily oriented wave may be split up into various waves, each formed by the orthogonal electric and magnetic field components propagating along different directions [7]. The use of the superposition principle, provided the shield material is linear, allows one to easily accomplish all the possible physical situations. It is worthy noting that, with reference to the coordinate system shown in Fig. 2, the two waves constituted by (E_y, H_z) and $(E_z, -H_y)$ propagate toward the shield and must be accounted for in shielding analyses, as they are the other waves responsible for sliding in directions parallel to the shield. Thus, two wave impedances are considered to extend the previous formulation to the oblique incidence case:

$$Z_{w1} = \frac{E_y}{H_z} \quad (11a)$$

$$Z_{w2} = -\frac{E_z}{H_y} \quad (11b)$$

These two wave impedances are used to impose the boundary conditions in Eqs. (10) and allow the evaluation of the total electric and magnetic field components transmitted beyond the shield.

2.2.2. Near-Field Sources. In order to analyze the performance of shields against near-field sources, it is useful to introduce the elementary EM field sources known as the *electric* and the *magnetic dipoles*. Although these sources are ideal (i.e., do not exist in the real world), the EM field that they produce is easy to determine and very similar to that of some common real sources. The EM field produced by these sources depends strongly on the distance r from the observation point. In fact, the amplitude

of the electric field due to an electric dipole is expressed, in spherical coordinates as the sum of three terms depending on $1/r$, $1/r^2$, and $1/r^3$, respectively, whereas the magnetic field is a function of $1/r$ and $1/r^2$ only:

$$E_r^i(r, \omega) = \sqrt{\frac{\mu_0}{\epsilon_0}} \frac{I(\omega)L}{4\pi} 2 \cos(\theta) \left[\frac{1}{r^2} + \frac{1}{j\beta r^3} \right] e^{-j\beta r} \quad (12a)$$

$$E_\theta^i(r, \omega) = \sqrt{\frac{\mu_0}{\epsilon_0}} \frac{I(\omega)L}{4\pi} \sin(\theta) \left[\frac{j\beta}{r} + \frac{1}{r^2} + \frac{1}{j\beta r^3} \right] e^{-j\beta r} \quad (12b)$$

$$E_\phi^i(r, \omega) = 0 \quad (12c)$$

$$H_r^i(r, \omega) = 0 \quad (12d)$$

$$H_\theta^i(r, \omega) = 0 \quad (12e)$$

$$H_\phi^i(r, \omega) = \frac{I(\omega)L}{4\pi} \sin(\theta) \left[\frac{j\beta}{r} + \frac{1}{r^2} \right] e^{-j\beta r} \quad (12f)$$

where $I(\omega)$ is the current flowing in the elementary source of length L . Therefore, at points far from an electric dipole (far-field region), at a distance r from the EM source much greater than the wavelength λ , the term proportional to $1/r$ prevails in the expressions for both the electric and magnetic fields, so that their ratio, representing the wave impedance Z_w at a distance r , assumes the same value it assumes in case of a uniform plane wave: 377Ω . On the contrary, in the near-field region, where $(r/\lambda) \ll 1$, the terms proportional to $1/r^3$ and $1/r^2$ are the dominant ones in the electric and magnetic field expressions, respectively. Consequently, the wave impedance Z_w is a function of both the position and the frequency; its value is generally greater than 377Ω and, because of this characteristic, the electric dipole is termed a *high-impedance source*. Magnetic dipoles present characteristics that are dual with respect to electric ones. The amplitude of the radiated magnetic field is expressed as the sum of three terms depending on $1/r$, $1/r^2$, and $1/r^3$, respectively, whereas the electric field is a function of $1/r$ and $1/r^2$ only

$$E_r^i(r, \omega) = 0 \quad (13a)$$

$$E_\theta^i(r, \omega) = 0 \quad (13b)$$

$$E_\phi^i(r, \omega) = -\frac{j\omega\mu_0 I(\omega)A}{4\pi} \sin(\theta) \left[\frac{j\beta}{r} + \frac{1}{r^2} \right] e^{-j\beta r} \quad (13c)$$

$$H_r^i(r, \omega) = \frac{j\beta I(\omega)A}{4\pi} 2 \cos(\theta) \left[\frac{1}{r^2} + \frac{1}{j\beta r^3} \right] e^{-j\beta r} \quad (13d)$$

$$H_\theta^i(r, \omega) = \frac{j\beta I(\omega)A}{4\pi} \sin(\theta) \left[\frac{j\beta}{r} + \frac{1}{r^2} + \frac{1}{j\beta r^3} \right] e^{-j\beta r} \quad (13e)$$

$$H_\phi^i(r, \omega) = 0 \quad (13f)$$

where $I(\omega)$ is the current flowing in the loop with surface A . In the far-field region, the EM field is characterized by the free-space wave impedance. Conversely, in the near-field region, the terms proportional to $1/r^3$ and $1/r^2$ are

the dominant ones in the magnetic and electric fields, respectively, and the wave impedance Z_w is lower than 377 Ω . For this reason, the magnetic dipole represents a low impedance source.

In Fig. 3, the trends of the wave impedances of an electric dipole and a magnetic dipole are reported, as functions of the distance, normalized by λ , of the observation point from the source.

These considerations are of great importance in extending the transmission-line approach to solve near field source problems. It should be noted that generally the electric and the magnetic fields are not perpendicular to each other and the various components directed toward the shield, according to the Poynting theorem, may be accounted for separately, as described for the oblique incidence of uniform plane waves. According to the studies carried out for the oblique incidence of a plane wave on a planar shield, the wave impedances associated with the various directions may be defined and utilized to determine the field incident onto a prefixed shield surface. In fact, the boundary conditions may be imposed following the procedure described for the plane-wave source, provided the electric and the magnetic field are considered space- and frequency-dependent.

2.2.3. Shielding Effectiveness Evaluation. In case of uniform plane waves, the electromagnetic field amplitudes remain constant in space and the shielding effectiveness may be evaluated as the ratio between the incident field and the outgoing field. Moreover, SE_E and SE_H are numerically coincident. SE may be expressed in the following very compact form

$$SE = A + R + B \tag{14}$$

where the absorption loss A , reflection loss R , and multiple reflections coefficient B for a planar shield of thickness d

Figure 3. Trend of the wave impedances associated with electric and magnetic dipoles, as a function of the normalized distance from the of the sinusoidal elemental source.

are respectively given (in decibels) by

$$A_{dB} = 20 \log_{10} |e^{\gamma d}| \tag{15a}$$

$$R_{dB} = 20 \log_{10} |(Z_w + \eta)^2 (4Z_w \eta)^{-1}| \tag{15b}$$

$$B_{dB} = 20 \log_{10} \left| 1 - \frac{(Z_w - \eta)^2}{(Z_w + \eta)^2} e^{-2\gamma d} \right| \tag{15c}$$

The absorption loss coefficient A_{dB} is a function of the shield characteristics only; the reflection loss coefficient R_{dB} depends on the mismatch between the wave impedance and the intrinsic impedance of the shield. The multiple-reflection coefficient B_{dB} depends on both the physical characteristics of the shield material and the incident field. Coefficient A_{dB} can be expressed in the following simple form:

$$A_{dB} = 131.44 \sqrt{f \mu_r \sigma_r} d \tag{16}$$

where μ_r and σ_r denote respectively the relative magnetic permeability and the relative conductivity (with respect to the conductivity of copper $\sigma_{Cu} = 5.8 \cdot 10^7$ S/m) of the material.

Different approximate expressions hold for coefficient R for plane-wave sources, high-impedance sources, and low-impedance sources, respectively:

$$R_{dB} = 168.1 - 20 \log_{10} \sqrt{\frac{f \mu_r}{\sigma_r}} \tag{17a}$$

$$R_{dB} = 321.7 - 10 \log_{10} \left(\frac{\sigma_r}{f^3 \mu_r r^2} \right) \tag{17b}$$

$$R_{dB} = 20 \log_{10} \left(5.35 \sqrt{\frac{\sigma_r f}{\mu_r}} r + 0.0117 \sqrt{\frac{\mu_r}{\sigma_r f}} \frac{1}{r} + 0.5 \right) \tag{17c}$$

Figure 4 shows the absorption loss coefficient A_{dB} as function of the frequency for different thicknesses of a copper shield. Figure 5 shows the frequency dependence of coefficient R_{dB} of copper against typical low- or high-impedance fields, respectively, both located at a distance of 30.48 cm from the shield surface.

It should be noted that in (and sometimes below) the microwave band of the frequency spectrum, the SE is completely dominated by the discontinuities, since the conductive materials behave like perfect electric conductors, present at a skin depth that is much lower than the shield thickness.

The coefficient B_{dB} in the radiofrequency range is often negligible. In case of low-impedance sources, the reflection loss coefficient exhibits values increasing with the frequency, for copper and aluminum, while for ferromagnetic materials it initially decreases and then increases. For high-impedance sources, the reflection loss coefficient always decreases for all the materials. The values of R_{dB} are much lower in the low-impedance source case, confirming the difficulty in shielding magnetic fields in the low-frequency range. It should also be noted that the previous expressions are rigorously valid for a plane-

Figure 4. Frequency dependence of the absorption loss coefficient A_{dB} for different shield thicknesses. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

wave source impinging normally onto a shield that is conductive, infinite, and planar. When extending the transmission-line-approach to waves with an oblique angle of incidence, another hypothesis is necessary—the electromagnetic field propagation inside the shield must occur normally to the shield surface; this assumption is generally satisfied in consideration of the high values of conductivity, as stated by Snell’s law of refraction [8]

$$\gamma_0 \sin(\theta_i) = \gamma_s \sin(\theta_s) \tag{18}$$

where γ_0 and γ_s are respectively the propagation constant in air and in the shield medium and θ_i and θ_s are the directions of propagation of the electromagnetic field in the two media, respectively.

2.3. Ideal Enclosures without Apertures

Real enclosures may be analyzed only by means of numerical methods because of their complex shape; however,

Figure 5. Frequency dependence of the reflection loss coefficient R_{dB} of copper against low-impedance and high-impedance sources. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

some formulations exist allowing an estimation of shielding performance under simplifying hypotheses and approximations concerning the absence of constructive defects and discontinuities in the structure and the shape of the shield configuration. The effect of the discontinuities such as junctions and apertures may be accounted for at a successive stage, as reported in the following. An analytical expression valid, for example, for the SE against a uniform magnetic field incident transversely onto a cylindrically shaped enclosure of infinite length is

$$SE = 20 \log_{10} \frac{1}{\cosh(\gamma \cdot d) + \left(\frac{r_0 \cdot \gamma}{2\mu_r} + \frac{\mu_r}{2r_0 \cdot \gamma} \right) \cosh(\gamma \cdot d)} \tag{19}$$

where r_0 is the radius of the cylindrical shield.

The SE of a spherically-shaped enclosure against an incident uniform magnetic field is given by the following expression, where r_0 represents the sphere radius:

$$SE = 20 \log_{10} \frac{1}{\cosh(\gamma \cdot d) + \frac{r_0 \cdot \gamma}{3\mu_r} \cosh(\gamma \cdot d)} \tag{20}$$

More complex shapes have been also analyzed, and several useful expressions are reported in [9,10].

2.4. Shielded Cables

Cables are critical components because they may connect apparatus sensitive to external radiofrequency EM fields, or they may radiate unintentionally, becoming sources of interference. With this twofold motivation, cables are often shielded in various ways and either compact or perforated braided shield may be effective in reducing EM susceptibility or interference [11,12]. Generally, a synthetic parameter termed *transfer impedance* is introduced to account for the penetration through the cable shield. The transfer impedance may be regarded as the per unit length voltage drop occurring on the external surface of the cable shield when the inner conductor is driven by a unit current or, by reciprocity, the effect on the inside of the shield due to a current on the external shield surface. Also of particular relevance are the status of ground connections at the ends of the cable, and the type of connectors, apart, of course, from the shield characteristics.

2.5. Numerical Methods for Shielding Analysis

The intrinsic limitations of analytical formulations have lead to a wide literature concerning studies of the application of various numerical methods to shielding problems, which would be an exhaustive, practically impossible report. However, examples of the application of the method of moments to shielding configurations may be found in Refs. 13 and 14, while the finite-difference time-domain method has been applied in Refs. 15 and 16, the boundary element method in Ref. 17, the transmission-line method in Ref. 18, and the finite-element method in Ref. 19.

3. OTHER FACTORS AFFECTING SHIELDING PERFORMANCE

The analytical methods described previously are based on the assumption that no discontinuities (e.g., apertures, holes, junctions, seams) are present in the shield; nevertheless, such a hypothesis is quite unrealistic because intentional apertures for various purposes and unintentional defects always exist and may considerably degrade the performance of real shields. Moreover, the presence of standing waves in closed enclosures may deteriorate the shielding performance even in absence of discontinuities.

No general theory is available to account for the discontinuities; however, some studies have been conducted to quantify the EM field transmitted through intentional apertures of some regular shapes. In fact, when the aperture is electrically small and the shield is perfectly conducting, its contribution to the EM field beyond the shield may be represented as that due to a combination of appropriate elementar electric and magnetic dipoles, located in the centre of the aperture with the shield removed [20]. Periodically perforated shields have been also studied to some extent [21]. Measured data and approximate formulations have been also presented to quantify the effect of various types of discontinuity in EM penetrable shields, and, in particular, in case of single or multiple apertures two approaches can be used to evaluate the overall effect of the aperture(s) in terms of EM leakage whose value must be subtracted from the SE value of the ideal shield [10], or to obtain a modified expression for the SE that individually accounts for various effects such as the number of openings per unit square, coupling between apertures, and reduced absorption loss terms [6].

3.1. Shielding Applications

Several practical rules and solutions are recommended for the design and evaluation of the SE performance of real shield configurations and may be found elsewhere [10]. It is worth mentioning that care must be taken to bond seams and joints according to their permanent or operational nature; permanent joints should be riveted or screwed, and SE performance is influenced by the spacing between the transverse components. Operational joints should be finished with the so-called gaskets, flexible and elastic conductive components capable of establishing a good electrical continuity between fixed and mobile parts of the shield enclosure. Various commercial gaskets are available, and their performance is generally good enough to limit efficiently the performance deterioration. Another situation requiring a special treatment is represented by windows for visualization; because of their aperture dimensions, their presence may considerably reduce the efficiency of an otherwise good structure. It is highly advisable to apply on the required aperture a conductive optical substrate or a shield realized by means of a thin wire mesh.

4. SHIELDING PERFORMANCE MEASUREMENT AND STANDARDS

The most common documents describing the test procedures recommended for assessment of the shielding characteristics of enclosures are:

- Military Standard 285: *Method of Attenuation Measurements for Enclosures, Electromagnetic Shielding, for Electronic Test Purposes.*
- National Security Agency (NSA) Specification 65-6: *General Specifications for RF Shielded Enclosures for Communications Equipment.*
- National Security Agency (NSA) Specification 73-2: *General Specifications for Foil RF Shielded Enclosures for Communications Equipment.*
- IEEE 299: *Standard Method of Measuring the Effectiveness of Electromagnetic Shielded Enclosures.*
- Several ASTM standards, including D4935-99, provide the procedures for measuring the SE of a planar material due to a plane-wave, far-field EM wave, in the frequency range from 30 MHz to 1.5 GHz.

All these documents describe antenna geometries and configurations and also delineate some measurement practices, classifying the source as a type of magnetic, electric, or plane wave. It is important to mention that the data obtained from any of the setups described above cannot be applied to source configurations different from those used in the experiments. Typical experimental setups are shown in Figs. 6–9. Thus, they have only reference value and other methods and experimental setups have been also proposed and applied [22,23].

5. FINAL REMARKS

Some controversial aspects concerning electromagnetic shielding have to be highlighted; the most important are represented by the definition itself of the figure of merit adopted for all the considerations and for design purposes.

Figure 6. Experimental configuration for the measurement of magnetic field shielding effectiveness, according to IEEE 299 and MIL-STD 285.

Figure 7. Experimental configuration for the evaluation of magnetic field shielding effectiveness, according to NSA 65-6.

In fact, the SE, as defined, is a local quantity, in the sense that it represents a field (or power) ratio at a specific point, giving no information on the situation over a finite surface or volume. For this reason, it is difficult to extrapolate a general evaluation of the real performance of the shield from such limited information. Moreover, the SE measurement may be cumbersome or even impossible in some real configurations because of either the shield dimensions (e.g., too small) or the coupling between the enclosure and the transmitting and receiving antennas. Other controversial aspects concern the validity of the transmission-line analogy, which must be assessed case by case, otherwise possibly leading to incorrect predictions.

6. CURRENT RESEARCH TOPICS

Various aspects of electromagnetic shielding are currently under investigation. One of the most challenging research

Figure 8. Typical NSA 65-6 setup for SE measurement in high-impedance source configuration.

Figure 9. Typical NSA 65-6 setup for SE measurement in plane-wave source configuration.

topics is the design of real shielding structures. The need for significant but measurable quantities is of paramount importance in the shielding practice, making possible the experimental verification of predictions, the design of shielding structures, as well as the promulgation of standards; in this regard, the search for new figures of merit is still underway, especially for small enclosures. Of course, new, reliable, and simple ways to perform measurements for the characterization of both materials and shielding structures are always under investigation.

Another important field of research is the development of new synthetic materials providing good performance in specific applications.

In addition, active shielding, realized by means of additional sources capable of generating an electromagnetic field opposite that undesired and to be mitigated, is a research topic of great interest, inasmuch as in the design of optimal configurations.

Finally, since all the abovementioned research topics necessitate the formulation of work hypotheses and their successive experimental verification, numerical modelling and analysis methods must continuously deal with more complex materials and configurations, and thus their improvement in terms of accuracy and efficiency represents a fundamental research topic in electromagnetic shielding.

ELECTROMAGNETIC SUBSURFACE REMOTE SENSING

S. Y. CHEN
W. C. CHEW
University of Illinois at Urbana-
Champaign
Urbana, Illinois

Subsurface electromagnetic (EM) methods are applied to obtain underground information that is not available from surface observations. Since electrical parameters such as dielectric permittivity and conductivity of subsurface materials may vary dramatically, the response of electromagnetic waves can be used to map the underground structure. This technique is referred to as geological surveying. Another major application of subsurface EM methods is to detect and locate underground anomalies such as mineral deposits.

Subsurface EM methods include a variety of techniques depending on the application, surveying method, system, and interpretation procedure, and thus a “best” method simply does not exist. Even though each system has its own characteristics, they still share some common features. In general, each system has a transmitter, which can be either natural or artificial, to send out the electromagnetic energy that serves as an input signal. A receiver is needed to collect the response signal. The underground can be viewed as a system, which is characterized by the material parameters and underground geometry. The task of subsurface EM methods is to derive the underground information from the response signal.

The EM transmitter radiates the primary field into the subsurface, which consists of conductive earth material. This primary field will induce a current, which in turn radiates a secondary field. Either the secondary field or the total field will be detected by the receiver. After the data interpretation, one can obtain the underground information.

One of the most challenging parts of subsurface EM methods is interpretation of the data. Since the incident field interacts with the subsurface in a very complex manner, it is never easy to subtract the information from the receiver signal. Many definitions, such as apparent conductivity, are introduced to facilitate this procedure.

Data interpretation is also a critical factor in evaluating the effectiveness of the system. How good the system is always depends on how well the data can be explained. In the early development of subsurface EM systems, data interpretation largely depended on the personal experience of the operator, due to the complexity of the problem. Only with the aid of powerful computers and improvements in computational EM techniques is it possible to analyze such a complicated problem in a reasonable time. Computer-based interpretation and inversion methods are attracting more and more attention. Nevertheless, data interpretation is still “an artful balance of physical understanding, awareness of the geological constraints, and pure experience” [1].

In the following sections, we will use several typical applications to outline the basic principles of subsurface

EM methods. Physical insight is emphasized rather than rigorous mathematical analysis. Details of each method can be found in the references.

1. BOREHOLE EM METHODS

Borehole EM methods are an important part of well-logging methods. Since water is conductive and oil is an insulator, resistivity measurements are good indicators of oil presence. Water has an unusually high dielectric constant, and permittivity measurement is a good detector of moisture content.

Early borehole EM methods consist of mainly electrical measurements using very simple low-frequency electrodes like the short and the long normal. Then more sophisticated electrode tools were developed. Some of these tools are mounted on a mandrel, which performs measurements centered in a borehole. These tools are called mandrel tools. Alternatively, the sensors can be mounted on a pad, and the corresponding tool is called a pad tool.

One of the most successful borehole EM methods is induction logging. Since Doll published his first paper in 1949 (2), this technique has been used widely with confidence in the petroleum industry. Extensive research work has been done in this area. The systems in use now are so sophisticated that many modern electrical techniques are involved. Nevertheless, the principles still remain the same and can be understood by studying a simple case.

The induction logging technique, as proposed by Doll, makes use of several coils wound on an isolating mandrel, called a sonde. Some of the coils, referred to as transmitters, are powered with alternating current (AC). The transmitters radiate the field into the conductive formation and induce a secondary current, which is nearly proportional to the formation conductivity. The secondary current radiates a secondary field, which can be detected by the receiver coils. The receiver signal (voltage) is normalized with respect to the transmitter current and represented as an apparent conductivity, which serves as an indication of underground conductivity.

To obtain information from the apparent conductivity, we need to understand how apparent conductivity and true conductivity are related. According to Doll's theory, the relation in cylindrical coordinates is given by

$$\sigma_a = \int_{-\infty}^{+\infty} dz' \int_0^{+\infty} d\rho' g_D(\rho', z') \sigma(\rho', z') \quad (1)$$

where σ_a is the formation conductivity. The kernel $g_D(\rho, z)$ is the so-called Doll geometric factor, which weights the contribution of the conductivity from various regions in the vicinity of sonde.

We notice that $g_D(\rho, z)$ is not a function of the true conductivity and hence is only determined by the tool configuration. The interpretation of the data would be simple if Doll's theory were exact. Unfortunately, this is rarely the case. Further studies show that Eq. (1) is true only in some extreme cases. The significance of Doll's theory, however, is that it relates the apparent conductivity and formation conductivity, even though the theory is not exact. In the

early development of induction logging techniques, tool design and data interpretation were based on Doll's theory, and in most cases it gives reasonable answers.

To establish a firm understanding of induction logging theory, we need to perform a rigorous analysis by using Maxwell's equations as follows:

$$\nabla \times \mathbf{H} = -i\omega\epsilon\mathbf{E} + \mathbf{J}_s + \sigma\mathbf{E} \quad (2)$$

$$\nabla \times \mathbf{E} = i\omega\mu\mathbf{H} \quad (3)$$

$$\nabla \cdot \mathbf{H} = 0 \quad (4)$$

$$\nabla \cdot \mathbf{D} = \rho \quad (5)$$

where $\nabla \cdot \mathbf{J}_s = i\omega\rho$.

In the preceding equations, the time dependence $e^{-i\omega t}$ is assumed, and \mathbf{J}_s corresponds to the impressed current source. Parameters μ, ϵ, σ are the magnetic permeability, dielectric permittivity, and electric conductivity, respectively. To simplify the analysis, we assume that both the impressed source and geometry of the problem are axisymmetric; consequently, all the field components are independent of the azimuthal angle. Furthermore, it can be shown that there is no stored charge under the preceding assumption. The working frequency of induction logging is about 20 kHz, so the displacement current $-i\omega\epsilon\mathbf{E}$ is very small compared to the conduction current $\sigma\mathbf{E}$ and hence is neglected in the following discussion. After these simplifications, we have

$$\nabla \times \mathbf{H} - \sigma\mathbf{E} = \mathbf{J}_s \quad (6)$$

$$\nabla \times \mathbf{E} - i\omega\mu\mathbf{H} = 0 \quad (7)$$

$$\nabla \cdot \mathbf{H} = 0 \quad (8)$$

$$\nabla \cdot \mathbf{E} = 0 \quad (9)$$

where we assume $\nabla \cdot \mathbf{J}_s = i\omega\rho = 0$.

For convenience, the auxiliary vector potential is introduced. Since $\nabla \cdot \mathbf{H} = 0$ and $\nabla \cdot (\nabla \times) = 0$, it is possible to define $\mathbf{H} = \nabla \times \mathbf{A}$. To specify the field uniquely, we choose $\mathbf{E} = i\omega\mu\mathbf{A}$, which is true only when there is no charge accumulation. Substituting these expressions into Eq. (6), we have

$$\nabla \times \nabla \times \mathbf{A} - i\omega\mu\sigma\mathbf{A} = \mathbf{J}_s \quad (10)$$

By using the vector identity, we have

$$\nabla^2 \mathbf{A} + k^2 \mathbf{A} = -\mathbf{J}_s \quad (11)$$

where

$$k^2 = i\omega\mu\sigma \quad (12)$$

To demonstrate how the apparent conductivity and formation conductivity are related, we first write down the solution of Eq. (11) in a homogeneous medium as

follows [3,4]:

$$\mathbf{A}(\rho, z, \phi) = \frac{1}{4\pi} \int_V \frac{\mathbf{J}_s(\rho', z', \phi')}{\bar{r}_1} e^{ik\bar{r}_1} dV' \quad (13)$$

where

$$\bar{r}_1 = \{(z - z')^2 + \rho^2 + \rho'^2 - 2\rho\rho' \cos(\phi - \phi')\}^{1/2} \quad (14)$$

The volume integration is evaluated over regions containing the impressed current sources and the coordinate system used in Eq. (13), as shown in Fig. 1. Usually, a small current loop is used as an excitation, which implies that only A_ϕ exists. Hence, Eq. (13) can be furthermore simplified as

$$A_\phi(\rho, z) = \frac{1}{4\pi} \int_V \mathbf{J}_\phi(\rho', z') \cos(\phi - \phi') \frac{e^{ik\bar{r}_1}}{\bar{r}_1} dV' \quad (15)$$

When the radius of the current loop becomes infinitely small, it can be viewed as a magnetic dipole, and thus the preceding integration can be approximated as

$$A_\phi = \frac{m}{4\pi r_1^3} (1 - ikr_1) e^{ikr_1} \quad (16)$$

where $m = N_T I (\pi a^2)$ is the magnetic dipole moment and N_T is the number of turns wound on the mandrel. At the receiver point, the voltage induced on the receiver with N_R

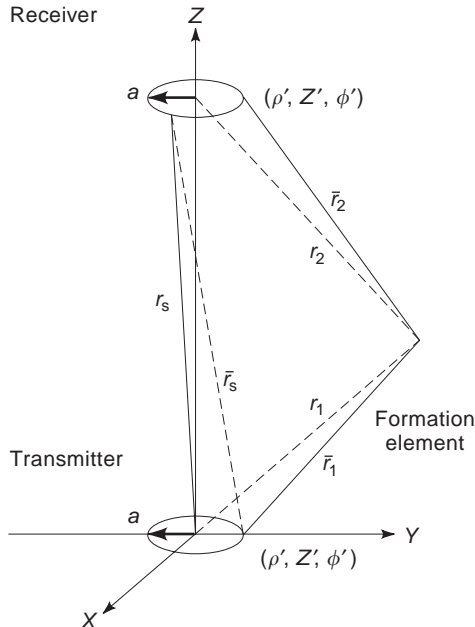

Figure 1. Induction logging tool transmitter and receiver coil pair used to explain the geometric factor theory. (Redrawn from Ref. 4.)

turns can be represented as

$$\begin{aligned} V &= 2\pi a N_R E_\phi \\ &= \frac{2N_T N_R (\pi a^2)^2 I}{4\pi} i\omega\mu (1 - ikL) \frac{e^{ikL}}{L^3} \end{aligned} \quad (17)$$

where

$$E_\phi = i\omega\mu A_\phi(a, L) \quad (18)$$

and L is the distance between the transmitter and the receiver. Since the voltage is a complex quantity, it can be separated into real and imaginary parts and expanded in powers of kL as follows [3]

$$V_R = -K\sigma \left(1 - \frac{2L}{3\delta} + \dots \right) \quad (19)$$

$$V_X = K\sigma \frac{\delta^2}{L^2} \left(1 - \frac{2L^2}{3\delta^3} + \dots \right) \quad (20)$$

where

$$K = \frac{(\omega\mu)^2 (\pi a^2)^2 N_T N_R I}{4\pi L} \quad (21)$$

and

$$\delta = \sqrt{\frac{2}{\omega\mu\sigma}} \quad (22)$$

The quantity K is known as the “tool constant” and is totally determined by the configuration of the tool, and σ is the so-called skin depth, which describes the attenuation of a conductor in terms of the field penetration distance. The quantity V_R is called the R signal. The apparent conductivity is defined as [3]

$$\sigma_a = -\frac{V_R}{K} \cong \sigma \left(1 - \frac{2L}{3\delta} \right) \quad (23)$$

In the preceding analysis, there are some important facts that need to be mentioned. In Eq. (19), we see that the apparent conductivity is a nonlinear function of the true conductivity, even in a homogeneous medium. The lower the working frequency or lower the true conductivity, the more linear it will be. The difference between true conductivity and apparent conductivity is defined as the skin effect signal:

$$\sigma_s = \sigma - \sigma_a \quad (24)$$

The leading term of the imaginary part V_X is not a function of true conductivity. In fact, it corresponds to the direct coupling field, which does not contain any formation information. What remains in V_X is the so-called X signal. Since the direct term is much larger than the residual part including V_R , it is difficult to separate the X signal. The

importance of the X signal is seen by comparing Eqs. (19) and (20), from which we find that the X signal is the first-order approximation of the nonlinear term in V_R , the R signal. This fact can be used to compensate for the skin effect.

So far we have introduced the concept of apparent conductivity by studying the homogeneous case. In practice, the formation conductivity distribution is far more complicated. The apparent conductivity and formation conductivity are related through a nonlinear convolution. As a proof we derive the solution in an integral form, instead of directly solving the differential equations. To this end, we first rewrite Eq. (11) as

$$\nabla^2 \mathbf{A} = -\mathbf{J}_s - \mathbf{J}_i \quad (25)$$

where $\mathbf{J}_i = -k^2 \mathbf{A}$ is the induced current. The solution of Eq. (25) can be written in the integral form as

$$\mathbf{A} = \frac{1}{4\pi} \int_V \frac{\mathbf{J}_s}{\bar{r}_s} dV' + \frac{1}{4\pi} \int_V \frac{\mathbf{J}_i}{\bar{r}_2} dV \quad (26)$$

The first integral is evaluated over the regions containing the impressed sources, and the second one is performed over the entire formation. Under the same assumption as we have made in the preceding analysis, the receiver voltage can be written as [4]

$$V = \frac{i2\pi a N_R \omega \mu}{4\pi} \int_V \frac{J_\phi}{\bar{r}_s} dV' - \frac{2\pi a N_R \omega^2 \mu^2}{4\pi} \int_V \frac{\sigma(\rho', z') A_\phi(\rho', z')}{\bar{r}_2} dV \quad (27)$$

The vector potential can also be separated into real and imaginary parts:

$$A_\phi = A_{\phi R} + iA_{\phi I} \quad (28)$$

Substituting Eq. (28) into Eq. (27) and separating out the real part of the receiver voltage, we have

$$V_R = \frac{-(\omega \mu)^2 (2\pi a N_R)}{4\pi} \int_{-\infty}^{\infty} dz' \int_0^{\infty} d\rho' \sigma(\rho', z') A_{\phi R} \int_0^{2\pi} \frac{\cos(\phi - \phi')}{\bar{r}_2} d\phi' \quad (29)$$

Applying the same procedure, we obtain the apparent conductivity as

$$\sigma_a = -\frac{V_R}{K} = \int_0^{\infty} d\rho' \int_{-\infty}^{\infty} dz' \sigma(\rho', z') g_P(\rho', z') \quad (30)$$

where

$$g_P = \frac{2\pi L \rho'}{(\pi a)^3 N_T I} A_{\phi R} \int_0^{2\pi} \frac{\cos(\phi - \phi')}{\bar{r}_2} d\phi' \quad (31)$$

The function g_P is the exact definition of the geometric factor. In comparison with Doll's geometric factor, g_P depends not only on the tool configuration but also on the formation conductivity, since the vector potential depends on the formation conductivity. The integral form solution does not provide any computational advantage, since the differential equation for the vector potential $A_{\phi, R}$ must still be solved. But it is now clear from Eq. (30) that the apparent conductivity is the result of a nonlinear convolution. Equation (30) also represents the starting point of inverse filtering techniques, which make use of both the R and X signals to reconstruct the formation conductivity.

Finding the vector potential A is still a challenge. Analytic solutions are available only for a few simple geometries. In most cases, we have to use numerical techniques such as the finite-element method (FEM), finite-difference method (FDM), numerical mode matching (NMM), or the volume integral equation method (VIEM). Interested readers may find Refs. 5 through 8 useful.

Previously, we mentioned that Doll's geometric factor theory is valid only under some extreme conditions. In fact, it can be derived from the exact geometric factor as a special case [4]. In a homogeneous medium, the vector potential $A_{\phi, R}$ can be calculated as

$$A_{\phi R} \cong \frac{(\pi a^2) N_T I \rho'}{4\pi r_1^3} \mathcal{R}e\{(1 - ikr_1)e^{ikr_1}\} \quad (32)$$

The integration with respect to ϕ' in Eq. (31) can also be performed for $\bar{r}_2 \gg a$. The final result is

$$\sigma_a = \int_{-\infty}^{\infty} \int_0^{\infty} \sigma_D(\rho', z') \mathcal{R}e\{(1 - ikr_1)e^{ikr_1}\} d\rho' dz' \quad (33)$$

where

$$g_D(\rho', z') = \frac{L \rho'^3}{2 r_1^3 r_2^3} \quad (34)$$

It is now clear that Doll's geometric factor and the exact geometric factor are the same when the medium is homogeneous and the wavenumber approaches zero.

So far we have discussed the basic theory of induction logging. We now use a simple example to show some practical concerns and briefly discuss the solutions. In Fig. 2, we show an apparent resistivity (the inverse of apparent conductivity) response of a commercial logging tool 6FF40 (trademark of the Schlumberger Company) in the Oklahoma benchmark. The black line is the formation resistivity, and the red line is the unprocessed data of 6FF40. We notice that the apparent resistivity data roughly indicate the variation of the true resistivity, but around 4850 ft the apparent resistivity R_a is much higher than the true resistivity R_t , which results from the "skin effect" [9]. From 4927 to 4955 ft, R_a is substantially lower than R_t ,

Figure 2. Apparent resistivity responses of a different tool in the Oklahoma benchmark. The improvement of resolution ability of the HR1 tool is significant.

which is caused by the so-called shoulder effect. The shoulder effect arises when two adjacent low-resistance layers generate strong signals, even though the tool is not in these two regions. Around 5000 ft, there are a number of thin layers, but the tool's response fails to indicate them. This failure results from the tool's limited resolution, which is represented in terms of the smallest thickness that can be identified by the tool.

The blue line is the processed 6FF40 data after skin effect boosting and a three-point deconvolution. Skin effect boosting is based on Eq. (19), which is solved iteratively for the true conductivity from the apparent conductivity. The three-point deconvolution is performed under the assumption that the convolution in Eq. (30) is almost linear [10]. These two methods do improve the final results to some degree, but they also cause spurious artifacts observed near 4880 ft, since the two effects are considered separately. The green curve is the response of the HRI (high-resolution induction) tool (trademark of Halliburton) [11]. A complex coil configuration is used to optimize the geometric factor. After the raw data are obtained, a nonlinear deconvolution based on the X signal is performed. The improvement in the final results is significant.

In 1991 Schlumberger Company released its AIT (array induction image tool), which uses eight induction coil arrays operating at different frequencies [12]. The deconvolutions are performed in both radial and vertical directions, and a quantitative two-dimensional image of formation resistivity is possible after a large number of measurements [13,14].

The aforementioned data processing techniques are based on the inverse deconvolution filter, which is computationally effective and easily run in real time on a logging

truck computer. An alternative approach is to use inverse scattering theory, which is becoming increasingly practical and promising with the development of high-speed computers [8,15].

Besides the induction method, there are other methods, such as electrode methods and propagation methods. Induction methods are suitable for the freshwater mud, oil-base mud, or air-filled boreholes, since the little or no conductivity in the borehole has a lesser effect on the measurement. If the mud is very conductive, it will generate a strong signal at the receiver and hence seriously degrade the tool's ability to make a deep reading. In such a case, electrode methods are preferable, since the conductive mud places the electrodes into better electrical contact with the formation. In the electrode methods, very low frequencies ($\ll 1000$ Hz) are used and Laplace's equation is solved instead of the Helmholtz equation. The typical tools are DLL (dual laterolog) and SFL (spherical focusing log), both from Schlumberger. The dual laterolog is intended for both deep and shallow measurements, while the SFL is for shallow measurements [16–19].

In addition, there are many tools mounted on pads to perform shallow measurements on the borehole wall. These may be just button electrodes mounted on a metallic pad. Due to their small size, they have high resolution but a shallow depth of investigation. Their high-resolution capability can be used to map out fine stratifications on the borehole wall. When four pads are equipped with these button electrodes, the resistivity logs they measure can be correlated to obtain the dip of a geologic bed. An example of this is the SHDT (stratigraphic high-resolution dip-meter tool), also from Schlumberger [20].

When an array of buttons are mounted on a pad, they can be used to generate a resistivity image of the borehole

wall for formation evaluation, such as dips, cracks, and stratigraphy. Such a tool is called a formation microscanner (FMS) and is available from Schlumberger [21].

For oil-based mud the SHDT does not work well, and microinduction sensors have been mounted on a pad to dipping bed evaluation. Such a tool is known as the OBMDT (oil-based mud dipmeter tool) and is manufactured by Schlumberger [22,23].

Sometimes information is needed relating not only to the conductivity but also to the dielectric permittivity. In such cases, the EPT (electromagnetic wave propagation tool), from Schlumberger can be used. The working frequency of EPT can be as high as hundreds of megahertz to 1 GHz. At such high frequencies, the real part of ϵ' is dominant, as follows:

$$\epsilon' = \epsilon + i \frac{\sigma}{\omega} \quad (35)$$

EPT measurements provide information about dielectric permittivity and hence can better distinguish fresh water from oil. Water has a much higher dielectric constant ($80\epsilon_0$) compared to oil ($2\epsilon_0$). Phase delays at two receivers are used to infer the wave phase velocity and hence the permittivity. Interested readers can find materials on these methods in Refs. 24 and 25.

Other techniques in electrical well logging include the use of borehole radar. In such a case, a pulse is sent to a transmitting antenna in the borehole, and the pulse echo from the formation is measured at the receiver. Borehole radar finds application in salt domes where the electromagnetic loss is low. In addition, the nuclear magnetic resonance (NMR) technique can be used to detect the percentage of free water in a rock formation. The NMR signal in a rock formation is proportional to the spin echos from free protons that abound in free water. An example of such a tool is the PNMT (pulsed nuclear magnetic resonance tool), from Schlumberger [26].

2. GROUND PENETRATING RADAR

Another outgrowth of subsurface EM methods is ground penetrating radar (GPR). Because of its numerous advantages, GPR has been widely used in geological surveying, civil engineering, artificial target detection, and some other areas.

The GPR design is largely application oriented. Even though various systems have different applications and considerations, their advantages can be summarized as follows: (1) because the frequency used in GPR is much higher than that used in the induction method, GPR has a higher resolution; (2) since the antennas do not need to touch the ground, rapid surveying can be achieved; (3) the data retrieved by some GPR systems can be interpreted in real time; and (4) GPR is potentially useful for organic contaminant detection and nondestructive detection [27–31].

On the other hand, GPR has some disadvantages, such as shallow investigation depth and site-specific applicability. The working frequency of GPR is much higher than

that used in the induction method. At such high frequencies, the soil is usually very lossy. Even though there is always a tradeoff between the investigation depth and resolution, a typical depth is no more than 10 m and highly dependent on soil type and moisture content.

The working principle of GPR is illustrated in Fig. 3a [28]. The transmitter T generates transient or continuous EM waves propagating in the underground. Whenever a change in the electrical properties of underground regions is encountered, the wave is reflected and refracted. The receiver R detects and records the reflected waves. From the recorded data, information pertaining to the depth, geometry, and material type can be obtained. As a simple example, we use Figs. 3b and 3c to illustrate how the data are recorded and interpreted. The underground contains one interface, one cavity, and one lens. At a single position, the receiver signals at different times are stacked along the time axis. After completing the measurement at one position, the procedure is iterated at all subsequent positions. The final results are presented in a two-dimensional map, which is called an echo sounder-type display. To locate objects or interfaces, we need to know the wave speed in the underground medium. The wavespeed in a medium of relative dielectric permittivity ϵ_r is

$$C_s = \frac{C_0}{\sqrt{\epsilon_r}} \quad (36)$$

where $C_0 = 3 \times 10^8$ m/s. Usually, the transmitter and the receiver are close enough, and thus the wave's path of propagation is considered to be vertical. The depth of the

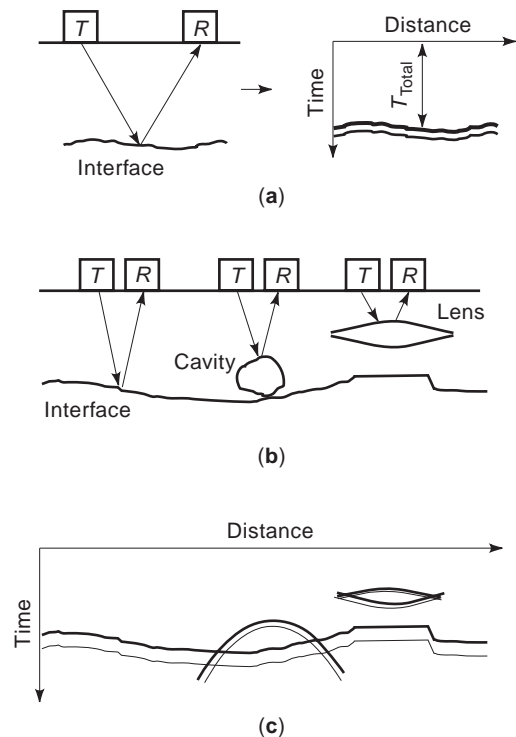

Figure 3. Working principle of the GPR. (Redrawn from Ref. 20.)

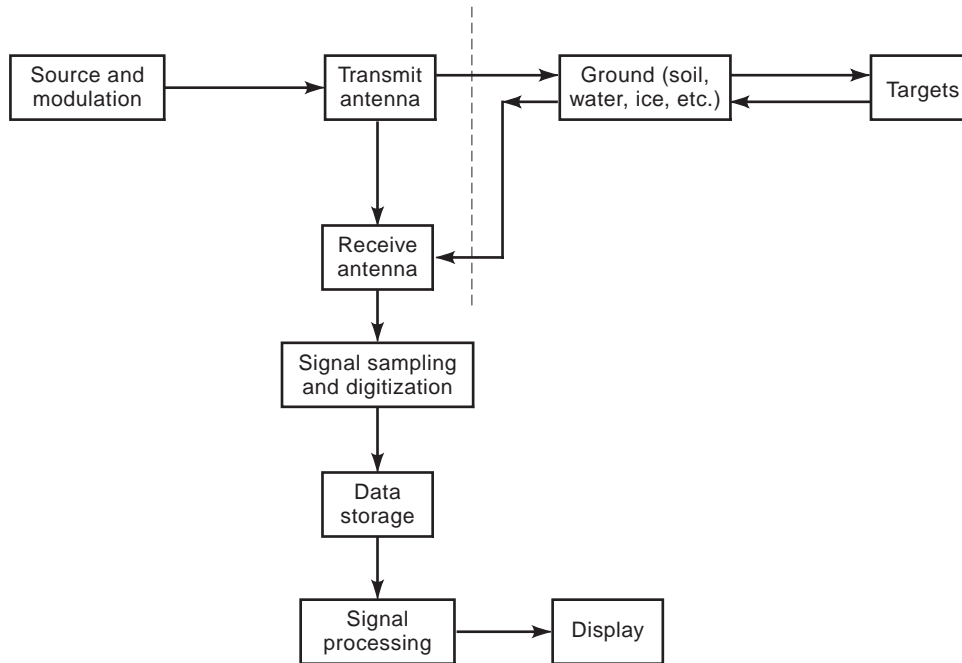

Figure 4. Block diagram showing operation of a typical baseband GPR system. (Redrawn from Ref. 19.)

interface is approximated as

$$D = 0.5 \times (C_s \times T_{\text{total}}) \quad (37)$$

where T_{total} is the total wave propagation time.

A practical GPR system is much more complicated, and a block diagram of a typical baseband GPR system is shown in Fig. 4. Generally, a successful system design should meet the following requirements [27]: (1) efficient coupling of the EM energy between antenna and ground, (2) adequate penetration with respect to the target depth, (3) sufficiently large return signal for detection, and (4) adequate bandwidth for the desired resolution and noise control.

The working frequency of typical GPR ranges from a few tens of megahertz to several gigahertz, depending on the application. The usual tradeoff holds—the wider the bandwidth, the higher the resolution but the shallower the penetration depth. A good choice is usually a tradeoff between resolution and depth. Soil properties are also critical in determining the penetration depth. It is observed experimentally that the attenuation of different soils can vary substantially. For example, dry desert and nonporous rocks have very low attenuation (about 1 dBm^{-1} at 1 GHz) while the attenuation of sea water can be as high as 300 dBm^{-1} at 1 GHz. Some typical applications and preferred operating frequencies are listed in Table 1 [27].

To meet the requirements of different applications, a variety of modulation schemes have been developed and can be classified in the following three categories: amplitude modulation (AM), frequency-modulated continuous wave (FMCW), and continuous wave (CW). We will briefly

discuss the advantages and limitations of each modulation scheme.

There are two types of AM transmission used in GPR. For investigation of low-conductivity medium, such as ice and fresh water, a pulse modulated carrier is preferred [32,33]. The carrier frequency can be chosen as low as tens of megahertz. Since the reflectors are well spaced, a relatively narrow transmission bandwidth is needed. The receiver signal is demodulated to extract the pulse envelope. For shallow and high-resolution applications, such as the detection of buried artifacts, a baseband pulse is preferred

Table 1. Desired Frequencies for Different Applications^a

Material	Typical Desired Penetration Depth ^b	Approximate Maximum Frequency at Which Operation May Be Usefully Performed
Cold pure fresh-water ice	10 km	10 MHz
Temperate pure ice	1 km	2 MHz
Saline ice	10 m	50 MHz
Fresh water	100 m	100 MHz
Sand (desert)	5 m	1 GHz
Sandy soil	3 m	1 GHz
Loam soil	3 m	500 MHz
Clay (dry)	2 m	100 MHz
Salt (dry)	1 km	250 MHz
Coal	20 m	500 MHz
Rocks	20 m	50 MHz
Walls	0.3 m	10 GHz

^aRedrawn from Ref. 19.

^bThe figures used under this heading are the depths at which radar probing gives useful information, taking into account the attenuation normally encountered and the nature of the reflectors of interest.

to avoid the problems caused by high soil attenuation, since most of the energy is in the low-frequency band. A pulsetrain with a duration of 1 to 2 ns, a peak amplitude of about 100 V, and a repetition rate of 100 kHz is applied to the broadband antenna. The received signal is downconverted by sampling circuits before being displayed. There are three primary advantages of the AM scheme: (1) it provides a real-time display without the need for subsequent signal processing, (2) the measurement time is short, and (3) it is implemented with small equipment but without synthesized sources and hence is cost-effective. But for the AM scheme, it is difficult to control the transmission spectrum, and the signal-to-noise ratio (SNR) is not as good as that of the FMCW method.

For the FMCW scheme, the frequency of the transmitted signal is continuously swept, and the receiver signal is mixed with a sample of transmitted signals. The Fourier transform of the received signal results in a time-domain pulse that represents the receiver signal if a time domain pulse were transmitted. The frequency sweep must be linear in time to minimize signal degradation, and a stable output is required to facilitate signal processing. The major advantage of the FMCW scheme is easier control of the signal spectrum; the filter technique can be applied to obtain better SNR. A shortcoming of the FMCW system is the use of a synthesized frequency source, which means that the system is expensive and bulky. Additional data processing is also needed before the display [34,35].

A continuous-wave scheme was used in the early development of GPR, but now it is mainly employed in synthetic aperture and subsurface holography techniques [36–38]. In these techniques, measurements are performed at a single or a few well-spaced frequencies over an aperture at the ground surface. The wave front extrapolation technique is applied to reconstruct the underground region, with the resolution depending on the size of the aperture. Narrowband transmission is used and hence high-speed data capture is avoided. The difficulty of the CW scheme comes from the requirement for accurate scanning of the two-dimensional aperture. The operation frequencies should be carefully chosen to minimize resolution degradation [27].

Antennas play an important role in the system performance. An ideal antenna should introduce the least distortion on the signal spectrum or else one for which the modification can be easily compensated. Unlike the antennas used in the atmospheric radar, the antennas used in GPR should be considered as loaded. The radiation pattern of the GPR antenna can be quite different due to the strong interaction between the antenna and ground. Separate antennas for transmission and reception are commonly used, because it is difficult to make a switch that is fast enough to protect the receiver signal from the direct coupling signal. The direct breakthrough signals will seriously reduce the SNR and hence degrade the system performance. Moreover, in a separate-antenna system, the orientation of antennas can be carefully chosen to reduce further the cross-coupling level.

Except for the CW scheme, other modulation types require wideband transmission, which greatly restricts the choice of antenna. Four types of antennas, including ele-

ment antennas, traveling-wave antennas, frequency-independent antennas, and aperture antennas, have been used in GPR designs. Element antennas, such as monopoles, cylindrical dipoles, and biconical dipoles, are easy to fabricate and hence widely used in GPR systems. Orthogonal arrangement is usually chosen to maintain a low level of cross-coupling. To overcome the limitation of narrow transmission bandwidth of thin dipole or monopole antennas, the distributed loading technique is used to expand the bandwidth at the expense of reduced efficiency [39–42].

Another commonly used antenna type is traveling-wave antennas, such as long-wire antennas, V-shaped antennas, and rhombic antennas. The traveling-wave antennas distinguish themselves from standing-wave antennas in the sense that the current pattern is a traveling wave rather than a standing wave. Standing-wave antennas, such as half-wave dipoles, are also referred to as *resonant antennas* and are narrowband, while traveling-wave antennas are broadband. The disadvantage of traveling-wave antennas is that half of the power is wasted at the matching resistor [43,44].

Frequency-independent antennas are often preferred in the impulse GPR system. It has been proved that if the antenna geometry is specified only by angles, its performance will be independent of frequency. In practice, we have to truncate the antenna, due to its limited outer size and inner feeding region, which determine the lower bound and upper bound of the frequency, respectively. In general, this type of antenna will introduce nonlinear phase distortion, which results in an extended pulse response in the time domain [27,45]. A phase correction procedure is needed if the antenna is used in a high-resolution GPR system.

A wire antenna is a one-dimensional antenna that has a small effective area and hence lower gain. For some GPR systems, higher gain or a more directive radiation pattern is sometimes required. Aperture antennas, such as horn antennas, are preferred because of their large effective area. A ridge design is used to improve the bandwidth and reduce the size. Ridged horns with gain better than 10 dBm over a range of 0.3–2 GHz and VSWR lower than 1.5 over a range of 0.2–1.8 GHz have been reported [46]. Since many aperture antennas are fed via waveguides, the phase distortion associated with the different modulation schemes needs to be considered.

Generally, antennas used in GPR systems require broad bandwidth and linear phase in the operating frequency range. Since the antennas work in close proximity to the ground surface, the interaction between them must be taken into account.

Signal processing is one of the most important parts in the GPR system. Some modulation schemes directly give the time-domain data while the signals of other schemes need to be demodulated before the information is available. Signal processing can be performed in the time domain, frequency domain, or space domain. A successful signal processing scheme usually consists of a combination of several kinds of processing techniques that are applied at different stages. Here, we outline some basic signal processing techniques involved in the GPR system.

The first commonly used method is noise reduction by time averaging. It is assumed that the noise is random, so that the noise can be reduced to $1/Nt$ by averaging N identical measurements spaced in time t . This technique only works for random noise but has no effect on the clutter.

Clutter reduction can be achieved by subtracting the mean. This technique is performed under the assumption that the statistics of the underground are independent of position. A number of measurements are performed at a set of locations over the same material type to obtain the mean, which can be considered as a measure of the system clutter.

The frequency filter technique is commonly used in the FMCW system. Signals that are not in the desired information bandwidth are rejected. Thus the SNR of the FMCW scheme is usually higher than that of the AM scheme.

In some very lossy soils, the return signal is highly attenuated, which makes interpretation of the data difficult. If the material attenuation information is available, the results can be improved by exponentially weighting the time traces to counter the decrease in signal level due to the loss. In practice, this is done by using a specially designed amplifier. Caution is needed when using this method, since the noise can also increase in such a system [27].

3. MAGNETOTELLURIC METHODS

The basic idea of the magnetotelluric (MT) method is to use natural electromagnetic fields to investigate the electrical conductivity structure of Earth. This method was first proposed by Tikhonov in 1950 [47]. In his paper, the author assumed that Earth's crust is a planar layer of finite conductivity lying on an ideally conducting substrate, such that a simple relation between the horizontal components of the E and H fields at the surface can be found [48]

$$i\mu_0\omega H_x \cong E_y\gamma \cosh(\gamma l) \tag{38}$$

where

$$\gamma = (i\sigma\mu_0\omega)^{(1/2)} \tag{39}$$

The author used the data observed at Tucson (Arizona) and Zui (former USSR) to compute the value of conductivity and thickness of the crust that best fit the first four harmonics. For Tucson, the conductivity and thickness were about 4.0×10^{-3} S/m and 1000 km, respectively. For Zui, the corresponding values are 3.0×10^{-1} S/m and 100 km.

The MT method distinguishes itself from other subsurface EM methods because very-low-frequency natural sources are used. The actual mechanisms of natural sources have been under discussion for a long time, but now it is well accepted that the sources of frequency above 1 Hz are thunderstorms while the sources below 1 Hz are due to the current system in the magnetosphere caused by solar activity. In comparison with other EM methods, the use of a natural source is a major advantage. The frequencies used

range from 0.001 Hz to 10^4 Hz, and thus investigation depth can be achieved from 50 to 100 m to several kilometers. Installation is much simpler and has less impact on the environment. The MT method has also proved very useful in some extreme areas where conventional seismic methods are expensive or ineffective. The main shortcomings of the MT method are limited resolution and difficulty in achieving a high SNR, especially in electrically noisy areas [49].

In MT measurements, the time-varying horizontal electrical and magnetic fields at the surface are recorded simultaneously. The data recorded in the time domain are first converted into frequency-domain data by using a fast Fourier transform (FFT). An apparent conductivity is then defined as a function of frequency. To interpret the data, theoretical apparent conductivity curves are generated by the model studies. The model whose apparent conductivity curve best matches the measurement data is taken as an approximate model of the subsurface.

Since it is more convenient and meaningful to represent the apparent conductivity in terms of skin depth, we first introduce the concept of skin depth by studying a simple case. The model we use is shown in Fig. 5, which consists of a homogeneous medium with conductivity σ and a uniform current sheet flowing along the x direction in the xy plane. If the density of current at the ground ($z = 0$) is represented as [50]

$$I_x = \cos \omega t, I_y = I_z = 0 \tag{40}$$

then the current density at depth z is

$$I_x = e^{-z\sqrt{2\omega\mu\sigma}/2} \cos(\omega t - z\sqrt{2\omega\mu\sigma}), I_y = I_z = 0 \tag{41}$$

When z increases, we notice that the amplitude of the current decreases exponentially with respect to z ; meanwhile the phase retardation progressively increases. To describe the amplitude attenuation, we introduce the skin depth p as [50]

$$p = \sqrt{\frac{2}{\omega\mu\sigma}} \tag{42}$$

where the current amplitude decreases to e^{-1} of the current at the surface. Since the unit in Eq. (42) is not

Figure 5. Current sheet flowing on Earth's surface, used to explain magnetotelluric method.

convenient, some prospectors like to use the following formula

$$p = \frac{1}{2\pi} \sqrt{10\rho T} \quad (43)$$

where T is the period in seconds, ρ is the resistivity in Ωm , and the unit for p is km. The skin depth indicates the depth the wave can penetrate the ground. For example, if the resistivity of the underground is 10 S/m and the period of the wave is 3 s, the skin depth is 2.76 km. Subsurface methods seldom have such a great penetration depth.

The data interpretation of the MT method is based on the model studies. Earth is modeled as a two- or three-layer medium. For a two-layer model as shown in Fig. 6, the general expression for the field can be written as [50] $0 \leq z \leq h$:

$$E_z = Ae^{a\sqrt{\sigma_1}z} + be^{-a\sqrt{\sigma_1}z} \quad (44a)$$

$$H_y = e^{i\pi/4} \sqrt{2\sigma_1 T} [-Ae^{a\sqrt{\sigma_1}z} + Be^{-a\sqrt{\sigma_1}z}] \quad (44b)$$

$h \leq z \leq \infty$:

$$E_x = e^{-a\sqrt{\sigma_2}z} \quad (45a)$$

$$H_x = e^{i\pi/4} \sqrt{2\sigma_2 T} e^{-a\sqrt{\sigma_2}z} \quad (45b)$$

where h is the thickness of the upper layer, and σ_1, σ_2 are the conductivities of the upper and lower layers, respectively. Matching the boundary conditions at $z = h$, we have

$$A = \frac{\sqrt{\sigma_1} - \sqrt{\sigma_2}}{2\sqrt{\sigma_1}} e^{-ah(\sqrt{\sigma_1} + \sqrt{\sigma_2})} \quad (46)$$

$$B = \frac{\sqrt{\sigma_1} + \sqrt{\sigma_2}}{2\sqrt{\sigma_1}} e^{ah(\sqrt{\sigma_1} - \sqrt{\sigma_2})} \quad (47)$$

Since we are interested in the ratio between the E and H field on the surface, Eq. (44) can be rewritten for $z = 0$ as

$$\frac{E_x}{H_y} = \frac{1}{\sqrt{2\sigma_1 T}} \frac{M}{N} e^{-i(\pi/4 + \phi + \psi)} \quad (48)$$

Figure 6. Two-layer model of Earth's crust, used to demonstrate the responses of the magnetotelluric method.

where M, N, ϕ , and ψ satisfy the following equations:

$$M \cos \phi = \left(\frac{1}{p_1} \cosh \frac{h}{p_1} + \frac{1}{p_2} \sinh \frac{h}{p_1} \right) \cos \frac{h}{p_1} \quad (49a)$$

$$M \sin \phi = \left(\frac{1}{p_1} \sinh \frac{h}{p_1} + \frac{1}{p_2} \cosh \frac{h}{p_1} \right) \sin \frac{h}{p_1} \quad (49b)$$

$$N \cos \psi = \left(\frac{1}{p_1} \sinh \frac{h}{p_1} + \frac{1}{p_2} \cosh \frac{h}{p_1} \right) \cos \frac{h}{p_1} \quad (49c)$$

$$N \sin \psi = \left(\frac{1}{p_1} \cosh \frac{h}{p_1} + \frac{1}{p_2} \sinh \frac{h}{p_1} \right) \sin \frac{h}{p_1} \quad (49d)$$

where p_1, p_2 are the skin depths of upper and lower layers, respectively.

For a multilayer medium, after applying the same procedure, we can obtain exactly the same relation between E_x and H_y as shown in Eq. (48) except that the expressions for M, N, ϕ , and ψ are much more complicated. Because of this similarity, we have

$$\left| \frac{E_x}{H_y} \right| = \frac{1}{\sqrt{2\sigma_a T}} = \frac{M}{N} \frac{1}{\sqrt{2\sigma_1 T}} \quad (50)$$

where σ_a is defined as the apparent conductivity. If the medium is homogeneous, the apparent conductivity is equal to the true conductivity. In a multilayer medium the apparent conductivity is an average effect of all layers.

To obtain a better understanding of the preceding formulas, we first study two two-layer models and their corresponding apparent conductivity curves, as shown in Fig. 7 (51). At very low frequencies, the wave can easily penetrate the upper layer, and thus its conductivity has little effect on the apparent conductivity. Consequently, the apparent resistivity approaches the true resistivity of the lower layer. As the frequency increases, less energy can penetrate the upper layer due to the skin effect, and thus the effect from the upper layer is dominant. As a result, the apparent resistivity is asymptotic to ρ_1 . Comparing the two curves, we note that both of them change smoothly, and for the same frequency, case A has lower

Figure 7. Diagrammatic two-layer apparent resistivity curves for the models shown. (Redrawn from Ref. 43.)

apparent resistivity than case B, since the conductive sediments of case B are thicker.

Our next example is a three-layer model as shown in Fig. 8 [51]. The center layer is more conductive than the two adjacent ones. As expected, the curve approaches ρ_1 and ρ_2 at each end. The existence of the center conductive bed is obvious from the curve, but the apparent resistivity never reaches the true resistivity of the center layer, since its effect is averaged by the effects from the other two layers.

So far we have only discussed the horizontally layered medium, which is a one-dimensional model. In practice, two-dimensional or even three-dimensional structures are often encountered. In a 2D case, the conductivity changes not only along the z direction but also along one of the horizontal directions. The other horizontal direction is called the “strike” direction. If the strike direction is not in the x or y direction, we obtain a general relation between the horizontal field components as [51]

$$E_x = Z_{xx}H_x + Z_{xy}H_y \tag{51a}$$

$$E_y = Z_{yx}H_x + Z_{yy}H_y \tag{51b}$$

Since $E_x, E_y, H_x,$ and H_y are generally out of phase, $Z_{i,j}$ are complex numbers. It can also be shown that $Z_{i,j}$ have the following properties:

$$Z_{xx} + Z_{yy} = 0 \tag{52}$$

$$Z_{xy} - Z_{yx} = \text{constant} \tag{53}$$

A simple vertical layer model and its corresponding curves are shown in Fig. 9 [51]. In Fig. 9b, the apparent resistivity with respect to $E_{||}$ changes slowly from ρ_1 to ρ_2 because of the continuity of H_{\perp} and $E_{||}$ across the interface. On the other hand, the apparent resistivity corresponding to E_{\perp} has an abrupt change across the contact, since the E_{\perp} is discontinuous at the interface. The relative amplitude of H_{\perp} varies significantly around the interface and approaches a constant at a large distance, as shown in

Figure 8. Diagrammatic three-layer apparent resistivity curve for the model shown. (Redrawn from Ref. 43.)

Fig. 9d. This is caused by the change in current density near the interface, as shown in Fig. 9f. We also observe that H_z appears near the interface, as shown in Fig. 9c. The reason is that the partial derivative of $E_{||}$ with respect to \perp direction is nonzero.

We have discussed the responses in some idealized models. For more complicated cases, their response curves can be obtained by forward modeling. Since the measurement data are in the time domain, we need to convert them into the frequency domain data by using a Fourier transform. In practice, five components are measured. There are four unknowns in Eqs. (51a) and (51b), but only two equations. This difficulty can be overcome by making use of the fact that $Z_{i,j}$ changes very slowly with frequency. In fact, $Z_{i,j}$ is computed as an average over a frequency band that contains several frequency sample points. A commonly used method is given in Ref. 52, according to which Eq. (51a) is rewritten as

$$\langle E_x A^* \rangle = Z_{xx} \langle H_x A^* \rangle + Z_{xy} \langle H_y A^* \rangle \tag{54}$$

and

$$\langle E_x B^* \rangle = Z_{xx} \langle H_x B^* \rangle + Z_{xy} \langle H_y B^* \rangle \tag{55}$$

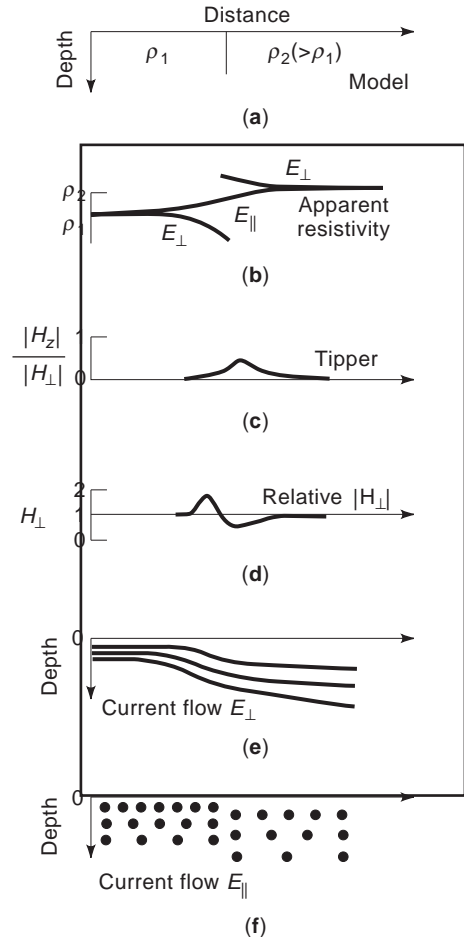

Figure 9. Diagrammatic response curves for a simple vertical contact at frequency f . (Redrawn from Ref. 43.)

where A^* and B^* are the complex conjugates of any two of the horizontal field components. The cross-powers are defined as

$$\langle AB^* \rangle_{(\omega_1)} = \frac{1}{\Delta\omega} \int_{\omega_1 - (\Delta\omega/2)}^{\omega_1 + (\Delta\omega/2)} AB^* d\omega \quad (56)$$

There are six possible combinations, and the pair (H_x, H_y) is preferred in most cases due to its greater degree of independence. Solving Eqs. (54) and (55), we have

$$Z_{xx} = \frac{\langle E_x A^* \rangle \langle H_y B^* \rangle - \langle E_x B^* \rangle \langle H_y A^* \rangle}{\langle H_x A^* \rangle \langle H_y B^* \rangle - \langle H_x B^* \rangle \langle H_y A^* \rangle} \quad (57a)$$

and

$$Z_{xy} = \frac{\langle E_x A^* \rangle \langle H_x B^* \rangle - \langle E_x B^* \rangle \langle H_x A^* \rangle}{\langle H_y A^* \rangle \langle H_x B^* \rangle - \langle H_y B^* \rangle \langle H_x A^* \rangle} \quad (57b)$$

Applying the same procedure to Eq. (51b), we have

$$Z_{yx} = \frac{\langle E_y A^* \rangle \langle H_y B^* \rangle - \langle E_y B^* \rangle \langle H_y A^* \rangle}{\langle H_x A^* \rangle \langle H_y B^* \rangle - \langle H_x B^* \rangle \langle H_y A^* \rangle} \quad (57c)$$

and

$$Z_{yy} = \frac{\langle E_y A^* \rangle \langle H_x B^* \rangle - \langle E_y B^* \rangle \langle H_x A^* \rangle}{\langle H_y A^* \rangle \langle H_x B^* \rangle - \langle H_y B^* \rangle \langle H_x A^* \rangle} \quad (57d)$$

After obtaining $Z_{i,j}$, they can be substituted into Eqs. (51a) and (51b) to solve for the other pair (E_x, E_y) , which is then used to check the measurement data. The difference is due either to noise or to measurement error. This procedure is usually used to verify the quality of the measured data.

4. AIRBORNE ELECTROMAGNETIC METHODS

Airborne EM methods (AEMs) are widely used in geologic surveys and prospecting for conductive ore bodies. These methods are suitable for large area surveys because of their speed and cost-effectiveness. They are also preferred in some areas where access is difficult, such as swamps or ice-covered areas. In contrast to ground EM methods, airborne EM methods are usually used to outline large-scale structures while ground EM methods are preferred for more detailed investigations [53].

The difference between airborne and ground EM systems results from the technical limitations inherent in the use of aircraft. The limited separation between transmitter and receiver determines the shallow investigation depth, usually from 25 to 75 m. Even though greater penetration depth can be achieved by placing the transmitter and receiver on different aircraft, the disadvantages are obvious.

The transmitters and receivers are usually 200–500 ft above the surface. Consequently, the amplitude ratio of the primary field to the secondary field becomes very small

and thus the resolution of airborne EM methods is not very high. The operating frequency is usually chosen from 300 to 4000 Hz. The lower limit is set by the transmission effectiveness, and the upper limit is set by the skin depth.

Based on different design principles and application requirements, many systems have been built and operated all over the world since the 1940s. Despite the tremendous diversity, most airborne EM systems can be classified in one of the following categories according to the quantities measured: phase component measuring systems, quadrature systems, rotating field systems, and transient response systems [54].

For a phase component measuring system, the in-phase and quadrature components are measured at a single frequency and recorded as parts per million (ppm) of the primary field. In the system design, vertical loop arrangements are preferred, since they are more sensitive to the steeply dipping conductor and less sensitive to the horizontally layered conductor [55]. Accurate maintenance of transmitter-receiver separation is essential and can be achieved by fixing the transmitter and receiver at the two wingtips. Once this requirement is satisfied, a sensitivity of a few ppm can be achieved [54]. A diagram of the phase component measuring system is shown in Fig. 10 [55]. A balancing network associated with the reference loop is used to buck the primary field at the receiver. The receiver signal is then fed to two phase-sensitive demodulators to obtain the in-phase and quadrature components. Lowpass filters are used to reject very-high-frequency signals that do not originate from the earth. The data are interpreted by matching the curves obtained from the modeling. Some response curves of typical structures are given in Ref. 56.

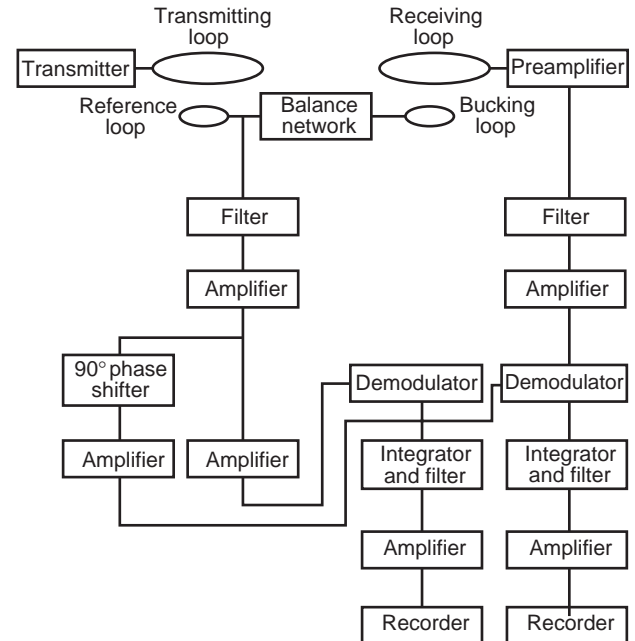

Figure 10. Block diagram showing operation of a typical phase component measuring system. (Redrawn from Ref. 43.)

The quadrature system employs a horizontal coil placed on the airplane as a transmitter and a vertical coil towed behind the plane as a receiver. The vertical coil is referred to as a “towed bird.” Since only the quadrature component is measured, the separation distance is less critical. To reduce the noise further, an auxiliary horizontal coil, powered with a current 90° out of phase with respect to the main transmitter current, is used to cancel the secondary field caused by the metal body of the aircraft. Since the response at a single frequency may have two interpretations, two frequencies are used to eliminate the ambiguity. The lower frequency is about 400 Hz, and the higher one is chosen from 2000 to 2500 Hz. The system responses in different environments can be obtained by model studies. Reference 57 gives a number of curves for thin sheets and shows the effects of variation in depth, dipping angle, and conductivity.

In an airborne system, it is hard to control the relative rotation of receiver and transmitter. The rotating field method is introduced to overcome this difficulty. Two transmitter coils are placed perpendicular to each other on the plane, and a similar arrangement is used for the receiver. The two transmitters are powered with current of the same frequency shifted 90° out of phase, so that the resultant field rotates about the axis, as shown in Fig. 11 [58]. The two receiver signals are phase-shifted by 90° with respect to each other, and then the in-phase and quadrature differences at the two receivers are amplified and recorded by two different channels. Over a barren area, the outputs are set to zero. When the system is within a conducting zone, anomalies in the conductivity are indicated by nonzero outputs in both the in-phase and quadrature channels. The noise introduced by the fluctuation of orientation can be reduced by this scheme, but it is relatively expensive and the data interpretation is complicated by the complex coil system [58].

The fundamental problem of airborne EM systems is the difficulty in detecting the relatively small secondary

Figure 11. Working principle of the rotary field AEM system. (Redrawn from Ref. 50.)

field in the presence of a strong primary field. This difficulty can be alleviated by using the transient field method. A well-known system based on the transient field method is INPUT (induced pulsed transient) [59], which was designed by Barringer during the 1950s. In the INPUT system, a large horizontal transmitting coil is placed on the aircraft and a vertical receiving coil is towed in the bird with the axis aligned with the flight direction.

The working principle of INPUT is shown in Fig. 12 [60]. A half-sine wave with a duration of about 1.5 ms and quiet period of about 2.0 ms is generated as the primary field, as shown in Fig. 12a. If there are no conducting zones, the current in the receiver is induced only by the primary field, as shown in Fig. 12b. In the presence of conductive anomalies, the primary field will induce an eddy current. After the primary field is cut off, the eddy current decays exponentially. The duration of the eddy current is proportional to the conductivity anomalies, as shown in Fig. 12c. The higher the conductivity, the longer the duration time. The decay curve in the quiet period is sampled successively in time by six channels and then displayed on a strip, as shown in Fig. 13. As we can see,

Figure 12. Working principle of the INPUT system. (Redrawn from Ref. 52.)

Figure 13. Responses of different anomalies appearing on different channels. (Redrawn from Ref. 52.)

the distortion caused by a good conductor appears in all the channels, while the distortion corresponding to a poor conductor only registers on the early channels.

Since the secondary field can be measured more accurately in the absence of the primary field, transient systems provide greater investigation depths, which may reach 100 m under favorable conditions. In addition, they can also provide a direct indication of the type of conductor encountered [58].

On the other hand, this system design gives rise to other problems inherent in the transient method. Since the eddy current in the quiet period becomes very small, a more intense source has to be used in order to obtain the same signal level as that in the continuous-wave method. The circuitry for the transient system is much more complicated, and it is more difficult to reject the noise due to the wideband property of the transient signal.

ELECTROMAGNETIC SURFACE WAVES

ZHIPENG WU
UMIST
Manchester, United Kingdom

1. INTRODUCTION

In electromagnetic waves, the term “surface wave” has been used to describe the nonradiating electromagnetic waves propagating along the interface between two media [1,2]. It has also been used to describe the electromagnetic waves propagating along the air-ground interface produced by an antenna on or near the ground surface [3–10]. Both types of surface wave will be introduced in this article, and the “surface wave” is broadly defined as the wave propagating along an interface separating two media, or an interface between air and a layered structure. The surface waves considered include

1. The Zenneck surface wave
2. Surface wave on a conductor-backed dielectric slab
3. Radial cylindrical surface wave on a flat surface
4. Axial cylindrical surface wave
5. Surface wave on a dielectric-coated conducting cylinder
6. Norton and trapped surface waves on flat ground interface
7. Surface-wave propagation over an inhomogeneous flat surface
8. Surface-wave propagation over a spherical ground

The governing equations and properties of these surface waves are presented in the following section.

2. SURFACE WAVES

2.1. Zenneck Wave

The Zenneck wave is a solution of Maxwell's equations obtained by Zenneck in 1907 [11]. It is a plane wave that

travels along an interface between two dielectric media. Consider the air–dielectric interface with the established rectangular coordinates shown in Fig. 1. The properties of the dielectric medium (medium 1) is characterized by conductivity σ_1 , permeability μ_0 , and permittivity ε_1 . The vertically polarised Zenneck wave is also a transverse magnetic (TM) plane wave with zero magnetic field in the propagation direction, z . The field components of the Zenneck wave above the surface ($x \geq 0$) in air (medium 2) with permeability μ_0 and permittivity ε_0 , are given by

$$\begin{aligned} H_{y2} &= Ae^{-u_2x}e^{-\gamma z} \\ E_{z2} &= -A \frac{u_2}{j\omega\varepsilon_0} e^{-u_2x}e^{-\gamma z} \\ E_{x2} &= A \frac{\gamma}{j\omega\varepsilon_0} e^{-u_2x}e^{-\gamma z} \end{aligned} \quad (1)$$

where A is a constant, and u_2 and γ are the propagation constants in x and z directions, respectively. The electromagnetic field components below the surface ($x < 0$) are

$$\begin{aligned} H_{y1} &= Ae^{u_1x}e^{-\gamma z} \\ E_{z1} &= A \frac{u_1}{\sigma_1 + j\omega\varepsilon_1} e^{u_1x}e^{-\gamma z} \\ E_{x1} &= A \frac{\gamma}{\sigma_1 + j\omega\varepsilon_1} e^{u_1x}e^{-\gamma z} \end{aligned} \quad (2)$$

where u_1 is the propagation constant along the x direction in the dielectric medium. The propagation constants satisfy the following equations

$$\begin{aligned} \gamma^2 + u_2^2 &= -\omega^2\mu_0\varepsilon_0 \\ \gamma^2 + u_1^2 &= j\omega\mu_0(\sigma_1 + j\omega\varepsilon_1) \\ \frac{u_1}{(\sigma_1 + j\omega\varepsilon_1)} &= -\frac{u_2}{j\omega\varepsilon_0} \end{aligned} \quad (3)$$

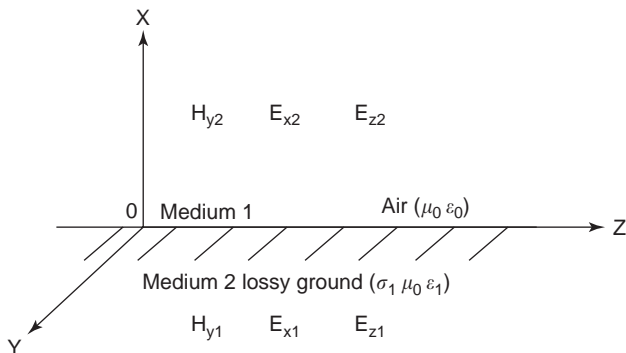

Figure 1. Zenneck wave on a planar surface separating two dielectric media.

where ω is the angular frequency of the electromagnetic wave. Solving these equations gives

$$\begin{aligned} u_1 = a_1 + jb_1 &= \frac{j\omega\mu_0(\sigma_1 + j\omega\varepsilon_1)}{\sqrt{j\omega\mu_0(\sigma_1 + j\omega\varepsilon_1) - \omega^2\mu_0\varepsilon_0}} \\ u_2 = a_2 - jb_2 &= \frac{\omega^2\mu_0\varepsilon_0}{\sqrt{j\omega\mu_0(\sigma_1 + j\omega\varepsilon_1) - \omega^2\mu_0\varepsilon_0}} \\ \gamma = \alpha + j\beta &= \sqrt{\frac{-j\omega\mu_0(\sigma_1 + j\omega\varepsilon_1)\omega^2\mu_0\varepsilon_0}{j\omega\mu_0(\sigma_1 + j\omega\varepsilon_1) - \omega^2\mu_0\varepsilon_0}} \end{aligned} \quad (4)$$

The Zenneck wave propagates along the surface and in the direction normal to the surface with two different propagation constants. The wave attenuates in both directions, particularly in the direction normal to the surface. For example, the attenuation constants a_2 , a_1 , and α of a surface wave at 300 MHz propagating over a dry ground of $\sigma_1 = 4$ and $\varepsilon_1 = 4\varepsilon_0$ are 0.167, 1.008, and 0.083 Np/m [nepers (napiers) per meter], respectively. The equal-amplitude contour of the H_y component above and below the dry ground surface with $A = 1$ is shown in Fig. 2 over the range $-5 \text{ m} < x < 5 \text{ m}$ and $0 < z < 20 \text{ m}$. The field attenuates more rapidly inside the ground. The surface wave above the surface has less attenuation. The phase velocity of the Zenneck wave is greater than the speed of light. Hence, the Zenneck surface wave is a fast wave.

On the surface, the ratio of the tangential electric field and magnetic field gives the surface impedance [1,2]:

$$Z_s = R_s + jX_s = \frac{E_{z2}(x=0)}{H_{y2}(x=0)} \quad (5)$$

Figure 2. Contour plot of the $|H_y|$ component of the Zenneck wave above and below a dry ground of $\sigma_1 = 4$ and $\varepsilon_1 = 4\varepsilon_0$ with $A = 1$ in range $-5 \text{ m} < x < 5 \text{ m}$ and $0 < z < 20 \text{ m}$.

The surface impedance and u_2 are related by

$$Z_s = R_s + jX_s = -\frac{u_2}{j\omega\epsilon_0} = \frac{1}{\omega\epsilon_0} (b_2 + ja_2) \quad (6)$$

Hence, the attenuation constant of the surface wave along the x direction above the surface is determined by the surface reactance, and the phase constant by the surface resistance as

$$a_2 = \omega\epsilon_0 X_s; \quad b_2 = \omega\epsilon_0 R_s \quad (7)$$

In order to support a Zenneck surface wave, the dielectric medium has to be lossy so that $a_2 > 0$, which is a feature of a Zenneck wave.

2.2. Surface Wave on a Conductor-Backed Dielectric Slab

A conductor-backed dielectric slab structure, as shown in Fig. 3, is a typical example of multilayered structures. This structure is commonly used in microwave printed circuits. For simplicity, the conductor is treated as a “perfect” conductor, and the dielectric of thickness d is assumed to be lossless with a real permittivity ϵ_1 , or a relative dielectric constant ϵ_r . With these assumptions, a surface wave can propagate along the surface with

$$\gamma = j\beta; \quad u_1 = jk_x; \quad u_2 = h \quad (8)$$

For a TM surface wave, the solutions of the field components above the dielectric surface ($x \geq d$) are [12,13]

$$\begin{aligned} H_{y2} &= \frac{j\omega\epsilon_0}{h} A \sin(k_x d) e^{-h(x-d)} e^{-j\beta z} \\ E_{x2} &= -\frac{j\beta}{h} A \sin(k_x d) e^{-h(x-d)} e^{-j\beta z} \\ E_{z2} &= A \sin(k_x d) e^{-h(x-d)} e^{-j\beta z} \end{aligned} \quad (9)$$

where A is a constant, and the fields in the dielectric slab are

$$\begin{aligned} H_{y1} &= -\frac{j\omega\epsilon_1}{k_x} A \cos(k_x x) e^{-j\beta z} \\ E_{x1} &= -\frac{j\beta}{k_x} A \cos(k_x x) e^{-j\beta z} \\ E_{z1} &= A \sin(k_x x) e^{-j\beta z} \end{aligned} \quad (10)$$

Figure 3. Surface wave on a conductor-backed dielectric slab.

The propagation constants satisfy the following equations

$$\begin{aligned} -h^2 + \beta^2 &= k_0^2 = \omega^2 \mu_0 \epsilon_0 \\ k_x^2 + \beta^2 &= \epsilon_r k_0^2 \end{aligned} \quad (11)$$

where k_0 is the wavenumber in air and k_x and h are related by the transcendental equation

$$k_x \tan(k_x d) = \epsilon_r h \quad (12)$$

with

$$k_x^2 + h^2 = (\epsilon_r - 1)k_0^2 \quad (13)$$

There exists a sequence of solutions of k_x and h , which give rise to a set of TM_n modes. The n th mode, where $n = 0, 1, 2, \dots$, has a cutoff frequency of

$$f_{c, TM_n} = \frac{nc}{2d\sqrt{\epsilon_r - 1}} \quad (14)$$

Similarly, for a transverse electric (TE) surface wave, the field components above the dielectric surface ($x \geq d$) are [12]

$$\begin{aligned} E_{y2} &= \frac{j\omega\mu_0}{h} A \cos(k_x d) e^{-h(x-d)} e^{-j\beta z} \\ H_{x2} &= -\frac{j\beta}{h} A \cos(k_x d) e^{-h(x-d)} e^{-j\beta z} \\ H_{z2} &= A \cos(k_x d) e^{-h(x-d)} e^{-j\beta z} \end{aligned} \quad (15)$$

where A is a constant, and the fields in the dielectric slab are

$$\begin{aligned} E_{y1} &= -\frac{j\omega\mu_0}{k_x} A \sin(k_x x) e^{-j\beta z} \\ H_{x1} &= \frac{j\beta}{k_x} A \sin(k_x x) e^{-j\beta z} \\ H_{z1} &= A \cos(k_x x) e^{-j\beta z} \end{aligned} \quad (16)$$

The propagation constants also satisfy Eq. (11), but k_x and h are related by the transcendental equation

$$k_x \cot(k_x d) = -h \quad (17)$$

with

$$k_x^2 + h^2 = (\epsilon_r - 1)k_0^2 \quad (18)$$

There exists, again, a sequence of solutions of k_x and h , which give rise to a set of TE_n modes. The n th mode, where $n = 1, 2, \dots$, has a cutoff frequency of

$$f_{c, TE_n} = \frac{(2n - 1)c}{4d\sqrt{\epsilon_r - 1}} \quad (19)$$

Hence, the surface wave may propagate above the dielectric slab in a sequence of $TM_0, TE_1, TM_1, TE_1, \dots$ modes if the frequency of the wave is greater than their cutoff frequencies. The phase velocities of these modes are less than the speed of light. Hence, the surface wave on a conductor-backed dielectric slab is a slow wave.

For example, a surface wave of 10 GHz on a microwave printed circuit board of $\epsilon_r = 4.4$ and $d = 0.6$ mm can propagate in TM_0 mode as the cutoff frequency of the next mode is 67.8 GHz. The k_x and h values of the mode are 385.6 rad/m and 20.6 Np/m, respectively. The surface wave attenuates slowly along the x axis at a rate of 0.0124 Np per slab thickness or 0.6 mm. The electromagnetic fields are not confined within the dielectric slab, as shown in Fig. 4 for the plot of the equal-amplitude contour of the H_y component with $A = 1000$ over the range $0 < x < 20d$ and $0 < z < 20d$. However, at 50 GHz, the fields are more confined within the dielectric slab with $k_x = 1783$ rad/m and $h = 740.5$ Np/m or 0.444 Np per slab thickness. The equal-amplitude contour plot of the H_y component with $A = 1000$ over the range $0 < x < 3d$ and $0 < z < 20d$ is shown in Fig. 5. The fields of the surface wave attenuate more rapidly as the frequency approaches the cutoff frequency of TE_1 mode.

2.3. Radial Cylindrical Surface Wave on a Flat Surface

The Zenneck wave in Section 2.1 is a plane surface wave on a flat surface with fields in $x, y,$ and z directions. A similar radial cylindrical surface wave can be set up on a flat surface with propagation and attenuation in r and x directions, as shown in Fig. 6. The electromagnetic fields

Figure 4. Contour plot of the $|H_y|$ component of the surface wave at 10 GHz above and inside the dielectric slab of $\epsilon_r = 4.4$ and $d = 0.6$ mm with $A = 1000$ in the range $0 < (x/d) < 20$ and $0 < (z/d) < 20$.

Figure 5. Contour plot of the $|H_y|$ component of the surface wave at 50 GHz above and inside the dielectric slab of $\epsilon_r = 4.4$ and $d = 0.6$ mm with $A = 1000$ in the range $0 < (x/d) < 3$ and $0 < (z/d) < 20$.

above the surface ($x \geq 0$) are [1]

$$\begin{aligned}
 H_{\phi 2} &= A e^{-u_2 x} H_1^{(2)}(-j\gamma r) \\
 E_{r 2} &= A \frac{u_2}{j\omega\epsilon_0} e^{-u_2 x} H_1^{(2)}(-j\gamma r) \\
 E_{x 2} &= A \frac{\gamma}{\omega\epsilon_0} e^{-u_2 x} H_0^{(2)}(-j\gamma r)
 \end{aligned} \tag{20}$$

where A is a constant, and $H_0^{(2)}$ and $H_1^{(2)}$ are the Hankel functions of the second kind and orders 0 and 1,

Figure 6. Planar surface with radial cylindrical surface wave.

respectively. The fields in the dielectric medium are

$$\begin{aligned} H_{\phi 1} &= Ae^{u_1 x} H_1^{(2)}(-j\gamma r) \\ E_{r1} &= -A \frac{u_1}{\sigma_1 + j\omega\epsilon_1} e^{u_1 x} H_1^{(2)}(-j\gamma r) \\ E_{x1} &= A \frac{j\gamma}{\sigma_1 + j\omega\epsilon_1} e^{u_1 x} H_0^{(2)}(-j\gamma r) \end{aligned} \tag{21}$$

where the propagation constants are determined in the same way as the Zenneck wave. For large r , we obtain

$$H_n^{(2)}(-j\gamma r) \Rightarrow \frac{e^{-\gamma r}}{\sqrt{r}} \tag{22}$$

Hence, the radial surface wave is a cylindrical wave with electric and magnetic fields proportional to $r^{-(1/2)}$ at large distances. The radial cylindrical surface wave is also a fast wave with phase velocity greater than the speed of light.

2.4. Axial Cylindrical Surface Wave

The axial cylindrical surface wave is also called the Sommerfeld–Goubau surface wave [1]. For a cylindrical dielectric structure, as shown in Fig. 7, with the radius a , conductivity σ_1 , permeability μ_0 and permittivity ϵ_1 , an axial surface wave may propagate along the air–dielectric interface in the z direction. The surface-wave fields of a TM wave outside the surface ($r \geq a$) are [1,7]

$$\begin{aligned} H_{\theta 2} &= A \frac{\omega\epsilon_0}{u_2} e^{-\gamma z} H_1^{(1)}(ju_2 r) \\ E_{z2} &= Ae^{-\gamma z} H_0^{(1)}(ju_2 r) \\ E_{r2} &= A \frac{\gamma}{ju_2} e^{-\gamma z} H_1^{(1)}(ju_2 r) \end{aligned} \tag{23}$$

where A is a constant and $H_0^{(1)}$ and $H_1^{(1)}$ are the Hankel functions of the first kind and orders 0 and 1, respectively.

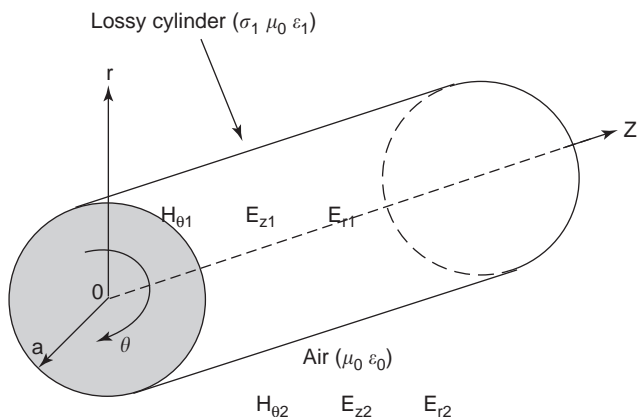

Figure 7. Cylindrical dielectric structure supporting axial cylindrical surface wave.

The fields in the dielectric cylinder are

$$\begin{aligned} H_{\theta 1} &= -A \frac{\sigma_1 + j\omega\epsilon_1}{ju_1} e^{-\gamma z} J_1(ju_1 r) \\ E_{z1} &= Ae^{-\gamma z} J_0(ju_1 r) \\ E_{r1} &= A \frac{\gamma}{ju_1} e^{-\gamma z} J_1(ju_1 r) \end{aligned} \tag{24}$$

where J_0 and J_1 are Bessel functions of the first kind, orders 0 and 1, respectively, and the propagation constants are determined in the same way as the Zenneck wave. The surface impedance of the axial cylindrical surface wave is

$$Z_s = \frac{u_2}{\omega\epsilon_0} \frac{H_0^{(1)}(ju_2 a)}{H_1^{(1)}(ju_2 a)} \tag{25}$$

For a large cylinder in which $u_2 a \gg 1$, the surface impedance can be approximated as

$$Z_s \approx \frac{u_2}{j\omega\epsilon_0} \tag{26}$$

which is the same as that of the Zenneck wave for a flat surface. Hence, for large cylinders, the axial cylindrical surface wave has propagation characteristics similar to those of the Zenneck wave on a flat surface. However, for small cylinders, the axial cylindrical surface wave may have characteristics different from those of the Zenneck wave [1].

2.5. Surface Wave on a Dielectric Coated Conducting Cylinder

Like the conductor-backed dielectric slab structure described in Section 2.2, a dielectric-coated conducting cylinder or wire as shown in Fig. 8 can support a surface wave [13]. The conductor of radius a is treated as a perfect conductor. The dielectric layer of thickness d is assumed to be lossless with a real permittivity ϵ_1 , or a relative dielectric constant ϵ_r . The propagation constants, γ in the

Figure 8. Dielectric-coated conducting cylinder.

z direction and u_1 and u_2 in the r direction in the dielectric layer and air medium, can be expressed as

$$\gamma = j\beta; \quad u_1 = jk_r; \quad u_2 = h \quad (27)$$

For a TM surface wave, the field components outside the dielectric surface [$r \geq (a + d)$] are

$$\begin{aligned} E_{z2} &= \frac{A}{K_0(hb)} \left[J_0(k_rb) - \frac{J_0(k_ra)}{Y_0(k_ra)} Y_0(k_rb) \right] K_0(hr) e^{-j\beta z} \\ E_{r2} &= \frac{j\beta A}{hK_0(hb)} \left[J_0(k_rb) - \frac{J_0(k_ra)}{Y_0(k_ra)} Y_0(k_rb) \right] K'_0(hr) e^{-j\beta z} \\ H_{\phi 2} &= \frac{k_0}{\beta Z_0} E_{r2} \end{aligned} \quad (28)$$

where A is a constant; $b = a + d$, Y_0 and Y_1 are the Bessel functions of the second kind, orders 0 and 1, respectively; and K_0 is the modified Bessel function of the second kind and order 0. The field components in the dielectric coating layer are

$$\begin{aligned} E_{z1} &= A \left[J_0(k_rr) - \frac{J_0(k_ra)}{Y_0(k_ra)} Y_0(k_rr) \right] e^{-j\beta z} \\ E_{r1} &= -\frac{j\beta}{k_r} A \left[J'_0(k_rr) - \frac{J_0(k_ra)}{Y_0(k_ra)} Y'_0(k_rr) \right] e^{-j\beta z} \\ H_{\phi 1} &= \frac{\varepsilon_r k_0}{\beta Z_0} E_{r1} \end{aligned} \quad (29)$$

where A is a constant, and

$$\begin{aligned} -h^2 + \beta^2 &= k_0^2 = \omega^2 \mu_0 \varepsilon_0 \\ k_r^2 + \beta^2 &= \varepsilon_r k_0^2 \end{aligned} \quad (30)$$

The parameters k_x and h are the solutions of the transcendental equation

$$\frac{K'_0(hb)}{K_0(hb)} = -\frac{\varepsilon_r h J'_0(k_rb) Y_0(k_ra) - Y'_0(k_rb) J_0(k_ra)}{k_r J_0(k_rb) Y_0(k_ra) - Y_0(k_rb) J_0(k_ra)} \quad (31)$$

with

$$k_r^2 + h^2 = (\varepsilon_r - 1) k_0^2 \quad (32)$$

There exists a sequence of solutions of k_x and h , corresponding to TM_n modes where $n = 0, 1, 2, \dots$. The cutoff frequency of the TM_0 mode is 0.

Similarly, for a TE surface wave, the field components outside the dielectric surface ($x \geq d$) are

$$\begin{aligned} H_{z2} &= \frac{A}{K_0(hb)} \left[J_0(k_rb) - \frac{J'_0(k_ra)}{Y'_0(k_ra)} Y_0(k_rb) \right] K_0(hr) e^{-j\beta z} \\ H_{r2} &= \frac{j\beta A}{hK_0(hb)} \left[J_0(k_rb) - \frac{J'_0(k_ra)}{Y'_0(k_ra)} Y_0(k_rb) \right] K'_0(hr) e^{-j\beta z} \\ E_{\phi 2} &= -\frac{k_0 Z_0}{\beta} H_{r2} \end{aligned} \quad (33)$$

and those inside the dielectric layer are

$$\begin{aligned} H_{z1} &= A \left[J_0(k_rr) - \frac{J'_0(k_ra)}{Y'_0(k_ra)} Y_0(k_rr) \right] e^{-j\beta z} \\ H_{r1} &= -\frac{j\beta}{k_r} A \left[J'_0(k_rr) - \frac{J'_0(k_ra)}{Y'_0(k_ra)} Y'_0(k_rr) \right] e^{-j\beta z} \\ E_{\phi 1} &= -\frac{\varepsilon_r k_0 Z_0}{\beta} H_{r1} \end{aligned} \quad (34)$$

The parameters k_x and h of the TE wave are the solutions of the following transcendental equation

$$\frac{K'_0(hb)}{K_0(hb)} = -\frac{\varepsilon_r h J'_0(k_rb) Y'_0(k_ra) - Y'_0(k_rb) J'_0(k_ra)}{k_r J_0(k_rb) Y'_0(k_ra) - Y_0(k_rb) J'_0(k_ra)} \quad (35)$$

There exists again a sequence of solutions of k_x and h , which give rise to a set of TE_n modes, such as that in a conductor-backed dielectric slab. As an approximation, the cutoff frequencies of the TE_n and TM_n modes can be estimated using the same formulas as those for the conductor-backed dielectric slabs.

For example, a surface wave of 50 GHz on a dielectric-coated cylinder with $d = 0.6$ mm, $\varepsilon_r = 4.4$, and $a = 10$ mm can propagate in TM_0 mode with $k_r = 1762$ rad/m and $h = 789.4$ Np/m or 0.473 Np per dielectric thickness. The equal-amplitude contour plot of the H_ϕ component with $A = 1000$ over the range $0 < r < 3d$ and $0 < z < 20d$ is shown in Fig. 9. The fields of the surface wave attenuate rapidly with the increase of radial distance r at this frequency. The plot is very similar to that for a conductor-backed dielectric slab shown in Fig. 5.

2.6. Norton and Trapped Surface Waves on Flat Ground Interface

When a short antenna radiates at a point above the ground surface of Earth, the general solution of electromagnetic fields in air consists of both "space wave" and "surface wave" [7–10]. The properties of the ground can be characterized either by conductivity σ_1 , permeability μ_0 , and permittivity ε_1 for a homogenous ground, or by the surface impedance Z_s , or the normalized surface impedance $\Lambda_s = Z_s/Z_0 = \text{constant } \Delta_0$, where $Z_0 = 120\pi$ for loaded ground, corrugated ground [2], and multilayered structures [7,9]. The surface impedance can be obtained by

Figure 9. Contour plot of the $|H_\phi|$ component of the surface wave at 50 GHz above and inside the dielectric coating layer of $\epsilon_r = 4.4$ and $d = 0.6$ mm on a conducting cylinder of radius 10 mm with $A = 1000$ in the range $0 < (r/d) < 3$ and $0 < (z/d) < 20$.

considering a plane-wave incidence onto the ground surface.

The historical development of the solution to such a radiation problem has not been straightforward since the

Highly Capacitive	Capacitive	Inductive (Normal Ground)	Highly Inductive
$-\pi/2 \leq \arg(Z_s) < -\pi/4$	$-\pi/4 \leq \arg(Z_s) < 0$	$0 \leq \arg(Z_s) < \pi/4$	$\pi/4 \leq \arg(Z_s) \leq \pi/2$
$-3\pi/2 \leq \phi_w < -\pi$	$-\pi \leq \phi_w < -\pi/2$	$-\pi/2 \leq \phi_w < 0$	$0 \leq \phi_w \leq \pi/2$

work of Sommerfeld in 1909 [1,5,7,14–17]. But the subject is now well understood [10,17], and the electromagnetic wave propagation over the ground surface can be accurately predicted [18]. The “surface wave” in the solution dominates when the antenna is on or close to the ground surface. For simplicity, the short antenna is considered to be on the ground surface as shown in Fig. 10. In this case,

Figure 10. Short antenna radiation on a homogeneous flat ground surface.

the “space wave” component vanishes. The short antenna is further considered to be vertically orientated so that it produces a TM wave with a vertical electric field component [7–10]

$$E_z = A \frac{e^{-jk_0 R_0}}{R_0} F(w) \tag{36}$$

where A is a constant, k_0 is the wavenumber in free space, R_0 is the distance from the antenna to the receiving point B at height z , and $F(w)$ is the Sommerfeld attenuation function given by

$$F(w) = 1 - j(\pi w)^{1/2} e^{-w} \operatorname{erfc}(jw^{1/2}) \tag{37}$$

with the numerical distance

$$w = -\frac{jk_0 R_0}{2} \Delta_s^2 \left(1 + \frac{z}{\Delta_s R_0}\right)^2 = |w| e^{j\phi_w} \tag{38}$$

and the complementary error function,

$$\operatorname{erfc}(jw^{1/2}) = \frac{2}{\sqrt{\pi}} \int_{jw^{1/2}}^{\infty} e^{-u^2} du \tag{39}$$

The modulus of the numerical distance $|w|$ is proportional to the physical distance R_0 and $|Z_s|^2$. Its argument is related to the argument of Z_s as listed below for different types of ground [8]:

For the range $0 \leq \operatorname{Re}(w) \leq 2.4$ and $-1 \leq \operatorname{Im}(w) \leq 3$, the equal-amplitude contour plots of $F(w)$ in dB and $\arg(F(w))$ in degrees are shown in Fig. 11. Both $|F(w)|$ and $\arg(F(w))$ have smooth variations when $\phi_w < 0$. However, when $\phi_w < 0$, several dips appear in the vicinity of those w values that make $|F(w)|$ small or zero. The amplitudes of $|F(w)|$ in dB are again shown in Fig. 12 for $10^{-2} \leq |w| \leq 10^3$ and $-90^\circ \leq \phi_w \leq 80^\circ$. The variation of $|F(w)|$ is now examined in terms of series expansion for large values of $|w|$.

For $-2\pi \leq \phi_w \leq 0$, or highly capacitive, capacitive, and inductive ground surfaces, the Sommerfeld attenuation function for large $|w|$ can be expanded to

$$F(w) = -\frac{1}{2w} - \frac{1.3}{(2w)^2} - \frac{1.3 \cdot 5}{(2w)^3} - \frac{1.3 \cdot 5 \cdot 7}{(2w)^4} - \dots \tag{40}$$

$$= F_{\text{Norton}}(w)$$

The wave associated with the attenuation function given in this series $[F_{\text{Norton}}(w)]$ is referred to as the *Norton surface wave* [7–10]. The Norton surface wave or its field

components decay as the inverse square of the distance. However, for $0 \leq \phi_w \leq \pi/2$ or a highly inductive surface, $F(w)$ has a different expansion for large $|w|$

$$F(w) = F_{\text{trapped}}(w) + F_{\text{Norton}}(w) \tag{41}$$

where

$$F_{\text{trapped}}(w) = -2j(\pi w)^{1/2}e^{-w} \tag{42}$$

An additional term [$F_{\text{trapped}}(w)$] has appeared in the series. This term dominates at short distances, but it attenuates exponentially as the distance increases. $F_{\text{trapped}}(w)$ has a maximum modulus value at $|w| = 0.5 \cos(\phi_w)$. The wave associated with this additional term of attenuation function is referred to as the *trapped surface wave* [7–10]. The dips in Fig. 11 are therefore the result of interference between the trapped and Norton surface waves. Unlike the Norton surface wave, the trapped wave or its field components decay inversely with the product of the square root of the distance and the exponential of this distance. A highly inductive surface impedance can be obtained by loading a metal surface with a thin dielectric

Figure 11. $|F(w)|$ and $\arg(F(w))$ contour plots for $0 \leq \text{Re}(w) \leq 2.4$ and $-1 \leq \text{Im}(w) \leq 3$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 12. Amplitudes of $|F(w)|$ in dB for $10^{-2} \leq |w| \leq 10^3$ and $-90^\circ \leq \phi_w \leq 80^\circ$.

layer or by corrugating a metal surface [2]. Such surfaces can therefore support a trapped surface wave.

For a normal dry ground with $\sigma_1 = 0.01$ and $\epsilon_r = 4$, the predicted electric field E_z of the surface wave at 10 MHz on the ground surface with transmitted power of 1 kW and antenna gain $G_t = 1$ using the software package in described in Ref. 18 is shown in Fig. 13 over a horizontal distance of 1–60 km. The amplitude of the electric field attenuates monotonically against the distance for the homogeneous (inductive) ground. The surface wave is thus a Norton surface wave. For comparison, a prediction of the electric field E_z of the surface wave over a highly inductive ground with $\Delta_0 = 0.01 + j0.09$ at the same frequency with the same transmitted power and antenna gain is shown in Fig. 14. It can be seen that $|E_z|$ does not decrease monotonically, but varies against distance as a result of the interference of Norton and trapped surface waves. Comparison between Figs. 13 and 14 shows that the surface wave on the ground surface is much stronger when the surface impedance is highly inductive.

The surface wave on the ground surface has a height gain factor when the receiving point is considered to move from the ground surface to a height z . The height gain

Figure 13. Prediction of surface-wave propagation at 10 MHz over a dry flat ground surface with $\sigma_1 = 0.01$ and $\epsilon_r = 4$: $|E_z|$ in dB versus horizontal distance.

Figure 14. Prediction of surface-wave propagation at 10 MHz over a highly inductive ground surface with $\Delta_0 = 0.01 + j0.09$: $|E_z|$ in dB versus horizontal distance.

factor is given by

$$G = 1 + jk_0 \Delta_0 z \tag{43}$$

For a highly capacitive or capacitive ground, the electric field tends to increase when the receiving point is raised. On the other hand, for a normal homogeneous ground or a highly inductive ground, the electric field tends to decrease as the receiving height is increased.

2.7. Surface Wave Propagation over an Inhomogeneous Flat Surface

If the flat ground surface is inhomogeneous along the path of propagation as shown in Fig. 15, the normalised surface impedance Δ_s will not be a constant, but a function of position. For the TM wave considered in Section 2.6 with the antenna on the ground surface, the Sommerfeld attenuation function in Eq. (36) has to be replaced by an attenuation factor $F(d)$, where d is the distance to the antenna, which takes into account the effect of boundary discontinuities along the propagation path. The vertical electric field on the inhomogeneous ground surface then becomes [7,9,10]

$$E_z = A \frac{e^{-jk_0 R_0}}{R_0} F(d) \tag{44}$$

Figure 15. Short antenna radiation on an inhomogeneous flat ground surface.

The attenuation factor is given by the integral equation

$$F(d) = 1 - \left(\frac{jk_0 d}{2\pi} \right)^{1/2} \int_0^d \Delta_s(y) F(y) \frac{dy}{[y(d-y)]^{1/2}} \tag{45}$$

where y is the distance from a point on the propagation path to the antenna. The integral equation can be solved numerically [10]. $F(d)$ can also be expressed in other forms of the integral equation, or in closed forms for special cases [10]. The propagation of the surface wave along the inhomogeneous path can thus be predicted.

Figure 16 shows an example prediction of the surface-wave propagation along a land-sea-land-sea-land mixed path over a range of 30 km using the software package in described in Ref. 18. The surface wave has a frequency of 10 MHz. Each mixed-path section has a length of 6 km. The electrical properties of the land are $\sigma = 0.01$ and $\epsilon_r = 4$, and those of the sea are $\sigma = 4$ and $\epsilon_r = 80$. The well-known “sea gain” phenomenon in ground-wave propagation can be seen from the prediction.

2.8. Surface-Wave Propagation over a Spherical Ground

If the curvature of Earth’s surface is taken into consideration, the surface wave guided along the curvature of Earth as shown in Fig. 17 can also be modeled [7,10,19–26]. For the TM wave considered in Section 2.6 with the antenna and the receiving points both on the ground surface, the electric field normal to the surface of the spherical Earth model with radius a at angle θ away from the antenna at $\theta = 0$ can be expressed as

$$E_r(\theta) = A \frac{e^{-jk_0 a \theta}}{a \theta} F(\theta) \tag{46}$$

where $F(\theta)$ is the attenuation factor given by the residue series [7,10]

$$F(\theta) = e^{-j(\pi/4)} (\pi x_0)^{1/2} \sum_{s=1}^{\infty} \frac{e^{-jx_s \theta}}{t_s} \tag{47}$$

Figure 16. Prediction of surface-wave propagation at 10 MHz over a land-sea-land-sea-land mixed path: $|E_z|$ in dB versus horizontal distance.

Figure 17. Short antenna radiation on a homogeneous spherical ground surface.

In the equation above, the electrical distance x_θ is defined as

$$x_\theta = \left(\frac{k_0 a}{2} \right)^{1/3} \theta \quad (48)$$

and t_s ($s = 1, 2, \dots$) are given by

$$t_s = |t_s| e^{-j\pi/3} \quad (49)$$

with

$$\begin{aligned} |t_1| &= 1.01879, & |t_2| &= 3.24820, & |t_3| &= 4.82010, \\ |t_4| &= 6.16331, & |t_5| &= 7.37218 \end{aligned} \quad (50)$$

and

$$|t_s| = [1.5(s - 0.75)\pi]^{2/3} \quad (51)$$

for $s > 5$. The correction due to the effect of Earth's curvature becomes necessary if the distance from the receiving point to the antenna is greater than $5 \times 10^3 (\lambda_0)^{1/3}$ or $10^4 (\lambda_0)^{1/3}$ meters [24].

Figure 18 shows an example prediction of the surface-wave propagation along the surface of a spherical Earth with $\sigma = 0.01$ and $\epsilon_r = 4$ at 10 MHz over a range of 1–500 km. The electric field normal to the surface attenuates at 26 dB per 100 km, as the surface wave is guided along the curvature of the spherical Earth, compared with 6 dB per 100 km for a flat Earth model shown in Figs. 18 and 19. Earth's curvature therefore causes the surface wave to attenuate more quickly as it propagates.

Figure 18. Prediction of surface-wave propagation at 10 MHz over a dry spherical ground surface with $\sigma_1 = 0.01$ and $\epsilon_r = 4$: $|E_z|$ in dB versus arc distance.

3. DISCUSSIONS

In this article, the “surface waves” guided along an interface between two media, or an interface between air and a multilayered structure in planar, cylindrical, and spherical geometries have been introduced. Several examples have been used to illustrate the propagation of surface waves in these geometric structures. In some cases, only TM surface waves are considered, but TE waves can be treated in a similar way. For propagation over a flat or spherical Earth, TE Norton surface waves tend to attenuate much more rapidly than do TM waves. Details of the formulation of both TM and TE waves over flat, spherical, homogeneous, and inhomogeneous ground can be found in Ref. 10, and the prediction of such propagation can be made using the software package described in Ref. 18.

The propagation of radio surface waves along Earth's surface can be utilized for long-distance wireless communications and remote sensing. On the other hand, the surface waves on microwave printed circuits and microstrip antenna systems should be avoided to minimize the electromagnetic coupling between circuit elements, or power loss in the systems. The understanding and control of surface waves are thus important in radio systems.

Figure 19. Prediction of surface-wave propagation at 10 MHz; the same path as Fig. 18, but without curvature correction.

1. INTRODUCTION

1.1. Historical Perspective

Electromagnetic waves play a major role in remote sensing and communication systems. The equations governing electromagnetic wave propagation were first established by J. C. Maxwell (1831–1879) in 1864. However, one should not overlook previous contributions of many scientists over the centuries, especially in optics. Speculations regarding the nature of light date since ancient Greece, when philosophers were already acquainted with the rectilinear propagation, reflection, and refraction of light [1]. The major contributions to the field, however, initiated during the Renaissance, on the foundations of the experimental method introduced by Galileo (1564–1642). Some examples are the law of refraction discovered by Snell (1580–1626) in 1621, the principle of least time established by Fermat (1601–1665) in 1657, the observation of light diffraction by Grimaldi (1618–1663) and Hooke (1635–1703) circa 1665, and Huygen's (1629–1695) envelope construction (leading to the principle named after him) in 1678 [1]. Such observations and experiments lead to the development of a wave theory to explain the nature of light as luminous sources vibrating in adjacent portions of an ethereal medium, an interpretation similar to that of acoustic waves. The wave theory of light was, however, later rejected by Newton (1642–1727), who proposed a corpuscular interpretation instead [1].

Many years passed until new experiments reinforced the wave theory of light. Among the leading scientists responsible for that is Fresnel (1788–1827), who developed the theory of light reflection and refraction in a more quantitative way and as well as a firmer mathematical basis for the interpretation of light as a transverse wave. Fresnel's work temporarily obscured the corpuscular theory of light, which regained strength only after Planck (1858–1947) and Einstein (1879–1955) started to unveil the quantum aspects of light in the beginning of the 1900s. The nineteenth century also witnessed the efforts of many

physicists to experimentally determine the speed of light, such as Michelson (1852–1931).

Apart from the developments in optics, many scientists dedicated efforts to establish the physical nature of magnetism and electricity. Among them, it is worth mentioning Coulomb (1736–1806), who demonstrated the inverse square law for electrical forces in 1785; Oersted (1777–1851), who was perhaps the first to observe experimentally the effect of electrical currents on the magnetic field in 1820; and Ampère (1775–1836), who formulated the circuit force law and postulated magnetism as an electrical phenomenon. The milestone experiment for the unification of magnetism and electricity, however, was carried out by Faraday (1791–1867), who discovered electromagnetic induction in 1831. The electromagnetic theory known at that time was put on analytical ground by Maxwell (1831–1879) in 1855/56. He further developed a model to explain electromagnetics as a mechanical phenomenon, which lead into the concept of displacement currents and the consequent generalization of Ampère’s law in 1861. The mechanical model was finally abandoned and Maxwell, in 1864, published his third paper on the subject, establishing the basis of the electromagnetic theory [2]. Besides postulating the displacement current, Maxwell was the first to predict the propagation of electromagnetic waves and to postulate light itself as an electromagnetic radiation. This provoked strong opposition from scientists at that time, as no evidence of such waves had been observed by experiments.

Maxwell did not survive to see his ideas been accepted by the majority of the scientists, which came just after the first experimental observation of electromagnetic wave propagation by Hertz, published in 1888. After that, the use of electromagnetic waves for practical purposes was just a matter of time, and in 1901 Marconi (1874–1937) achieved the first transmission of radio signals across the Atlantic. Today, electromagnetic waves permeate most of modern technologies.

In this article, we will briefly discuss some fundamental aspects of the electromagnetic wave propagation. Further details on this vast subject can be found in several books, such as Refs. 1 and 3–11.

1.2. The Electromagnetic Wave Spectrum

Electromagnetic waves can propagate at different frequencies. It is common to classify electromagnetic waves according to their frequency range as 3–30 Hz, ELF (extra-low-frequency or extremely-LF) waves; 30–300 Hz, SLF (super-low-frequency) waves; 300 Hz–3 kHz, ULF (ultra-low-frequency) waves; 3–30 kHz, VLF (very-low-frequency) waves; 30–300 kHz, LF (low-frequency or long) waves; 300 kHz–3 MHz, MF (medium-frequency or medium) waves, which include most AM radiowaves; 3–30 MHz, HF (high-frequency or short) waves, which include most of shortwave radio; 30–300 MHz, VHF waves, which include FM radio and TV signals; 300 MHz–3 GHz, UHF waves, which include TV signals, radar waves at L and S bands, and microwave oven radiation; 3–30 GHz, SHF (centimeter) waves, which include radars at C, X, Ku,

and K bands, satellite communication links, and aircraft landing systems; and 30–300 GHz, EHF (millimeter) waves, which include radars at Ka band.

Electromagnetic waves can also be classified by their wavelength. For an electromagnetic wave propagating in air or vacuum, the wavelength λ and frequency f are related by $\lambda = c/f$, where $c \approx 3 \times 10^8$ m/s is the speed of light in vacuum. Microwaves correspond to electromagnetic waves with λ around 1 cm–1 m (300 MHz–30 GHz). Millimeter and submillimeter waves have λ around 1 mm–1 cm (30–300 GHz) and just below it, respectively. Visible light is a form of electromagnetic wave with $\lambda = 0.38$ – $0.72 \mu\text{m}$. Wavelengths just below visible light correspond to ultraviolet waves, while wavelengths just above visible light correspond to near-infrared waves (0.72–1.3 μm) and thermal infrared waves (7–15 μm). At even smaller wavelengths (higher frequencies) one encounters X and gamma rays [10].

2. MAXWELL’S EQUATIONS AND THE WAVE EQUATION

The propagation of electromagnetic waves is governed by Maxwell’s equations, which in SI units and for macroscopic field quantities are

$$\begin{aligned} \nabla \times \mathcal{E} &= -\frac{\partial \mathcal{B}}{\partial t} & \nabla \cdot \mathcal{D} &= q \\ \nabla \times \mathcal{H} &= \mathcal{J} + \frac{\partial \mathcal{D}}{\partial t} & \nabla \cdot \mathcal{B} &= 0 \end{aligned} \quad (1)$$

These four equations are supplemented by *constitutive relations* that relate \mathcal{D} and \mathcal{B} to \mathcal{E} and \mathcal{H} . We shall assume propagation in *simple media*, with vacuum as a special case. The term *simple media* in this context denotes linear, homogeneous, and isotropic materials, which will be assumed lossless for the time being. The constitutive relations in this case are expressed as (see MAXWELL’S EQUATIONS article)

$$\mathcal{D} = \varepsilon \mathcal{E} \quad \text{and} \quad \mathcal{B} = \mu \mathcal{H} \quad (2)$$

where ε is the permittivity ($\varepsilon = \varepsilon_0 \approx 8.85418782 \times 10^{-12}$ F/m in vacuum) and μ is the permeability ($\mu = \mu_0 = 4\pi \times 10^{-7}$ H/m in vacuum), constant scalar numbers for simple media. The electric current \mathcal{J} and charge q densities can be interpreted as the sources of the electromagnetic field and are interrelated by the *continuity equation*:

$$\nabla \cdot \mathcal{J} = -\frac{\partial q}{\partial t} \quad (3)$$

which is implicit in (1) (see MAXWELL’S EQUATIONS article). From (1) one can also derive a law for the conservation of electromagnetic energy, the *Poynting theorem* (see MAXWELL’S EQUATIONS article). For our purposes, we just need to emphasize the *Poynting vector*, defined as

$$\mathcal{S} = \mathcal{E} \times \mathcal{H} \quad (4)$$

This vector gives the magnitude and direction of power flow density (watts per square meter).

We will discuss the relations between sources (\mathcal{J}) and fields (\mathcal{E} and \mathcal{H}) later. For now, we shall only investigate simple characteristics of the electromagnetic propagation. In regions of a simple media where no source is present (i.e., $\mathcal{J} = q = 0$) the (homogeneous) *wave equations* below can be derived from (1) (see MAXWELL'S EQUATIONS article):

$$\begin{aligned} \nabla^2 \mathcal{E} - \frac{1}{c^2} \frac{\partial^2 \mathcal{E}}{\partial t^2} &= 0 \\ \nabla^2 \mathcal{H} - \frac{1}{c^2} \frac{\partial^2 \mathcal{H}}{\partial t^2} &= 0 \end{aligned} \tag{5}$$

where $c = 1/\sqrt{\mu\epsilon}$ is the *speed of light* in the medium ($c = c_0 = 299,792,458$ m/s in vacuum, by definition). From (5) one can readily show that each Cartesian component of \mathcal{E} and \mathcal{H} also satisfies the following homogeneous (scalar) wave equation

$$\nabla^2 \psi - \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2} = 0 \tag{6}$$

where ψ represents one of such components. This wave equation governs the behavior of ψ with respect to both position (x, y, z) and time (t). For simplicity, let us consider a one-dimensional problem (i.e., with no variation in x or y), such that (6) simplifies to

$$\frac{\partial^2 \psi}{\partial z^2} - \frac{1}{c^2} \frac{\partial \psi}{\partial t} = 0 \tag{7}$$

It can be easily verified that a solution to (7) is

$$\psi = f(z - ct) + g(z + ct) \tag{8}$$

where f and g are arbitrary real functions [12]. These are called *D'Alembert's solutions*, where $f(z - ct)$ represents an arbitrary waveform propagating in the positive z direction with speed equal to c , while $g(z + ct)$ represents another waveform with the same speed but propagating in the negative z direction.

Although (8) represents the solution of an idealized problem, it illustrates one fundamental property of the solutions of (6); namely, for unbounded simple media they represent a wave traveling with the speed of light. In real-life situations, obstacles (ground, vegetation, human-produced constructions, etc.) are present and impose additional constraints (*boundary conditions*) on the solutions of (6). In general, the presence of obstacles complicates the problem and simple analytical solutions can be found only for simple geometries.

2.1. Time-Harmonic Regime

Most RF and microwave applications deal with time-invariant linear media [6]. In this case, the use of a time-harmonic representation is often more convenient for dealing with electromagnetic wave phenomena. Assuming a $e^{j\omega t}$ time variation, where ω is the angular

frequency, Maxwell's equations (1) are rewritten as [6]

$$\begin{aligned} \nabla \times \mathbf{E} &= -j\omega \mathbf{B} & \nabla \cdot \mathbf{D} &= \rho \\ \nabla \times \mathbf{H} &= \mathbf{J} + j\omega \mathbf{D} & \nabla \cdot \mathbf{B} &= 0 \end{aligned} \tag{9}$$

where the functions (of space only) in (9) are now complex phasor representations of the corresponding quantities in (1), according to

$$\mathcal{E} = \text{Re}(\mathbf{E}e^{j\omega t}) \tag{10}$$

Here Re denotes the real part. A similar relation holds for the other fields (and sources). For simple media and from (2), the constitutive relations are then

$$\mathbf{D} = \epsilon \mathbf{E} \text{ and } \mathbf{B} = \mu \mathbf{H} \tag{11}$$

The wave equations (5) also assume a simpler representation [6]:

$$\begin{aligned} \nabla^2 \mathbf{E} + k^2 \mathbf{E} &= 0 \\ \nabla^2 \mathbf{H} + k^2 \mathbf{H} &= 0 \end{aligned} \tag{12}$$

known as the (homogeneous) *Helmholtz equations*, where $k = \omega\sqrt{\mu\epsilon}$ is the *wave number*.

It is useful to define *time-average* powers when dealing with time-harmonic fields. For instance, from (4) and the definition in (10) one can define the *complex Poynting vector*

$$\mathbf{S} = \frac{1}{2} \mathbf{E} \times \mathbf{H}^* \tag{13}$$

The real part of the complex Poynting vector is the time average of \mathcal{S} [4]. Equation (13) stresses an important characteristic of electromagnetic wave propagation. In-phase components of \mathbf{E} and \mathbf{H} contribute to $\text{Re}(\mathbf{S})$, representing the *power density* propagating in the direction of $\text{Re}(\mathbf{S})$ [6]. On the other hand, components of \mathbf{E} and \mathbf{H} in phase quadrature contribute to the imaginary part of \mathbf{S} , representing a (stationary) *reactive power density*.

In the time-harmonic regime, (7) becomes

$$\frac{d^2 \Psi}{dz^2} + k^2 \Psi = 0 \tag{14}$$

where Ψ is the complex representation of ψ according to (10). The solution of (14) is

$$\Psi = p_1 e^{j(kz + \phi_1)} + p_2 e^{-j(kz + \phi_2)} \tag{15}$$

Consequently, from (10) and observing that for simple media $k = \omega/c$, we obtain

$$\psi = p_1 \cos[k(z + ct) + \phi_1] + p_2 \cos[k(z - ct) + \phi_2] \tag{16}$$

which is a particular time-harmonic solution of (7) and (8) known as a *plane wave*.

3. PLANE, TEM, AND STATIONARY WAVES

The plane wave is the simplest solution of the homogeneous wave equation. Many important properties of electromagnetic wave propagation can be inferred from this fundamental solution. Moreover, an arbitrary electromagnetic wave in sourceless linear media can be decomposed in terms of plane waves ($e^{\pm jkz}$ in one dimension) in a manner similar to the decomposition of a time-domain signal in terms of its spectral components $e^{j\omega t}$ [13].

The complex representation of a plane wave in (15) specifies an amplitude (p) and phase ($kz + \phi$). Moreover, since Ψ represents a Cartesian component of \mathbf{E} or \mathbf{H} , it also indicates the orientation (i.e., the *polarization*) of the vector field.

The plane-wave solution of Ψ in three dimensions is written as $e^{-j(k_x x + k_y y + k_z z)}$, where $k_{x,y,z}/k$ can be understood as the cosine directors of the wavefront. By defining the *propagation vector* $\mathbf{k} = k_x \hat{\mathbf{x}} + k_y \hat{\mathbf{y}} + k_z \hat{\mathbf{z}}$ and putting the components of \mathbf{E} and \mathbf{H} back together, we arrive at a more general complex representation for plane waves [6]

$$\mathbf{E} = \mathbf{E}_0 e^{-j\mathbf{k} \cdot \mathbf{r}} \quad \text{and} \quad \mathbf{H} = \mathbf{H}_0 e^{-j\mathbf{k} \cdot \mathbf{r}} \quad (17)$$

where $\mathbf{r} = x\hat{\mathbf{x}} + y\hat{\mathbf{y}} + z\hat{\mathbf{z}}$ denotes the observation point, and amplitudes and phases of each component are incorporated in the constant complex vectors \mathbf{E}_0 and \mathbf{H}_0 (which also determine the wave polarization). Substituting (17) into (12), one obtains the *characteristic equation* or *dispersion relation* (for simple media):

$$k^2 = \omega^2 \mu \epsilon = k_x^2 + k_y^2 + k_z^2 \quad (18)$$

The plane-wave relations for \mathbf{E} and \mathbf{H} in simple media are obtained by substituting (11), (17), and (18) into (9) with no sources present

$$\begin{aligned} \mathbf{k} \times \mathbf{E} &= \omega \mu \mathbf{H} & \mathbf{k} \cdot \mathbf{E} &= 0 \\ \mathbf{k} \times \mathbf{H} &= -\omega \epsilon \mathbf{E} & \mathbf{k} \cdot \mathbf{H} &= 0 \end{aligned} \quad (19)$$

from which one observes that for sourceless simple media Ampère's and Faraday's laws are independent equations. Actually, this is also true for any wave solution in such media, which can be inferred from (9) and (11) [6].

Note that $k_{x,y,z}$ can be complex and still satisfy (18). Consequently, it is useful to regard \mathbf{k} as a complex vector

$$\mathbf{k} = \beta - j\alpha \quad (20)$$

where α and β are real vectors [6]. Since both α and β are real, they can be interpreted geometrically. Substituting (20) into (17), one verifies that the plane-wave spatial variation in complex notation is of the form $e^{-\alpha \cdot \mathbf{r}} e^{-j\beta \cdot \mathbf{r}}$, representing the variations of the amplitude (first term) and phase (second one) of the wave as it propagates through the medium. Consequently, the constant amplitude and phase surfaces are planes (hence the name plane waves), with α and β pointing to their normal directions, respectively. If such planes coincide (i.e., $\alpha \parallel \beta$), then the plane wave is denoted as a *uniform* plane wave. Other-

wise, it is denoted as *nonuniform*. Furthermore, $\hat{\boldsymbol{\beta}}$ (i.e., unit normal vector to the equiphase surface) denotes the *direction of propagation* of the plane wave.

For uniform plane waves, one can show from (18) and (20) that $\mathbf{k} = k\hat{\boldsymbol{\beta}}$, where $\hat{\boldsymbol{\beta}} = \hat{\mathbf{k}}$ is the direction of propagation. Now \mathbf{k} has a geometrically defined direction and one can inspect from (19) that Ampère's and Faraday's laws reduce to

$$\begin{aligned} \mathbf{H} &= \frac{k}{\omega \mu} \hat{\mathbf{k}} \times \mathbf{E} = \frac{1}{\eta} \hat{\mathbf{k}} \times \mathbf{E} \\ \mathbf{E} &= \frac{-k}{\omega \epsilon} \hat{\mathbf{k}} \times \mathbf{H} = -\eta \hat{\mathbf{k}} \times \mathbf{H} \end{aligned} \quad (21)$$

where $\eta = \sqrt{\mu/\epsilon}$ is the *intrinsic impedance* of the medium ($\eta = \eta_0 \approx 376.730313 \Omega$ in vacuum). So, a uniform plane wave has \mathbf{E} , \mathbf{H} , and $\hat{\mathbf{k}}$ mutually orthogonal to each other (which is not the case for nonuniform plane waves). Waves with such characteristics, that is, obeying the relations in (21), are called *transverse electromagnetic* (TEM) waves, the simplest example of which is the plane wave.

3.1. Wavelength and Phase Velocity

For simplicity, let us consider a uniform plane wave propagating in the $\hat{\mathbf{k}} = \hat{\mathbf{z}}$ direction. Consequently, $\mathbf{k} \cdot \mathbf{r} = kz$. Since $\hat{\mathbf{k}} \cdot \mathbf{E} = 0$, let us further consider $\mathbf{E} = E_0 e^{-jkz} \hat{\mathbf{x}}$ with $E_0 = p e^{j\phi}$. Consequently, from (21), $\mathbf{H} = (E_0/\eta) e^{-jkz} \hat{\mathbf{y}}$. Note that this is a one-dimensional problem; specifically, the components of \mathbf{E} and \mathbf{H} satisfy (14), with constant amplitude and phase planes perpendicular to $\hat{\mathbf{z}}$.

To obtain corresponding expressions in time domain, we apply the definition in (10):

$$\begin{aligned} \mathcal{E} &= p \cos(\omega t - kz + \phi) \hat{\mathbf{x}} \\ \mathcal{H} &= \frac{p}{\eta} \cos(\omega t - kz + \phi) \hat{\mathbf{y}} \end{aligned} \quad (22)$$

So, for a certain instant of time, the spatial variation of \mathcal{E} and \mathcal{H} is sinusoidal with a period equal to $\lambda = 2\pi/k$, the *wavelength* of the electromagnetic wave. Since $k = \omega/c$, then

$$\lambda = \frac{c}{f} \quad (23)$$

where f is the frequency. For such sinusoidal variation, $\omega/k = c$ is called the *phase velocity* (v_p) of the TEM wave.

3.2. Polarization

In the previous example we have assumed $\mathbf{E} \parallel \hat{\mathbf{x}}$, but any combination between x and y components also satisfies $\hat{\mathbf{k}} \cdot \mathbf{E} = 0$ for $\hat{\mathbf{k}} = \hat{\mathbf{z}}$. In this situation, such components are said to be *orthogonal* to each other and their phase and amplitude relationships describe the nature of the wave polarization. Wave polarization plays an important role in RF and microwave systems, as the interaction between fields and obstacles can strongly depend on it. In principle,

it is possible to transmit and receive orthogonal polarizations in a communication channel independently, thus doubling the capacity of the channel. In practice, *depolarization* effects (partial conversion of energy in one polarization to another) often occur. This effect can cause, for instance, cochannel interference in wireless communications. Orthogonal polarizations can also be used in closely spaced radiolinks to minimize cochannel interference.

According to (21), TEM wave polarization can be fully characterized by \mathbf{E} and $\hat{\mathbf{k}}$. So, let us assume $\mathbf{E} = (p_x e^{j\phi_x} \hat{\mathbf{x}} + p_y e^{j\phi_y} \hat{\mathbf{y}}) e^{-jkz}$. Then, from (10), we obtain

$$\mathcal{E} = p_x \cos(\omega t - kz + \phi_x) \hat{\mathbf{x}} + p_y \cos(\omega t - kz + \phi_y) \hat{\mathbf{y}} \quad (24)$$

If the x and y components are in phase (i.e., $\phi_x = \phi_y$), then (24) can be rewritten as

$$\mathcal{E} = (p_x \hat{\mathbf{x}} + p_y \hat{\mathbf{y}}) \cos(\omega t - kz + \phi_x) \quad (25)$$

and, for any position and time, \mathcal{E} is always parallel to the plane containing $\hat{\mathbf{z}} (= \hat{\mathbf{k}})$ and $p_x \hat{\mathbf{x}} + p_y \hat{\mathbf{y}}$. Then, the wave is said to have a *linear polarization*, as depicted in Fig. 1. Note that $\phi_x = \phi_y \pm \pi$ also provides a linear polarization. Now, let us assume that $p_x = p_y = p$ and $\phi_y - \phi_x = \pm \pi/2$. Then, from (24), we have

$$\mathcal{E} = p[\cos(\omega t - kz + \phi_x) \hat{\mathbf{x}} \mp \sin(\omega t - kz + \phi_x) \hat{\mathbf{y}}] \quad (26)$$

and the wave has a *circular polarization*, as the tip of \mathcal{E} describes a circular helix in space with an axis in the direction of $\hat{\mathbf{z}}$. This is depicted in Fig. 2. For $\hat{\mathbf{k}} = \hat{\mathbf{z}}$, $\phi_y - \phi_x = \pi/2$ ($= -\pi/2$) defines a *left (right)-hand circular polarization*. For any other combination between ϕ_x, ϕ_y and p_x, p_y , the wave polarization is *elliptical*. Finally, from the discussion conducted here it should be clear that any circular or elliptical polarization can be decomposed into two orthogonal linear polarizations with appropriate amplitude and phase relations. For pictorial depictions of the different wave polarizations, the reader is referred to, for instance, the text by Balanis [14].

Figure 1. Snapshot of the electric field vector of a linearly polarized wave traveling in the z direction.

Figure 2. Snapshot of the electric field vector of a circularly polarized wave traveling in the z direction.

3.3. Complex Poynting Vector and Stationary Waves

We will now investigate in further detail the behavior of \mathbf{S} for uniform plane waves.

From (13) and (21) we can verify that for a TEM plane wave

$$\mathbf{S} = \frac{|\mathbf{E}|^2}{2\eta} \hat{\mathbf{k}} = \frac{\eta |\mathbf{H}|^2}{2} \hat{\mathbf{k}} \quad (27)$$

indicating that (in a lossless simple media) \mathbf{S} is real (i.e., a pure active power density) and, consequently, the direction of propagation of a uniform plane coincides with the direction of energy flux. For instance, in the examples of Sections 3.1 and 3.2, one immediately observes that $\text{Re}(\mathbf{S}) \parallel \hat{\mathbf{z}}$.

So, let us now extend the example of Section 3.1 to investigate the case of a *stationary wave*, which is described here as a superposition of two TEM plane waves propagating in opposite directions (i.e., $\hat{\mathbf{k}} = \pm \hat{\mathbf{z}}$)

$$\begin{aligned} \mathbf{E} &= (E_0^+ e^{-jkz} + E_0^- e^{jkz}) \hat{\mathbf{x}} \\ \mathbf{H} &= \frac{1}{\eta} (E_0^+ e^{-jkz} - E_0^- e^{jkz}) \hat{\mathbf{y}} \end{aligned} \quad (28)$$

where \mathbf{H} was directly obtained from (21), noting that each individual wave has its $\hat{\mathbf{k}}$ pointing in the opposite direction of the other. Substituting (28) into (13), we obtain

$$\mathbf{S} = \left[\frac{|E_0^+|^2}{2\eta} - \frac{|E_0^-|^2}{2\eta} + j \frac{|E_0^+| |E_0^-|}{\eta} \sin(2kz - \phi^+ + \phi^-) \right] \hat{\mathbf{z}} \quad (29)$$

where ϕ^\pm are the corresponding phases of E_0^\pm . So, (29) indicates that \mathbf{S} has real (corresponding to the net flux of power density) and imaginary (corresponding to the stationary reactive power density) parts. This is the case, for instance, of fields on a transmission line terminated by a load that does not match the line impedance. If $|E_0^+| = |E_0^-|$ the wave of (28) is *purely stationary* and there is no average power flux [i.e., $\text{Re}(\mathbf{S}) = \mathbf{0}$, that occurs when the line is terminated, for example, by a short circuit].

4. WAVES AND SOURCES

Until this point, we have focused on wave propagation through regions of simple media where no source is present. We shall now present relations describing fields produced by elementary electric current sources in simple media. The most common way to accomplish this objective is by obtaining the so-called *Green's functions*. For a systematic treatment, the reader is referred to Collin's text [7] (for guided-wave examples) and Silver's treatise [9] (for radiation examples with applications to antenna theory). The approach adopted here is more restricted and can be found in most of the Bibliography.

Observing from (1) that $\nabla \cdot \mathcal{B} = 0$, one can define the *magnetic vector potential* \mathcal{A} such that $\nabla \times \mathcal{A} = \mathcal{B}$. In simple media, and after applying the *Lorenz gauge condition* given by $c^2 \nabla \cdot \mathcal{A} = -\partial \Phi / \partial t$, where Φ is the *electric scalar potential*, it can be shown that \mathcal{A} satisfies a wave equation as follows [4]:

$$\nabla^2 \mathcal{A} - \frac{1}{c^2} \frac{\partial^2 \mathcal{A}}{\partial t^2} = -\mu \mathcal{J} \quad (30)$$

For time-harmonic fields, this equation can be represented in complex notation as

$$\nabla^2 \mathbf{A} + k^2 \mathbf{A} = -\mu \mathbf{J} \quad (31)$$

A solution of these equations can be written in a generic form as [4]

$$\mathbf{A} = \mu \iiint_V \mathbf{J}(\mathbf{r}') G(\mathbf{r}, \mathbf{r}') dv' \quad (32)$$

where V denotes the volumetric region encompassing \mathbf{J} ; \mathbf{r}' and \mathbf{r} denote source and observation points, respectively; and $G(\mathbf{r}, \mathbf{r}')$ is the *Green's function*. $G(\mathbf{r}, \mathbf{r}')$ can be interpreted physically as the field produced by a point source, namely, the solution of

$$\nabla^2 G + k^2 G = -\delta(\mathbf{r} - \mathbf{r}') \quad (33)$$

satisfying the appropriate boundary conditions [4]. For instance, for bounded sources in unbounded simple media (free space), it can be shown that

$$G(\mathbf{r}, \mathbf{r}') = \frac{e^{-jk|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \quad (34)$$

which is known as the *free-space Green's function*. Furthermore, the time-harmonic electromagnetic field can be written in terms of \mathbf{A} as [4]

$$\mathbf{H} = \frac{1}{\mu} \nabla \times \mathbf{A} \quad (35)$$

$$\mathbf{E} = -j\omega \left[\mathbf{A} + \frac{1}{k^2} \nabla(\nabla \cdot \mathbf{A}) \right]$$

Use of the Lorenz condition in the derivation of (30) has an important consequence—one does not need to explicitly consider the charge densities to obtain the field. That should come as no surprise, since charges are related to currents by the continuity equation (3). In the time-harmonic regime their effects become implicit in (35). In any event, it is important to mention that (in a classical sense) gauge conditions other than those due to Lorenz can be applied [4].

As a simple example, we consider a uniform time-harmonic electric current distribution over a small segment (wire) ℓ along the z axis, centered at the origin ($z=0$). The length ℓ is assumed very small, such that $\ell \ll \lambda$. The electric current flows along $\hat{\mathbf{z}}$, with a constant phasor I_0 for $|z| \leq \ell/2$ ($I_0=0$ for $|z| > \ell/2$). This source distribution is called *infinitesimal electric dipole*. If the dipole radiates in free space, then the resulting vector potential \mathbf{A} is given by (32) and (34). Since $\mathbf{r}' = z'\hat{\mathbf{z}}$ with $|z'| \leq \ell/2 \ll \lambda$, then $k|\mathbf{r} - \mathbf{r}'| \approx kr$ and, consequently, $G(\mathbf{r}, \mathbf{r}') \approx e^{-jkr}/(4\pi r)$. The integral in (32) can then be readily evaluated to give [9]

$$\mathbf{A} = \frac{\mu I_0 \ell e^{-jkr}}{4\pi r} \hat{\mathbf{z}} \quad (36)$$

where $I_0 \ell$ is the *electric dipole moment*. The expressions for the associated electric and magnetic fields are obtained by substituting (36) into (35). The result can be easily extended to arbitrary dipole's locations and orientations [9].

Note from (35) and (36) that the dipole radiation depends on the length ℓ multiplied by k , that is, on the ratio ℓ/λ (also called the *electrical length*). Any bounded source distribution in a simple medium can be written as a superposition of infinitesimal dipoles. As a result, the free-space radiation properties of any bounded source distribution depend on its electrical dimension, namely, its dimension relative to the wavelength. This is also the case for scattering by bounded obstacles immersed in simple media.

We note that the integral (32) is generally difficult to evaluate except for simple current distributions and simple Green's functions (such as the free-space Green's function described above).

4.1. Far-Field (Radiation) Region

In free space and for observation points located sufficiently far away from (bounded) sources, (34) and, consequently, (32) can be simplified by means of a Taylor expansion on $|\mathbf{r} - \mathbf{r}'|$ for small values of $|\mathbf{r}'|$ with respect to $|\mathbf{r}|$. By keeping just the first few terms on this expansion, one ends up with a simplified relation valid for the so-called radiation (or *far-field*) region [9]

$$\mathbf{A} \approx \frac{\mu}{4\pi r} e^{-jkr} \iiint_V \mathbf{J}(\mathbf{r}') e^{jk\hat{\mathbf{r}} \cdot \mathbf{r}'} dv' \quad (37)$$

where $r = |\mathbf{r}|$, in which case relations (35) simplify to

$$\begin{aligned} \mathbf{E} &\approx -j\omega[\mathbf{A} - (\mathbf{A} \cdot \hat{\mathbf{r}})\hat{\mathbf{r}}] \\ \mathbf{H} &\approx \frac{1}{\eta} \hat{\mathbf{r}} \times \mathbf{E} \end{aligned} \tag{38}$$

4.2. Spherical and Cylindrical TEM Wavefronts

A closer look at (37) and (38) reveals some interesting properties of the far-field radiation of bounded sources in simple media. The field dependence on the radial distance r is of the form e^{-jkr}/r . This indicates that the surfaces of constant phase are concentric spheres and that the field intensity decays with $1/r$. Also, the propagation direction (normal to the equiphase surface) is $\hat{\mathbf{r}}$. Furthermore, \mathbf{E} , \mathbf{H} , and $\hat{\mathbf{r}}$ are mutually orthogonal. This characterizes a *spherical TEM wave*, for which the basic TEM relations of Section 3 still hold, but now with $\hat{\mathbf{k}} = \hat{\mathbf{r}}$. For instance, a complex E -field notation of the form $\mathbf{E} = p(\theta, \phi)(\hat{\theta} \pm j\hat{\phi}) \exp(-jkr)/r$ characterizes a spherical TEM wave with a circular polarization, according to the basic definitions of Section 3.2. For such a wave, the complex Poynting vector is given by $\mathbf{S} = \hat{\mathbf{k}}|E|^2/(2\eta) = \hat{\mathbf{r}}|p(\theta, \phi)|^2/(\eta r^2)$, according to (27).

Such observations show that the average power density of a spherical TEM wave decays with $1/r^2$ in lossless simple media. This result is also expected from simple considerations about energy conservation. Since total radiated power in a lossless medium is conserved and the spherical area of the wavefront increases with r^2 , the power *density* of the spherical wavefront must decay with $1/r^2$. Furthermore, note that a spherical TEM wave behaves *locally* as a plane wave when $kr \gg 1$, so that, in free space, the field close to a receiver antenna located sufficiently far away from the transmitter antenna can be locally approximated as a plane wave.

Apart from plane and spherical waves, another simple kind of wavefront is the cylindrical one. It is useful to picture a cylindrical wave as the field produced by an infinitely long line current [6]. For observation points far away from the current axis, the corresponding wavefronts can be approximated as cylindrical surfaces with a cross-sectional area that increases linearly with distance (the cylindrical ρ -coordinate). Consequently, from considerations on energy conservation, the radiating field decays with $\rho^{-1/2}$ [6]. It can also be shown that such cylindrical wave is also a TEM field obeying those basic relations of Section 3, now with $\hat{\mathbf{k}} = \hat{\rho}$. Furthermore, for $k\rho \gg 1$ the cylindrical wavefront can also be *locally* approximated as a plane wave.

4.3. Ray Optics Limit

The discussion in the previous section leads toward the picture of TEM wavefronts propagating far away from the radiating sources, with directions of propagation normal to the corresponding equiphase surfaces. As stressed previously, distances and dimensions are to be considered large or small vis-à-vis the wavelength of operation. In the limit of $\lambda \rightarrow 0$ or, alternatively, $k \rightarrow \infty$, the electromagnetic

field is expected to behave locally as a TEM wave (i.e., far away from sources). This is often called the *geometric optics* (GO) limit, where diffraction effects are neglected and a number of simplifications of the nature of electromagnetic wave propagation can be made, such as those in (21) [15].

The GO principles are directly related to the classical treatment of light. The developments date from ancient Greece and are intrinsically related to those of Euclidean geometry [1]. Obviously, such studies were not based on Maxwell's equations, but, as expected, the GO principles can be derived from Maxwell's equations. The usual starting point for this derivation is to assume a monochromatic wave (i.e., a time-harmonic field) governed by (12) in complex notation. Adopting the notation of Section 2.1, we let Ψ be a Cartesian component of \mathbf{E} or \mathbf{H} (a function of position only). Consequently

$$\nabla^2 \Psi + k^2 \Psi = 0 \tag{39}$$

From the TEM waves discussed up to here, it can be assumed, as a first-order *ansatz*, that [1]

$$\Psi \approx p(\mathbf{r})e^{-jk_0\Phi(\mathbf{r})} \tag{40}$$

where p represents the (complex) amplitude variation, Φ represents the phase variation with position only, and k_0 is the wavenumber for vacuum. For other simple media one can define the *index of refraction*

$$n = \sqrt{(\mu\epsilon)/(\mu_0\epsilon_0)} \tag{41}$$

such that $k = nk_0$. In (40), n is accounted for by $\Phi(\mathbf{r})$. Furthermore, the wavefront is given by the surfaces of constant $\Phi(\mathbf{r})$ (equiphase surfaces). Consequently, the direction of propagation is $\hat{\mathbf{k}} = \nabla\Phi/|\nabla\Phi|$. The equation that establishes the optical path (trajectory) in terms of the wavefront properties is accomplished by substituting (40) into (39) and, in the $k_0 \rightarrow \infty$ limit, assuming that any variation of $p(\mathbf{r})$ with position is negligible with respect to that of $k_0\Phi(\mathbf{r})$. After some algebraic manipulations, one arrives at the so-called *eikonal equation* [1]:

$$|\nabla\Phi|^2 = n^2 \tag{42}$$

This equation can be used to derive Fermat's principle [1]

$$\Phi(\mathbf{r}_2) - \Phi(\mathbf{r}_1) = \int_{r_1}^{r_2} n \, d\ell = \int_{t(r_1)}^{t(r_2)} c \, dt \tag{43}$$

where $\Phi(\mathbf{r}_2) - \Phi(\mathbf{r}_1)$ is the optical arc length (along the optical path ℓ) between points \mathbf{r}_1 and \mathbf{r}_2 , as illustrated in Fig. 3. This principle states that light (or, more precisely, electromagnetic waves in the GO limit) follows the path corresponding to the shortest travel time [1]. For simple media, both n and c are constants, but (43) holds for inhomogeneous media as well. From (43) one can also derive the laws of reflection and refraction [1], or establish approximate trajectories of radiowave propagation through Earth's atmosphere [16].

Figure 3. Wavefront and optical path in the geometric optics approximation.

GO principles are useful (although approximate) tools for the characterization of electromagnetic wave propagation not only at optical frequencies but also often at RF and microwave frequencies. For instance, such approximation can be used (possibly augmented by small corrections) for characterization of some radio channels at UHF or higher frequencies [17]. The range of validity of such approximation can depend on many factors, but it is fair to say that GO can be used as long as the characteristic lengths of the problem (obstacle feature sizes, mutual distances, etc.) are much larger than λ .

5. WAVES IN LOSSY AND DISPERSIVE MEDIA

So far, we have considered the propagation of electromagnetic waves in simple media without losses or dispersion. This assumption implies that the permittivity and permeability in the constitutive relations (2) and (11) are constant scalar parameters. In general, however, constitutive relations are not that simple. For example, ferroelectric and ferromagnetic materials are an example of *nonlinear media*, where the constitutive parameters at a point depend on the field strength at that point [4]. Even dielectrics can exhibit nonlinear effects under sufficiently large field strengths (e.g., breakdowns inside capacitors or transmission lines). On the other hand, crystals present a well-organized atomic structure, where the field response is highly dependent on wave polarization. Crystals are an example of *anisotropic* materials, where the permittivity (or permeability) has a tensorial nature [18]. The ionosphere is another example of anisotropic medium at radiofrequencies, although due to very different reasons [4].

Wave propagation on nonlinear or anisotropic media will not be considered here; The interested reader may consult Refs. 4 and 18 for further details. We shall continue to assume simple (linear, homogeneous, and isotropic) media, but now accounting for the presence of losses (lossy simple media).

In simple media and for a time-harmonic regime, losses in the medium cause a phase delay between the electric displacement (\mathcal{D}) and the electric field (\mathcal{E}), such that, in complex notation, we obtain

$$\mathbf{D} = \varepsilon(\omega)\mathbf{E} = [\varepsilon'(\omega) - j\varepsilon''(\omega)]\mathbf{E} \quad (44)$$

where ε' and $-\varepsilon''$ are the real and imaginary parts of the *complex permittivity* ε , respectively. The negative imaginary part of ε indicates the phase *delay* on \mathbf{D} . Here, we still assume that (11) applies for the magnetic relation, since for conductors and dielectrics $\mu \approx \mu_0$ at radiofrequencies, although, in general, a complex permeability of the form $\mu(\omega) = \mu'(\omega) - j\mu''(\omega)$ can also be defined [6].

For dielectrics, the ratio $\varepsilon''/\varepsilon'$ defines the *loss tangent*, where $\tan^{-1}(\varepsilon''/\varepsilon')$ is the phase difference between \mathbf{E} and \mathbf{D} due to the polarization inertia of the atomic structure (macroscopic interpretation). For conductors, net free charges are present and generate a *conduction current* \mathbf{J}_c whenever an external field is applied. For most conductors, \mathbf{J}_c is given by Ohm's law [4]

$$\mathbf{J}_c = \sigma\mathbf{E} \quad (45)$$

where σ is the material conductivity of the medium (approximately constant for frequencies below the infrared region). For conductive media, \mathbf{J}_c and the corresponding net charge density ρ_c can be subtracted from \mathbf{J} and ρ in (9), respectively, and Maxwell's equations in complex notation can be rearranged in the same form as in (9), but now with the permittivity replaced by the complex permittivity of (44), where ε' is the real permittivity and $\varepsilon'' = \sigma/\omega$ [6]. After that, \mathbf{J} and ρ in (9) correspond to the impressed (external) sources only, as \mathbf{J}_c and ρ_c are implicitly taken into account by the complex ε .

It is important to note that, once the complex permittivity in (44) is adopted, $k = \omega\sqrt{\mu\varepsilon}$ and $\eta = \sqrt{\mu/\varepsilon}$ are complex quantities as well. These quantities now depend on ω but are still spatially uniform (for homogeneous media). Therefore, all the results derived from Maxwell's equations (in complex notation) in previous sections still hold true, except for those where one had to deal with conjugate or absolute values (i.e., relations regarding average energy and power densities). For instance, (4) is still valid, since it is a general definition. However, for a TEM wave propagating in a lossy simple medium, (27) must account to the fact that η is now complex and hence generalizes to

$$\mathbf{S} = \frac{|\mathbf{E}|^2}{2\eta^*} \hat{\mathbf{k}} = \frac{\eta|\mathbf{H}|^2}{2} \hat{\mathbf{k}} \quad (46)$$

5.1. Wave Attenuation and Frequency Dispersion

One of the important consequences of losses is the attenuation of electromagnetic waves inside the medium. To illustrate this, we revisit the problem of Section 3.1, where a uniform plane wave propagates in the $\hat{\mathbf{z}}$ direction, but now in a lossy simple medium. From (20), and as the wave is considered uniform, then $\alpha\|\beta\|\hat{\mathbf{z}}$ and, consequently, $\mathbf{k} = k\hat{\mathbf{z}} = k\hat{\mathbf{k}}$, where k is a complex-valued quantity. So, if one defines

$$k = \beta - j\alpha \quad (47)$$

where α and β are nonnegative real quantities, then $\alpha = \alpha \hat{\mathbf{k}}$ and $\beta = \beta \hat{\mathbf{k}}$. Such definition is valid for any TEM wave propagating through a lossy simple medium in the direction $\hat{\mathbf{k}}$. The expressions for α and β are obtained from the definition $k = \omega \sqrt{\mu \epsilon}$ and (44):

$$\begin{cases} \alpha \\ \beta \end{cases} = \omega \sqrt{\frac{\mu \epsilon'}{2} \left(\sqrt{1 + \left(\frac{\epsilon''}{\epsilon'}\right)^2} \pm 1 \right)} \quad (48)$$

The plane-wave complex representation of Section 3.1 now becomes

$$\begin{aligned} \mathbf{E} &= E_0 e^{-\alpha z} e^{-j\beta z} \hat{\mathbf{x}} \\ \mathbf{H} &= \frac{E_0}{\eta} e^{-\alpha z} e^{-j\beta z} \hat{\mathbf{y}} \end{aligned} \quad (49)$$

Note that η is now complex. We observe from (49) that the *phase factor* β controls the phase variation with distance, whereas the *attenuation factor* α controls the amplitude attenuation as the wave propagates (i.e., as z increases). Despite the attenuation effect, the surfaces of constant amplitude and phase are still planes perpendicular to $\hat{\mathbf{z}}$, characterizing a uniform plane wave.

Note that the oscillatory behavior is controlled by $e^{-j\beta z}$, and this factor defines the wavelength and phase velocity, now represented as

$$\lambda = \frac{2\pi}{\beta} \quad \text{and} \quad v_p = \frac{\omega}{\beta} \quad (50)$$

To have a better picture of the wave behavior, we apply the definition in (10) to (49) in order to obtain \mathcal{E} in time domain. Assuming $E_0 = p e^{-j\phi}$, we obtain

$$\mathcal{E} = p e^{-\alpha z} \cos(\omega t - \beta z + \phi) \hat{\mathbf{x}} \quad (51)$$

So, the picture here is that of a sinusoidal function (with spatial period λ) multiplied by an envelope variation given by $|p e^{-\alpha z}|$. The field behavior is sketched in Fig. 4 for a fixed instant of time.

By extending the present analysis to the spherical wave solution of Section 4.1, one arrives at a field dependence with the radial distance r according to $e^{-\alpha r} e^{-j\beta r}/r$. The definitions in (50) still apply in this case. Besides the original (algebraic) amplitude attenuation caused by the spherical spreading factor $1/r$, the presence of losses produce an additional (exponential) attenuation factor $e^{-\alpha r}$.

Equation (48) indicates that both β and α have a non-linear variation with ω , due to $\epsilon'(\omega)$ and $\epsilon''(\omega)$. Consequently, one observes from (50) that v_p varies with ω , that is, different frequency components travel at different phase velocities. This causes the *dispersion* of an electromagnetic wave composed by several frequencies. In RF and microwave applications, electromagnetic waves often have a certain frequency bandwidth, and dispersion may cause waveform distortion as the wave propagates. In general, losses can significantly decrease the signal-to-noise ratio (SNR) over RF and microwave links, and need

Figure 4. Uniform plane wave propagating in a lossy medium.

to be minimized and/or compensated (by using, e.g., repeaters through long-distance links).

5.2. Group Velocity

In a dispersive (simple) medium, the phase velocity v_p depends on ω . In this case, it becomes necessary to define the velocity of a wavepacket (i.e., a wave composed by different spectral components) for v_p is no longer adequate. To better understand this aspect, let us assume a wavepacket composed of two time-harmonic TEM components, propagating in a lossy simple medium in the $\hat{\mathbf{z}}$ direction and with the same linear polarization, such that

$$\begin{aligned} \mathcal{E} &= [p_1 e^{-\alpha_1 z} \cos(\omega_1 t - \beta_1 z + \phi_1) \\ &+ p_2 e^{-\alpha_2 z} \cos(\omega_2 t - \beta_2 z + \phi_2)] \hat{\mathbf{x}} \end{aligned} \quad (52)$$

For the sake of simplicity, we assume $p_1 = p_2 = p$, $\phi_1 = \phi_2 = 0$, and small losses, so that $\alpha_1 \approx \alpha_2 \approx 0$. Furthermore, we define $\omega_c = (\omega_1 + \omega_2)/2$, such that $\omega_{1,2} = \omega_c \mp \delta_\omega$, where $\delta_\omega = (\omega_2 - \omega_1)/2$. By so doing, (52) can be rewritten as

$$\mathcal{E} = 2p \cos \left[\omega_c t - (\beta_2 + \beta_1) \frac{z}{2} \right] \cos \left[\delta_\omega t - (\beta_2 - \beta_1) \frac{z}{2} \right] \hat{\mathbf{x}} \quad (53)$$

which corresponds to the envelope distribution depicted in Fig. 5. The first cosine (representing, e.g., a carrier with angular frequency ω_c) propagates with a velocity equal to $2\omega_c/(\beta_2 + \beta_1)$. In the limit $\delta_\omega \rightarrow 0$, $(\beta_2 + \beta_1)/2 \approx \beta_c$ (where β_c is the phase constant at ω_c) and, consequently, the carrier's velocity tends to the phase velocity at ω_c . The second cosine in (53) modulates the amplitude of the carrier (see Fig. 5) and propagates with a velocity equal to $\delta_\omega/\delta\beta$, where $\delta\beta = (\beta_2 - \beta_1)/2$ corresponds to the variation of β around ω_c . We then define the *group velocity*

$$v_g = \lim_{\delta_\omega \rightarrow 0} \frac{\delta_\omega}{\delta\beta} = \left(\frac{\partial\beta}{\partial\omega} \right)^{-1} \Bigg|_{\omega=\omega_c} \quad (54)$$

as the velocity of the wavepacket envelope, which can also be interpreted as the velocity of the signal (information)

Figure 5. Group and phase velocities for a wave with two spectral components with distinct frequencies.

that modulates the carrier. A spectral analysis will demonstrate that (54) still holds for more arbitrary but bandlimited wavepackets propagating through a medium with little dispersion (i.e., with relatively small variations of β) [4]. As the wave energy is intrinsically related to the field strength (amplitude), for bandlimited signals v_g is also defined as the *velocity of energy flow* [4]. Obviously, $v_g = v_p = c$ for a TEM propagating through a lossless simple medium. More detailed discussions on wave velocities can be found in Refs. 4 and 5.

6. ELECTROMAGNETIC WAVE INTERACTION WITH OBSTACLES

6.1. Boundary Conditions

Boundary conditions are needed for the proper solution of Maxwell's equations at the interface between two dissimilar media (due to the discontinuity on their physical properties) or at discontinuous source distributions.

One boundary condition is associated with each one of (1) [6]. For a time-invariant interface between two regions 1 and 2, the four boundary conditions read as

$$\begin{aligned} \hat{\mathbf{n}} \times (\mathcal{E}_2 - \mathcal{E}_1) &= 0 & \hat{\mathbf{n}} \cdot (\mathcal{D}_2 - \mathcal{D}_1) &= q_s \\ \hat{\mathbf{n}} \times (\mathcal{H}_2 - \mathcal{H}_1) &= \mathcal{J}_s & \hat{\mathbf{n}} \cdot (\mathcal{B}_2 - \mathcal{B}_1) &= 0 \end{aligned} \quad (55)$$

where $\hat{\mathbf{n}}$ is the unit normal to the interface pointing toward region 2 and \mathcal{J}_s and q_s denote surface (or line) current and charge distributions over the interface, respectively. In (55), the field components are evaluated right next to each side of the interface, at region 1 or 2, respectively. In the time-harmonic regime, the complex representation of the boundary conditions have the same form as (55). If both regions represent simple media, then

(11), (44), and the complex representation of (55) gives

$$\begin{aligned} \hat{\mathbf{n}} \times (\mathbf{E}_2 - \mathbf{E}_1) &= 0 & \hat{\mathbf{n}} \cdot (\varepsilon_2 \mathbf{E}_2 - \varepsilon_1 \mathbf{E}_1) &= \rho_s \\ \hat{\mathbf{n}} \times (\mathbf{H}_2 - \mathbf{H}_1) &= \mathcal{J}_s & \hat{\mathbf{n}} \cdot (\mu_1 \mathbf{H}_2 - \mu_1 \mathbf{H}_1) &= 0 \end{aligned} \quad (56)$$

where μ_j and ε_j refer to region j ($j = 1, 2$).

In simple media and if no surface currents or charges are present at the interface, both (55) and (56) indicate that the tangential (to the interface) components of the electric and magnetic fields must be continuous across the interface, and these are the only boundary conditions that must be imposed for the proper wave solution, as at regions of a simple medium without sources only Faraday's and Ampère's laws are needed [6]. A particular case of interest is that at the interface of a perfect electric conductor, which will be discussed in Section 6.3.

6.2. Reflection and Refraction of Plane Waves

The plane-wave reflection and refraction at a planar interface is a canonical problem in electromagnetic wave theory and provides many useful insights into the behavior of waves in the presence of more general obstacles [19–22]. Consider a plane interface between two simple media (lossy or not), characterized by their (complex)

Figure 6. Plane-wave incidence on a plane interface: (a) perpendicular and (b) parallel polarizations.

permeabilities (μ_1 and μ_2) and permittivities (ε_1 and ε_2), as shown in Fig. 6. An incident plane wave (index i) impinges on the interface from medium 1, generating a reflected plane wave (index r), propagating back into medium 1, and a transmitted plane wave (index t) into medium 2. The exact reflected and transmitted energies of the corresponding waves depend on the media properties and on the direction of propagation and polarization of the incident wave.

Any arbitrary polarization can be decomposed into two linear and orthogonal ones in simple media (see Section 3.2). For the present analysis, the most commonly used are the perpendicular (no E -field component normal to the interface) and parallel (no H -field component normal to the interface) linear polarizations, as depicted in Figs. 6a and 6b, respectively. The formulas to be presented are valid for any incident plane wave, uniform or not. According to the discussion in Section 3, the geometric interpretation illustrated in Fig. 6 (i.e., with real-valued θ angles) is valid only for uniform waves. Depending on the case, some θ angles may come out complex, indicating that the corresponding plane wave is nonuniform. In any event, Fig. 6 is indeed useful for establishing the tangential (and normal) components of the fields at the interface, necessary for the application of the pertinent boundary conditions and, consequently, the solution of the problem. For uniform waves, Fig. 6 also provides a nice picture of the problem.

We will assume a time-harmonic regime (i.e., monochromatic waves) and use the complex phasor notation. According to (19), we can assume, without loss of generality, that the incident propagation vector (\mathbf{k}_i) has no component in the $\hat{\mathbf{y}}$ direction. The boundary conditions will further prove that the same occurs for the reflected (\mathbf{k}_r) and transmitted (\mathbf{k}_t) propagation vectors. With that we can define the xz plane in Fig. 6 as the *plane of incidence*. For uniform plane waves, that is in conformity with Fermat's principle; specifically, the trajectories are rectilinear (in simple media) and corresponding to the least travel time (see Section 4.3).

Starting with the perpendicular polarization and with the help of (17) and Fig. 6a, we define the electric fields of the plane waves as

$$\begin{aligned} \mathbf{E}_i &= E_0 e^{-j\mathbf{k}_i \cdot \mathbf{r}} \hat{\mathbf{y}} \\ \mathbf{E}_r &= \Gamma_{\perp} E_0 e^{-j\mathbf{k}_r \cdot \mathbf{r}} \hat{\mathbf{y}} \\ \mathbf{E}_t &= T_{\perp} E_0 e^{-j\mathbf{k}_t \cdot \mathbf{r}} \hat{\mathbf{y}} \end{aligned} \quad (57)$$

where Γ_{\perp} and T_{\perp} are Fresnel's reflection and transmission coefficients for the perpendicular polarization, respectively, relating the amplitude and phase of the corresponding field to those of the incident one. The propagation vectors are written as

$$\begin{aligned} \mathbf{k}_i &= k_1 (\sin \theta_i \hat{\mathbf{x}} + \cos \theta_i \hat{\mathbf{z}}) \\ \mathbf{k}_r &= k_1 (\sin \theta_r \hat{\mathbf{x}} - \cos \theta_r \hat{\mathbf{z}}) \\ \mathbf{k}_t &= k_2 (\sin \theta_t \hat{\mathbf{x}} + \cos \theta_t \hat{\mathbf{z}}) \end{aligned} \quad (58)$$

where $k_j = \omega \sqrt{\mu_j \varepsilon_j}$ (with $j=1,2$). Note that (58) is in agreement with (18). From (19), (57), and (58) one immediately obtains the H -field expressions, observing that $\eta = \eta_j = \sqrt{\mu_j / \varepsilon_j}$ with $j=1$ for the incident and reflected waves and $=2$ for the transmitted wave.

Enforcing the boundary conditions (i.e., the continuity of the tangential E - and H -field components) at the interface plane $z=0$, one comes up with *Snell's law*

$$k_1 \sin \theta_i = k_1 \sin \theta_r = k_2 \sin \theta_t \quad (59)$$

and also with

$$\begin{aligned} \Gamma_{\perp} &= \frac{\eta_2 \cos \theta_i - \eta_1 \cos \theta_t}{\eta_2 \cos \theta_i + \eta_1 \cos \theta_t} \\ T_{\perp} &= \frac{2\eta_2 \cos \theta_i}{\eta_2 \cos \theta_i + \eta_1 \cos \theta_t} \end{aligned} \quad (60)$$

Snell's law (59) comes from the matching of the phase variation of the fields at the interface. For a uniform incident wave (with a real-valued θ_i), (59) imposes that $\theta_r = \theta_i$ (i.e., the reflected wave is also uniform), which is the law of reflection known for centuries in optics and in conformity with Fermat's principle [1]. The Snell law for refraction is given by the second equality in (59), which can be rewritten with the help of (41)

$$n_1 \sin \theta_i = n_2 \sin \theta_t \quad (61)$$

where $n_{1,2}$ are the indices of refraction at regions 1 and 2, respectively. Equations (59) and (61) provide the value of θ_t with respect to θ_i and the physical properties of the medium. If one obtains a complex-valued θ_t , this indicates simply that the transmitted wave is nonuniform. That may happen even for a uniform incident wave if losses are present in one of the media (resulting in a complex index of refraction) or at *total reflection*.

The analysis of the parallel polarization follows along a line similar to that of its perpendicular counterpart and a comparison between Figs. 6a and 6b provides the necessary insights. After enforcement of the boundary conditions at the interface, one comes up with (59) and (61) once more (i.e., Snell's law is valid for any plane-wave polarization) and

$$\begin{aligned} \Gamma_{\parallel} &= \frac{\eta_2 \cos \theta_t - \eta_1 \cos \theta_i}{\eta_2 \cos \theta_t + \eta_1 \cos \theta_i} \\ T_{\parallel} &= \frac{2\eta_2 \cos \theta_i}{\eta_2 \cos \theta_t + \eta_1 \cos \theta_i} \end{aligned} \quad (62)$$

which are the Fresnel's reflection and transmission coefficients for the parallel polarization, respectively.

For simplicity, we shall assume next that both media are lossless simple dielectrics (i.e., $\mu_1 \approx \mu_2 \approx \mu_0$ and real-valued ε_1 and ε_2) and that the incident plane wave is uniform (θ_i is real). The incidence is defined *external* if $\varepsilon_2 > \varepsilon_1$ (e.g., the incidence of a radiowave on ground in a RF link). For real-valued θ_t , (61) provides that $\theta_t < \theta_i$ for

external incidences. Otherwise, the incidence is *internal* (e.g., a refraction from water into air).

The behavior of $|\Gamma|$ and $|T|$ with respect to θ_i is sketched in Figs. 7a and 7b for external and internal incidences, respectively. From the figures one observes two particular angles of incidence: the *Brewster* (or polarizing) angle θ_B , for which $|\Gamma_{\parallel}| = 0$, and the *critical* angle θ_C , such that, at internal incidence and for $\theta_i \geq \theta_C$, $|\Gamma| = 1$ and *total reflection* occurs. For lossless and simple media, the Brewster angle just occurs for the parallel polarization [1]. Its value can be determined from (61) and (62) by setting $\Gamma_{\parallel} = 0$:

$$\tan \theta_B = \frac{n_2}{n_1} \quad (63)$$

If losses are present, then Γ_{\parallel} is complex and $|\Gamma_{\parallel}| = 0$ is never met for any θ_i . Instead, $|\Gamma_{\parallel}|$ passes through a minimum, and that defines an *effective* Brewster angle. In any event, one can infer from Fig. 7 that $|\Gamma_{\parallel}| \leq |\Gamma_{\perp}|$

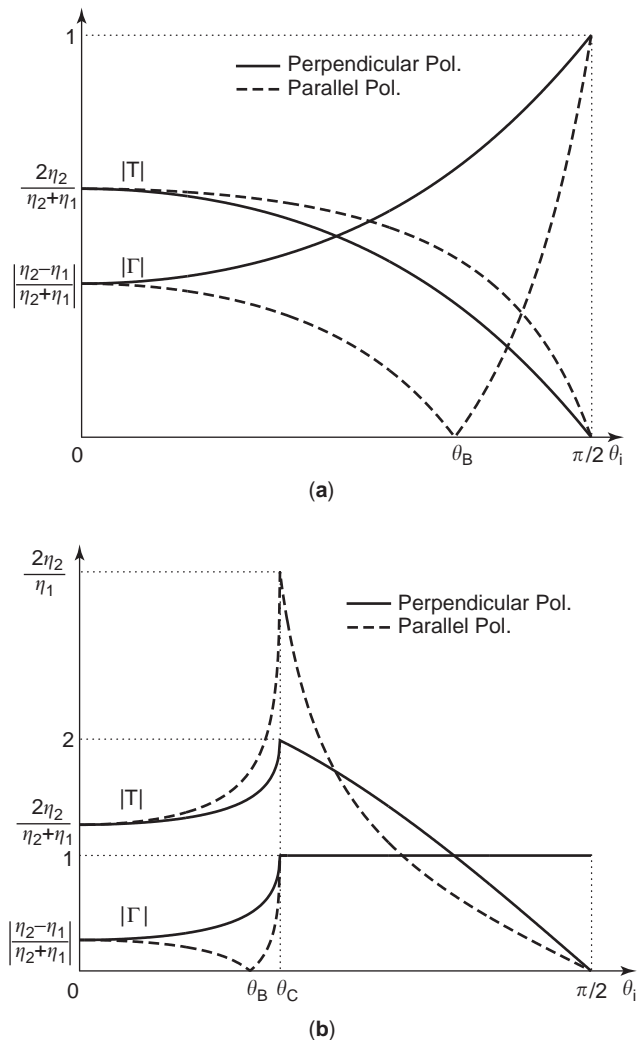

Figure 7. $|\Gamma|$ and $|T|$ as a function of θ_i : (a) external and (b) internal incidences.

for $0 < \theta_i < \pi/2$. For this reason, polarizing glasses are designed to block horizontally polarized light reflected by the ground. For this reason also, vertically polarized RF waves are preferred when attempting to obtain a uniform coverage of a urban cell in mobile communications at UHF (due to reflections from vertical buildings).

In lossless simple media, the critical angle θ_C occurs just at internal incidence. This is established from (61) and from the fact that $n_1 > n_2$ for internal incidence, yielding $\theta_t > \theta_i$ for $\theta_i \leq \theta_C$ with $\theta_t = \pi/2$ when $\theta_i = \theta_C$ by definition. Besides, θ_t becomes complex for $\theta_C < \theta_i \leq \pi/2$, indicating that the transmitted wave is nonuniform for incidence angles greater than θ_C . The primary consequence is $|\Gamma| = 1$ for $\theta_i \geq \theta_C$, as depicted in Fig. 7b.

To better understand the behavior of the transmitted wave at total reflection, let us recall the propagation vector \mathbf{k}_t of (58). For the present scenario and from (59) one will verify that the x component of \mathbf{k}_t is real-valued while its z component is purely imaginary, such that the transmitted wave propagates along the \hat{x} direction while its intensity dies off exponentially from the interface. So, the transmitted wave is strongly localized near the interface and propagates parallel to it, characterizing a *surface wave*. Also, if one obtains the \mathbf{E} - and \mathbf{H} -field components—with the help of (21) and (58)—and substitutes them into (13), it will be shown that the complex Poynting vector has a purely imaginary \hat{z} component and, consequently, there is no average flux of active (real) power through the interface (i.e., the incident power is totally reflected by the interface). In practical situations, losses will prevent such idealized conditions from occurring and a (small) amount of energy will eventually be transmitted through the interface [4]. The critical angle and the consequent total reflection helps in providing a nice picture of how light is guided throughout an optical fiber [23].

6.3. Waves on Good Electric Conductors

The equations of Section 6.2 can also be used to investigate the behavior of a plane wave incident on the surface of a good electric conductor. Let us assume that region 1 in Fig. 6 is a lossless simple medium (i.e., μ_1 and ϵ_1 are real-valued constants), while region 2 is a good conductor, in which case $\mu_2 \approx \mu_0$ and ϵ_2 is complex and according to (44). By definition, for good conductors $\sigma \gg \omega\epsilon$, such that $\epsilon_2 \approx -j\sigma/\omega$ for our purposes, where σ is the conductivity of region 2. Consequently, $k_2 \approx \sqrt{-j\mu_0\sigma/\omega}$ and $\eta_2 \approx \sqrt{j\omega\mu_0/\sigma}$.

Applying such definitions to (59), one should observe that $\theta_i = \theta_r$, as expected, and that $\theta_t \approx \pi/2$ as $\sigma \rightarrow \infty$. Besides, from (58) it is verified that $\mathbf{k}_t \approx k_2 \hat{z} \approx \sqrt{-j\mu_0\sigma/\omega} \hat{z}$. So, we come to the conclusion that the transmitted plane wave tends to behave as a uniform one inside the good conductor, propagating in the direction normal to the conductor's surface. The corresponding amplitude factor $\alpha_2 \approx \sqrt{(\mu_0\sigma)/(2\omega)}$ has a considerably large value, so that the field intensity dies off very rapidly away from the surface (tending to zero when $\sigma \rightarrow \infty$, as expected). Thus, a *skin depth* (δ) is defined as the propagation distance

needed for the field intensity to decay by e^{-1} , namely, $\delta = 1/\alpha_2 \approx \sqrt{(2\omega)/(\mu_0\sigma)}$.

As a consequence, \mathbf{E}_t is highly concentrated nearby and parallel to the surface. So, from (45) we end up concluding that there will be a volumetric conduction current highly concentrated nearby and flowing parallel to the conductor's surface. In the limit of a perfect electric conductor (i.e., $\sigma \rightarrow \infty$), such a current behaves as a surface one (\mathbf{J}_s), in which case (55) and (56) apply with null fields inside region 2 (note that $\hat{\mathbf{n}} = \hat{\mathbf{z}}$ in Fig. 6).

It is interesting to stress that the results presented here are valid for any angle of incidence θ_i and for any wave polarization. So, according to the discussion in the beginning of Section 3, the results are valid for any electromagnetic wave impinging on the surface of a good electric conductor.

The limiting case of a perfect electric conductor is not useful just for good conductors. As an example, let us assume an horizontally polarized radiowave propagating over ground and at *grazing incidence* (i.e., with $\theta_i \rightarrow \pi/2$, which is generally the case in a long-distance UHF radiolink). This corresponds to a perpendicular polarization and, according to (60), $\Gamma_{\perp} \rightarrow -1$. Note also from (60) that $\Gamma_{\perp} \rightarrow -1$ as well for incidences on a good electric conductor, as $|\eta_2| \rightarrow 0$ in this case. So, it is often used to approximate the ground as a perfect (or good) electric conductor to simplify the analysis [16]. For vertical polarization the approximation to be adopted also depends on other factors (such as the value of θ_B) [16].

6.4. Scattering and Diffraction

The scattering of an electromagnetic wave by an arbitrary obstacle is a difficult problem to solve using purely analytical techniques. Usually, numerical methods are employed. Among these, one can cite the method of moments [24], the finite-element method [25], and the finite-difference time-domain method [26].

However, if the incidence wave is locally TEM and if the obstacle is immersed in a simple medium and has a smooth surface, the concepts discussed in Sections 4.3 and 6.2 can be adopted (as approximations), to the extent that the obstacle's dimensions are large compared to the wavelength. Corrections to account for the curvatures of the incident wavefront (in case it is not a plane wave) and of the obstacle surface can be derived from GO principles and included in Γ of (60) and (62), according to the wave polarization [15,27]. The procedure is then conducted by *tracing rays* from the transmitter point to the receiver, such that any reflection on the obstacle must obey Fermat's principle, according to which the trajectories are rectilinear (in simple media) and $\theta_i = \theta_r$ with respect to the surface's normal. The difficulty of such technique generally appears in the determination of the *specular* points (where reflection occurs) over the surface of the obstacle.

If the obstacle presents curvature discontinuities (such as, e.g., at the edge of a wedge or at the border of a reflector antenna), then the propagation mechanisms associated with the incidence on such regions is classified as a *diffraction* (as the diffraction of a laser beam by a metallic slit). Asymptotic (in the sense of $k \rightarrow \infty$) techniques based

on the geometric theory of diffraction (GTD) can be applied to account for diffraction [27]. Such techniques are also based on ray tracing and can be accommodated together with GO principles to characterize the wave propagation through regions with several obstacles, such as a urban scenario in mobile communications [18].

7. GUIDED WAVES

Electromagnetic waves can propagate either in open space or through guiding structures such as transmission lines and waveguides. The choice of transmission lines depends on characteristics such as frequency of operation, bandwidth, power-handling capability, and losses. Some of the most usual transmission lines are two-wire lines, coaxial cables, rectangular and circular waveguides, microstrips, and striplines. These structures are discussed in more detail elsewhere in this encyclopedia in the article titled HIGH FREQUENCY TRANSMISSION LINES.

Some authors employ the *waveguide* denomination for guiding structures that allow propagation only of *transverse electric* (TE) and/or *transverse magnetic* (TM) waves, as described below, while the term *transmission lines* is used for guiding structures that allow propagation of TEM waves as well. Other authors use these terms interchangeably, as we will do here. We discuss TE and TM waves next.

7.1. TE and TM Waves

We will assume that the waves are guided in the z direction. TE and TM waves are a class of solutions of Maxwell's equations. As we are looking for propagating fields, their z dependence will be assumed on the form $e^{-jk_z z}$. In this case, the transverse components of the electric and magnetic fields can be written as [20]

$$\begin{aligned} \mathbf{E}_t &= \frac{1}{k^2 - k_z^2} [-j\omega\mu(\nabla_t H_z) \times \hat{\mathbf{z}} - jk_z \nabla_t E_z] \\ \mathbf{H}_t &= \frac{1}{k^2 - k_z^2} [j\omega\epsilon(\nabla_t E_z) \times \hat{\mathbf{z}} - jk_z \nabla_t H_z] \end{aligned} \quad (64)$$

where ∇_t stands for the transverse (to the z direction) portion of the ∇ operator. The electric field of the TE component is entirely transverse ($E_z = 0$), while the magnetic field has a longitudinal component ($H_z \neq 0$). From (64), the TE field is given by H_z and the corresponding transverse components \mathbf{E}_t and \mathbf{H}_t . On the other hand, the magnetic field of the TM component is entirely transverse ($H_z = 0$), while the electric field has a longitudinal component ($E_z \neq 0$). From (64) the TM field is given by the longitudinal electric field E_z and the corresponding transverse components.

TE and TM waves are supported by waveguides containing one or more perfect conductors and a homogeneous dielectric. In this case, each wave (or mode) satisfies the boundary conditions at the waveguide walls, and these waves are decoupled from each other. A useful example of such structure is the rectangular waveguide, formed by four metallic walls (perfect conductors), as shown in Fig. 8.

Figure 8. Rectangular waveguide geometry.

In general, a rectangular waveguide may be empty inside or *loaded*, that is, partially or completely filled with a dielectric. We will consider homogeneous (i.e., empty or completely filled with a uniform dielectric) rectangular waveguides next.

For TE modes (also known as *H modes*), the longitudinal component $H_z(x,y,z)$ is given by the solution of the scalar wave equation that satisfies the appropriate boundary conditions at the four metallic walls (in this case, $\partial H_z/\partial n = 0$)

$$H_z = H_0 \cos\left(\frac{m\pi x}{a}\right) \cos\left(\frac{n\pi y}{b}\right) e^{-jk_z z} \quad (65)$$

where $k_z = \sqrt{k^2 - (m\pi/a)^2 - (n\pi/b)^2}$, $m = 0, 1, 2, \dots$, $n = 0, 1, 2, \dots$ (but not $m = n = 0$). The transverse components of the electric and magnetic fields can be obtained directly from (64). These modes are denoted TE_{mn} , in reference to the indices m and n of (65). According to the frequency of operation, the TE_{mn} modes may propagate or not inside the waveguide. A propagating mode is characterized by a real k_z . The parameter k_z is real only if $k^2 > (m\pi/a)^2 + (n\pi/b)^2$. Otherwise, the mode is *evanescent* (exponentially decaying). The threshold frequency (where $k_z = 0$) is called *cutoff frequency* and is given by

$$f_{mn} = \frac{1}{2\sqrt{\mu\epsilon}} \sqrt{\left(\frac{m}{a}\right)^2 + \left(\frac{n}{b}\right)^2} \quad (66)$$

For TM modes (also known as *E modes*), the longitudinal component of the electric field is obtained from the solution of the scalar wave equation satisfying the boundary conditions at the four metallic walls (in this case, $E_z = 0$)

$$E_z = E_0 \sin\left(\frac{m\pi x}{a}\right) \sin\left(\frac{n\pi y}{b}\right) e^{-jk_z z} \quad (67)$$

where $m = 1, 2, \dots$, $n = 1, 2, \dots$, and k_z is the same as above. The transverse components of the fields are obtained by substituting (67) into (64). Again the TM_{mn} modes propagate only for frequencies above the cutoff frequency f_{mn} given by (66).

Assuming that $a > b$, the first mode that propagates (i.e., the one with smallest cutoff frequency) is the TE_{10} , which is called the *dominant* (or *fundamental*) mode. Usually, waveguides are designed to operate in a frequency range where only the dominant mode can propagate. This avoids intermodal dispersion [7] that results from the different phase velocities of two or more propagating modes. Note that if the waveguide is filled with a lossy dielectric, the modes are attenuated even above cutoff.

Mathematically, TE and TM modes are orthogonal to each other and form a complete set. This means that any field distribution inside the waveguide can be represented as a superposition of TE and TM modes [7]. However, when the finite conductivity of the metallic walls are considered, this orthogonality is no longer valid, and the modes become coupled. Also, when the dielectric is not homogeneous, the propagating modes become a combination of TE and TM fields, also called *hybrid modes* [7].

7.2. Surface and Leaky Waves

Surface waves were introduced in Section 6.2, under the condition of total internal reflection. This type of wave exhibits an exponential decay away from a guiding interface, while propagating in a direction parallel to it. Such a wave is also supported by dielectric waveguides, where no conductor is needed to guide the fields. A simple example of this kind of waveguide is the dielectric slab waveguide, formed by a dielectric layer (infinite in \hat{x} and \hat{z} directions), surrounded by air, as shown in Fig. 9. In the air, surface-wave modes are evanescent, and there is no average power flow from the dielectric to the air. TE and TM modes can be obtained for dielectric waveguide by following a procedure similar to the one described in Section 7.1 [6]. For TE and TM modes, there is also a possibility of even and odd modes. For example, even TM modes are given by [6]

$$E_z = \begin{cases} E_d \cos(\beta_y y) e^{-jk_z z} & \text{for } |y| \leq \frac{d}{2} \\ E_0 e^{-\alpha_y |y|} e^{-jk_z z} & \text{for } |y| \geq \frac{d}{2} \end{cases} \quad (68)$$

The associated transverse field components are obtained by substituting (68) into (64). The characteristic equations

Figure 9. Dielectric slab waveguide.

in the dielectric and in air are given by $k_z^2 + \beta_y^2 = \omega^2 \mu_0 \epsilon_d$ and $k_z^2 - \alpha_y^2 = \omega^2 \mu_0 \epsilon_0$. The boundary conditions at the dielectric interfaces provides the relation between the amplitudes $[E_d \cos(\beta_y d/2) = E_0 e^{-\alpha_y d/2}]$ and require that [6]

$$\beta_y \cot \frac{\beta_y d}{2} = \frac{-\alpha_y \epsilon_d}{\epsilon_0} \quad (69)$$

which is the transcendental equation for k_z , and consequently β_y and α_y . Multiple solutions of this transcendental equation are often identified by a subscript n (TM_{*n*} mode).

These modes present surface waves properties when α_y is real and positive. The cutoff frequency of the TM_{*n*} mode is the lowest frequency for which it propagates with no attenuation [$\alpha_y = 0, \beta_y = \omega \sqrt{\mu_0(\epsilon_d - \epsilon_0)}$]. In this case, (69) results in

$$f_n = \frac{n}{2d \sqrt{\mu_0(\epsilon_d - \epsilon_0)}}, \text{ with } n = 1, 3, 5, \dots \quad (70)$$

For frequencies below the cutoff, the power is no longer confined within the dielectric, and part of it is radiated into air. As a consequence of this radiation loss, the modes propagate with attenuation, having complex $k_z = \beta_z - j\alpha_z$. This kind of wave is called a *leaky wave* [7]. A simple interpretation of these waves comes from the plane-wave expansion of a field within the dielectric. As mentioned earlier, any field can be written as a superposition of plane waves in a sourceless linear medium. From the dielectric interface problem, it is known that the plane waves with incidence angles above the critical angle will be totally reflected back to the dielectric, forming a surface wave. But those plane waves with incidence angles below the critical angle will be refracted into the air (radiation), forming a leaky wave. Odd TM modes and both even and odd TE modes can be obtained similarly, and present the same properties as described for even TM modes.

An important example of dielectric waveguide is the optical fiber [23], which is extensively used in long-distance and high-bandwidth communications. An optical fiber is formed by a dielectric rod, called *core*, and one or more surrounding cylindrical dielectric layers, called *claddings*. In the simplest format, only one cladding is used. Usually the refraction index of the core is slightly above that of the cladding, allowing the propagation of surface waves. When the refraction index of the core is constant, the configuration is known as a *stepped-index fiber*. Otherwise, it is known as a *graded-index fiber*. The modes that propagate in the fiber are, in general, hybrid (combination of TE and TM), and the dominant mode is called the *HE₁₁* mode, with no cutoff frequency [23].

8. COHERENT AND INCOHERENT WAVES

Electromagnetic waves can also be classified as coherent or incoherent [1]. Coherent waves have definite phase

fronts (for each wavelength), while incoherent waves do not. Coherent waves are produced by sources that emit energy through a collectively dependent process such as antennas. Most electromagnetic waves produced by synthetic devices at RF and microwave frequencies are coherent, as we have been considering here. Lasers are also an example of coherent wave sources.

On the other hand, incoherent waves result from the radiation of many collectively independent sources. In this case, the wavefront is not well defined and random phase fluctuations occur across space (spatial incoherence) and with varying wavelengths at random intervals (temporal incoherence). Incoherent sources include most natural sources of radiation such as the sun, light from fluorescent lamps and lightbulbs, and LEDs (light-emitting diodes). In general, electromagnetic waves exhibit some *partial* degree of coherence. As such, this classification corresponds to two ideal extremes. In reality, electromagnetic waves are at most highly incoherent (in one extreme) or mostly coherent (in the other extreme).

9. FURTHER REMARKS

In this article, we have focused mainly on classical aspects of electromagnetic wave propagation in simple media. For the vast majority of RF and microwave applications, this classical description is sufficient. However, the detailed interaction and propagation of electromagnetic waves in material media, including molecular and atomic effects, depends on quantum aspects that are not covered by a strictly classical description. The theory of electromagnetic interaction that takes into account the laws of quantum mechanics is called *quantum electrodynamics* (QED) [28,29]. The development of QED was the basis for the 1965 Nobel Prize in Physics, shared by Tomonaga (1906–1979), Schwinger (1918–1994), and Feynmann (1918–1988), who followed earlier developments by Dirac (1902–1984). When averaged at a macroscopic level, QED reduces to Maxwell's equations augmented by phenomenological equations that can be expressed in terms of macroscopic constitutive laws.

As a final side remark, it should also be noted here that Maxwell's equations in their classical form are invariant to Lorentz transformations [30] and already incorporate special relativity. Indeed, the need to preserve the form of Maxwell's equations in any nonaccelerated frames of reference (special relativity principle) was a major motivation to the development of special relativity theory by Einstein [31].

ELECTROMAGNETIC WAVE SCATTERING

RANDALL L. MUSSELMAN
USAF Academy
Colorado Springs, Colorado

1. TYPES OF ELECTROMAGNETIC SCATTERING

Fundamentally, there are three types of electromagnetic scattering mechanisms: reflection, refraction, and diffraction. These scattering mechanisms can radiate specularly or diffusely. *Specular scattering*, caused by electrically large flat objects, means that electromagnetic reradiation travels in parallel rays. *Diffuse scattering*, caused by irregular or electrically small objects, means that the electromagnetic reradiation spreads as it propagates away from the scattering object.

1.1. Specular Scattering

Of the three fundamental scattering mechanisms, the most familiar are specular reflection and refraction. If any corners or bends that exist at the boundary are very gradual compared to the wavelength of the incident field, then the boundary tends to cause *specular* scattering. Optical scattering is often assumed to be specular because most obstructing bodies that are smooth are electrically large compared to optical wavelengths. Specular scattering can be modeled with the specular law of reflection and Snell's law of refraction.

1.1.1. Reflection. A familiar example of specular reflection is the common reflection of a visible image in a mirror, since the dimensions of the mirror would be huge compared to the wavelength of visible light. Other examples are the radar return from a large flat target, cellular telephone multipath from a water tower, or a parabolic dish used to reflect microwave energy to the antenna at its focal point. The ratio of the reflected electric field E_r , to the incident electric field E_i , is called the *reflection coefficient*:

$$\Gamma = \frac{E_r}{E_i} \quad (1)$$

If the electric field in Fig. 1 is parallel to the plane of incidence containing all three propagation paths (i.e., incident, reflected, and transmitted paths), then it has *parallel polarization*. When the electric field is perpendicular to the plane of incidence (the x - z plane in Fig. 1), then it has *perpendicular polarization*. The reflection coefficients for parallel and perpendicular polarizations are

$$\Gamma_{\parallel} = \frac{\eta_2 \cos \theta_t - \eta_1 \cos \theta_i}{\eta_2 \cos \theta_t + \eta_1 \cos \theta_i} \quad (2a)$$

$$\Gamma_{\perp} = \frac{\eta_2 \cos \theta_i - \eta_1 \cos \theta_t}{\eta_2 \cos \theta_i + \eta_1 \cos \theta_t} \quad (2b)$$

Figure 1. Illustration of Snell’s law. A plane-wave electromagnetic field obliquely incident onto a plane boundary, separating medium 1 ($\mu_1, \epsilon_1, \sigma_1$) from medium 2 ($\mu_2, \epsilon_2, \sigma_2$). A reflected field and a transmitted field scatter from this discontinuity in electrical constants.

where $\eta = (\mu/\epsilon)^{1/2}$ is the intrinsic impedance for each medium.

1.1.2. Refraction. The energy that is not reflected from the electrically large boundary is transmitted through the boundary. The ratio of the transmitted field strength to the incident field strength is called the *transmission coefficient*:

$$\tau = \frac{E_t}{E_i} \tag{3}$$

The transmission coefficients for parallel and perpendicular polarizations are

$$\tau_{||} = \frac{2\eta_2 \cos \theta_i}{\eta_2 \cos \theta_t + \eta_1 \cos \theta_i} \tag{4a}$$

$$\tau_{\perp} = \frac{2\eta_2 \cos \theta_i}{\eta_2 \cos \theta_i + \eta_1 \cos \theta_t} \tag{4b}$$

Equations (2) and (4) are known as *Fresnel’s equations*.

In the process of propagating from one electrical medium to the next, the speed of propagation changes. This change in speed causes a change in the propagation angle at the boundary, known as *refraction*. This phenomenon is commonly seen with visible light at the surface of a calm pool of water. The fact that an object extending from the air into the water appears bent is due to the increase in the propagation velocity of light as it leaves the water and enters the air. This phenomenon can be modeled with Snell’s law of refraction.

1.2. Diffuse Scattering

The laws for specular scattering are valid only for electrically large scattering bodies. If the object causing the elec-

tromagnetic scattering is small compared to the wavelength of the incident electromagnetic field, the induced currents would tend to radiate around the contour of the object, creating *diffuse* scattering. Unlike specular scattering, diffuse scattering results when the electromagnetic energy spreads outward as it radiates from the scattering object. The smaller the object, the more the energy will spread as it reradiates.

A simple example of diffuse scattering is an electromagnetic field incident on a very thin cylindrical conductor of length L along the z axis. At frequencies at or below the microwave region of the electromagnetic spectrum ($f \leq 20$ GHz), a thin copper wire will have an electrically small radius. A first approximation is to assume that the cylinder is a uniform line source [1], with a current distribution of

$$I(z) = \begin{cases} I_0 e^{j\beta_0 z} & -\frac{L}{2} < z < \frac{L}{2} \\ 0 & \text{elsewhere} \end{cases} \tag{5}$$

assuming that the source of the incident field is sufficiently far away that the induced current magnitude is approximately constant across the entire cross section and along the length of the wire. The phase angle $\beta_0 z$ along the length of the wire, is a result of the angle of incidence, where β_0 is the phase shift per unit length along the wire. The scattered or reradiated field from this wire is similar to the field radiated from a wire antenna and will radiate as

$$E = j\omega\mu \frac{e^{-j\beta r}}{4\pi r} \sin \theta \int_{-L/2}^{L/2} I_0 e^{j\beta_0 z} e^{j\beta z \cos \theta} dz \tag{6}$$

The radiation pattern of this scattered field is of the form $(\sin u)/u$, where $u = (\beta_0 + \beta \cos \theta)L/2$. The total field around the wire is the superposition, or vector sum at each point in space, of the scattered field and the original incident field that would have existed without the wire present. The scattered field added to the incident field creates a pattern with constructive reinforcement in some directions, and destructive cancellation in other directions. This is the function of the passive elements found on the Yagi-Uda antenna, common in television and other VHF and UHF communications.

In the Yagi-Uda antenna, only one set of elements is active. A half-wavelength dipole antenna usually makes up the active (or driven) element. The other elements are simply conductive cylinders or wires that reradiate some of the energy incident on them from the active element. Depending on the relative lengths of these passive elements, each of their re-radiated fields will add to the incident field of the active element, to create an overall pattern of power flow [2]. This focusing of energy is called *directivity* or *antenna gain*. Other forms of diffuse scattering by electrically small bodies are not so intentional.

1.3. Diffraction

Another form of scattering that cannot be accounted for by reflection or refraction is diffraction. For electrically large

scattering bodies, diffraction appears to occur at geometric discontinuities such as edges and corners. A first approximation is that currents induced only at these discontinuities reradiate electromagnetic energy. Diffraction is the scattering mechanism that accounts for radiation filling in the region that would have been completely blocked (shadowed) by an opaque obstruction.

Diffraction and reflection are important scattering mechanisms in communications. Whether in an urban or rural environment, a cellphone user will rarely have direct line of sight to the cell base station. Often, the communication link can be established only by energy reflecting off of a nearby building, or energy diffracted around a building or over a hill. Since these obstructions are typically electrically large, ray tracing techniques, which incorporate the laws for specular reflection and diffuse diffraction at edges, are often used to model the propagation characteristics of the communication channel.

2. THE LAWS OF SPECULAR REFLECTION AND REFRACTION

In many applications, an electromagnetic field can be assumed to be a plane wave. A plane wave is a convenient approximation amounting to the assumption that the electromagnetic field does not vary over the plane perpendicular to the direction of propagation. This approximation is similar to assuming that over small geographic areas, the planet Earth is flat. For wave propagation, this assumption is valid for a small observation area at a great distance from the source of a spherically propagating wave.

Figure 1 shows a plane-wave electromagnetic field incident on a boundary in the x - y plane. The generalized electric field will have components in the x , y , and z directions, that is

$$\mathbf{E} = (\hat{x}E_x + \hat{y}E_y + \hat{z}E_z)e^{-j\beta(\sin \theta_x + \cos \theta_z)} \quad (7)$$

where $\beta = \omega(\mu\epsilon)^{1/2}$ is the phase constant or wavenumber in units of radians per meter, μ is the permeability in henries per meter, and ϵ is the permittivity of the material in farads per meter. Imposing the tangential boundary condition for the electric field, the sum of the tangential components of the incident and reflected fields must equal that of the transmitted field [3–5]:

$$\begin{aligned} & (\hat{x}E_x^i + \hat{y}E_y^i)e^{-j\beta_1 \sin \theta_{1x}} + (\hat{x}E_x^r + \hat{y}E_y^r)e^{-j\beta_1 \sin \theta_{1x}} \\ & = (\hat{x}E_x^t + \hat{y}E_y^t)e^{-j\beta_2 \sin \theta_{2x}} \end{aligned} \quad (8)$$

This equality can be true for all x only when the exponents, or phases, are equal:

$$\beta_1 \sin \theta_{1x} = \beta_1 \sin \theta_{1r} = \beta_2 \sin \theta_{2x} \quad (9)$$

Equation (9) proves the well-known specular law for reflection, namely

$$\theta_i = \theta_r \quad (10)$$

which simply states that the angle of reflection equals the angle of incidence. Equation (9) also leads to Snell's law of refraction:

$$\frac{\sin \theta_i}{\sin \theta_t} = \left(\frac{\mu_2 \epsilon_2}{\mu_1 \epsilon_1} \right)^{1/2} \quad (11)$$

For most materials, the permeability is the same as that of free space, $\mu = \mu_0$. Assuming $\mu_1 = \mu_2$, Eq. (11) reduces to $n_1 \sin \theta_1 = n_2 \sin \theta_2$, where $n = (\epsilon_r)^{1/2}$ is the index of refraction and ϵ_r is the relative permittivity or dielectric constant.

3. ELECTROMAGNETIC THEOREMS

Few electromagnetic scattering problems lend themselves to the simple application of the laws of reflection and refraction. To develop more sophisticated analysis tools, a discussion of some basic electromagnetic theorems will be useful.

3.1. Uniqueness Theorem

Knowledge of the sources (currents) induced on the surface of a scattering body S enables unique solutions of the fields reradiated by those induced sources. Conversely, the known fields allow a unique calculation of the induced sources. The electric field \mathbf{E} and magnetic field \mathbf{H} are uniquely determined if [6,7]

1. $\hat{n} \times \vec{\mathbf{E}}$, the tangential component of \mathbf{E} , is specified on S .
2. $\hat{n} \times \vec{\mathbf{H}}$, the tangential component of \mathbf{H} , is specified on S .
3. $\hat{n} \times \vec{\mathbf{E}}$ is specified on part of S , and $\hat{n} \times \vec{\mathbf{H}}$ is specified on the remaining part of S .

3.2. Induction Theorem

In general, sources, such as conduction, displacement, and polarization currents, are induced at electrical discontinuities in the medium through which the incident field is propagating. Figure 2 shows a typical discontinuity represented by region 2. Region 2 represents a scattering body of material consisting of a permittivity ϵ , permeability μ , and conductivity σ , different from those of the surrounding region 1. Region 2 is bounded by a surface S . Assume that an electric field \mathbf{E}_1 and its associated magnetic field \mathbf{H}_1 , originate from a source current density \mathbf{J}_0 . This source could simply be the current oscillating in a transmitting antenna. These fields propagate undisturbed, through region 1, until they become incident upon the scattering body of region 2. As the fields cross the boundary between regions 1 and 2, they will be perturbed, that is, \mathbf{E}_2 and \mathbf{H}_2 in region 2 will generally not be equal to the fields \mathbf{E}_1 and \mathbf{H}_1 propagating in region 1. This abrupt change or discontinuity in electric and magnetic field strength results in currents that are induced at the discontinuity. In general, these currents will be

Figure 2. A scattering body. The incident field propagates from the source current, J_0 , through region 1. As this field strikes region 2, the currents J_s and M_s are induced at the surface S of the scattering body.

distributed through the volume of regions 1 and 2, depending on their electrical constants.

According to the induction theorem, whenever there is a discontinuity of the \mathbf{E} and \mathbf{H} fields crossing a boundary S between two media with different electrical constants, one can assume that induced currents at S cause the discontinuities in the fields. The induced current can be an electric current sheet [6–8]

$$\vec{J}_s = \hat{n} \times (\vec{H}^s - \vec{H}^i) = -\hat{n} \times \vec{H}^i \quad (12a)$$

or a fictitious, but mathematically useful, magnetic current sheet

$$\vec{M}_s = -\hat{n} \times (\vec{E}^s - \vec{E}^t) = \hat{n} \times \vec{E}^t \quad (12b)$$

The superscripts “i,” “s,” and “t,” pertain to the incident, outwardly scattered (reflected), and transmitted fields, respectively, and \hat{n} is the normal unit vector pointing out of the scattering body. If the scattering object is a perfect conductor, the transmitted fields vanish, leaving

$$\vec{J}_s = -\hat{n} \times \vec{H}^i = \hat{n} \times \vec{H}^s \quad (13a)$$

and

$$\vec{M}_s = \hat{n} \times \vec{E}^i = -\hat{n} \times \vec{E}^s \quad (13b)$$

The induction theorem alleviates the problem of knowing the exact distribution of current densities throughout the volume of the scattering body. The assumed currents exist only on the boundary S between the two media. Furthermore, the induced currents can be calculated directly from knowledge of the incident field that would have existed in the absence of any scattering object.

3.3. Equivalence Principle

If two different sources produce the same radiating field within a region, these sources are equivalent [8]. If both regions have the same electrical constants, only an inwardly scattered (transmitted) field exists. It follows from

Eq. (13) that the fields that are incident on the boundary S can be replaced by the equivalent current sheets

$$\vec{J}_s = \hat{n} \times \vec{H}^s = \hat{n} \times \vec{H}^i \quad (14a)$$

and

$$\vec{M}_s = -\hat{n} \times \vec{E}^s = -\hat{n} \times \vec{E}^i \quad (14b)$$

where in this case, \hat{n} is pointing in the direction of the transmitted or scattered wave. The equivalence theorem is useful for modeling radiation through apertures, such as a slot in a conductive plane or a horn antenna.

4. DIFFRACTION

Diffraction is the scattering mechanism that neither reflects off nor transmits through an obstruction. Even with opaque material allowing no transmission, diffraction accounts for radiation into the geometric shadow region. This scattering mechanism cannot be modeled with the specular laws of reflection and refraction, such as Snell’s law. To analyze diffraction exactly would require more knowledge about the induced current distribution around the scattering structure than would typically be feasible. Therefore approximations must be made to simplify the analysis. Two common approaches to analyzing diffraction are the use of geometrical optics and physical optics.

4.1. Geometrical Optics

Geometrical optics (GO) is a ray tracing technique that assumes that the electromagnetic energy travels in straight parallel lines or *rays* that are perpendicular to the wavefront. These rays travel from the point of reradiation to the observation point. While relatively easy to implement [9,10], GO is an approximation that relies on some important assumptions, primarily that the wavelength of the electromagnetic field must approach zero. Clearly, GO is an asymptotic technique valid only for sufficiently high frequencies, such that the wavelength is infinitesimal compared to the dimension of the obstruction. Since GO assumes infinite frequency, it ignores the wave nature of the electromagnetic scattering field, thus ignoring diffraction. The GO model creates an abrupt change in energy at the transition from the illuminated region to the shadow region. The abrupt change in field strength, without currents or charges to account for this discontinuity, violates boundary conditions. Therefore, GO provides only the crudest model, accounting only for reflection and refraction, but not for diffraction.

The geometrical theory of diffraction (GTD) extends GO to account for diffraction, by introducing a diffraction coefficient D , analogous to Γ for reflection and to τ for transmission [11–13]. The total electric field \mathbf{E}^T around the obstruction is

$$\mathbf{E}^T = \mathbf{E}^g + \mathbf{E}^d \quad (15)$$

where E^g is the electric field predicted by GO and is zero in the shadow region. The diffracted field for a plane wave of incidence is given by [14]

$$E^d(r) = DE_0(r)^{-1/2} e^{-j\beta r} \tag{16}$$

Figure 3 shows a plane wave incident on a perfectly absorbing half-screen. The diffraction coefficient can be quite involved even for this simple scattering structure. However, away from the shadow boundary [15]

$$E^d = -\frac{1}{2} E_0 \frac{(\lambda)^{1/2} r}{\pi x} e^{-j\beta r} \tag{17}$$

In the shadow ($-x$), the diffracted field given in Eq. (17) is the only field present. In the region of GO illumination ($+x$), the magnitude of the diffracted field of Eq. (17) subtracts from the incident field. Figure 4 illustrates the sum of the diffracted field and the GO incident field for (a) $z = 2\lambda$ and (b) $z = 20\lambda$. Clearly, there is a discontinuity at the transition between the GO illumination and shadow regions, around $x = 0$. This is an obvious limitation of the GTD, since there should be a smooth transition. One crude solution would be to simply draw a smooth curve connecting each side of the discontinuity through the point $x = 0, E = E_0/2$. A more sophisticated method is the uniform theory of diffraction (UTD), which is an extension of GTD that forces a smooth transition between the GO illumination and the shadow boundary [16].

Many common diffraction problems, such as hilltops and buildings, can be modeled with this half-screen or knife-edge approximation. However, the GTD still relies on several assumptions. The diffracted ray is assumed to depend entirely on the incident ray and the characteristics of the discontinuity itself, such as an edge of a scattering

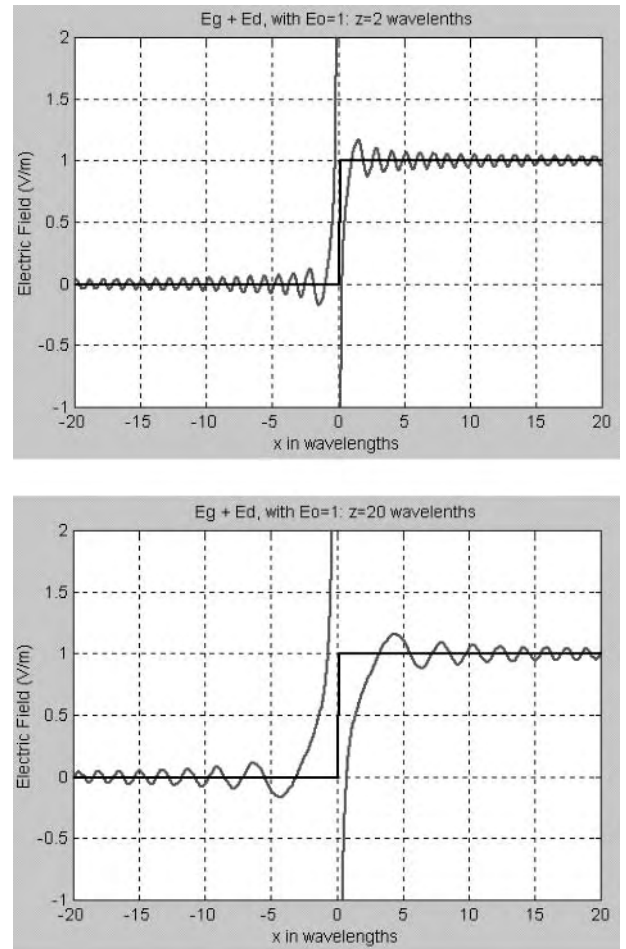

Figure 4. Simulation of half-screen diffraction by GTD. The solid straight line represents the GO incident field. The oscillating curve is the diffracted field, calculated by GTD, added to the GO field, at a distance behind the screen of (a) $z = 2$ wavelengths and (b) $z = 20$ wavelengths. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

structure [17]. The GTD is still a high-frequency asymptotic approximation because it assumes that the structure is electrically large and conductive [18]. Furthermore, GTD suffers from the unrealistic discontinuity problem at the GO illumination–shadow boundary.

4.2. Physical Optics

The edge diffraction problem of Fig. 3 can also be analyzed using the concept of physical optics (PO), which relies on Huygen’s principle. Huygen’s principle states that each point of a primary wavefront acts as a secondary point source. Each of these secondary sources radiates a spherical wave [14]. The primary difference between PO and GTD is that GTD assumes rays connect from the geometric discontinuity to the observation point, while PO assumes that secondary spherical waves radiate from the unobstructed primary wavefront. Figure 5 shows Huygen sources radiating into the GO shadow region behind the absorbing half-screen. The elemental electric field due to

Figure 3. Half-screen diffraction using GTD. The currents induced at the edge, of the conducting half-screen, radiate into the GO shadow region.

Figure 5. Half-screen diffraction using PO. The unblocked secondary sources radiate into the GO shadow region, accounting for diffraction.

each secondary point source is

$$dE = \frac{E_0}{r + \delta} e^{-j\beta(r+\delta)} \quad (18)$$

where E_0 is the electric field incident on the half plane, r is the distance from the observation point to the absorbing half plane, and δ is the additional distance to the secondary sources. From Fig. 5, we obtain

$$(r + \delta)^2 = r^2 + 2r\delta + \delta^2 = x^2 + r^2 \quad (19)$$

Clearly, the secondary sources closest to the half-screen will dominate the amplitude term in Eq. (18). Therefore, one could assume that $r > \delta$ in the amplitude term and $r^2 > \delta^2$ in the phase term of Eq. (18). Thus, Eq. (19) reduces to

$$\delta = \frac{x^2}{2r} \quad (20)$$

and Eq. (18) for the total electric field becomes

$$E = \frac{E_0}{r} e^{-j\beta r} \int_{x_0}^{\infty} e^{-j\beta(x^2/2r)} dx \quad (21)$$

where r is a constant of integration. Letting $u = (2/\lambda r)^{1/2}x$, and $u_0 = (2/\lambda r)^{1/2}x_0$, Eq. (21) becomes

$$E = \left(\frac{\lambda}{2r}\right)^{1/2} E_0 e^{-j\beta r} \int_{u_0}^{\infty} e^{-j(\pi u^2/2)} du \quad (22)$$

The limits of integration can be split into two terms:

$$E = \left(\frac{\lambda}{2r}\right)^{1/2} E_0 e^{-j\beta r} \left(\int_0^{\infty} e^{-j(\pi u^2/2)} du - \int_0^{u_0} e^{-j(\pi u^2/2)} du \right) \quad (23)$$

which has the form of Fresnel cosine and sine integrals. Equation (23) can be written as

$$E = \left(\frac{\lambda}{2r}\right)^{1/2} E_0 e^{-j\beta r} \left\{ \frac{1}{2} + j \frac{1}{2} - [C(u_0) + jS(u_0)] \right\} \quad (24a)$$

where $C(u_0)$ and $S(u_0)$ are the Fresnel sine and cosine integrals, respectively [19–21]. The solution to Eq. (24a) is similar to the GTD solution found in Fig. 3, with the exception that Eq. (24a) for PO does not suffer the discontinuity of Eq. (17) for GTD. In fact, Eq. (18a) has an analytic solution in the GO illumination–shadow transition region. The total electric field at $x_0 = 0$ is

$$E(x_0 = 0) = \left(\frac{\lambda}{2r}\right)^{1/2} E_0 e^{-j\beta r} \left(\frac{1}{2} + j \frac{1}{2} \right) \quad (24b)$$

and has a magnitude of $(E_0/2)(\lambda/r)^{1/2}$.

5. DIFFRACTION THROUGH AN APERTURE

The equivalence principle can be combined with PO to analyze scattering through an aperture. Let an electromagnetic plane wave be incident normal to the $a \times b$ aperture in a thin conducting screen of infinite extent, shown in Fig. 6. While this assumption of a screen with infinite extent may not be realistic, it can provide a good approximation for an aperture in an electrically large conductive plane. From the equivalence principle, the reradiated field appears to be generated by the current sheets described in Eq. (12). Starting from Maxwell's equations, the electric and magnetic fields radiated from the electric and magnetic current sources are

$$\begin{aligned} \vec{E} &= -j \frac{\omega\mu}{4\pi} \iint_{S'} \vec{J}' \frac{e^{-j\beta R}}{R} dx' dz' - \\ &\nabla \times \left(\frac{1}{4\pi} \iint_{S'} \vec{M}' \frac{e^{-j\beta R}}{R} dx' dz' \right) \end{aligned} \quad (25a)$$

and

$$\begin{aligned} \vec{H} &= -j \frac{\omega\epsilon}{4\pi} \iint_{S'} \vec{M}' \frac{e^{-j\beta R}}{R} dx' dz' + \\ &\nabla \times \left(\frac{1}{4\pi} \iint_{S'} \vec{J}' \frac{e^{-j\beta R}}{R} dx' dz' \right) \end{aligned} \quad (25b)$$

where the primed terms refer to the source, rather than the field. The equivalence principle allows the electric field in the aperture to be replaced by the magnetic current sheet \vec{M}_s over a continuous conducting screen [7]. The aperture is essentially short-circuited, which cancels \vec{J}_s .

From image theory, it appears as though an identical image of M_s lay on the opposite side of the screen. Since these two current sheets nearly coincide, the entire problem can be replaced with $2M_s$ at the aperture location, and no screen at all. Then Eq. (25b) becomes

$$\vec{H} = -j \frac{\omega\epsilon}{2\pi} \iint_{S'} M' \frac{e^{-j\beta R}}{R} dx' dz' \quad (26)$$

Rather than solving the integrodifferential equation (25a), Ampere's law can be used to obtain directly the scattered electric field in the source-free region:

$$\nabla \times \vec{H} = j\omega\epsilon \vec{E} \quad (27)$$

The distance R from each elemental source to the field point can be obtained from the law of cosines

$$R = [r^2 + (r')^2 - 2rr' \cos \psi]^{1/2} \quad (28)$$

where $r' \cos \psi = x' \sin \theta \cos \phi + y' \sin \theta \sin \phi$. Equation (26) would be difficult to integrate with a direct substitution of Eq. (28). However, if the scattered field is observed in the far-field Fraunhofer region, R and r will be virtually parallel. The far-field limit is usually taken to be

$$r \geq \frac{2D^2}{\lambda} \quad (29)$$

where D is the largest dimension of the aperture, in this case, the length of the diagonal [19]. The far-field assumption allows for the approximation $R \approx r - r' \cos \psi$ for the phase, and $R \approx r$ in the amplitude. Furthermore, in the far field, $E = \eta H$, where $\eta = (\mu/\epsilon)^{1/2}$ is the intrinsic impedance of the surrounding medium. This eliminates the need to solve Eq. (25a) or (27). Since in this case the incident plane wave is normal to the aperture, it will not vary over the aperture. Therefore, it can be brought out of the integral. Then the equation for the scattered magnetic field becomes

$$H = -j \frac{\omega\epsilon}{2\pi r} E_0 \int_{-a/2}^{a/2} \int_{-b/2}^{b/2} e^{-j\beta(x' \sin \theta \cos \phi + y' \sin \theta \sin \phi)} dx' dz' \quad (30)$$

While appearing messy, Eq. (30) is a straightforward integral. After integrating the two exponential terms, substituting the limits, and applying the identity

$$\sin \alpha = \frac{e^{j\alpha} - e^{-j\alpha}}{j2}$$

the scattered magnetic field in Eq. (30) becomes

$$H = j \frac{abe^{-j\beta r}}{\eta\lambda r} \left(\frac{\sin(X)}{X} \right) \left(\frac{\sin(Y)}{Y} \right) \quad (31a)$$

where

$$X = \frac{\beta a \sin \theta \cos \phi}{2} \quad (31b)$$

and

$$Y = \frac{\beta b \sin \theta \sin \phi}{2} \quad (31c)$$

Figure 7 is a plot of Eq. (31), with the amplitude normalized. The x dimension is $a = 6\lambda$, the y dimension is $b = 3\lambda$, and the observation screen is $z = 100\lambda$ from the aperture.

The normal angle of incidence was chosen for this problem to illustrate the concept, while keeping the mathematics simple. However, Eq. (31) can be extended to oblique incidence by modifying the current source M_s . Assuming that the source of the incident field is far from the aperture, the amplitude will not vary significantly across the aperture. However, the phase of each differential element of M_s will vary. The procedure is the same as for this analysis, except that some angle terms for the incident field will be added to X and Y in Eq. (25). The integration then follows in a similar manner [22].

6. BABINET'S PRINCIPLE

Scattering from a conductive plate can be modeled in a manner that virtually parallels the preceding solution to the aperture. In the case of scattering from a conductive plate, the current sources are obtained using the induction theorem. In fact, scattering through the aperture is the exact complement to the scattering off of the conductive plate that was essentially cut out of the conductive screen to create the aperture. If every electric parameter and every magnetic parameter were swapped, the solutions would be identical. Babinet's principle originally stated

Figure 6. Coordinate system for the aperture diffraction problem. R is the vector pointing from the differential element $dx dy$ to the field point, and is the resultant vector sum of r and r' . The position vector from the origin to the secondary source in the aperture plane is $r' = [(x')^2 + (y')^2]^{1/2}$.

that the sum of the intensities from an obstruction and its complement (i.e., a similarly shaped aperture in the infinite screen) is equal to the intensity that would have existed if no obstruction existed at all

$$S_a + S_c = S_0 \tag{32}$$

While this relationship works for optics, it does not take into account polarization. To apply Babinet’s principle to vector fields, it must be modified to [23]

$$\frac{H^a}{H^i} + \frac{E^c}{E^i} = 1 \tag{33}$$

The first term in this equation is the ratio of the field diffracted by the aperture to the field with no screen present at all, and the second term is the ratio of the field produced by the complementary screen to the conjugate source. The *conjugate source* refers to the opposite field rotated by 90°. In vector form, Eq. (33) can be rewritten as

$$E^c = E^i - \eta H^a \tag{34}$$

which indicates that the electric field scattered from a conductive plate can be calculated from the field scattered from the aperture, by subtracting the latter from the incident field [22].

7. SPECIAL CASES OF ELECTROMAGNETIC WAVE SCATTERING

7.1. Rayleigh Scattering

If the scattering object is much smaller than a wavelength, its scattered energy varies inversely as the fourth power of the wavelength [1,24,25]. Therefore, for a given subwavelength object, higher frequencies will scatter more than will lower frequencies. This is the basis behind the concept of Rayleigh scattering for small scatterers. In fact, Rayleigh scattering answers the proverbial question: Why is the sky blue? Since the blue end of the visible spectrum has the shortest wavelength, blue light scatters more than does the rest of the visible spectrum from dust, water, and even air molecules. As the scattering objects become larger, they fall into the category called *Mie scattering*.

7.2. Radar Cross Section

Electromagnetic wave scattering is the basis by which radar signals are returned to the radar receiver from a target. Since the typical radar system employs a collocated transmit/receive antenna, the source and observation points are the same. This scenario is a specific case of electromagnetic wave scattering, known as *monostatic scattering*.

As the transmitted power P_T propagates through space, it spreads over an increasing surface area A , resulting in decreased power density $S_T = P_T/A$. If P_T spreads spherically as with a point source or isotropic radiator, then $A = 4\pi d^2$, where d is the distance from the transmitter. A target can intercept part of the transmitted power and scatter it in various directions. The radar cross section

Figure 7. Normalized scattering pattern through the aperture. The dimensions of the aperture are 6×3 wavelengths; the observation screen is 100 wavelengths from the plane of the aperture. The scattering pattern is wider in the x direction, since the x dimension of the aperture is twice that of the y dimension. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

(RCS) is the effective area of the target that would return the monostatic power density back to the source, if this target scattered the power isotropically [1,26,27]. The amount of power returned to the source is

$$P_R = \frac{P_T G^2 \lambda^2 (\text{RCS})}{(4\pi)^3 d^4} \tag{35}$$

where G is the antenna gain and λ is the wavelength of the radar signal. The RCS is related to the physical cross-sectional area of the target but also depends on factors such as the frequency and polarization of the radar signal as well as the target’s shape, material, and orientation with respect to the transmitter.

Bistatic radar differs from monostatic radar in that the receiver and transmitter are not collocated. In the case of bistatic radar, we obtain

$$P_R = \frac{P_T G_T G_R \lambda^2 (\text{RCS})}{(4\pi)^3 d_1^2 d_2^2} \tag{36}$$

where G_T and G_R are the gains of the transmitting and receiving antennas, respectively, and d_1 and d_2 are the distances from the transmitter to the scatterer and the distance from the scatterer to the receiver, respectively. This can be a useful model for determining the power density and thus the electric field scattered off of an object when the transmitter power and antenna gain are known. [The product of transmitter power and antenna gain is known as *effective isotropic radiated power* (EIRP).] The scattered power density (in Watts per square meter) is

$$S \text{ (in } W/m^2) = \frac{P_T G_T (\text{RCS})}{(4\pi)^2 d_1^2 d_2^2} \tag{37}$$

and the RMS electric field (in volts per meter) is $E = (\eta S)^{1/2}$. If the EIRP is not known, Eq. (37) can be modified by substituting a measured power density S_0

measured at a distance d_0 from the original source. In terms of the measured power density, the scattered power density is

$$S \text{ (in } \text{W/m}^2\text{)} = S_0 \left(\frac{d_0}{d_1} \right)^2 \frac{\text{RCS}}{4\pi d_2^2} \quad (38)$$

8. SUMMARY

Since electromagnetic scattering perturbs the incident field, it can create interference, both constructive and destructive. The three main mechanisms of scattering are reflection, refraction, and diffraction. Reflection and refraction are the most common, and since these scattering mechanisms tend to be specular, they are easiest to analyze. Diffraction is much more difficult to analyze, and is typically not as dominant as the other two. Various approximations can lead to solutions of diffraction problems. The two main approximations covered were the GTD, which takes advantage of ray tracing, and PO, which relies on Huygen secondary sources. Slight modifications to the PO solution for the aperture problem can lead to solutions for backscattering, and forward scattering from a conductive plate. This simple structure can serve as a building block for more complicated structures, which can be modeled as composites of conductive plates.

Although the emphasis of this encyclopedia is on the higher frequencies in the radio spectrum, the importance of the solar-terrestrial environment on radiowaves of all frequencies is of considerable importance to engineers designing radio systems for various services. An idealized representation of the solar-terrestrial environment is shown in Fig. 1.

It is interesting to note that EM waves over a very large spectral range interact with the terrestrial ionosphere and with radio receivers on Earth's surface or in space: (1) solar radiation, including the extreme ultraviolet (EUV):

measured at a distance d_0 from the original source. In terms of the measured power density, the scattered power density is

$$S \text{ (in } \text{W/m}^2\text{)} = S_0 \left(\frac{d_0}{d_1} \right)^2 \frac{\text{RCS}}{4\pi d_2^2} \quad (38)$$

8. SUMMARY

Since electromagnetic scattering perturbs the incident field, it can create interference, both constructive and destructive. The three main mechanisms of scattering are reflection, refraction, and diffraction. Reflection and refraction are the most common, and since these scattering mechanisms tend to be specular, they are easiest to analyze. Diffraction is much more difficult to analyze, and is typically not as dominant as the other two. Various approximations can lead to solutions of diffraction problems. The two main approximations covered were the GTD, which takes advantage of ray tracing, and PO, which relies on Huygen secondary sources. Slight modifications to the PO solution for the aperture problem can lead to solutions for backscattering, and forward scattering from a conductive plate. This simple structure can serve as a building block for more complicated structures, which can be modeled as composites of conductive plates.

ELECTROMAGNETIC WAVES IN IONOSPHERE

ROBERT D. HUNSUCKER
RP Consultants
Klamath Falls, Oregon

Although the emphasis of this encyclopedia is on the higher frequencies in the radio spectrum, the importance of the solar-terrestrial environment on radiowaves of all frequencies is of considerable importance to engineers designing radio systems for various services. An idealized representation of the solar-terrestrial environment is shown in Fig. 1.

It is interesting to note that EM waves over a very large spectral range interact with the terrestrial ionosphere and with radio receivers on Earth's surface or in space: (1) solar radiation, including the extreme ultraviolet (EUV):

Figure 1. Idealized schematic representation of the solar-terrestrial environment.

102.7–111.8 nm), soft X rays, Lyman Alpha (121.5 nm); hard X rays (0.2–0.8 nm) and cosmic rays produce the ionospheric layers; (2) solar radio noise of frequencies ~20 MHz up to 1 GHz penetrates the terrestrial ionosphere and can degrade the signal-to-noise ratio (SNR) received on various radio services; (3) radio signals from ELF through low VHF (~10 Hz to ~35 MHz) propagate over long terrestrial paths by reflection and refraction by the ionosphere.

The main ionizing agents are listed in the preceding paragraph. At high geomagnetic latitudes, energetic electrons and protons also can produce areas of high ionization density. The terrestrial ionosphere is a roughly spherical shell of weakly ionized plasma that surrounds Earth. A plasma is a gas that has been ionized by radiation or by charged particles, so that it consists of free electrons, ions, and neutrals; it is sometimes referred to as the fourth state of matter [1], the characteristics of various plasmas are displayed in Fig. 2.

This spherical shell is stratified into distinct layers; the lowest region is the D layer, starting at about 50 km height; the E region, starting at about 100 km; the F1 layer (during the day) near 250 km; and the F2 layer at about 350 km. At high geomagnetic latitudes, solar energetic charged particles are also important ionizing agents. Figure 2 is a plot of log density versus log kinetic temperature showing the relative state of ionization of various plasmas, and Fig. 3 illustrates the various ionospheric layers and their ionizing agents.

1. THE RADIO SPECTRUM

A considerable portion of the radio spectrum (ELF through HF) is affected by our ionosphere, and the ITU

nomenclature for the frequency bands, along with the principal modes and uses, are shown in Table 1. The so-called wireless frequencies lie in the UHF and SHF bands.

Figure 2. Logarithmic plot of approximate magnitudes of some typical laboratory and natural plasmas.

Figure 3. The ionospheric regions and their ionizing agents. (From Ref. 2.)

2. IONOSPHERIC INTERACTION WITH EM WAVES

The basic interaction mechanism between radio- (EM) waves and the ionosphere involves the oscillation of the electric component of the wave acting on free electrons, which are 1800 times less massive than the ionospheric neutrals or ions. The E wave induces motion of the electrons, and at the same time the ionosphere abstracts energy from the electrons, resulting in a bending of the radio wave and in some energy loss from the wave. Figure 4

illustrates the attenuation of radiowaves in the ionosphere as a function of frequency from 1 Hz to 30 MHz.

As may be seen in Fig. 4, there is a variation in radio-wave attenuation from day to night. The virtual height (the height at which radiowaves at vertical incidence are reflected) varies with time of day, with season of the year, and with geomagnetic activity. The most regular variation is the local time variation, as shown in Fig. 5.

There are many techniques used to investigate the characteristics of the ionosphere [2-4]. The propagation

Table 1. The Radio Spectrum as Defined by the International Telecommunications Union (ITU); Primary Modes of Propagation, and Effects of the Terrestrial Ionosphere

ITU Designation	Frequency Range	Principal Propagation Modes	Principal Uses
Extralow frequency (ELF)	30–300 Hz	Ground wave and Earth–ionosphere waveguide mode	Submarine communication
Very low frequency (VLF)	3–30 kHz	Same as above	Navigation, standard-frequency and -time dissemination
Low frequency (LF)	30–300 kHz	Same as above	Navigation LORAN-C ^a
Medium frequency (MF)	300–3000 kHz	Primarily ground wave, but sky wave ^b at night	AM broadcasting, maritime, aeronautical communication
High frequency (HF)	3–30 MHz	Primarily sky wave, some ground wave	Shortwave broadcasting, amateur, fixed services
Very high frequency (VHF)	30–300 MHz	Primarily LoS, ^c some sky wave at lower VHF	FM broadcasting, television, aeronautical communication
Ultrahigh frequency (UHF)	300–3000 MHz	Primarily LoS, some refraction and scattering by the ionosphere	Television, radar, navigation, ^d aeronautical communication
Superhigh frequency (SHF)	3–30 GHz	Same as above	Radar, space communication

^aThe LORAN-C system will probably be superseded by the GPS system.

^bSky wave denotes the Earth–ionosphere–Earth reflection mode.

^dGlobal Positioning System satellite constellation.

of radio waves in the ionosphere is described in considerable detail in Ref. 5, and solar–terrestrial relations and their effects on radio propagation are covered in Ref. 6. Radiowave propagation at all frequencies depends to different degrees on the geographic and geomagnetic latitudinal region of the ionosphere. The most benign latitudinal region is the midlatitudes; the most disturbed regions are the auroral, equatorial, and polar regions, as described in detail in Ref. 4.

In the next section we describe qualitatively the salient propagation modes and ionospheric effects on radiowaves as a function of frequency. The section after provides a mathematical description and the physical principles of the interaction of radiowaves with the ionosphere. The final section will introduce the reader to the frontiers of ionospheric research at the start of the twenty-first century.

3. EFFECTS ON SPECIFIC RADIO SERVICES

3.1. Extremely Low and Very Low Frequencies (ELF and VLF)

As indicated in Table 1, at the lowest frequencies (ELF–VLF) the basic propagation mode is a spherical waveguide mode, with the D and E regions of the ionosphere forming the upper boundary, and Earth’s surface the lower boundary. A simplified Earth–ionosphere waveguide geometry is shown in Fig. 6. A schematic diagram of the first two waveguide modes in an ideal earth-ionosphere mode is presented in Fig. 7.

In reality, the ELF–VLF waveguide mode is considerably more complicated because of its spherical nature and the electrical characteristics of the upper and lower boundaries. At ELF frequencies, the wavelength is of the same order of magnitude as the transverse dimensions of the waveguide, and the signal propagates deeply into both land and sea because of the skin-depth effect.

At global distances, the signal is very stable, but extremely long antennas and high transmitter powers are required and the signaling rate is extremely slow. One unique advantage of ELF is the ability of the signal to penetrate relatively deeply into seawater (at 100 Hz, the attenuation in seawater is 0.3 dB/m, which is $\approx \frac{1}{3}$ of the

Figure 5. Average variation of ionospheric layer height as a function of season and local time. Note the large change in height of the F2 layer in summer.

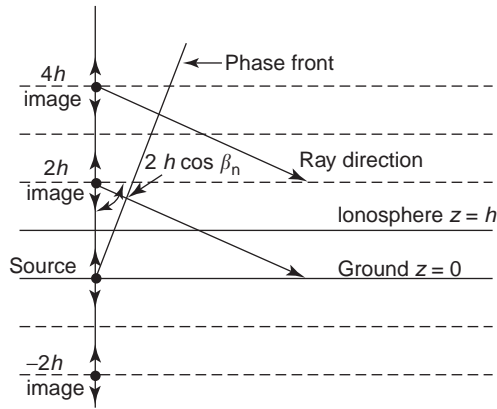

Figure 6. Simplified ray geometry for the first-order and second-order VLF-ELF modes. The two conducting planes are representative at the earth surface and the ionosphere.

attenuation in the Earth-ionosphere waveguide). The attenuation of ELF signals penetrating normal Earth is approximately $\frac{1}{10}$ th that in seawater, so ELF signals can also be used to probe or communicate into the solid Earth. There is also some evidence that high-latitude effects such as D-region irregularities can cause some phase anomalies in ELF and VLF transmissions [7-9].

VLF (3-30 kHz) transmissions also require large antennas and high-power transmitters, but are used more than ELF for time- and frequency-standard dissemination and navigational systems. VLF signals are also influenced by anomalies on Earth's surface [10] and in the high-latitude ionosphere [4].

3.2. Low Frequencies (LF)

Moving up in frequency to the LF band (30-300 kHz), the basic propagation mode below ≈ 100 kHz is by the ground

Figure 7. The E field for ideal Earth-ionosphere waveguide modes.

(surface) wave, which follows Earth's curvature, and above 100 kHz is the sky wave and the waveguide mode. The sky wave is, of course, influenced by the ionospheric diurnal, seasonal, and latitudinal variations.

3.3. Medium Frequencies (MF)

Propagation during the daytime in the MF (300-3000 kHz) band is by ground wave, and for frequencies above 500 kHz, at night by sky wave. At geomagnetic latitudes greater than 55° , the auroral ionosphere introduces some anomalous sky-wave propagation modes [10].

3.4. High Frequencies (HF)

The ionosphere has the most profound effect on signals in the HF (3-30 MHz) band, making the sky-wave mode the dominant means of propagation. The ground wave at HF is sometimes used in the frequency range of 3-6 MHz, especially over seawater, whose conductivity is much greater than that of ordinary land. At HF wavelengths relatively high efficiency, gain, and directivity can be achieved in the antenna systems, so directive communications and broadcasting are realizable. Above 6 MHz, the sky wave is dominant, so one must really understand ionospheric behavior and phenomenology in order to predict propagation. Since the ionosphere varies with time of day, season, solar activity, and sunspot cycle, predicting HF propagation over a specific path can be somewhat complicated. Propagation paths up to $\approx 10,000$ km are quite common for shortwave (SW) broadcasters, who use antennas with gains of up to 20 dBi (dBi is gain referenced to an isotropic source) and transmitter powers of 250 kW and higher. With much less reliability, amateur radio operators (hams) sometimes also achieve two-way communications over similar pathlengths using antenna gains of 3-12 dB and transmitter powers of 5-1000 W.

The ionosphere also behaves differently in the equatorial, midlatitude, auroral, and polar latitudinal regions. Fortunately, several fairly reliable and easy-to-use HF propagation prediction programs are now available to HF system planners for PCs (ASAPS, VOACAP, PropLab-Pro, etc.). The sources of these programs may be found in more recent books and articles [4,5,12,13] and in the amateur radio magazines (*QST*, *CQ*, *Worldradio*, etc.).

Unfortunately, none of the existing prediction programs gives very reliable results at equatorial and high latitudes. They are based on climatological data, so they are not intended for forecasting. A following section describes the mathematical essentials of ionospheric propagation in considerable detail.

3.5. Very High Frequencies (VHF)

Propagation in the VHF band (30-300 MHz) is primarily by line of sight (LoS) to the optical horizon, so if the antenna patterns direct most of the RF power in the horizontal plane, there are essentially no ionospheric effects. For Earth-space propagation paths, however, the ionosphere can affect the signal adversely by refraction, diffraction, scattering, or reflection. These effects can be

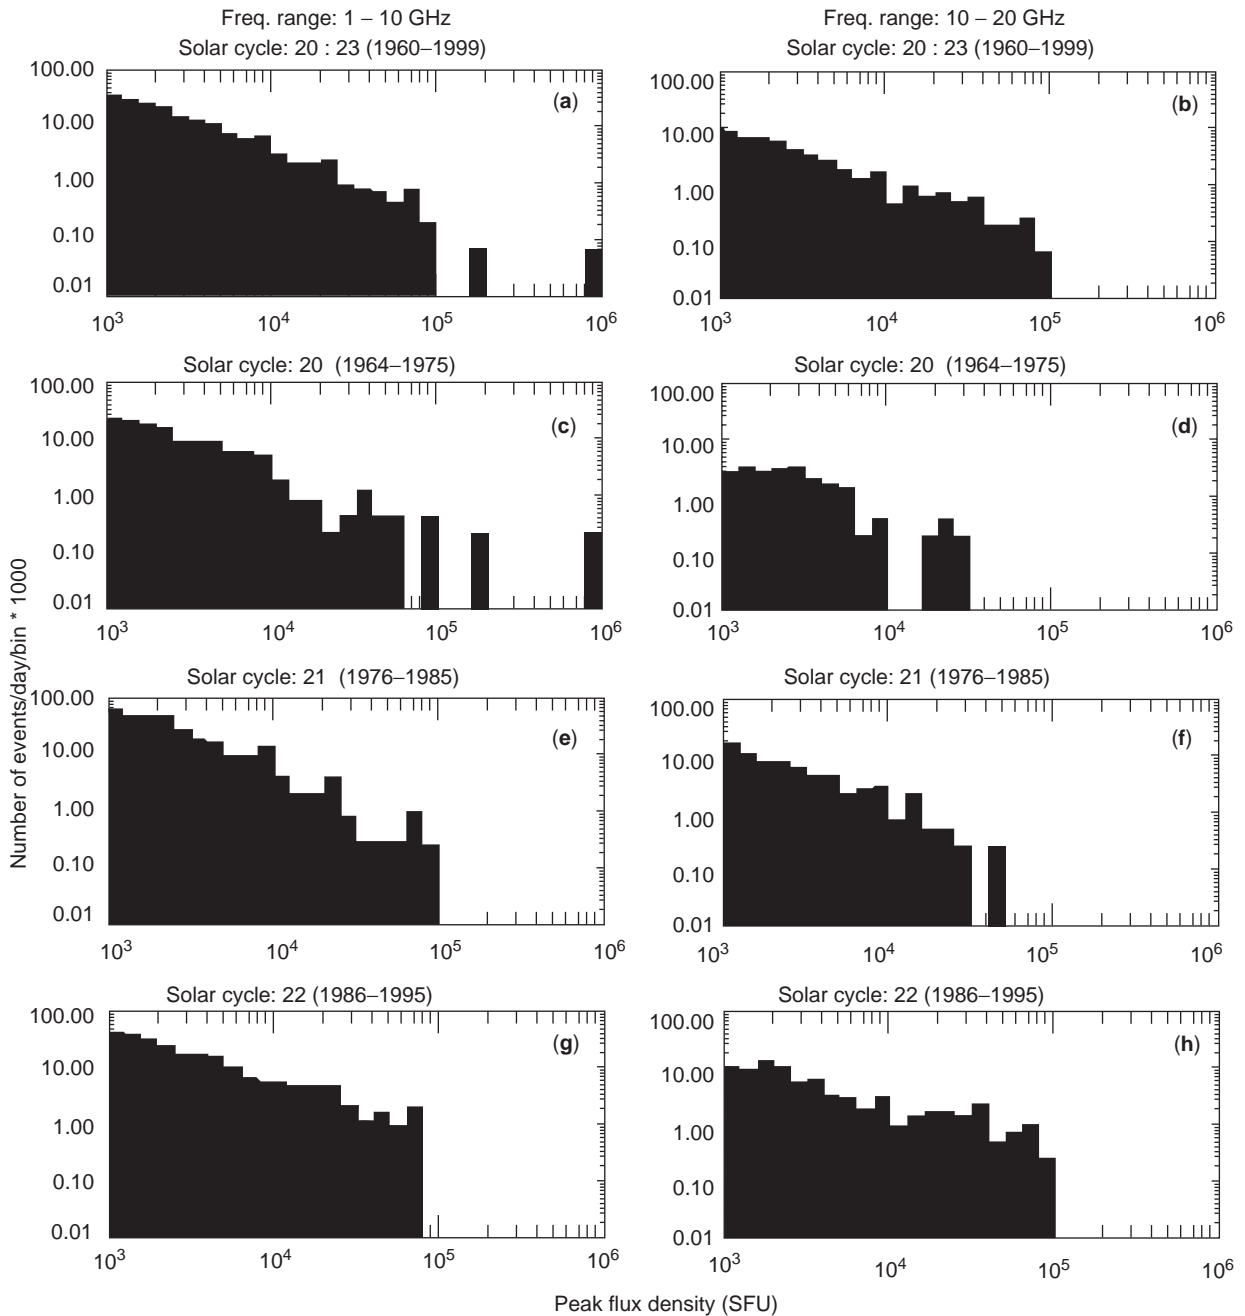

Figure 8. Number of events per day with amplitudes $> 10^3$ SFU (a,b) for 40 years, (c,d) for cycle 20, (e,f) for cycle 21, and (g,h) for cycle 22. The frequency ranges are 1–10 GHz (excluding 10 GHz) shown in the left panels and 10–20 GHz (excluding 20 GHz) in the right panels. Here, the number of events per day per bin is multiplied by 1000.

especially important when the path traverses the equatorial, auroral, and polar ionosphere. The amplitude, phase, and polarization of the signal may change measurably. These effects will be quantified in the following section.

3.6. Ultra High Frequencies (UHF)

At UHF and above, propagation is primarily LoS, and because of the higher frequencies ($f \geq 300$ MHz), these

signals are less affected by the ionosphere than lower frequencies. On Earth–space paths that traverse the equatorial and/or high-latitude ionosphere, however, the signal quality can be significantly degraded at certain times. At “wireless” frequencies ($f \approx 800$ MHz–20 GHz) solar radio bursts can sometime seriously degrade certain wireless systems. Figure 8 shows the variation of peak flux density of solar radio noise with frequency and time, and Fig. 9 shows the total number of events per day as a

Figure 9. Total number of events/day as a function of time in years (a) for peak flux > 10³ SFU and (b) for peak flux > 10⁴ SFU. The frequency ranges are 1–2, 2–4, and 4–10 GHz.

function of time in years for two different solar flux levels [14].

In a 2002 paper [15], the ionospheric effects on satellite land–mobile services tabulated the estimated maximum ionospheric effects on these services as shown in Table 2. The complete report may be seen at <http://www.utexas.edu/mopro/>.

To summarize, the radio services most affected by the ionosphere lie in the frequency range of 1–150 MHz [fixed communication services, AM (amplitude modulation) and SW (shortwave) broadcasting, amateur radio]. To a lesser degree, services in the 20 kHz–300-MHz region (mainly some of the navigation services) also suffer some ionospheric perturbation effects.

There is a plethora of radio instrumentation currently deployed globally that operates routinely or on a campaign

basis to measure characteristics of the terrestrial ionosphere. It is beyond the scope of this article to describe these techniques, but they have been described in considerable detail in the literature [2–4].

4. PHYSICAL PRINCIPLES AND MATHEMATICAL DESCRIPTION OF ELECTROMAGNETIC INTERACTION WITH THE IONOSPHERE

Because of the complexity of the terrestrial ionosphere (a weakly ionized plasma with a superimposed magnetic field in which electric currents flow), we must utilize the magnetoionic theory to quantify the ionosphere physical parameters. The most successful formulation of the appropriate magnetoionic theory was derived by Appleton and others in the mid-1920s [15–18]. We can obtain some first-order properties of the ionosphere by ignoring the magnetic field [19,20]. A simple dispersion equation for electromagnetic (EM) waves in the ionosphere is

$$\mu = \sqrt{1 - \frac{Ne^2}{\pi mf^2}} \tag{1}$$

where

- μ = refractive index of the ionosphere (real part of complex refractive index n)
- N = electron number density of the ionosphere (electrons/cm³ or electrons/m³)
- e = electronic charge = 1.6×10^{-19} C
- m = mass of the electron = 9.1×10^{-31} kg
- f = frequency of the radiowave in the ionosphere (Hz)

For reflection at vertical incidence, $\mu = 1$ and

$$\begin{aligned} N &= \frac{\pi mf^2}{e^2} \\ &= 1.24 \times 10^4 f^2 \text{ (electrons/cm}^3 \text{ and } f \text{ in MHz)} \\ &= 1.24 \times 10^{10} f^2 \text{ (electrons/cm}^3 \text{ and } f \text{ in MHz)} \end{aligned} \tag{2}$$

Table 2. Estimated Maximum Ionospheric Effects (Elevation Angle of 30°, One-Way Traversal)

Effect	Frequency Dependence	0.1 GHz	0.25 GHz	0.5 GHz	1 GHz	3 GHz	10 GHz
Faraday rotation	f^{-2}	30 rot. ^a	4.8 rot.	1.2 rot.	108°	12°	1.1°
Time (group) delay	f^{-2}	25 μs	4 μs	1 μs	0.25 μs	0.028 μs	0.0025 μs
Refraction	f^{-2}	<1°	<0.16°	<2.4'	<0.6'	<4"	<0.36"
Change in direction of arrival	f^{-2}	20'	3.2'	48"	12"	1.33"	0.12"
Absorption (auroral and/or polar cap)	f^{-2}	5 dB	0.8 dB	0.2 dB	0.05 dB	0.006 dB	0.0005 dB
Absorption (mid-latitude)	f^{-2}	<1 dB	<0.16 dB	<0.04 dB	<0.01 dB	<0.001 dB	<0.0001 dB
Dispersion	f^{-3}	400 ps/kHz	26 ps/kHz	3.2 ps/kHz	0.4 ps/kHz	45 ts/kHz	0.4 ts/kHz

^aRotations.

Note: Extrapolated from 1-GHz values given by the former CCIR Study Group 6 in Table VII of Report 263, and based on a total electron content (TEC) of 10¹⁸ electrons/m², which is a high value of TEC encountered at low latitudes in daytime with high solar activity. A similar chart may be found in Recommendation ITU-R P.618-6 of Study Group III.

Another useful quantity is the plasma frequency,

$$\begin{aligned}
 F_n &= \sqrt{\frac{Ne^2}{\pi m}} \\
 &= 9\sqrt{N} \quad (f \text{ in kHz and } N \text{ in electrons/cm}^3) \\
 &= 9 \times 10^{-3}\sqrt{N} \quad (f \text{ in MHz and } N \text{ in electrons/cm}^3)
 \end{aligned}
 \tag{3}$$

4.1. The Virtual Height Concept

If we consider an RF pulse traveling vertically upward into the ionosphere at the speed of light, $v = c$, it will be reflected at the virtual height, h' . The time required for the pulse to be reflected from an ionospheric layer and return to Earth is

$$t = \frac{2}{c} \int_0^h \frac{dz}{\mu} \tag{4}$$

then the virtual height can be found from $h(f) = \frac{1}{2} ct$, or

$$h'(f) = \int_0^h \frac{dz}{\sqrt{1 - f_n^2/f^2}} \tag{5}$$

Since the pulse always travels more slowly in the layer than in free space, the virtual height of a layer is always greater than the true height. The true height and virtual height are related by the integral equation

$$h'(f) = \int_0^{Z_{\max}} \frac{dz}{\mu(f, z)} \tag{6}$$

where z is the true height, Z_{\max} is the maximum height reached by the frequency f , and n is the refractive index at Z_{\max} for the frequency f . A good discussion of the relation between true height and virtual height is given in Ref. 20.

4.2. Vertical and Oblique Propagation

Before considering the behavior of a radio signal in a magnetoionic medium, we will state three theorems that relate oblique and vertical incidence propagation as depicted in Fig. 10. The first is the secant law, which relates the vertical-incidence frequency f_v reflected at B to the oblique-incidence frequency f_{ob} reflected at the same true height. A typical derivation of this relation is given in Ref. 5, and it is usually written as

$$f_{ob} = f_v \sec \varphi_0 \tag{7}$$

The secant law, then, relates the two frequencies f_v and f_{ob} reflected from the same true height (the distance BD in Fig. 10).

In order to determine $\sec \varphi$ and f_{ob} values from vertical-incidence soundings (which measure the virtual height h'), we need two more theorems. Breit and Tuve's theorem states that the time taken to traverse the actual curved path $TABCR$ in Fig. 10 at the group velocity v_g equals the

Figure 10. Plane geometry describing vertical and oblique ionospheric propagation.

time necessary to travel over the straight-line path TER at the free-space velocity c . Referring to the geometry shown in Fig. 10, we can write the expression

$$\begin{aligned}
 T &= \frac{1}{c} \int_{TER} \frac{dx}{\sin \varphi_0} \\
 &= \frac{D}{c} \sin \varphi_0 \\
 &= \frac{TE + ER}{c}
 \end{aligned}
 \tag{8}$$

Martyn's theorem may be written concisely as

$$h' = h'_v \tag{9}$$

Smith [21] devised a set of logarithmic transmission curves, parametric in range, for the curved earth and ionosphere. They are shown in Fig. 11 and are sufficiently accurate for the distances shown.

4.3. Radio Propagation in a Magnetized Plasma

Before proceeding with a discussion of the Appleton (magnetoionic) equations, we need to define two quantities contained explicitly in the equations. The first is ν , the number of collisions per second (collision frequency) between electrons and heavier particles (ions and neutrals). Another quantity, the gyro-magnetic frequency or gyrofrequency, is the natural frequency (Hz) of gyration of an ion or electron in a magnetic field of strength B_0 (Wb/m²) and is given by

$$f_H = \frac{|e|\hbar}{2\pi m} B_0 \approx 2.80 \times 10^{10} B_0 \tag{10}$$

and the angular gyrofrequency is given by

$$\omega_H = \frac{|e|\hbar}{m} B_0 \approx 1.76 \times 10^{11} B_0 \tag{11}$$

Since electrons are much less massive than ions, the electron gyrofrequency affects the propagation of HF waves in the ionosphere more than the ion gyrofrequencies. For example, since $B \approx 0.5 \times 10^{-4}$ Wb/m², the electron gyrofrequency is ≈ 1.40 MHz, which falls at the upper end of the medium waveband.

Figure 11. Logarithmic transmission curves for curved Earth and ionosphere, parametric in distance between transmitter and receiver.

4.4. The Dispersion Relation

Using the recommended URSI (International Union at Radio Science) notation, the magnetoionic dispersion equation for a radiowave in a homogeneous, partially absorbing ionized gas on which a constant magnetic field is impressed is given by

$$n^2 = 1 - \frac{X}{(1-jZ) - \left[\frac{Y_T^2}{2(1-X-jZ)} \right]} \pm \left[\frac{Y_T^4}{4(1-X-jZ)^2} + Y_L^2 \right]^{1/2} \quad (12)$$

where

n = complex refractive index $= (\mu - jX)$
 ω = angular frequency of the exploring wave (rad/s)
 ω_N = angular plasma frequency
 ω_H = angular gyrofrequency $= B_o |e| / m$ (rad/s)
 ω_L = longitudinal angular gyrofrequency $= (B_o |e| / m) \cos \theta$
 ω_T = transverse angular gyrofrequency $= (B_o |e| / m) \sin \theta$
 $X = \omega_N^2 / \omega^2$
 $Y = \omega_H / \omega$
 $Y_L = \omega_L / \omega$
 $Y_T = \omega_T / \omega$
 $Z = \nu / \omega$
 θ = angle between the wave-normal and the magnetic field inclination

4.5. The Polarization Relation

We begin by defining the polarization ratio R as

$$R = \frac{-H_y}{H_x} = \frac{E_x}{E_y} \quad (13)$$

Then we can write the double-valued polarization equation as

$$R = -\frac{j}{Y_L} \left[\frac{1}{2} \frac{Y_T^2}{(1-X-jZ)} \mp \left(\frac{1}{4} \frac{Y_T^2}{(1-X-jZ)^2} + Y_L^2 \right)^{1/2} \right] \quad (14)$$

In the upper F region of the ionosphere where the electron-ion collision frequency is very low, we may simplify the dispersion and polarization equations by dropping the Z term (since $\nu \approx 0$). Equations (12) and (14) then become (for no absorption)

$$n^2 = 1 - \frac{2X(1-X)}{2(1-X) - Y_T^2 \pm [Y_T^4 + 4Y_L^2(1-X)^2]^{1/2}} \quad (15)$$

and

$$R = -\frac{H_y}{H_x} = -\frac{j}{Y_L} \left(1 + \frac{X}{n^2 - 1} \right) \quad (16)$$

If we further simplify Eq. (12) by dropping the Y terms (no magnetic field), then we obtain $n^2 = 1 - X$, which is equivalent to Eq. (1).

According to magnetoionic theory, a plane-polarized EM wave traveling in a medium like the terrestrial ionosphere will be split into two characteristic waves. The wave that most closely approximates the behavior of a signal propagating in this medium without an imposed magnetic field, is called the *ordinary wave*, and the other is called the *extraordinary wave*. These terms are taken from the nomenclature for double refraction in optics, although the magnetoionic phenomena are more complicated than the optical ones. The ordinary wave is represented by the upper sign in the polarization Eq. (14), except when the wavenormal is exactly along the direction of the magnetic field. Anomalous absorption

occurs for the extraordinary wave when its frequency equals the electron gyrofrequency ($f_H = |B|e/me \approx 0.8\text{--}1.6$ MHz). These frequencies lie in the medium-frequency (MF) band; consequently the absorption of the extraordinary wave [$A \approx (f - f_H)^2$] is large and the polarization of the transmitted wave is important in the determination of the fraction of the incident power that goes into the extraordinary wave. This is especially true near the magnetic dip equator, where the magnetic field is nearly horizontal.

In addition to anomalous absorption effects near the electron gyrofrequency, the wave may also experience significant lateral deviation. This is illustrated for vertical and oblique propagation in Sections 11.2.2–11.2.4 of Ref. 4.

If Eq. (16) is recast as a function of ω and we define $f(\theta) = \frac{1}{2}(\sin^2 \theta)/\cos \theta$ and $\omega_c = (B_0 |e|/m) f(\theta)$, then it will be seen to describe an ellipse. The quantities $f(\theta)$ and ω_c play an important part in the description of the polarization behavior of waves in magnetoionic theory. The magnitude of ω_c is independent of frequency, but varies with the angle between the wavenormal and the magnetic field θ , whereas the sign of ω_c depends on the sign of the charge e and the direction of the magnetic field. For longitudinal propagation $\omega_c = 0$, and for transverse propagation $\omega_c \rightarrow \infty$. In the case where $X=1$, the quantity ω_c primarily determines the polarization of the wave. A very complete discussion of R as a function of X and of the variation of the polarization ellipse is given in Ref. 22.

A more complete understanding of the behavior of EM waves in the terrestrial ionosphere may be obtained by employing two approximations. The quasilonitudinal (QL) approximation applies when the wave is propagating nearly parallel to the geomagnetic field, and the quasitransverse (QT) approximation applies when the wave propagates in a direction nearly normal to the geomagnetic field. References 22 and 23 contain extended discussions of the QL and QT approximations:

$$\text{QT: } Y_T^4 \gg 4(1-X)^2 Y_L^2$$

$$\text{QL: } Y_T^4 \ll 4(1-X)^2 Y_L^2$$

4.6. Absorption of Radiowaves in the Ionosphere

The refractive index n is modified when one introduces collisions between the electrons and heavy particles, and the wave then experiences absorption, which physically is due to the conversion of ordered momentum into random motion of the particles after collision. For each collision, some energy is transferred from the EM wave to the neutral molecules and appears as thermal energy. We will follow the standard treatment of absorption of radio waves in the ionosphere presented by Davies [23] and Budden [24].

For the propagation of an EM wave in an unmagnetized plasma, we can define the absorption index (or coefficient) as

$$K = \frac{\omega}{c} X \quad (17)$$

where X is the imaginary part of the refractive index n . For a magnetized plasma without collisions, we can write

$$K = \frac{e^2}{2\varepsilon_0 m c \mu} \cdot \frac{N\nu}{\omega^2 + \nu^2} \quad (18)$$

On this basis, we can conveniently divide absorption into two limiting types, commonly called *nondeviative* and *deviative absorptions*. Nondeviative absorption occurs in regions where the product $N\nu$ is large and $\mu \approx 1$, and is characterized by the absorption of HF waves in the D region. Deviative absorption, on the other hand, occurs near the top of the ray trajectory or anywhere else on the ray path where significant bending takes place (for small $N\nu$ and $\mu < 1$).

When the refractive index ≈ 1 , there is essentially no bending of the ray and we can write

$$K \approx 4.6 \times 10^{-2} \frac{N\nu}{\mu(\omega^2 + \nu^2)} \text{ dB/km} \quad (19)$$

We can further simplify Eq. (19) for the VHF case, since $\omega^2 \gg \nu^2$, as

$$K = 1.15 \times 10^{-3} \frac{N\nu}{f^2} \text{ dB/km} \quad (20)$$

In the MF and HF bands, Eq. (19) may be written as

$$K = 4.6 \times 10^{-2} \frac{N}{\nu} \text{ dB/km} \quad (21)$$

Unlike nondeviative absorption, deviative absorption occurs when the wave experiences significant group retardation and consequently spends a relatively long time in the absorbing layer and there is considerable curvature of the ray path. The general expression for the absorption index in a deviating region of a nonmagnetic plasma is

$$K = \frac{\nu}{2c\mu} (1 - \mu^2 - X^2) \quad (22)$$

In the ionosphere, Eq. (22) reduces to

$$K = \frac{\nu}{2c} \mu' \quad (23)$$

where μ' is the group refractive index. For large values of μ' , we can write the preceding equation as

$$K = \frac{\nu}{2c} \frac{X}{\sqrt{1-X}} \quad (24)$$

We should remember that the concepts of deviative and nondeviative absorption are limiting cases, and that as a wave approaches the reflecting level, ray theory breaks down, so we must employ full wave theory to obtain a complete description of the behavior of the wave. Extended discussions of application of the QL and QT approximations to ionospheric absorption may be found in Refs. 5 and 23.

4.7. Scattering of Radiowaves in the Ionosphere

The principles of scattering of radiowaves in general are discussed in the articles on electromagnetic wave scattering in this encyclopedia. One can qualitatively describe ionospheric scattering as either strong or weak in terms of the received signal strength of the scattered signal at the receiving radar antenna. An example of the former is VHF–UHF backscatter echoes received from electron density gradients in the auroral E region, and an example of the latter is incoherent backscatter received by a VHF–UHF radar from the undisturbed E or F layer.

Another way of classifying scattered echoes is in terms of their backscatter cross section (using a pulsed radar system) and their temporal stability. A coherent echo exhibits a statistical correlation of the amplitude and phase from one pulse to another and emanates from quasideterministic gradients in electron density, which have correlation times usually greater than 1 ms, corresponding to a spectral width of the radar echo of less than 1000 Hz (sometimes less than 100 Hz). It also has a backscatter cross section 10^4 – 10^9 times greater than that from an incoherent echo. Other important considerations in the case of coherent backscatter are the relation between the scattering irregularity size relative to the backscatter sounder free-space wavelength, the mean fractional deviation in electron density of the scatterer, and the aspect angle between the radar line of sight and the major axis of the irregularity. On the other hand, an incoherent echo arises from random thermal fluctuations in the ionosphere, which have typical correlation times of $\approx 20 \mu\text{s}$, corresponding to a radar echo spectral width of $\approx 50 \text{ kHz}$.

The physical principles governing coherent and incoherent scattering from the ionosphere are covered in Refs. 2, 5, and 6, while plasma wave theory is covered in detail in Ref. 5, and extended descriptions of techniques for studying the ionosphere using coherent- and incoherent-scattering sounders are given in Refs. 2,3,5, and 6.

Because of charged particle precipitation of solar origin, ionospheric electric currents and fields, and plasma dynamics, there exists a wide spectrum of scale sizes of ionospheric irregularities, as shown in Fig. 12. Irregularities are most prevalent at auroral, polar, and equatorial latitudes, although they also exist at midlatitudes [23]. The global morphology of ionospheric irregularities is covered in Refs. 4–6.

4.8. Ionospheric Scintillation

Ionospheric scintillations are fluctuations of amplitude, phase, and angle of arrival of a VHF–UHF signal passing through irregularities located mainly in the F region. Ionospheric scintillations can have deleterious effects on satellite-based communication and navigation systems. Either extragalactic sources (such as radio stars) or satellite beacon transmitters may be used as the signal sources for Earth-observed studies of ionospheric scintillations, and both geostationary and orbiting satellite beacons have been used. There is a voluminous body of literature since

Figure 12. Composite spectrum of ionospheric irregularities as a function of wavenumber over a large spatial scale. (Courtesy of H. G. Booker.)

1970 describing the theory, technique, and results of ionospheric scintillation measurements [2–6].

4.9. Faraday Rotation

One physical principle that makes possible the determination of ionospheric columnar electron content is Faraday rotation. This effect (for optics) was discovered by Michael Faraday in 1845, when he subjected a block of glass to a strong magnetic field. He observed that a plane-polarized monochromatic beam of light passing through the glass in a direction parallel to the imposed magnetic field has its plane of polarization rotated. The amount of rotation is given by the expression

$$\Omega = KHI \quad (25)$$

where Ω is the angle of rotation, K is a constant associated with each substance, l is the pathlength of light through the substance (m), and H is the magnetic field intensity (A/m).

The Faraday rotation of the electric vector of a radio-wave (see Ref. 45) propagating from a satellite radio beacon in a direction parallel to Earth's magnetic field (as seen by an observer looking up, in the Northern Hemisphere) is counterclockwise, as shown in Fig. 13.

Figure 13. Simplified plane geometry of satellite–Earth propagation path in the Northern Hemisphere to explain Faraday rotation effects.

Ignoring refraction, the Faraday rotation of the electric vector is given by

$$\Omega = \frac{\pi f}{2c} \int_R^S X \sqrt{\frac{Y_T^4 + 4(1 - X)^2 Y_L^2}{(1 - X)(1 - Y_L^2 - Y_T^2)}} ds \quad (26)$$

where

Ω = Faraday rotation (rad/s)

f = wave frequency (Hz)

$c = 2.998 \times 10^8$ m/s

$X = kN/f^2$

$k = 80.61$

N = electron density (electrons/m³)

and Y_L, Y_T are as previously defined.

The integration is between the receiver R , and the satellite S . For VHF frequencies the QL approximation holds and we can express Eq. (26) as

$$\Omega = \frac{\pi K}{c f^2} \int_R^S f_L N ds \quad (27)$$

where $N ds$ is the ionospheric electron content. Evaluating the constants yields the relation

$$\Omega \approx 8.447 \times 10^{-7} f^{-2} \int_R^S f_L N ds \text{ rad} \quad (28)$$

where $f_L = 2.80 \times 10^{10} B_L$, the electron gyrofrequency corresponding to the longitudinal component of the geomagnetic field along the ray path. Details of the application of Faraday rotation theory and other techniques to deduce ionospheric columnar electron content may be found in Refs. 2, 5, and 6.

4.10. Whistlers

Whistlers are bursts of EM radiation at VLF that are initiated by lightning discharges and then travel through the ionosphere and magnetosphere in ducts approximately parallel to geomagnetic lines of force. When translated into sound waves, whistlers are distinguished by tones of decreasing (or sometimes increasing) frequency, and they may easily be detected by connecting a suitable antenna to the input of a very sensitive audio amplifier. In fact, whistlers were first observed in the last years of the nineteenth

Figure 14. Sketch of basic manifestations of a whistler and its initiating disturbance: (a) the frequency spectrum; (b) frequency–time curve of a typical whistler; (c) curve of $\sqrt{1/f}$ with time. Initiating disturbance and multiple hops when the source and receiver are at the same end of a magnetic line of force. (After Helliwell [26].)

century, and were also heard on the primitive field telephone systems used in World War I. They have been studied intermittently since 1898, basically as a diagnostic probe of the ionosphere and magnetosphere [2,26]. A graphical representation of whistler behavior is shown in Fig. 14, and the somewhat rarer nose whistler behavior is illustrated in Fig. 15.

The dispersion relation for whistlers is

$$T = \frac{1}{2c} \int_S \frac{(f_N f_L ds)}{f^{1/2} (f_L - f)^{3/2}} = \frac{D}{f^{1/2}} \quad (29)$$

Figure 15. Idealized sketch of the frequency–time characteristics of a nose whistler. (After Davies [5].)

where D is dispersion $= (1/2c) \int_s (f_N/f_L^{1/2}) ds$, f_N is plasma frequency, and f_L is a longitudinal component of the plasma frequency. This is the time T for a signal burst to go from one hemisphere to its conjugate point in the opposite hemisphere.

Other natural VLF emissions (called “dawn chorus,” “risers,” “hiss,” etc.) that are thought to originate in the ionosphere can also be heard on whistler detection equipment. Since the 1960s, high-power VLF transmitters have been used to generate whistlers to study properties of the magnetosphere [27–29].

5. FRONTIERS OF IONOSPHERIC RESEARCH

The use of radiowaves to explore the terrestrial ionosphere began with the pioneering efforts of Appleton and of Breit and Tuve in 1926, when they independently used different techniques to detect the ionospheric layers. Their work was founded on Marconi’s demonstration of transatlantic radio transmission and on the hypotheses of Kennelly and Heaviside, who independently in 1922 postulated that there must be radio-reflecting layers in the upper atmosphere to explain certain experimental results. The foregoing discoveries rested on the bedrock of the experimental and theoretical work of Heinrich Hertz (1893) and James Clerk Maxwell (1873), respectively.

There seems to have been several crests in the history of ionospheric research: (1) in the 1920s, following World War I; (2), starting shortly after the end of World War II; and (3) perhaps starting in the mid-1970s with the advent of digital techniques, and (4) more recently with the advent of the National Space Weather Program (see Ref. 30 or <http://www.geo.nsf.gov/atm/>).

While much of the ionospheric research up until about 1960 was in support of HF communications, the advent of satellite communications changed the emphasis to ionospheric research concerning the effects of the ionosphere on transionospheric propagation and research relating the ionosphere to the magnetosphere. Most current ionospheric research is related to the interrelationship and coupling between regions over the entire height region of the terrestrial atmosphere from the troposphere to the magnetosphere and through interplanetary space to the sun.

There are several areas of ionospheric research that currently seem to be producing exciting new results, and these areas will probably continue to be emphasized in the twenty-first century. These areas include (not necessarily in order of importance) satellite sensors, ionospheric mod-

ification by using high-power HF transmissions, ionospheric imaging, coherent radars operating from HF through VHF, and incoherent scatter radars [2–5]. Most of these techniques are employed at high geomagnetic latitudes as part of the Space Weather Program [31], but some are also deployed in equatorial regions. We will briefly describe the essentials of each of these areas of current ionospheric research emphasis.

5.1. Satellite Sensors

The total number of currently operational solar-terrestrial environment satellite probes is too numerous to list in this article, but examples of representative satellite sensors may be found at <http://www.nasa.gov>, and <http://www.esa.int>. These satellites probe the solar physical properties, the solar wind, the interplanetary magnetic field, and the terrestrial magnetosphere and ionosphere and provide realtime data to aid in forecasting and describing solar-terrestrial conditions.

5.2. Ionospheric Modification

In the late 1960s the availability of military surplus equipment such as very-high-voltage and -current power supplies and HF vacuum tubes capable of many kilowatts of RF output, together with advances in antenna array theory and practice, induced experimenters to design systems to heat or otherwise modify the ionosphere. As a result of experiments performed in the early 1970s at the Platteville, Colorado HF high-power heating facility [32], some 10 new ionospheric modification facilities were established and have produced significant information on ionospheric physics. (see Chapter 14 of Ref. 5). The various modification facilities are listed in Table 3. Other ionospheric modification facilities are located in Russia and Ukraine at Kharkov, Moscow, Zimenki, and Monchegorsk. More information on the HAARP and other heaters may be obtained on the Internet at <http://www.haarp.alaska.edu>.

5.3. Ionospheric Imaging by Radio

For over three decades now (as of 2003), ionospheric scientists have investigated using radio methods to image the ionosphere. Rogers [33] was probably the first to suggest using the wavefront reconstruction method for this purpose. Many attempts have been made to produce holographic images of the ionosphere, but it has not proved to be a very successful technique—probably because of the difficulty in uniformly illuminating a sufficiently large

Table 3. Ionospheric Modification Facilities (1970–1978)

Facility	First Used	Latitude	Longitude	Geomagnetic Latitude	Transmit Power	Frequency Range (MHz)	Antenna Gain (dB)
Platteville, CO	1970	40.2°N	104.7°W	49°	1.6 MW	2.7–25	18
Arecibo, PR	1980	18°N	67°W	32°	800 kW	3–15	25
SURA, Russia	1980	56.1°N	46.1°E	71°	750 kW	4.5–9	26
Tromsø, Norway	1980	69.6°N	19.2°E	67°	1.5 MW	2.5–8	28
HIPAS, Alaska	1977	64.9°N	146.8°W	65°	800 kW	2.8, 4.5	17
HAARP ^a Alaska	1997	62.4°N	145.2°W	62°	3.6 MW ^a	2.8–10	30 ^a

^aHAARP is currently under construction. Values given are for the completed facility.

Figure 16. Basic satellite–Earth geometry for computer ionospheric tomography, illustrating the multiple ray paths on which the total electron content is measured.

horizontal slab of the ionosphere, not using a sufficient number of receivers, and the inability to achieve precise enough measurements of amplitude and phase of the reflected wave.

On the other hand, another technique (borrowed from medical technology), computerized ionospheric tomography (CIT), has produced quite significant results in imaging the regular (and some irregular) features of the ionosphere. Basically, this technique utilizes radio beacons on satellites in near-polar orbits and a latitudinal chain on the Earth subsatellite path of carefully calibrated TEC receivers, to make many measurements of total electron content (TEC). The basic geometry is illustrated in Fig. 16.

Currently, VHF–UHF beacons on the TRANSIT, GLONASS, and GPS satellites are the most used as signal sources to measure TEC to use in CIT ionosphere reconstructions. One must also use some a priori informa-

tion (ionospheric models) and ionosonde data in the algorithms in order to achieve realistic results. Some recent results are summarized in Refs. 34–39 and on the Internet at <http://www.nwra-az.com/iitc>, and at <http://sideshow.jpl.nasa.gov:80/gpsiono>.

Another ionospheric imaging technique is the IRIS system (imaging riometer–ionospheric studies) [46], which uses an antenna array of up to 64 elements to provide images of enhanced auroral absorption structure in the D region.

5.4. Coherent Radars

As described in the Section 4.7, HF–UHF coherent backscatter from ionospheric irregularities can provide very useful information on the morphology and physics of a wide range of irregularity scale sizes. At this time there are about 20 of these backscatter sounders deployed, operating on frequencies from 8 to 200 MHz, distributed mainly in the high-latitude and equatorial regions. These radars are sited so that the main antenna lobe is directed to intercept irregularities at near-normal incidence at E- and F-region heights.

The HF coherent radars are mainly grouped into a large network, which covers approximately half of the northern polar cap ionosphere—the SuperDARN network [40], which is shown on the map in Fig. 17. Much information has been gained on the F-region plasma convection patterns in the polar cap, atmospheric gravity waves, and other ionospheric phenomena related to ionosphere magnetosphere interaction; see Refs. 40–43 or <http://sd-www>.

Figure 17. Map of Northern Hemisphere showing coverage of SuperDARN high-frequency radars.

jhuapl.edu/RADAR. The VHF–UHF coherent radars are documented in Refs. 2–5, and a useful Internet sources is to be found at http://www.dan.sp-agency.ca/www/canopus_home.html.

5.5. Incoherent Scatter Radars

One of the most powerful Earth-based radio methods for studying the ionosphere is the incoherent scatter radar (ISR) technique, which has been in use since the early 1960s. ISRs can reveal the electron density, electron and ion temperature, plasma velocity, and other ionospheric parameters, even during very disturbed conditions [2–5]. At the present time there are some seven ISRs in operation, located from the north polar cap to the magnetic equator and spread longitudinally from Scandinavia to Japan. The newest ISR is located at Svalbard, Norway [44]. Data from ISRs are essential in studying the relation between the magnetosphere, ionosphere, and middle atmosphere at high and equatorial latitudes [47,48].

5.6. Large-Scale Ionospheric Data Assimilation

At this time there is a staggering amount of solar terrestrial and ionospheric data available from many diverse sources—especially from the “Space Weather” sensors, and there are several sophisticated ionospheric computer models [49].

1. INTRODUCTION

1.1. Electromagnetics Overview

The modeling, design, and optimization of RF/microwave structures is a very challenging and time-consuming task because of the difficulties in predicting the high-frequency effects (multimoding, loss mechanisms, parasitics) for specific devices and their interaction with other devices in close proximity. Even if a single component is well char-

acterized in isolation, effects such as surface waves and parasitics lead to signal corruption and degraded performance when the element is placed in a circuit with other components. The study of electromagnetic interaction is key to properly understanding the operation of any RF or microwave device. In these devices, it is often better to think in terms of electromagnetic fields rather than voltages and currents, as is usually done in lower-frequency circuits. The characterization of low-frequency circuits by voltage and current is possible because Maxwell's equations, which govern electromagnetic interaction, can be approximated with circuit equations when a structure is significantly smaller than the maximum wavelength supported by the device. As the wavelength approaches and becomes comparable to the size of the device being studied, as in RF devices (and, as another example, in low-frequency power transmission lines), these approximations are no longer valid. When electromagnetic interactions are not evaluated in these devices, performance degradation often results. For example, when digital circuitry and RF components are used in close proximity, digital switching noise can corrupt RF signals, rendering the device useless. Proper consideration of electromagnetics in this case can account for this interaction and lead to the creation of a successful design.

To analyze these components and their interaction mechanisms, it is often necessary to use electromagnetic simulation software. There are a number of commercial simulation packages, and significant research is ongoing to find new methods and to solve new classes of problems such as MEMS (microelectromechanical systems), periodic structures, and metamaterials. These tools allow the characterization of RF and microwave devices before the fabrication stage, which can save considerable time and money in the design process. In addition, they can be used to optimize devices, allowing hundreds or thousands of configurations to be tested. Because of the complexities of modern microwave structures, it would be impossible to design many modern RF devices and modules without the use of electromagnetic simulators.

Electromagnetics is the study of the fields created from the motion of charge. If these charges are stationary, a static, or unchanging, electric field results. If these charges are moving with constant velocity, a static magnetic field results. If these charges accelerate (change speed or direction with time), then the result is a coupled electromagnetic field. This is because a changing electric field creates a magnetic field, and a changing magnetic field creates an electric field. The result is a propagating electromagnetic wave. The equations that govern electromagnetic phenomena are called *Maxwell's equations*.

Because of the difficulty of applying the necessary boundary conditions on arbitrary structures, Maxwell's equations cannot be solved analytically for most cases of interest to the RF or microwave designer. Beyond special cases no analytic expressions can be found that relate the fields in the structure to a specific source condition. Instead, the equations that represent electromagnetic interaction must be discretized (expressed as simple arithmetic equations) so that they can be solved numerically. Although it is possible to solve these equations by hand, the

number required to accurately characterize a typical RF device is usually in the millions or billions, necessitating the use of computers. As these methods use computers to perform mathematical operations on numbers, they are referred to as *computational* or *numerical electromagnetic methods*. Numerical methods are a branch of mathematics in their own right, and are used in all of science and engineering, from quantum mechanics to meteorology. These techniques are chosen and applied largely according to the type of differential equation modeled. In electromagnetics, they are often split into two categories: time-domain and frequency-domain methods.

Maxwell's equations are usually expressed in terms of either time or frequency. The time form of the equations shows the propagation of electromagnetic fields as they could be observed by recording the time variation of the electromagnetic fields at any point in space. Another method of representing electromagnetic phenomena is by considering the response to a harmonic (single sinusoidal frequency) or "monochromatic" source. Maxwell's equations can be transformed to give frequency-domain solutions in this case. The choice of the domain of the simulator depends on whether the response of the device has to be modeled over a wide or narrow frequency band and whether the field variation changes significantly for different bands (multimode propagation). Results in either domain can be transformed to the other, but computational requirements vary.

In the world of electromagnetics, there are distinct advantages to both time- and frequency-domain simulations. Each frequency-domain simulation is valid for only a single frequency. If the response of the device over a band is desired, then several frequency points over the band must be simulated. Time domain simulations, on the other hand, can be transformed to give results over a wide frequency band. A drawback of time-domain techniques is that it is more difficult to apply the effects of materials that have characteristics that change with frequency, such as dispersive media. These materials are common in RF circuits, and thus complicated methods must be used to allow their accurate modeling in the time domain. Likewise, it is difficult to extract transient data from a frequency-domain simulation.

The two major computational criteria for the selection of a specific numerical simulator are speed and accuracy. These are not independent parameters, all simulators can be made more accurate at the expense of speed. It is not possible to choose a simulator that is the best for all situations. Many comparisons have been made between simulators [1,2], and depending on the problem type, certain techniques are often preferred.

The purpose of this article is to give an overview of the most widely used time-domain simulation techniques. In addition, specific advantages and weaknesses of each method are highlighted, along with some references that can provide more details about each method. With the information presented here, the reader should be able to understand how the different simulation techniques can be applied to specific problems and how the features of that problem place restrictions on the simulation techniques. The article begins with a quick overview of elec-

tromagnetics and then uses this information to explain the simulation methods.

2. THEORY

2.1. Maxwell's Equations

The differential form of Maxwell's equations in the time domain can be expressed as

$$\nabla \times \mathbf{E}(t) = -\frac{\partial \mathbf{B}(t)}{\partial t} \quad (1)$$

$$\nabla \times \mathbf{H}(t) = \frac{\partial \mathbf{D}(t)}{\partial t} + \mathbf{J}(t) \quad (2)$$

$$\nabla \cdot \mathbf{D}(t) = \rho(t) \quad (3)$$

$$\nabla \cdot \mathbf{B}(t) = 0 \quad (4)$$

where \mathbf{E} is the electric field (V/m), \mathbf{H} is the magnetic field (A/m), \mathbf{D} is the electric flux density (C/m²), \mathbf{B} is the magnetic flux density (Wb/m²), ρ is charge density (C/m³), and \mathbf{J} is the electric current density (A/m²). These equations relate the electric and magnetic fields at points in space. Likewise, these equations can be expressed in integral form that relates the fields over contours and areas. In isotropic, nondispersive linear media the constitutive equations are

$$\mathbf{D}(\mathbf{r}) = \varepsilon(\mathbf{r})\mathbf{E}(\mathbf{r}) \quad (5)$$

$$\mathbf{B}(\mathbf{r}) = \mu(\mathbf{r})\mathbf{H}(\mathbf{r}) \quad (6)$$

where \mathbf{r} is the position vector. In general, the relationship between the fields and their flux density is dependent on the media parameters in tensor form and is a convolution due to frequency dependence.

An alternative frequency-domain representation of Maxwell's equations that is often presented in the literature makes use of the phasor form of the fields, assuming a harmonic time dependence ($e^{j\omega t}$). While equations (3) and (4) remain the same (with the exception that t is transformed to ω), the time derivatives in (1) and (2) disappear, giving

$$\nabla \times \tilde{\mathbf{E}}(\omega) = -j\omega \tilde{\mathbf{B}}(\omega) \quad (7)$$

$$\nabla \times \tilde{\mathbf{H}}(\omega) = j\omega \tilde{\mathbf{D}}(\omega) + \tilde{\mathbf{J}}(\omega) \quad (8)$$

This representation is often used to derive frequency-domain methods. The form of the equations given in (1)–(4) is usually used as the starting point for the derivation of time-domain computational methods. However, derivations have been given for several techniques using the integral form of Maxwell's equations as well as the differential form.

Maxwell's equations, with the appropriate constitutive equations and boundary conditions at media interfaces, can be used to solve for the electric and magnetic fields due to any source fields, charges, and currents in any

given structure. For a general material interface, the boundary conditions are

$$\hat{\mathbf{n}} \cdot (\mathbf{D}_2 - \mathbf{D}_1) = \rho_s \quad (9)$$

$$\hat{\mathbf{n}} \cdot \mathbf{B}_2 = \hat{\mathbf{n}} \cdot \mathbf{B}_1 \quad (10)$$

$$\hat{\mathbf{n}} \cdot \mathbf{E}_2 = \hat{\mathbf{n}} \cdot \mathbf{E}_1 \quad (11)$$

$$\hat{\mathbf{n}} \times (\mathbf{H}_2 - \mathbf{H}_1) = \mathbf{J}_s \quad (12)$$

where ρ_s and \mathbf{J}_s are the charge and electric current densities on the interface and $\hat{\mathbf{n}}$ is the normal unit vector to the interface. In the more specific case of a dielectric interface, no charge or surface currents exist. As such, (9)–(12) simply state that the normal components of the electric and magnetic fluxes are constant across the boundary, while the tangential electric and magnetic fields are constant across the boundary. Likewise, on a perfect electrical conductor (PEC) interface the tangential electric field and normal magnetic flux are zero, while the normal electric flux and tangential magnetic field are equal to the charge and current densities, respectively, on the PEC. While (1)–(12) can be used to create a system of equations that can be solved for the fields in any problem, in most cases the resulting partial differential equations have no closed-form solution, requiring the use of numerical methods.

The first simulation technique presented is the finite-difference time-domain (FDTD) [3] technique. It is one of the oldest and most widely used electromagnetic simulation techniques. Many methods, such as finite-volume time-domain (FVTD) [4], finite-element time-domain (FETD) [5], and multiresolution time-domain (MRTD) [6] techniques, which are also presented in this article, have advantages over the FDTD technique at the expense of added complexity. Also presented in this article is the transmission-line matrix (TLM) [7] technique. Mathematically it can be shown to be similar to FDTD while possessing unique advantages. Another interesting feature of TLM is that it is directly based on a physical model of wave propagation, instead of a mathematical discretization of Maxwell's equations. The purpose of this article is to give a basic overview of the operation of these techniques, a summary of the limitations of each, and an overview of how they can be used to determine useful device characteristics such as S parameters and radiation patterns.

3. TIME-DOMAIN NUMERICAL TECHNIQUES

3.1. FDTD

The finite-difference time-domain (FDTD) technique was originally proposed by K. S. Yee in his seminal 1966 paper [3]. The defining factor of the Yee FDTD scheme is the arrangement of the FDTD gridpoints that became known as the ‘‘Yee cell.’’ This scheme is sometimes referred to as the ‘‘Yee leapfrog scheme,’’ for the manner in which the electric and magnetic gridpoints are interleaved in both space and time, as shown in Fig. 1 for three-dimensional grids. In this field arrangement, the electric field Cartesian components are located half a cell width apart along their axis

from each gridpoint. Similarly, the magnetic field components are located half a cell width in both directions normal to their axis from each gridpoint. This arrangement places the electric field components along the edges of the cells and the magnetic fields in the faces. The importance of this arrangement becomes clear when the FDTD update scheme is examined.

The FDTD update scheme can be derived by applying central differences to Maxwell's curl equations [8]. Specifically, Faraday's and Ampere's laws, (1) and (2), in differential form are used. The Yee cell field arrangement is convenient in this case because it defines the fields at discrete points, and the differential form of Maxwell's equations relates the fields at a point instead of an area or loop.

Equations (1) and (2) are vector equations, which can be easily split into three scalar equations. For example, (2) can be written as

$$\frac{\partial E_x}{\partial t} = \frac{1}{\varepsilon} \left[\frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} - J_x \right] \quad (13)$$

$$\frac{\partial E_y}{\partial t} = \frac{1}{\varepsilon} \left[\frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x} - J_y \right] \quad (14)$$

$$\frac{\partial E_z}{\partial t} = \frac{1}{\varepsilon} \left[\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} - J_z \right] \quad (15)$$

if the constitutive relationship for linear, isotropic, non-dispersive media, (5), is used. Central differences can then be applied to discretize the time and space derivatives of these equations. A central-difference discretization of a first derivative

$$\frac{\partial F}{\partial x} = \frac{F_{x+\Delta x/2} - F_{x-\Delta x/2}}{\Delta x} \quad (16)$$

approximates the derivative of a function F at the point x by using the ratio of the difference of two surrounding points, $F_{x+\Delta x/2}$ and $F_{x-\Delta x/2}$, and the distance between those points, Δx .

Observing the field configurations in Fig. 1 it is clear that each E -field component is surrounded by the H -field components that appear in its scalar equation, and vice versa. Furthermore, they are separated from each H component by half a cell in the direction of differentiation of the H component. The time offset between the E and H components can similarly be set to $\Delta t/2$. If (13) is expanded in finite differences, ignoring the current terms (loss and source currents), we obtain

$$\begin{aligned} & \frac{E_{x;ij,k}^{t+\Delta t} - E_{x;ij,k}^t}{\Delta t} \\ &= \frac{1}{\varepsilon} \left[\frac{H_{z;ij+\Delta y/2,k}^{t+\Delta t/2} - H_{z;ij-\Delta y/2,k}^{t+\Delta t/2}}{\Delta y} \right. \\ & \quad \left. - \frac{H_{y;ij,k+\Delta z/2}^{t+\Delta t/2} - H_{y;ij,k-\Delta z/2}^{t+\Delta t/2}}{\Delta z} \right] \end{aligned} \quad (17)$$

Figure 1. Yee cell in three dimensions.

where i, j, k specify coordinates in a grid of Yee cells ($x, y, z = i\Delta x, j\Delta y, k\Delta z$).

In (17) the value of the E_x component at time $t + 1$ is given in terms of prior values of the surrounding H -field components and the prior value of the E_x field at the same point. Solving for $E_{x;i,j,k}^{t+\Delta t}$

$$E_{x;i,j,k}^{t+\Delta t} = E_{x;i,j,k}^t + \frac{\Delta t}{\varepsilon} \left[\frac{H_{z;i,j+\Delta y/2,k}^{t+\Delta t/2} - H_{z;i,j-\Delta y/2,k}^{t+\Delta t/2}}{\Delta y} - \frac{H_{y;i,j,k+\Delta z/2}^{t+\Delta t/2} - H_{y;i,j,k-\Delta z/2}^{t+\Delta t/2}}{\Delta z} \right] \quad (18)$$

gives a discrete update equation for E_x that requires only the surrounding fields at the previous timestep. Similar equations can be found for the other E - and H -field components, and a time-marching scheme results. If the current terms are not neglected a scheme that includes source currents and Ohmic losses results. It is important to reinforce that the E and H fields are not evaluated at the same time instant; they are separated by half timestep.

The derivation of the FDTD update equations presented do not provide a method for choosing the temporal and spatial steps. It has been shown [8] that the spatial step required for accurate results with an acceptable numerical dispersion performance is related to the spectrum of the excitation waveform and is at maximum one-tenth of the smallest wavelength in the excited waveform. For this reason, the input waveform must be bandlimited. Gaussian pulses, the derivative of Gaussian pulses, and other easily parameterized waveforms are popular choices. Using these functions it is possible to simulate the fre-

quency band of interest without generating nonphysical results.

In the FDTD update equations, such as (18), the value of ε and μ are specified by gridpoint. PEC structures are represented by setting electric field components tangential to PEC structures to zero. In order to accurately simulate a structure, several gridpoints must be used across each feature. Most RF structures have features that are significantly smaller than the wavelength at their frequency of operation, and thus the spatial step is constrained by the structure.

The timestep used in FDTD must be specified as a function of the spatial step [8]. In order for the scheme to be stable

$$\Delta t = \frac{1}{\sqrt{\frac{1}{\mu\varepsilon} \left(\frac{1}{\Delta x^2} + \frac{1}{\Delta y^2} + \frac{1}{\Delta z^2} \right)}} \quad (19)$$

is the maximum value of Δt [known as the Courant-Friedrichs-Levy (CFL) Limit] that can be used in the simulation. One other important rule of thumb for the application of FDTD is that Δx , Δy , and Δz should differ by a factor of ≤ 10 .

Because of the discrete nature of the FDTD grid, the numerical propagation velocity of a wavefront becomes frequency-dependent, an effect that is called *numerical dispersion*. This places a limitation on cell size (usually it must be smaller than $\frac{1}{10}$ th of the wavelength) and the timestep. Often fine grids are required because of the features of the modeled structure, leading to a large number of gridpoints and a small timestep. One modification to the FDTD technique that has been created to address this limitation is the ADI (alternating-direction-implicit) FDTD [9] technique. In this technique the timestep is no longer fixed by stability requirements and can be made larger than the CFL limit, although the fact that ADI is an implicit technique complicates its application. Still the size of the timestep affects the numerical accuracy of ADI simulations.

3.2. Transmission-Line Matrix

The transmission-line matrix (TLM) method is a powerful technique that is unique because of its historical basis and its derivation from Huygens' principle. Before modern computers were available to simulate wave propagation problems, methods were developed that utilized the relationship between electromagnetic propagation and voltages and currents in lumped-element networks [10,11]. As modern computers were made available that could represent these circuits, it became possible to translate these physical simulators to computer models. In this way, the TLM method is a digital representation of an analog simulator. Both of the models are based on a discretization of Huygens' principle.

The TLM method was first suggested by Johns and Beurel [7]. Huygens' principle states that a propagating wavefront consists of an infinite number of radiating sources, and the sum of the radiation from these sources

forms the new wavefront. This principle is rarely presented mathematically, but can be used as the basis of a numerical method that describes radiation through a discrete grid. A two-dimensional discretization of the TLM method is presented here; a number of references provide a 3D representation as well as a broader overview of the method [12,13].

In order to discretize Huygens' principle in two dimensions, a Cartesian grid is chosen such that the distance between elements, Δl corresponds to the distance that the electromagnetic wave will propagate in one timestep Δt ; therefore

$$\Delta t = \Delta l / c \tag{20}$$

A pulse incident on a node in this grid must be equally radiated in all four directions. The grid and pulse radiation on a node are demonstrated in Fig. 2. From this it can be seen that this matrix of nodes acts like a network of transmission-line elements. If these pulses are thought of as voltages in the transmission-line matrix, then the following equation represents the radiated pulses on the lines surrounding a node at timestep $n + 1$ based on the incident pulses at timestep n [14].

$$\begin{pmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \end{pmatrix}_{n+1}^r = \begin{pmatrix} -1 & 1 & 1 & 1 \\ 1 & -1 & 1 & 1 \\ 1 & 1 & -1 & 1 \\ 1 & 1 & 1 & -1 \end{pmatrix}_n \begin{pmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \end{pmatrix}_n^i \tag{21}$$

As the radiated pulses become the incident pulses on the neighboring nodes, the incident pulses for the next time-

Figure 2. Mesh demonstrating incident (dashed) pulse and radiated pulses (solid).

step are computed as

$$\begin{aligned} k_{+1}V_1^i(x,z) &= k_{+1}V_3^i(x,z-1) \\ k_{+1}V_2^i(x,z) &= k_{+1}V_4^i(x-1,z) \\ k_{+1}V_3^i(x,z) &= k_{+1}V_1^i(x,z+1) \\ k_{+1}V_4^i(x,z) &= k_{+1}V_2^i(x+1,z) \end{aligned} \tag{22}$$

if the distance between the gridpoints is normalized. These equations can be used to in a timestepping fashion by setting an initial condition on the TLM grid and then using (21) and (22) to update the values on each node in the grid.

The grid presented in Fig. 2 and the update equations given in (21) and (22) demonstrate the propagation of any wave. The derivation of the TLM technique will be presented for the two-dimensional TE simulations, utilizing the E_y , H_x , and H_z fields. It was already stated that this network of grids acts like an electrical network of interconnected transmission lines, so it is natural to develop a transmission-line network in which the field values can be determined from the currents and voltages in the network. This unit cell is presented in Fig. 3. The equations that represent signal propagation on these transmission lines are very similar to Maxwell's equations. In fact, there is a simple relationship [14]

$$\begin{aligned} E_y &\equiv V_y \\ H_z &\equiv I_x \\ H_x &\equiv -I_z \\ \mu &\equiv L \\ \epsilon &\equiv 2C \end{aligned} \tag{23}$$

that equates the electromagnetic fields to voltages and currents in the network.

Figure 3. Lumped-element unit cell for TLM [12].

In order to apply the algorithm to a physical problem, it is important to understand the conditions under which it can be used. The line matrix does not represent a continuous space, but rather a tightly spaced periodic structure. As such, electromagnetic waves cannot propagate in any direction, as they can in nature, but only along the lines of the grid. By reducing the spacing between the gridpoints, the space can be made to closely represent natural propagation. However, because of the nature of the discrete grid, the speed of wave propagation through the grid will not match the speed through a physical medium. Furthermore, this difference between physical and numerical propagation speeds is a function of both frequency and propagation direction, and is thus referred to as *grid dispersion*. For diagonal propagation, the grid experiences no dispersion. The maximum dispersion occurs in the axial direction and the velocities are related as [12]

$$\frac{v_n}{c} = \frac{\omega}{\beta_n c} = \frac{\beta}{\beta_n} = \frac{\pi \Delta l / \lambda}{\arcsin(\sqrt{2} \sin(\pi \Delta l / \lambda))} \quad (24)$$

The TLM grid propagation velocity is naturally $c/2^{1/2}$ for square cells in the diagonal direction [12] (as the grid represents a medium with a permittivity twice that of free space); but for a Δl that is a quarter a-wavelength, the network velocity is $c/2$ in the axial direction. Therefore, for an accurate simulation, a grid size much smaller than $\lambda/4$ must be chosen. In practice, however, the grid size is often constrained by the structure being simulated, resulting in grids significantly smaller than this limit.

A major advantage of the TLM method is that it simulates actual electromagnetic wave propagation; no approximations are applied to the wave equations. This makes it more computationally intensive than other methods (although on the same order as others presented here), an aspect that becomes apparent in the requirement that is placed on the grid size. However, the advantage of this method is that it can be used to simulate almost any structure. The model that has been presented thus far only allows free-space propagation, but can be easily extended to simulate structures such as perfect electrical conductors (PEC), perfect magnetic conductors (PMC), dielectric interfaces, and lossy metals.

By modifying the unit cell presented in Fig. 3, the effects mentioned above can be modeled. All of these techniques have been presented in the literature [12]. PEC interfaces can be modeled with short circuits; PMC interfaces, with an open circuit. In a similar way, the reflection from a lossy boundary can simply be represented by setting the reflected field to be equal to the incident field multiplied by a loss parameter ρ (which is, of course, less than 1). Homogeneous materials other than free space can be modeled by simply setting the values of μ and ϵ to match the desired materials. Of course, it is also possible to model inhomogeneous and dispersive materials, but their treatment is beyond the scope of this article.

3.3. Conformal Mesh Techniques

The FDTD and TLM techniques that have been presented are the two most widely used time-domain simulation

techniques. Both techniques have proved to model an extremely wide variety of cases from radar cross sections of aircraft to circuits in broadband communications devices. Nevertheless, there are many structures that cannot conform to a Cartesian grid. When these structures, such as circular metal and dielectric elements, are encountered, they are typically treated in FDTD and TLM by staircasing a fine grid around the nonconformal shape. When staircased finely enough, it is often possible to accurately simulate the structure. However, this can lead to extremely fine grids and thus excessive execution time. Furthermore, some structures cannot be accurately modeled with a staircase configuration [15]. To more accurately represent these structures, methods have been developed that use conformal, nonorthogonal meshes with fewer cells, although the update of each cell is more computationally intensive. As an added benefit, a number of codes produce unstructured meshes that are compatible with these methods. As all of these methods are quite complex, complete derivations will not be presented here. However, the major points and differences of three of the most popular methods, the generalized Yee scheme [16,17] and the finite-volume time-domain (FVTD) [4] and finite-element time-domain (FETD) [5] techniques will be briefly presented.

The Yee FDTD technique presented earlier in this article has been actively researched since the early 1970s. As such, a number of methods have been developed that allow FDTD to be used to model structures that do not conform to the fixed Cartesian grid. One of the simplest of these methods is the variable-grid technique [18]. A similar method has been presented for the TLM technique [19]. This grid is very easy to use with any existing code, as the orthogonality between the grid directions is maintained. By simply varying the Δx , Δy , and Δz values as a function of position along their respective axes, a much wider variety of structures can be modeled. In addition, the grid can be dense in the area of fine features while remaining relatively sparse in large homogeneous areas. Figure 4a depicts a two-dimensional variable grid. In this grid the two coordinate directions are independently varied, thus allowing a much finer grid to be used in a localized region.

Another simple extension to FDTD is subgridding [20]. In these methods, the resolution is increased in a subset of the grid, as shown in Fig. 4b. This allows fine features to be locally matched while adding no additional computational demands away from the finely detailed region. The difficulty of applying this method comes from the interface between the subgridded region and the surrounding mesh. At these interfaces, cells intersect where there are no gridpoints. In these regions the fields must be interpolated to obtain values where gridpoints do not exist, introducing nonphysical dispersion and numerical velocity mismatch. The subgridding method allows the fine grid to be applied in a more local fashion than variable gridding. However, as with the variable grid method, the timestep is constrained by the smallest cell; whereas the simulation uses fewer gridpoints (and is thus faster), it requires the same number of timesteps as a grid made entirely of the smallest cell.

Figure 4. Alternate gridding methods for Yee FDTD: (a) variable gridding; (b) subgridding; (c) locally conformal mesh.

A final extension that will be mentioned here is a method of local conformal modeling where individual cells are modified such that an interface that intersects a cell is modeled while the surrounding cells are treated as normal FDTD cells [21]. An example of this grid is presented in Fig. 4c, where a circle is inscribed into the Cartesian grid. Cells that are intersected by the circle approximate the curve with a diagonal edge. These methods can allow the modeling of curved elements with significantly fewer cells than staircasing, and they converge more accurately to the actual shape as the cell size is reduced. For more complex structures a grid that is conformal everywhere, such as in Fig. 5, is appropriate. This method can be viewed as a local, limited version of the generalized Yee scheme.

The generalized Yee scheme [16,17] is so named because it extends the use of the Yee cell, which is based on a Cartesian grid, into a scheme where the space is filled with interlocking polyhedra, the faces and edges on which the field values are constant. As the polyhedra that represent the electric fields intersect at the centroids of the magnetic field polyhedra, the resulting field orientation is similar to the conventional Yee scheme. However, in the generalized scheme the points do not have to be regularly spaced, and the edges that connect them are not orthogonal. Furthermore, all the polyhedra do not have the same shape. Removing the structure of the grid adds significant

Figure 5. Conformal mesh using triangular elements, created with HFSS (high-frequency structure simulation) [22].

complexity to the method. However, there are several benefits to using the technique: (1) as in traditional FDTD, the electric and magnetic fields are offset, allowing a second-order representation while remaining explicit; (2) complex shapes can be modeled with fewer cells than conventional FDTD because the need for staircasing has been eliminated; and (3) the update of each field point is still dependent only on the nearest neighbors, allowing the technique to be efficiently parallelized.

Another technique that uses a conformal mesh is the finite-volume time-domain (FVTD) method [4]. While it uses a similar grid as the generalized Yee scheme, it has a very different derivation and characteristics. The FVTD method is derived using the integral form of Maxwell's equations on contours made in the grid and collocates all the fields in both time and space (as opposed to the leapfrog arrangement of the Yee scheme). One difference between this method and FDTD is that it is not dispersive, but rather dissipative [4].

The final conformal method that will be reviewed here is the finite-element time-domain (FETD) technique [5]. Finite-element schemes are very different from the techniques presented thus far because the fields are represented on elements on which a field distribution is assumed and coefficients representing the magnitude of the fields on these elements are determined. Like the FVTD and generalized Yee scheme, the FETD method can use a conformal mesh and thus represent complex structures with larger cells than can the FDTD method. The FETD method can be complicated in a full 3D scheme, but, as it is an important and widely used time-domain method, a brief derivation is presented here.

3.4. Finite-Element Time Domain

A multitude of algorithms apply finite-element techniques to time-domain electromagnetic modeling. The technique presented here is the point-matched time-domain finite-element method [5], which was developed in the mid-1980s. It is one of the earliest finite-element methods in the time domain, and is representative of the techniques used in finite-element time-domain (FETD) modeling.

FETD shares many similarities to FDTD. As in FDTD, Maxwell's equations in differential form, Eqs. (1)–(4) are used as a starting point. However, instead of discretizing the equations using finite differences, the electric and magnetic fields in the equations are replaced with a sum

of coefficients multiplied by basis functions chosen by the user. The electric and magnetic fields are expressed as

$$\mathbf{E}(\mathbf{r}, t) = \sum_{i=1}^M \varphi_i(\mathbf{r}) \mathbf{E}_i(t) \quad (25)$$

$$\mathbf{H}(\mathbf{r}, t) = \sum_{j=1}^N \psi_j(\mathbf{r}) \mathbf{H}_j(t) \quad (26)$$

where M and N are the number of nodes (\mathbf{r}_i and \mathbf{r}_j , respectively) used to represent the fields over the simulated space. These nodes are not necessarily collocated. It is important to note that, unlike in the finite-difference technique, all components of each field are collocated at their respective gridpoints. The characteristics of the resulting simulator are dependent on the basis functions, φ and ψ , chosen.

The basis functions are restricted such that

$$\varphi_i(\mathbf{r}) = \begin{cases} 1 & \mathbf{r} = \mathbf{r}_i \\ 0 & \text{all other nodes} \end{cases} \quad (27)$$

$$\psi_j(\mathbf{r}) = \begin{cases} 1 & \mathbf{r} = \mathbf{r}_j \\ 0 & \text{all other nodes} \end{cases} \quad (28)$$

The domain of each basis function ends at the neighboring grid locations. The effect of the functions is to interpolate the fields over the cell. The electric and magnetic gridpoints are offset, in much the same way as in the FDTD method, so that the locations of the magnetic gridpoints are in the center of the electric field cells. With this arrangement, update equations very similar to the FDTD update equations can be developed. The basis functions for the electric or magnetic gridpoints located at the points \mathbf{r}_i and \mathbf{r}_j , respectively, will only overlap the neighboring gridpoints of the corresponding magnetic or electric field. If each element has K nodes, and (25) and (26) are inserted into (1) and (2) (ignoring the current term), the following results

$$\frac{\partial \mathbf{H}_j(t)}{\partial t} = -\frac{1}{\mu(\mathbf{r}_j)} \sum_{l=1}^K \nabla \varphi_l(\mathbf{r}_j) \times \mathbf{E}_l(t) \quad (29)$$

$$\frac{\partial \mathbf{E}_i(t)}{\partial t} = \frac{1}{\mu(\mathbf{r}_i)} \sum_{l=1}^K \nabla \psi_l(\mathbf{r}_i) \times \mathbf{H}_l(t) \quad (30)$$

where the points denoted by the index l correspond to the points where the basis functions overlap.

The coefficients $\mathbf{E}_i(t)$ and $\mathbf{H}_j(t)$ in (25) and (26) are discrete functions of time. They can be used to determine the magnitude of the electric and magnetic fields at integer multiples of the timestep Δt . The size of the timestep required for a stable simulation is limited by the grid, but its calculation will not be covered here. In (29) and (30) the time derivative is not discretized. If central differences are

used, we obtain

$$\mathbf{H}_j^{n+(1/2)} = \mathbf{H}_j^{n-(1/2)} - \frac{1}{\mu(\mathbf{r}_j)} \sum_{l=1}^K \nabla \varphi_l(\mathbf{r}_j) \times \mathbf{E}_l(t) \quad (31)$$

$$\mathbf{E}_i^{n+1} = \mathbf{E}_i^{n+1} + \frac{1}{\mu(\mathbf{r}_i)} \sum_{l=1}^K \nabla \psi_l(\mathbf{r}_i) \times \mathbf{H}_l(t) \quad (32)$$

where n is the timestep index. As in the finite-difference technique, the \mathbf{E} and \mathbf{H} fields are interleaved in time, and an explicit time-marching scheme results. The only step remaining to determine the time-marching scheme is to calculate the derivatives in (31) and (32), which is an easy task once the basis functions have been chosen.

While the scheme presented seems relatively straightforward, several details involved in implementing the method can be quite daunting. First, the grid used in this method, unlike that in FDTD and TLM, does not have to be rectangular. Each element can be shaped differently. This is an advantage of the method, but the grid generation can be challenging. A common method is to use a rectangular mesh everywhere except at material boundaries. This significantly simplifies grid generation. There are several existing codes and algorithms that can be used for mesh generation. The creation of an effective meshing algorithm can be at least as complicated as the FETD technique itself. Similar grids are used for finite-element discretizations in a variety of applications, such as mechanics, aerodynamics, and frequency-domain electromagnetics.

The second difficulty that must be mentioned is the intricacy of representing boundary conditions in the finite-element method. A system of equations that can be used to solve for the fields on the boundary of a PEC are

$$\hat{\mathbf{n}} \times \mathbf{E}^1 = -\hat{\mathbf{n}} \times \mathbf{E}^2 \quad (33)$$

$$\nabla_0 \cdot (\hat{\mathbf{n}} \times \mathbf{H}_{\text{total}}) = -\epsilon \hat{\mathbf{n}} \cdot \frac{\partial \mathbf{E}_{\text{total}}}{\partial t} \quad (34)$$

where ∇_0 is the surface divergence (derivatives are taken only along the surface). In the finite-difference time-domain method, only (33) is used. This is because the components of the electric field are offset in space, and only the tangential fields ever contact a PEC surface. Thus, instead of simply zeroing components, such as in the FDTD method, a system of equations must be solved at each timestep. Similar considerations must be taken when implementing dielectric boundaries.

3.5. Multiresolution Time Domain

The multiresolution time-domain (MRTD) technique [6] was originally introduced by M. Krumpholz and L. P. B. Katehi in 1996. The MRTD method is derived through the application of wavelets to the space discretization of Maxwell's equations (multiresolution analysis). Time differentiation is modeled using central differences as in FDTD. One of the advantages of using MRTD is that the resolution of the discretization can be altered as a function of

time and space. This timespace-adaptive grid can result in a significant reduction in operations per timestep and significantly quicker simulations. Another advantage of the MRTD method is that, depending on the wavelet basis functions used, the numerical dispersion relationship can allow the use of significantly fewer basis functions per wavelength than required in the FDTD method [23]. The adaptive nature of wavelets and their ability to efficiently represent complex waveforms has led to their use in several frequency- and time-domain techniques.

Many wavelet bases are commonly used in electromagnetics, each with distinct advantages and challenges in its implementation. Several of these techniques allow not only adaptive resolution but also the use of fewer points per wavelength and are comparable to high-order FDTD techniques. For simplicity, a 2D derivation of MRTD using the relatively simple Haar wavelets is presented here. This set of basis functions has the same dispersion properties as FDTD, and thus requires the same number of basis functions per wavelength [24]. The Haar basis functions are chosen over other wavelet basis functions for several reasons: (1) they are based on pulses and thus are simpler to apply than other basis functions and (2) when the basis functions are summed to determine the field values, they form regions of constant field value. Therefore, when set to zero, they form a finite region of zero field value. This enables efficient modeling of PECs. The main advantage of Haar MRTD over FDTD is the timespace adaptive gridding capability. The Haar scaling function and mother wavelet are presented in Fig. 6.

The Haar scaling function is a simple pulse function in space. If the MRTD update derivation is followed using only the Haar scaling functions, the FDTD scheme results [25]. All wavelets used in the Haar MRTD scheme are based on the mother wavelet. With each increase in resolution level, the number of wavelets is doubled, the domain of each is halved, and the magnitude is increased so that the norm (integral of the function multiplied by itself over

Figure 6. Haar basis scaling function ϕ and mother wavelet ψ_0 .

its entire domain) of each function is 1. The wavelet basis functions for resolution 1 and 2 are presented in Fig. 7.

MRTD update equations can be determined by expanding Maxwell's curl equations in terms of wavelets and scaling coefficients in space and pulses in time and then applying the method of moments. Maxwell's curl equations, in the 2D TE_z mode, are given by

$$\frac{\partial E_x}{\partial t} = \frac{1}{\varepsilon} \frac{\partial H_z}{\partial y} \quad (35)$$

$$\frac{\partial E_y}{\partial t} = -\frac{1}{\varepsilon} \frac{\partial H_z}{\partial x} \quad (36)$$

$$\frac{\partial H_z}{\partial t} = \frac{1}{\mu} \left[\frac{\partial E_x}{\partial y} - \frac{\partial E_y}{\partial x} \right] \quad (37)$$

E_x can be expanded as

$$E_x(x) = \sum_{n,i,j} h_{n\Delta t} \left[\begin{aligned} & n E_{ij}^{x,\phi\phi} \phi_i(x) \phi_j(y) + \sum_{r=0}^{r_{\max}} \sum_{p=0}^{2^r-1} n E_{ij,r,p}^{x,\phi\psi} \psi_{i,p}^r(x) \phi_j(y) \\ & + \sum_{r=0}^{r_{\max}} \sum_{p=0}^{2^r-1} n E_{ij,r,p}^{x,\psi\psi} \phi_i(x) \psi_{j,p}^r(y) \\ & + \sum_{r=0}^{r_{\max}} \sum_{p=0}^{2^r-1} \sum_{s=0}^{2^s-1} n E_{ij,r,p,s,q}^{x,\psi\psi} \psi_{i,p}^r(x) \psi_{j,q}^s(y) \end{aligned} \right] \quad (38)$$

following the notation in Ref. 6. In this case $\phi_i(x) = \phi(x/\Delta x - i)$ and $\psi_{i,p}^r(x) = 2^{r/2} \psi_0(2^{r/2}(x/\Delta x - i) - p)$, and $h(t)$ is a simple pulse of duration Δt . The maximum level of wavelet resolution is r_{\max} . The four groups of terms in the equations above represent the product of the x - and y -oriented wavelet expansions. The terms are the x -scaling/ y -scaling, x -wavelet/ y -scaling, x -scaling/ y -wavelet, and x -wavelet/ y -wavelet terms, respectively. In each cell, represented by (i,j) in 2D, there is a set of $2^{D(r_{\max}+1)}$ coefficients, where D is the dimension of the simulator [$2^{2(r_{\max}+1)}$ in the 2D case]. It has been noted [24,25] that an offset of $1/2^{r_{\max}+2}$ between the E and H cells in space leads to a true doubling of resolution for each increase in r_{\max} , and dispersion performance equivalent to an FDTD grid that has cell spacings of the MRTD equivalent gridpoints. For this scheme, there are $2^{2(r_{\max}+1)}$ equivalent gridpoints per cell, distributed evenly in the cell. These gridpoints exist at each independent field value that can be determined by summing all of the basis functions in a cell. It should be noted that there are as many of these points as there are basis functions.

The MRTD update equations can be determined by inserting the scaling/wavelet function expansions of the fields into Maxwell's equations and applying the method of moments. The method of moments is applied by multiplying both sides of the equation by user chosen testing functions and then taking an integral over their domain. In MRTD, Galerkin's method is normally used, where the testing functions are the same as the basis functions. For

Figure 7. Haar wavelets for resolution levels 1 and 2.

example, time localization (limiting the time coefficients required for an update to the current and previous time step) is achieved by multiplying both sides of the equation by the time pulse, positioned at the point of the fields in the space derivative of the equation. As in FDTD, the coefficients for the field values are interleaved in time, using (38), the electric field coefficients are calculated at times $n\Delta t$, and in a similar expansion the magnetic fields are calculated at times $(n + \frac{1}{2})\Delta t$. The method of moments can be applied to discretize time as

$$\int h_{[n+(1/2)\Delta t]} \frac{\partial \mathbf{E}_x}{\partial t} \partial t = \int h_{[n+(1/2)\Delta t]} \frac{1}{\epsilon} \frac{\partial H_z}{\partial y} \partial t \quad (39)$$

where $h_{[n+(1/2)\Delta t]}$ represents a pulse of duration Δt centered at time $(n + \frac{1}{2})\Delta t$. The integral

$$\int h_{[n+(1/2)\Delta t]} h_{[m\Delta t]} \partial t \quad (40)$$

which appears on the left hand side of (39), evaluates to 1 when $n = m$ and $n = m - 1$ and 0 elsewhere. Thus, the only electric field components that are needed to update the coefficients are the current and previous timesteps. On the right hand side of (39), the integral

$$\int h_{[n+(1/2)\Delta t]} h_{[m+(1/2)\Delta t]} \partial t \quad (41)$$

is nonzero only when $n = m$. Thus, the magnetic field components are only required at one location in time. A similar procedure can be applied for each of the wavelet and scaling coefficients, so that each the update of each wavelet/scaling coefficient is in terms of its previous value and the values of the wavelet/scaling values of the surrounding fields.

Using a vector notation similar to [25], the following results are derived

$$\mathbf{n} \mathbf{E}_{ij}^x = \mathbf{n}_{-1} \mathbf{E}_{ij}^x + \frac{\Delta t}{\epsilon \Delta y} \mathbf{U}_{\mathbf{E}_x} \begin{bmatrix} \mathbf{n}_{-1} \mathbf{H}_{ij}^z \\ \mathbf{n}_{-1} \mathbf{H}_{i,j-1}^z \end{bmatrix} \quad (42)$$

$$\mathbf{n} \mathbf{E}_{ij}^y = \mathbf{n}_{-1} \mathbf{E}_{ij}^y - \frac{\Delta t}{\epsilon \Delta x} \mathbf{U}_{\mathbf{E}_y} \begin{bmatrix} \mathbf{n}_{-1} \mathbf{H}_{ij}^z \\ \mathbf{n}_{-1} \mathbf{H}_{i-1,j}^z \end{bmatrix} \quad (43)$$

$$\mathbf{n} \mathbf{H}_{ij}^z = \mathbf{n}_{-1} \mathbf{H}_{ij}^z + \frac{\Delta t}{\mu} \left(\frac{1}{\Delta y} \mathbf{U}_{\mathbf{H}_{E_x}} \begin{bmatrix} \mathbf{n}_{-1} \mathbf{E}_{ij}^x \\ \mathbf{n}_{-1} \mathbf{E}_{i,j+1}^x \end{bmatrix} - \frac{1}{\Delta x} \mathbf{U}_{\mathbf{H}_{E_y}} \begin{bmatrix} \mathbf{n}_{-1} \mathbf{E}_{ij}^y \\ \mathbf{n}_{-1} \mathbf{E}_{i+1,j}^y \end{bmatrix} \right) \quad (44)$$

This vector representation appears very similar to its FDTD analogue. To give an example of the vectors in (42)–(44), if the maximum resolution $r_{\max} = 0$, then

$$\mathbf{n} \mathbf{E}_{ij}^x = \begin{bmatrix} \mathbf{n} \mathbf{E}_{ij}^{x,\phi\phi} \\ \mathbf{n} \mathbf{E}_{ij}^{x,\psi\phi} \\ \mathbf{n} \mathbf{E}_{ij}^{x,\phi\psi} \\ \mathbf{n} \mathbf{E}_{ij}^{x,\psi\psi} \end{bmatrix} \quad (45)$$

The U matrices represent the results of the inner products from the method of moments. For the $r_{\max} = 0$ case, we obtain

$$\mathbf{U}_{\mathbf{H}_{E_y}}(r_{\max} = 0) = \begin{bmatrix} -1 & -1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 1 & -3 & 0 & 0 & -1 & -1 & 0 & 0 \\ 0 & 0 & -1 & -1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & -3 & 0 & 0 & -1 & -1 \end{bmatrix} \quad (46)$$

The MRTD method has a timestep requirement similar to that of FDTD:

$$\Delta t = \frac{1}{c \sqrt{\left(\frac{2^{r_{\max}+1}}{\Delta x}\right)^2 + \left(\frac{2^{r_{\max}+1}}{\Delta y}\right)^2}} \quad (47)$$

In the case of Haar wavelets, the resolution r_{\max} is equivalent to having $2^{r_{\max}+1}$ FDTD gridpoints per cell.

As an alternative to the Haar techniques presented here, other wavelet bases are commonly used with the

MRTD technique. Two of the most popular are the Battle-Lemarie [6] and CDF wavelets [26]. These techniques have the advantage of requiring the use of fewer basis functions per wavelength than FDTD or Haar MRTD. One disadvantage of these techniques is that it is difficult to apply hard boundary conditions, such as PECs and PMCs using these basis functions. Extending these techniques to allow the modeling of more structures is currently a busy research area.

3.6. Parallelization

One common method of decreasing the execution time of these computationally intensive codes is parallelization. Code parallelization allows programmers to rewrite code to distribute the problem over the several processors in a multiprocessor system. This is becoming especially popular with the advent of low-cost computer clusters. These clusters, sometimes referred to as *Beowulf clusters* (as named by their developers at NASA) or workstation clusters, allow the combination of several off-the-shelf computers into a networked supercomputer. These computers are significantly cheaper than traditional supercomputers, and several rank among the fastest in the world. While the slower interconnects between the computers can limit their application, most time-domain methods are ideal for workstation cluster parallelization.

Most of the time-domain methods presented here are explicit, meaning that the fields are updated directly from other field values and no matrices are inverted. Furthermore, they are nearest-neighbor techniques; the field update at any given point depends only on the fields at the neighboring points. Therefore, these techniques can be parallelized by dividing the computational space into subgrids. The only data that needs to be exchanged between the processes are the data on the edges of the subgrids. As these data are two-dimensional, and the data to be updated are three-dimensional, the computation time grows on the order of the number of gridpoints faster than the time taken to pass data between grids. As the problem size increases, the communication time becomes less of a hindrance, resulting in excellent performance on workstation clusters.

4. IMPORTANT FEATURES OF TIME-DOMAIN SIMULATION TECHNIQUES

4.1. Performing Simulations and Analyzing Output

All the simulators that have been presented in this article are full-wave simulators. They are so named because they simulate Maxwell's equations without approximations, and thus give the electric and magnetic fields over the entire simulation domain as they evolve in time. For most applications, the quantities of interest from simulation are not the values of the fields, but rather macroscopic parameters of the devices being simulated (such as S parameters, input impedance, and bandwidth). In addition, while the methods that have been presented here allow for the simulation of field propagation through various media, no mention has been made of how to terminate the com-

putational space, or introduce a source condition. This section contains information about how to use the information obtained from these simulators.

It is important to remember when using these tools that they simulate actual physical phenomena. As such, when an excitation is introduced, it should closely match the source condition in the physical circuit. This may include introducing a gap voltage in a dipole antenna or a current on a wire in a waveguide probe feed. In many ways not only the circuit but also the measurement environment are simulated. A network analyzer, for example, excites a field on a feedline and then analyzes the output of the device. In simulation, fields can be probed in response to an excitation. By doing this in as close a fashion to actual measurement as possible, useful information can be obtained. Of course, simulated fields can be injected and measured at any point in space, even where it would be physically impossible in practice. Used wisely, this allows for results that are independent of many common sources of measurement error.

An example structure that can be used to explain many of these concepts is presented in Fig. 8. The presented structure is a microstrip coupled-line filter. The physical structure being simulated consists of metal lines printed on a dielectric substrate. This is a two-port structure, with ports 1 (input) and 2 (output) labeled in the figure. If this structure were to be fabricated and measured, connectors would have to be added at the ports to allow connection to the network analyzer. These could be either coaxial or coplanar waveguide depending on the measurement equipment. In either case, the input and output lines would be made long enough to prevent coupling between the measurement ports and the structure. In the case of

Figure 8. Example simulation structure showing location of absorbers, excitations, and probes.

simulation, these connectors are not required. Instead, a microstrip excitation is impressed on the grid. To prevent reflections of the impressed signal from the input and output ports, an absorber is placed around the structure. This numerical absorber is analogous to the absorbing materials used in antenna measurement systems. The voltage under the microstrip is then measured at the input and output ports. By simulating the structure over the entire frequency band of interest and transforming the probed voltages to the frequency domain, S parameters and other important parameters such as input impedance and bandwidth can be determined. Field plots, showing the field distribution in a 2D cross section of the grid, in both the time and frequency domains, can also be used to optimize structures by highlighting areas that cause unwanted crosstalk, radiation, loss, and maximum coupling.

4.2. Source Conditions

When exciting a structure it is necessary to consider both the spatial distribution of the excitation (how much of the grid is covered and which mode is excited) and the frequency content of the source signal. As most methods are numerically dispersive, there is a grid-dependent maximum frequency that can be accurately simulated. For the simulation of RF and wireless circuits, it is usually desirable to provide an excitation over a small portion of the grid to represent a physical incident source condition. The frequency content of the pulse is chosen to cover the frequencies of operation of the device. For many structures, such as rectangular and circular waveguides, there are closed-form expressions for the modes that can propagate. These expressions give relative field magnitudes as a function of space that are dependent on the structure. To excite these structures, the mode shape must be discretized, and then the field values can be set to match the mode shape. Due to discretization error, it is often difficult to excite just the modes of interest, and mode decomposition must be performed when the output is analyzed. For other structures, such as microstrip lines, no exact closed-form expressions exist. In this case, the mode shape is approximated [8]. As the signal propagates through the circuit, it will automatically assume the proper mode shape. It is also possible to build a library of these nonanalytic excitations by simulating lines and storing the mode shapes created on the line by a simpler excitation.

To restrict the excitation to a specific frequency band, its waveform must be shaped in time. The frequency content of the input signal can then be determined by Fourier-transforming the time-shaping function. As the simulation time must be finite, the actual frequency response of any time waveform is infinite. As such, pulse shapes that have quickly decreasing magnitude as frequency is increased are necessary. In order to accurately control the frequency content of the pulse, expressions with well-defined Fourier transforms are often chosen. Commonly chosen waveforms are Gaussian pulses, Gaussian derivative pulses, sinusoidal pulses, and modulated Gaussians (Gaussians multiplied by sinusoids). It is important to remark that while sinusoidal pulses will give the response to a single frequency, this is not a very efficient use of time-

domain methods. One of the chief advantages of time-domain methods is that they simulate a broad band in comparable time to a single frequency in a frequency domain code. For this reason it is usually best to use a broadband excitation.

Alternatives to these excitations are plane-wave sources. For many applications, such as illuminating targets for radar cross section evaluation or modeling bulk material properties [e.g., electronic bandgap (EBG) and metamaterials], the response to a plane-wave illumination is desired. In FDTD it is often useful to use a total-field/scattered-field formulation [27]. In this formulation the computational domain is divided into total-field region that is surrounded by a scattered-field region. A connecting surface is developed that effectively removes the incident field from the scattered region. An alternate method is a pure scattered-field formulation [28], in which the incident wave is not impressed on the grid, but rather the response of the surface of the scatterer is applied, and thus the scattered field is generated. As the scatterer responses must be calculated analytically, this can be a difficult method to apply, however, there is no error due to the incident field propagating through the numerical grid.

4.3. Numerical Absorbers

For all of the presented methods, the fields at any one point in time and space are dependent on the fields at previous timesteps and neighboring spatial points. The computational domain, however, must be finite. In order to update the field points, the fields on the boundaries must be known. Two conditions on which the fields are always known are perfect electrical conductors (PECs) and perfect magnetic conductors (PMCs). On these surfaces the tangential electric or magnetic fields, respectively, are zero. In techniques with staggered grids, such as FDTD and TLM, these conditions can be applied by simply zeroing the appropriate field values. In collocated grid techniques, such as FVTD and FETD, these conditions must be applied using all the field values. For either type of simulator, these boundaries will cause total reflection of an incident signal. If the response of a structure is to be known to an incident signal, then the reflection from the boundaries will combine with the response of the structure, and the results will be useless. To use these hard boundary conditions, the computational space must be sufficiently large for the time response of the device to end before reflections interfere. This can easily result in impractically large grids. Therefore, another technique, an *absorbing* (sometimes called *radiating*) *boundary condition* (ABC), must be applied. The goal of these techniques is to absorb incoming waves with a minimum of numerical reflection.

There are several techniques for applying absorbing boundary conditions (ABCs), most of which can be applied to the methods presented here. A number of these methods, usually referred to by the surnames of their developers, such as Bayliss-Turkel [29], Mur [30], and Ramahi [31], can often reduce reflections by 50–80 dB. Another technique, which has become the standard for numerical absorbers, is the perfectly matched layer (PML). Introduced

by Berenger in 1994 [32], the PML is manifested in a simulator as a physical material with very specific properties. It offers excellent performance over a wide frequency band and range of incident angles. It has been shown to be equivalent to a similar method, the uniaxial perfectly matched layer (UPML) [33]. The UPML is the numerical representation of a uniaxial anisotropic medium with both electric and magnetic permittivity tensors, that offers numerical reflection coefficient lower than -100 db for most RF open structures.

4.4. S Parameters

The output of a time-domain simulator is the values of the electric and magnetic fields at all points in space over the time period simulated. To calculate useful characteristics of the device being simulated, these responses must be transformed into meaningful parameters. The S parameters are frequency-domain characteristics that provide the response at a port of a structure due to an incident signal. As such, in time-domain simulators, the input and output voltages/currents on a structure can be recorded, converted to the frequency domain, and postprocessed to give S parameters. The structure in Fig. 8 can be used as an example for determining S parameters.

The nature of the input and output signal depends on the type of device being simulated. For a quasi-TEM structure, such as the microstrip of Fig. 8, the voltage from ground to signal line and the current in the signal line can be used to determine S parameters. The voltage can be determined by summing the electrical fields normal to the line from the ground to the signal line, numerically integrating

$$V = - \int_a^b \mathbf{E} \cdot d\mathbf{s} \quad (48)$$

Likewise, the current on the line can be determined using

$$I = \oint \mathbf{H} \cdot d\mathbf{l} \quad (49)$$

which is numerically equivalent to summing the magnetic fields tangential to a contour surrounding the conductor.

These parameters are then transformed to the frequency domain using either a fast or discrete Fourier transform. In order for the Fourier transform to be accurate, the simulation must run until the fields at the measurement points go to zero (or a very small value relative to their peaks, usually less than 0.1%). Once the frequency domain voltages/currents are determined, they can be processed to determine the S parameters. The general formula for an S parameter is to divide the output signal at port m by the incident signal on port n :

$$S_{mn}(\omega) = \frac{V_{m,\text{out}}(\omega)}{V_{n,\text{in}}(\omega)} \left(\frac{Z_n(\omega)}{Z_m(\omega)} \right)^{1/2} \quad (50)$$

The expression in (50) is valid for the general case where the impedance of the input and output ports are not equal.

It should be noted that this is not always the ratio of the total signal at the input and output probes.

The fields recorded during the simulation are the total fields. For example, the input probe of Fig. 8 will record the incident field from the excitation as well as the reflection from the filter. For the computation of S_{21} , however, voltage used in (50) must be only the incident. In this case the incident voltage can be determined by performing a separate simulation with an identical probe on an identical transmission line (without the filter). To compute S_{11} , the output field can be computed by subtracting the incident from the total field.

One other parameter that can be easily calculated using voltage and current probes is the characteristic impedance of a transmission line. For a signal traveling through a transmission line, the characteristic impedance can be determined as the ratio of the voltage to the current on the line. It is important to note that to measure these values, only one signal should propagate on the line, with no reflections. For most simulators, exciting a transmission line terminated with PML on both ends will suffice. For a simulator that has electric and magnetic field collocated in time and space, the impedance formula is

$$\tilde{Z}(\omega) = \frac{\tilde{V}(\omega)}{\tilde{I}(\omega)} \quad (51)$$

while, for other simulators, the offset must be accounted for. In FDTD, for example, the half-space-cell offset can be accounted for by using the geometric average of two current probes that surround a voltage probe, and an exponential multiplier can be used to compensate for the half-timestep offset. For FDTD, the impedance formula is [34]

$$\tilde{Z}_0(x) = \frac{\tilde{V}(x)e^{-j\omega(\Delta t/2)}}{\sqrt{\tilde{I}(x + \frac{1}{2})\tilde{I}(x - \frac{1}{2})}} \quad (52)$$

This discussion has focused on microstrip structures; however, it can easily be extended to more general lines. For any given structure, it is necessary to determine what output voltage can be used to characterize the device. For a coplanar waveguide, for example, the energy is also carried between the signal and ground lines; however, they are in the same plane and thus the recorded voltage is tangential to the lines. Similarly, stripline, slotline, and coaxial structures can be characterized by determining the voltage between the appropriate conductors. Finally, using the S parameters, other important parameters such as input impedance, insertion loss, and bandwidth can be directly calculated.

4.5. Near-Field/Far-Field Transformation

Antennas are often simulated with time-domain simulators. The techniques presented in the previous section can be used to calculate antenna parameters such as input impedance and bandwidth, but they do not give the polarization, directivity, gain, and many other antenna parameters. To analyze the antenna in terms of these

parameters, it is necessary to know the far-field radiation pattern of the antenna. The far field is often tens of wavelengths away from the antenna structure, and an enormous grid is required for accurate simulation. Fortunately, there is another method that can be used to determine the far-field radiation pattern, the near-to-far-field (NFF) transform.

The far-field radiation pattern is calculated by first reducing the radiation problem to one set of electric and magnetic equivalent sources on a closed surface surrounding the radiating structure. The problem of an antenna radiating into free space is demonstrated in Fig. 9, in which the entire antenna and feeding structure are surrounded by free space. This space is terminated with an absorbing boundary condition, such as PML. A transformation surface is placed in between the antenna and the absorber. This surface has no effect on the simulation; it is used only to record fields.

The surface equivalence theorem [35] states that the problem in Fig. 9 can be represented by electric and magnetic current sources placed on the NFF transformation surface. Using these current sources, the fields outside the surface are the same as those produced by the radiator, and the radiation at any point outside the contour can be determined mathematically. The first step in performing the NFF transformation is to determine the equivalent currents on the transformation surface.

If the electric and magnetic fields on the surface are known, the sources can be calculated as

$$\tilde{\mathbf{J}}_s = \mathbf{n} \times \tilde{\mathbf{H}} \quad (53)$$

$$\tilde{\mathbf{M}}_s = -\mathbf{n} \times \tilde{\mathbf{E}} \quad (54)$$

where \mathbf{n} is the unit vector normal to the transformation surface. Of course, the antenna pattern has meaning only as a function of frequency, and thus the fields on the transformation surface must be transformed to the frequency domain. To Fourier-transform the fields, the field

values at all timesteps are required. As the surface completely surrounds the antenna, and thus consists of a very large number of points, the Fourier transform is performed during simulation to avoid the burden of storing the field values for all points on the surface at all timesteps. Once the currents are known, they can be used to solve for the far (or near)-field radiation pattern. The equation that gives the radiation at any point in space due to these sources can be simplified to give results for only the far field. For these simplifications, the distance from any point on the radiating surface to an observation point is assumed to be the same, except for the phase terms. This is possible because the source is very far from the observation point.

Using these approximations, the electric field in the far field is [35]

$$\tilde{\mathbf{E}}_r \approx 0 \quad (55)$$

$$\tilde{\mathbf{E}}_\theta \approx -\frac{jke^{-jkr}}{4\pi r} (\tilde{\mathbf{L}}_\theta + \eta_0 \tilde{\mathbf{N}}_\theta) \quad (56)$$

$$\tilde{\mathbf{E}}_\phi \approx -\frac{jke^{-jkr}}{4\pi r} (\tilde{\mathbf{L}}_\phi - \eta_0 \tilde{\mathbf{N}}_\phi) \quad (57)$$

where

$$\tilde{\mathbf{N}} = \int_S \int \tilde{\mathbf{J}}_s e^{jkr' \cos \psi} dS \quad (58)$$

$$\tilde{\mathbf{L}} = \int_S \int \tilde{\mathbf{M}}_s e^{jkr' \cos \psi} dS \quad (59)$$

where r' is the distance between the origin and the source point on the contour and ψ is the angle between the vector to the surface and the vector to the observation point.

This procedure yields the far electric and magnetic fields at any position on a sphere surrounding the antenna. By normalizing these fields, one can plot the radiation pattern. The total radiated power can be found by calculating the Poynting vector and integrating over the surface. Using the total radiated power and the field values, directivity and gain can be determined. This technique demonstrates that while the electromagnetic simulation techniques discussed here are powerful tools, analyzing the output can also be a difficult, time-consuming task.

5. SUMMARY

An overview of the purpose and application of time-domain electromagnetic simulation methods has been presented. These methods serve as powerful tools for RF designers if used correctly. The reader should take from this section not a complete understanding of time-domain computational methods, but rather an appreciation of how they can be applied and, hopefully, where mistakes can be avoided in simulation. Often the choice of simulator depends on software already at hand, and this article should help the reader gain confidence in determining how different packages can be applied. In addition, this article

Figure 9. Diagram demonstrating setup of antenna simulation.

provides a strong background that can be used as a starting point for further research in time-domain electromagnetic methods. Through the discussion not only of the techniques but also how to analyze the results, the usefulness of time-domain simulation techniques has been demonstrated. Almost any problem can be simulated using these techniques, and understanding their operation is the first step in using them properly.

ELECTRONIC WARFARE

ANTHONY E. SPEZIO

 FRANCIS J. KLEMM
 STANLEY A. MOROZ
 JAMES M. TALLEY
 Naval Research Laboratory

Electronic warfare (EW) is the systems discipline that exploits an adversary's use of the electromagnetic spectrum to overcome threats that use communications, navigation, and radar systems. It is an important tool in pursuing military objectives and advancing national policy and sovereignty. EW provides the means to counter, in all battle phases, hostile actions that use the electromagnetic spectrum—from the beginning, when enemy forces are mobilized for an attack, through to the final engagement. EW exploits the electromagnetic spectrum through electromagnetic sensing, analysis, and countermeasures to establish operational advantage in a hostile encounter.

The use of electronic warfare accelerated rapidly during World War II, and it has been used in most military conflicts since. The aircraft used by Nazi Germany to bomb the fog-shrouded British Isles were guided by radio beacons from the European mainland. By using false guidance signals, the British were able to redirect the German bombing attacks from densely populated urban areas to less populated rural areas. In this same conflict, U.S. bombers used chaff (packets of tinfoil cut into thin strips) jettisoned from the attacking U.S. aircraft to reflect anti-aircraft radar signals, thereby reducing the effectiveness of the German anti-aircraft batteries and bomber force attrition. In the Pacific theater of operations during World War II, U.S. Navy submariners detected and determined

the bearing and location of Japanese ship radio transmissions for weapons targeting. In the Korean conflict, detection and location of North Korean anti-aircraft radar signals provided targeting data for subsequent air strikes. In Vietnam, the exploitation of anti-aircraft and missile radars was refined with the use of U.S. Air Force Wild Weasel weapons—suppression aircraft that used sensors to detect and locate the weapons-associated threat signals to provide targeting information for ordnance delivery. Electronic warfare applications are described extensively in military accounts of the past half century.

Military operations use EW as one means to gather tactical intelligence from noncooperative forces and to counter their electromagnetic, radio-, and radar-controlled weapons. Land, sea, and air forces use the electromagnetic spectrum for command and control, weapons targeting, and weapons control. Figure 1 shows multiple land, sea, and air platforms in a typical tactical environment. Also indicated are links for sensing, communications, and navigation in support of the military mission.

Electronic warfare provides use of the electromagnetic (EM) spectrum by the host force and denial or limitation of its use by an adversary. Realization of this goal occurs when host force systems use the EM spectrum while adversary systems are denied its use. Countermeasures (CM) to threat systems that use the EM spectrum can be selectively applied on a time- and/or frequency-multiplexed basis so that host force use of the EM spectrum is uninhibited.

Electronic warfare includes the *operational* functions of electronic support (ES), electronic self-protection (EP), and electronic attack (EA). ES provides surveillance and warning information for EW system use. CM to threat systems, including jamming, false-target generation, and decoying, are performed for EP (protection of the host platform against an electronically controlled threat). EA performs these same CM functions to protect a battle force

Figure 1. Tactical operational concept indicating systems that use the EM spectrum.

composed of several platforms or battle units. The ES, EA, and EP functions are interrelated because EA and EP can be queued using ES information, and EA and EP can use some of the same sensing and CM equipment for distinct operational objectives.

This article includes a description of the EW timeline and the various phases of conflict. Also provided is a summary description of the signal environment in which EW systems operate. Those interested in more detailed descriptions of the EM communications, radar, and navigation technology against whose signals EW systems operate are referred to the appropriate sections of this encyclopedia. A discussion of EW functional areas ES, EP, and EA provides a functional framework for supporting EW technologies.

1. ELECTRONIC WARFARE TIMELINE

Electronic warfare is used in a layered operational interaction with electronically controlled threat systems. The electronic warfare system provides its own force with data for self-protection and threat weapons suppression. Figure 2 graphically illustrates the EW functional timeline.

Electronic support provides operational intelligence relating to electronically controlled threat systems and communications systems in the battle group or theater environment. Electronic threat-warning information derives from ES surveillance data, recognizing that hostile force deployments or weapons-related transmissions constitute a threat. Air defense combines electronic and radar surveillance with tactics and countermeasures to control the air battle. EA and active EP, using countertargeting (CTAR) jamming, false target generation, and/or decoying, attempt to deny target acquisition by adversary sensors. CTAR endeavors to deny weapon's sensors use of the spectrum, and decoys dispersed into the environment provide preferred target signatures to the threat weapon's sensor.

The EW battle timeline provides the general context in which the discipline of EW is used in the tactical environ-

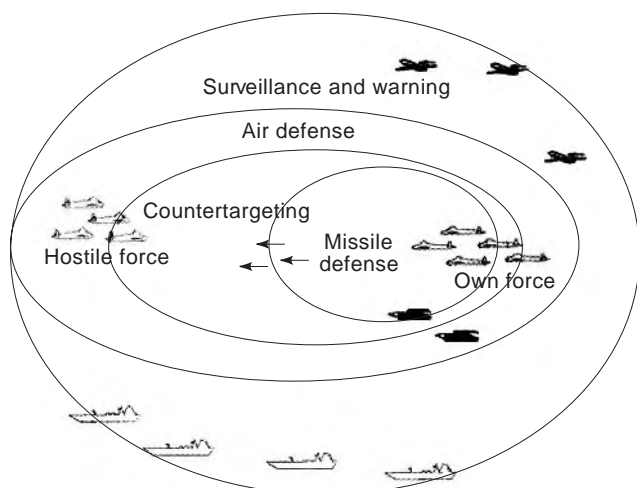

Figure 2. Electronic warfare battle situation showing various phases of the engagement timeline.

ment. The EW timeline stage in a specific engagement depends on the deployment of forces and the perceived imminence of hostile engagement. Note that the technologies used in the various stages of the engagement are dynamic, and EW systems and weapon systems technologies evolve to overcome susceptibilities. The boundaries and definitions of EW timeline stages are redefined with each new advance in weapon and EW technology.

1.1. Electronic Support

Electronic support provides operational intelligence that is related to radiated signals in the battle group or theater environment. Surveillance includes monitoring of both combatants and commercial transports. Control of contraband and critical materials is an EW surveillance mission that provides critical intelligence data to the area commander. Surveillance of noncooperative combatant forces provides deployment intelligence in the area of observation. Early threat-warning information extracted from surveillance data occurs by recognizing hostile force weapons-related transmissions.

Within the lethal range of hostile force weapons, battle space surveillance updates are required rapidly. Deployment and operational modes of hostile forces are monitored closely to determine imminence of hostile activity. In some environments, potentially hostile forces remain within weapons' lethal range and a high level of vigilance is necessary to maintain security.

1.2. Air Defense

Air defense is used to maintain control of the battle group airspace and defend against threat aircraft and missiles. Battle group surveillance, implemented by the combination of EW, infrared/electrooptic (IR/EO), and radar sensors, provides environmental data required for air defense. Electronic combat techniques and weapons are used to counter an airborne threat.

Air defense is an extensive, complex, electronic combat interaction between hostile forces. EW assets are a key tool of the battle force commander and of the individual elements within the command. These assets provide information for developing tactical intelligence in all phases of the engagement. The outcome of the air battle is by no means established by the quantity of EW assets possessed by each of the opposing forces, but depends greatly on how the EW assets are used in conjunction with other sensor systems, weapons, and air defense tactics.

Aircraft ships and/or battlefield installations participate in air defense. Own force aircraft operating at altitude can engage a threat force at long line-of-sight ranges. Aircraft, together with ship and battlefield installations, provide coordinated air defense as the hostile force approaches own force locations. The EW objective in the early air defense or outer air battle is to prevent threat force detection and location of own force. Electronic combat actions that prevent or delay own force detection provide a distinct advantage by allowing additional time to develop tactics to counter the threat force. In addition, the threat force battle timeline and interplatform coordination are perturbed. Fragmentation or dissolution of the hostile

force attack can occur if own force electronic combat is effective in the outer battle.

As the hostile force overcomes the outer battle electronic attack and approaches the own force within weapons range, air defense assumes the role of denying targeting information to the hostile sensors. The EW objective at this stage of the engagement is to prevent hostile force weapons launch by denying targeting data to their sensors. Electronic combat surveillance, warning, and countermeasure assets are used for countertargeting. Surveillance sensors assess hostile force deployment and provide information about the adversarial tactics being used. Warning sensors indicate the status of threat sensors as they attempt to acquire targeting data for weapons systems handoff. Countermeasure assets, including jamming, spoofing, and decoying, continue to provide a virtual environment to threat platform sensors to prevent own force target acquisition by the hostile force.

The terminal phases of an air defense engagement are characterized by heightened activity. The combatants, both hostile and own force, are confined to a smaller portion of the battle space. Weapons and decoys in flight add to the physical and EM signal density. Electronically, both own force and hostile forces struggle to exploit the EM environment to achieve their respective operational objectives. Countermeasures jamming and spoofing are used with full appreciation that coordinated jamming produces degradation of hostile force sensors, but that weapons with home-on-jam (HoJ) capability can exploit this action to the destructive detriment of the radiating platform.

1.3. Countertargeting

Countertargeting (CTAR) is a subset of radar electronic countermeasures (ECM) used in electronic attack. CTAR provides specially modulated radiofrequency (RF) signal transmissions to counter hostile force longrange surveillance or targeting radar. The transmission modulation can be amplitude-modulated (AM) or frequency-modulated (FM) noise, or combinations of these, and they can be pulsed or continuous-wave. CTAR transmission is used both to disrupt and interfere with the threat radar operation, thereby preventing it from correctly locating and identifying own force target(s).

Countertargeting success criteria includes mission completion prior to threat force interdiction or weapon launch. Realistically, the results of a CTAR electronic attack against a hostile force are probabilistic, in that some opposing forces at some time during the battle timeline succeed in launching missiles. CTAR can delay and reduce the coordination of hostile missile firings and, consequently, reduce the number of missiles fired and the attrition of personnel, ships, and aircraft.

1.4. Terminal Defense

Terminal defense against electronically controlled missiles and guns is the final phase of the EW battle timeline. Weapons are launched in the terminal phase of hostile force engagement, and EP and EA capability is brought to bear on the weapons and their electromagnetic (EM) guidance and control signals. Onboard jamming and

false-target radiation that is effectively used for counter-targeting is less effective for terminal defense. Jamming or false-target radiation makes the target platform vulnerable to missiles with home-on-jam capability. Home on jam is an electronic counter-countermeasure that exploits the target countermeasure's radiation to steer the missile to the target. Consequently, offboard countermeasures, or decoys, are used to lure the missile away from the high-value target.

2. THE ELECTRONIC WARFARE ENVIRONMENT

2.1. Threat Systems

Electronic warfare interacts with an adversary's EM systems for signal exploitation and potentially for electronic attack. Threat systems of EW interest include radar, communications, and weapons control. Some of the threat systems exploited by EW are briefly described in the following.

2.1.1. Radar. Radar uses radiofrequency transmissions ranging from high frequency (HF) to millimeter waves (from 30 MHz to 40 GHz) in pulsed and continuous-wave (CW) modes to illuminate targets and collect reflected echoes. Radar-transmission-reflected echoes are used to measure target characteristics and determine target location. Military forces use radar for both offensive and defensive weapon systems. Radar functions include target detection and identification, target acquisition, target tracking, and navigation. Weapons systems using radar may be land-based, airborne, shipboard, or in space. A typical radar system contains a transmitter that produces a high-powered RF signal, tunable over a band of frequencies; an antenna system that radiates energy and collects reflected echoes; a receiver that detects signal return; and signal processing electronics that extract target measurements, such as range, bearing, and speed. Target location information is provided to a weapon system to control and direct the weapon onto the target.

Land-based radars function as ground-controlled intercept (GCI) systems, surface-to-air missile (SAM), anti-aircraft artillery (AAA) batteries, and space tracking systems. GCI is used to direct interceptor aircraft against attacking aircraft and to coordinate the air battle. SAM sites use early warning/surveillance radar, target acquisition radar, target tracking (TT) radar and/or illuminators for missile guidance, beam-riding systems. AAA radars have operating frequencies and data rates similar to those of SAM tracking radars and usually receive targeting information from SAM surveillance and target acquisition (TA) facilities. Advanced SAM systems handle ballistic missile defense with higher data rates against high-speed targets. Airborne intercept and control (IC) radars provide early warning and information for the command and control of forces operating in the tactical environment. Space surveillance and tracking radars usually use large, fixed, phased arrays operating in the HF (3–30 MHz) to 1 GHz frequency range. Table 1 gives parameters of typical radars categorized by radar function. The reader is referred

Table 1. Parameter Ranges Associated with Radar Functions

Radar Parameter	Radar Function					
	GCI	IC	Surveillance	TA	TT, AA	Space Surveillance
Frequency range	30 MHz–3.0 GHz	3.0–10.0 GHz	30 MHz–3.0 GHz	3.0–8.0 GHz	6.0–10.0 GHz	30 MHz–1.0 GHz
PRF range	100–500 pps	1000–3000 pps	100–500 pps	1000–2000 pps	2000–4000 pps	—

to radar and electromagnetic wave propagation articles within this encyclopedia.

Radar advancements can be expected in the areas of phased-array antennas, complex modulations on the radar pulse, improved signal processing to extract enhanced data from the radar return, and frequency diversity to cover the less used regions of the spectrum. Advanced designs from the U.S., European, and Russian inventories can be expected because of operational needs for enhanced sensor performance and the availability of affordable technologies to provide additional capability.

2.1.2. Communications. Communications systems provide information exchange for command and control to coordinate between surveillance sites and between combat units. Communications networks range from basic field radio networks to long-distance, wide-area systems and point-to-point, high-data-rate installations. Communications systems cover the spectrum from very low frequency (5 Hz) to the frequencies of visible light, and they can be either free-space transmissions or confined to a transmission line. Free-space transmission links may be line of sight or cover longer distances by reflecting from the ionosphere, atmospheric layers, or troposcatter, or by relaying via satellite.

Command and control communication links, using HF direct microwave and satellite relay, disseminate voice and digital data transmissions to land forces, air forces, and ships. Land combat units use ultrahigh frequency (UHF) (300 MHz–3 GHz), very high frequency (VHF) (30–300 MHz), landlines, and cellular phones over shorter distances mainly for voice transmissions. Surveillance activities and weapons sites may exchange data via voice or digital data link over a transmission path appropriate for the link span. Such links are used to transmit surveillance radar reports to an operations center or directly to a SAM battery. Communication link data rates depend on link bandwidth, modulation technique, and signal-to-noise ratio. Individual transmission link throughput rates are in the range of hundreds of megabytes per second. Computer technology has enabled increased communication link capacity for handling and processing data. The high data rates attainable permit transmission from airborne observers and between precision weapons and launch platforms.

Communications in hostile environments are transmitted via protected cable between fixed sites, thus providing protection from physical damage, security from intercept, and immunity from jamming. Mobile communications require free-space transmissions that are susceptible to intercept and jamming. Communications counter-countermeasures, complex modulation, encryption, and spatial radiation constraints are used to miti-

gate the effects of EA. The use of modulation techniques increases privacy, reduces interference, improves reception, and reduces the probability of detection. Spread-spectrum communication systems that use four categories of signal modulation [direct sequence-modulated, frequency hopping, intrapulse FM (chirp), and time hopping] provide some level of signal protection from detection, demodulation, and interference. However, this is at the expense of increased bandwidth.

2.1.3. Passive Weapons Sensors. Electrooptical and infrared (EO/IR) systems sense spectral energy that is radiated by an object or reflected from an object from a source such as the sun, moon, or stars. The electrooptical spectral regions are categorized according to atmospheric propagative characteristics or spectral transmittance. The EO/IR spectrum used for passive weapons sensors spans the 0.2–15 μm wavelength range.
