Electrooptical/infrared guidance provides angle target tracking information only. EO/IR weapons system guidance sensors fall into three classes: nonimaging, pseudoimaging, and imaging. Generally, countermeasure techniques exhibit preferential effectiveness against guidance approach. Some countermeasures techniques may be effective against pseudoimaging sensors and less effective against nonimaging and imaging sensors. Other countermeasures techniques may be preferentially effective against nonimaging and imaging sensors. Figure 3 illustrates the most common seeker design approaches. These approaches are quadrant, spin scan, conical scan (conscan), transverse-line scan, and rosette scan. In the quadrant approach, an intentionally defocused spot images on a four-element square array. Tracking is achieved by balancing the signal on all four detectors. In spin scan, a spinning reticle provides phase and amplitude information with respect to a fixed reference. With conscan, the target image is nutated by using a scanning mirror or optical wedge imaged onto a fixed reticule or pattern of detectors. The nutated target image generates a modulated frequency proportional to the angular and radial offset from the center. In the transverse-line scan approach, a rotating or reciprocating mirror at a depressed elevation angle generates a scanline transverse to the missile axis, and the forward motion of the missile creates the orthogonal axis of the search pattern. With the rosette scan, a petal pattern is scanned over a small instantaneous field of view (IFoV) by two counterrotating optical elements.

Rosette-scan tracking is accomplished by balancing the signal output from all petals with the target present in the central apex of the rosette. The small IFoV of the transverse-line scan and rosette scan provide high spatial resolution and the ability to resolve multiple sources

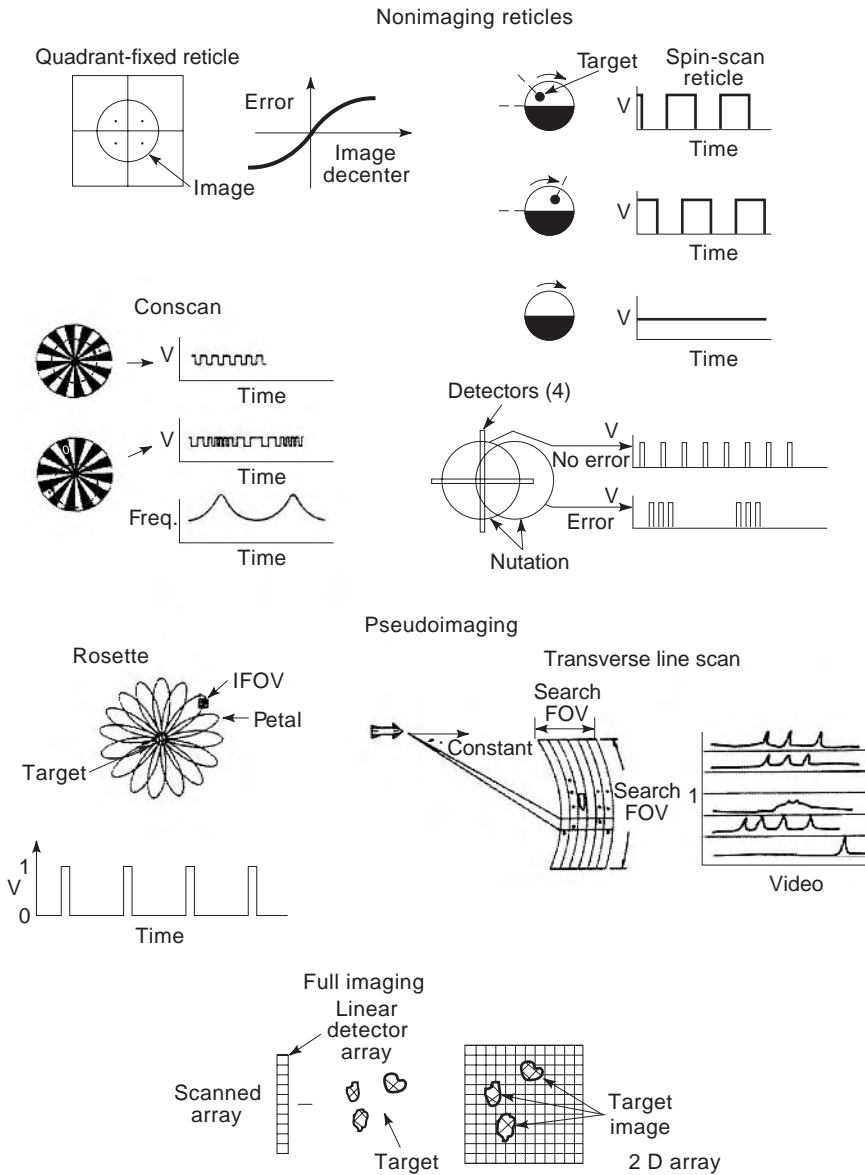

Figure 3. Common IR/EO sensor types including nonimaging reticules, line scanning detectors, and area array imagers.

within the scanned field of view. Focal plane arrays, scanning-linear arrays, or two-dimensional arrays of detectors in the image plane provide high-resolution “pictures” of the target space. Many image-processing algorithms are available to classify targets and establish track points. Figure 3 illustrates the basic features of common seekers.

Passive electro-optic sensors are desirable targeting and weapons guidance systems because they radiate no energy to warn the target of an impending attack. These sensor systems are vulnerable to decoys, with thermal signatures similar to true targets and to high-intensity sources that can saturate the electro-optic sensor detector or cause physical damage.

3. ELECTRONIC WARFARE FUNCTIONAL AREAS

Threat systems use the EM spectrum extensively. This section discusses functional aspects of EW. The

relationships that govern their systems’ application are described in the following section. These functional areas are electronic support (ES), electronic protection (EP), and electronic attack (EA). Electronic attack uses countertargeting (CTAR), jamming, false-target generation, and decoys to defeat the threat sensors. Electronic protection uses electronic support and electronic attack for own-platform self-protection.

3.1. Electronic Support

Electronic support provides surveillance and warning information to the EW system. ES is a passive, nonradiating, EW system function that provides a fast, accurate assessment of the EM radiating environment. ES is the aspect of EW that involves techniques to search for, intercept, locate, record, and analyze radiated energy for exploitation in support of military operations. Electronic support provides EW information for use in EA and EP

and in tactical planning. ES directly provides threat identification/detection and early warning. It also provides data for electronic countermeasures (ECM), electronic counter-countermeasures (ECCM), threat avoidance, target acquisition, and homing.

Electronic support provides timely EM environment information for the EW system. The spatial and spectral environment over which ES operates may span a hemispherical spatial segment and a spectrum of tens of gigahertz. In tactical EW systems, signals in the environment are analyzed and reports of environment activity are provided on the order of a second after threat signal reception.

3.2. Electronic Attack

As an EW function, EA provides an overt active response capability against enemy combat systems with the intent of degrading, deceiving, neutralizing, or otherwise rendering them ineffective or inoperative. EA responds to threat systems to protect multiple platform or battle group units. EA includes measures and countermeasures directed against electronic and electrooptical systems by using the electromagnetic spectrum (radio, microwave, infrared, visual, and ultraviolet frequencies). EA technical functions include radio and radar signal jamming, false target generation, and the use of decoys for threat system confusion and distraction.

Electronic attack is reactive to environment threats. To function effectively, therefore, the EA system requires threat information from the environment, including threat classification, bearing and, if possible, range. These functions are performed by the ES system or by other surveillance systems such as radar or infrared search and track (IRST). Effective EA response selection requires knowledge of the threat class and operating mode. Threat signal data are derived from measuring signal parameters (frequency, scan type, scan rates, pulse repetition frequency, or continuous-wave radiation characteristics). Absence of radiation may indicate that the threat uses a passive RF or an electrooptical sensor. The detected threat electronic parameters are compared to an extensive emitter database. The EW database, derived from intelligence sources, is used to identify the threat and correlate the threat and operating mode with effective EA techniques. Operational threat exploitation is often impeded by intelligence gaps and/or threat use of parameters reserved for wartime.

3.2.1. Nondestructive Electronic Attack. Nondestructive EA produces electromagnetic signals at a predetermined radio, infrared, visual, or ultraviolet frequency with characteristics that temporarily interfere with the threat's receiving system, that is, power level, frequency, and polarization. EA degrades or overcomes threat system operation by overpowering the target signal at the threat sensor. "Dazzling" is laser or high-power lamp EO/IR jamming. Dazzling saturates the detectors or focal plane arrays of electrooptical (infrared, visual, ultraviolet) guided missiles and target tracking systems. Deceptive EA presents a confusing signal to the threat sensor that degrades

its performance to the point where it is no longer effective. Power levels used for deception are less than those required for jamming because deception does not require threat sensor saturation.

3.2.2. Destructive Electronic Attack. Destructive EA physically damages or destroys the threat electronic system. Specially designed missiles such as the HARM (high-speed antiradiation missile) missile, shown being released from an A-6 aircraft in Fig. 4, are equipped with radar-homing seekers that attack the threat radar antenna and nearby electronic equipment within the blast radius of the missile warhead. More recently, similar seekers have been fitted to loitering remotely piloted vehicles for a similar purpose. Advances in high-power microwave and laser technology have made directed energy more practical. At very high power levels, microwave energy destroys the components in a missile seeker or threat radar, rendering them inoperative. High-power lasers also physically damage both RF and electrooptical threat systems.

3.3. Electronic Protection

Electronic protection provides EW protection for the host platform. Key environment surveillance and threat-warning information is provided by the ES system function (as it is for EA). EP responds to threats in the environment with information for evasive action and with the countermeasure responses described previously. EP is primarily directed against the terminal threat targeted on the host platform, and preferred EP techniques use decoys that are less susceptible to the home-on-jam weapon mode.

4. ELECTRONIC WARFARE TECHNICAL AREAS

Technical areas that support the ES, EA, and EP functional EW systems areas are discussed in this section. All aspects of EW are addressed by modeling and simulation because this is the most practical means for functional

Figure 4. HARM missile (shown after separation from an EA-6B aircraft) is an EW weapon for physically destroying the source of hostile radiation.

evaluation. System architectural analyses address the formulation of efficient EW system configurations to provide the operational functions required within the constraints of available equipment, techniques, and technology. Technical areas that address ES primarily are signal detection, measurement, and processing issues that deal with environment surveillance and warning. Technical areas associated with EA and EP include CTAR jamming and false-target generation, EO/IR CM, and decoys. Also included in these technical area discussions are technology challenges to EW technologies for future capability.

4.1. Modeling and Simulation for Electronic Warfare

Electronic warfare uses modeling and simulation extensively in three areas of investigation: research into new hardware, threat domination/exploitation, and tactics development. The effectiveness of an EW architecture or equipment suite is assessed by using a computer model and parametric studies run against the model. Estimates of a threat system's capabilities are incorporated into the model as environment sources because acquiring foreign hardware and measuring its performance is difficult. Environment signal models stimulate the EW system model. The EA effectiveness modeled against the threat is measured, and tactics are developed to further reduce threat system efficiency.

Modeling and simulation (M&S) combine detailed antiship missile models with ship models, antiair missile models with aircraft models, electromagnetic propagation models, and chaff RF decoy models. (Chaff RF decoys are described later.) Chaff effectiveness evaluation considers the spatial relationship between the missile seeker and the ship while accounting for radar clutter and multipath returns. Signals at the missile are processed through the seeker receiver and missile guidance and tracking logic. A chaff cloud(s) injected into the simulation provides a false radar target signal at the missile seeker. By varying the amount of chaff and/or the chaff round spatial relationship with respect to both the defended ship and the threat missile, chaff effectiveness and tactics can be evaluated. However, the accuracy of the M&S results depends on the accuracy of the models used. An accurate missile sensor and control model is necessary to determine the effects of the complex signal returns from the target ship and the chaff on the missile controls and resultant flight path. In a simulated engagement, detailed missile functions are required to provide an accurate assessment of chaff effectiveness. These functions include monopulse antenna processing, range and angle tracking, missile guidance, and aerodynamics. Multiple threat seeker modes, such as acquisition, reacquisition, track, home-on-jam (HoJ), and simulated coherent combinations of signal segments are also required in the model.

Target ship, aircraft, and chaff radar cross section (RCS) must be accurately modeled. Typically, a multireflector target simulation is used to represent the RCS signature. Ideally, a model of thousands of scatterers would provide greater accuracy. However, careful selection of several hundred scatterers is adequate.

The accuracy of the missile and target interaction depends on the propagative environment model including multipath. Typically, a ray-tracing algorithm models the propagation of RF energy. Useful models rely on a stochastic representation of clutter as a function of wind-speed, grazing angle, frequency, polarization, and ducting. Modeling of an ocean environment can be extended to include reflection from wave segments. Models are verified by using measured field test data.

4.1.1. Electronic Warfare System Architectures. The EW system architecture ties system functional elements into an efficient configuration optimized to the operational mission. Figure 5 shows a typical EW system architecture. The system performs signal acquisition and parameter measurement, direction finding, countermeasure generation, and decoy deployment. The system central processing unit (CPU) provides sensor and countermeasure coordination and EW system interface with other onboard systems.

Fusing the measurements of EW sensors and processors is a complex technological challenge. This information includes radar, communications, EO/IR, direction finding, and signal analysis. Data fusion within the EW system requires algorithmic development and significant enhancement in computational throughput. The EW system includes antenna(s), receiver(s), and processor(s) elements that provide data on signals in the environment. System sensors detect and measure threat signal characteristics. Multiple sensor subsystems measure the characteristics of the signal. For example, a signal acquisition detects the presence of a signal and measures the envelope characteristics (frequency, time of arrival, and signal duration). Another sensor that may include multiple antennas and receivers provides signal bearing-angle data. Separate subsystem sensors measure intrapulse signal modulation and/or received polarization.

A countermeasures receiver may use an independent electromagnetic environment interface. The countermeasures receiver accepts signals from the environment and provides them to the techniques generator. Target signals designated by CPU algorithms are selected for countermeasure generation as are the countermeasure modulation

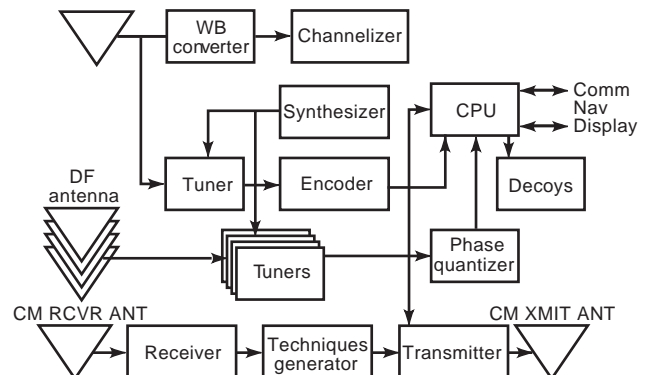

Figure 5. Electronic warfare system architecture indicating system functional elements required to provide ES, EA, and EP functions to the host platform and operational battle group.

techniques to be applied. The resulting jamming signals are amplified to the desired power levels and radiated into the environment.

Decoys are part of the EW system architecture. This subsystem is controlled by the CPU based on sensor inputs. Decoys provide the important function of separating the countermeasure signal source from the host platform. In this operational mode, decoys provide alternative highly visible targets to divert a weapon from its intended target. Also required are the means, such as the coordination of jamming with the use of decoys, to neutralize the HoJ weapons threat.

4.2. Surveillance and Warning

Electronic support surveillance and warning perform the functions of noncooperative intercept and exploitation of radiated energy in the EM environment. Surveillance and warning detection relationships are those associated with communications systems. Additional signal detection constraints result because the signal’s spatial location and its characteristics may not be known. Signal unknowns require tradeoffs of detection sensitivity and environment search. Once detected and measured, environment signals require sophisticated signal processing for signal sorting, formation, and characterization before they can be correlated with signal intelligence libraries for classification. Some fundamental tradeoff relationships for detection and warning are discussed below.

4.2.1. Threat Signal Detection. Threat signal detection occurs as the electronic support system is illuminated above the system sensitivity level with signals that satisfy the single-pulse detection criteria. Detection is performed as the ES system scans the environment. Detection metrics include incident radiation sensitivity, detection probability, false detection probability, corruption probability, simultaneous detection, and throughput rate.

Aircraft are often used to carry electronic warfare battlefield surveillance equipment. The operating altitude of surveillance aircraft provides a long line-of-sight range to the horizon. The range to the electromagnetic horizon accounting for nominal atmospheric refractions is given by

$$R = \left[\left(\frac{3}{2} \right) h \right]^{1/2} \tag{1}$$

where h is the aircraft sensor altitude in feet and R is the observer-to-horizon range in statute miles.

The time required to survey the environment depends on the surveillance alert status, system sensitivity, instantaneous observation segment, and rate of environment search. The number of instantaneous environment segments in frequency and bearing establish the number of environment dwell periods required for an environment scan. The larger the environment segments, the more rapidly the system performs the scan. The dwell at given environment segment is scheduled to span the signal event

period. Time to intercept is modeled by

$$T_I = \frac{(T_D N M)}{P_T} \tag{2}$$

where T_I is the time required to survey the environment, T_D is the EW support system dwell period, N is the number of frequency segments in the environment, M is the number of spatial segments in the environment, and P_T is the probability that the signal occurs above the sensitivity level.

In Eq. (2), spatial environment segmentation, spectral environment segmentation, and detection probability combine multiplicatively to define the time required to survey the environment. Wide instantaneous bandwidths and a large instantaneous field of view reduce environment survey time unless equipment choices reduce system sensitivity and the corresponding probability of signal detection. Equations (3) and (4) describe receiver sensitivity and aperture gain functional relationships:

$$S = (NF)(SNR)(kTB) \tag{3}$$

where S is receiver sensitivity, NF is receiver noise factor, SNR is the required sensitivity for detection and false alarm criteria, k is Boltzmann’s constant, T is temperature in degrees kelvin, and B is bandwidth in hertz

$$G = 2K\pi/\theta \tag{4}$$

where G is antenna gain, K is antenna efficiency (less than unity), and θ is antenna beamwidth in steradians.

A tradeoff between sensitivity and time to intercept is implied in Eqs. (3) and (4). By using multichannel processing, the tradeoff can be resolved in either domain. A wideband channelizer provides instantaneous spectral coverage equal to the span of the channelizer frequency coverage, and receiver sensitivity is established by the bandwidth of an individual channel. Multichannel spatial processing provides the instantaneous spatial coverage of the sum of the channels being processed. System antenna gain is based on channel beamwidth.

Detection sensitivity requires consideration of the desired detection range. Equation (5) defines the electronic support detection range in terms of the threat signal parameters and the electronic support antenna, receiver, and processor system parameters:

$$R_{MAX} = \left[\frac{P_t G_t G_r \lambda^2}{(4\pi)^3 \left(\frac{S}{N} \right)_{MIN} kTB_n L} \right]^{1/2} \tag{5}$$

where R_{MAX} is the maximum detection range, P_t is the threat signal transmit power, G_t is the threat signal antenna gain, G_r is the antenna gain of the electronic support subsystem, λ is the wavelength of the threat signal transmission, $(S/N)_{MIN}$ is the minimum signal-to-noise ratio required by the electronic support subsystem for detection, k is Boltzmann’s constant, T is absolute temperature, B_n is the effective noise bandwidth of the electronic support

receiver, and L represents the combined feed losses of the threat transmitter and the electronic support receiver.

The probabilistic characteristic of signal detection is illustrated by considering the intercept of a threat at a signal level considerably above the receiver threshold level. Detection probability arises primarily from the independent probabilities that the ES system observes the environment in the spatial and spectral location of the threat emitter and that the threat emitter illuminates the receiver with the required power for detection.

Also of importance is the probability of signal detection once the ES system is steered to the signal spatial and spectral location. Then detection probability P_D is based on the signal characteristics, that is, the probability that the threat signal illuminates the EW system during the observation period. The time required to perform a detection T_I is derived from the scan interval T_S and is given by $T_I = T_S/P_D$.

False reports from the electronic support receiver are highly undesirable. Limited computational resources are needed to process each pulse received in an attempt to form an association with other pulse reports. The rate of false reports is established by the proximity of the detector threshold level to the noise level. Figure 6 shows the relationship between the single-event probability of detection, the probability of false signal report generation, and the signal-to-noise ratio. This figure shows that both the probability of detection and the probability of false generation are strong functions of the signal-to-noise ratio.

The probability of pulse interference P_{OL} depends on the duration T_D of the signal and the rate R at which signals are expected. A reduction in P_{OL} results from adding parallel measurement channels. The functional relationship approximating P_{OL} is

$$P_{OL} = \frac{(T_D R)^N}{N!} \left(1 + \sum_{N=1}^N \left(\frac{T_D R}{N} \right) \right) \quad (6)$$

Figure 6. Detection probability and false detection probability for various signal-to-noise ratio conditions.

where T_D is the event duration, R is the event repetition rate, N is the number of parallel measurement functions provided, and P_{OL} is less than 0.9.

4.2.2. Electronic Support Signal Processing. The ES signal processor derives signal information from the multitude of environment event measurements. Signal processing is the focal point of the ES subsystem where operationally relevant sense is made of large data inputs. ES processing includes sorting event data and correlating sorted event data with emitter libraries to establish the class or family of signals to which the emitter belongs. Beyond sorting, intensive processing is applied to identify intercepted emitters specifically and to locate them precisely within the battle space.

Sorting, a key electronic support signal processing function, correlates event descriptors from the same emitter. Correlation is performed on the basis of both instantaneous and temporal signal parameters. Instantaneous parameter sorts are less computationally demanding than temporal deinter-leaving.

The initial signal sorting is histogramming based on instantaneous signal parameters. The signal parameters used for histogram-based sorting are those available from a single event or pulse measurement. They include external signal parameters, such as signal frequency, start time, duration, power level, and angle of arrival. Other instantaneous parameters used are measurements of signal modulation. Signals measurements with like parameters are binned together, and it is postulated that each bin contains event descriptor data from the same emitter.

After sorting, event descriptors are placed in individual emitter-associated groups. The monopulse and interpulse characteristics of the event group measurements are quantified into a signal descriptor. The signal descriptors are classified into an emitter class by correlation with a library database.

In some instances, high-resolution signal measurements identify specific emitters. As might be expected, identification parameter sets and the processing required to establish them are significantly in excess of that required for classification. Here, as in the case of classification, detailed signal descriptors are correlated with a library to define a specific emitter.

The spatial distribution of threat signals in the environment is operationally important. Determining the threat signal bearing angle with respect to own platform is a key step toward establishing threat signal position information. Conventional techniques used for direction-finding measurements include the use of differential amplitude processing of squinted antennas (antennas aimed in different directions), differential phase measurements from a phased-array antenna, and differential time of arrival measurements from spatially separated receivers.

Both hostile and benign operational scenarios require information about the location of both noncooperative fixed and mobile emitter installations. Electronic warfare target location exploits direction-finding data and navigational data to provide a signal location solution. Single or multiple platforms are used to generate location data.

The accuracy of target location depends on the precision of the direction-finding data and the navigation measurement and on the length of the baseline between measurements and the range to the target. Figure 7 shows target location geometry. The major error location axis A is modeled by

$$A = R\varphi \csc\left(\frac{\psi}{2}\right) \quad (7)$$

where R is the range from observer to the target emitter, φ is the direction-finding measurement error, and ψ is the angle subtended by the maximum difference in observation bearings with respect to the target, which provides location measurement error for the condition $\psi < \pi/2$. The range R from the observer to the target is given by

$$R = L \frac{\sin(\pi - \theta - \gamma)}{\sin \theta} \quad (8)$$

where L is the separation between observations, θ is the angle between the baseline and the opposite bearing angle, and γ is the angle between the baseline and the adjacent bearing angle.

4.2.3. Electronic Support Digital Signal Processing Technology. Electronic warfare system processing, both dedicated and programmable, assimilates environment data from the receivers and wideband processors. It uses these data to sort, classify, and identify the sources of emissions to represent the environment relevantly. The digital signal processor provides the means for applying an array of algorithms to both predetection and detection signal data to extract threat information for EW system use. Digital signal processing metrics include high-rate signal throughput processing in a compact module.

Digital signal processing is the heart of the ES function. It provides the flexibility of applying an extensive array of algorithms to system data. Critical digital signal processing technology challenges include processing throughput and developing efficient processing algorithms. Although signal data can be refined by applying sequential algorithms, the ES response is time-critical; it

must provide the most accurate assessment of available data within the required response time. Great potential exists for advancing digital signal processing technology, but optimum ES performance can be expected from judicious allocation of processing tasks between wideband processors and the digital signal processor.

An example of digital signal processing technology is L-MISPE (little monopulse information signal processing element), a special-purpose signal processor designed to operate with high-quality superheterodyne RF receiver systems. L-MISPE provides extremely accurate pulse analysis and parameter extraction for signal classification and specific emitter identification (SEI). It is contained in a single rack-mounted enclosure.

4.2.4. Surveillance and Warning Technology. Surveillance and warning are the sensor and environment processing functions for the EW system. Speed and accuracy of measurements and processing functions are the primary metrics for ES. Accurate throughput is important in providing sufficient time for effective threat response to the EA or platform commander. In addition, precision threat assessment provided to the EA subsystem facilitates optimum technique selection and conservation of EA power resource for engaging multiple threats. The ES performance challenge is further constrained by space limitations aboard platforms, particularly aircraft. Receiver technology performs environment sensing for the EW application.

4.2.5. Receiver Technology. Electronic support throughput and physical displacement metrics are addressed in developing wideband, small-size monolithic microwave integrated circuit (MMIC) technology. MMIC monolithic integrated analog processing at multigigahertz operating frequencies provides a capability suited to ES receiver applications. Advantages sought in the exploitation of this technology base include economies of size, weight, power, and cost. Increased receiver dynamic range for continuous environment intercept during active countermeasures transmission remains a receiver technology challenge. The MMIC receiver shown in Fig. 8 is an example of this technology.

4.2.6. Wideband Processing. Wideband receivers provide high probability of signal intercept. Wide spectral segment processing is necessary to increase signal detection sensitivity and to provide copulse reception of multiple simultaneous signals and rejection of interference signals. Requirements for wide instantaneous bandwidth, rapid throughput, and small modules are wideband processing metrics.

Acoustooptic channelization technology is being developed for wideband processing as a compact, economical means for performing high-resolution environment segmentation. Wide-band signal frequency demultiplexing is performed using Bragg regime acoustooptic diffraction and electronic signal detection and encoding. Functions performed by these acoustooptic processors include channelized correlation, convolution, and spectral processing.

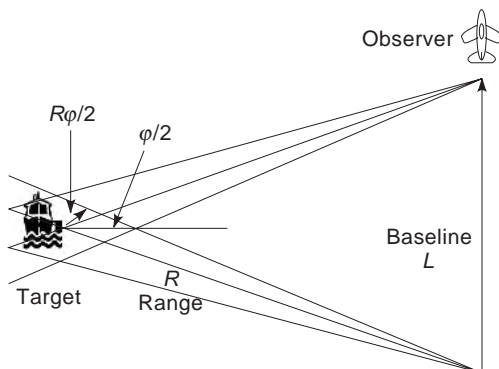

Figure 7. Emitter location geometry supporting Eq. (7), with observer track and signal measurement angles indicated.

Figure 8. The MMIC receiver, a combination of monolithic microwave, analog, and digital circuits, performs signal selection and conversion to a convenient intermediate frequency.

Acoustooptic channelizers are based on Bragg diffraction of light (Fig. 9). The Bragg cell serves as the optical deflection or optical modulator element within the processor. The Bragg cell is an optically transparent medium, such as a crystal, that is driven at the applied RF frequency by using a piezoelectric RF-to-acoustic transducer. The Bragg cell transduces the RF signal into acoustic waves that are collimated into the Bragg cell crystal. The propagating acoustic wave creates sequential regions of crystal compression and extension that correspond to the period of the acoustic wave. The acoustically induced diffraction grating in the Bragg cell interacts with a coherent optical source to perform RF input frequency demultiplexing. The deflected lightbeams output from the Bragg cell are focused onto a detector array where light is detected to indicate energy in segments of the applied RF spectrum.

4.2.7. Wideband Interconnections. Electronic warfare sensors require broad access to the electromagnetic

Figure 9. The acoustooptic Bragg regime signal transform processing principle used for signal frequency analysis, sensitivity enhancement, and direction-finding functions.

environment to provide quick response to hostile electromagnetic activity. For convenience and efficiency, central stowage of signal processing functional elements is important. To assure signal visibility, environment apertures, antennas, and EO/IR sensors must occupy locations on the periphery of the aircraft, ship, or land vehicle. Wideband interconnects transmit electromagnetic environment data from the EW system apertures to processing subsystems.

With the current RF bandwidth of the electronic warfare environment expanding through tens of gigahertz, just finding a medium that supports that level of frequency coverage is a challenge. At light frequencies, however, a 100-GHz spectrum spans less than a third of 1% of light frequency. In addition, low-loss-transmission optical fibers provide a nearly lossless means to transfer wide spectra across a platform. Indeed, wideband interconnect technology is developing the use of fiberoptics.

Usable optical fiber bandwidth is limited by dispersion. Conventional fiber exhibits dispersion of 20 ps/km/nm of bandwidth. A typical signal operating within a 10MHz bandwidth would exhibit dispersion of less than 0.1°. Clearly, bandwidth limitations are elsewhere in the link.

Detectors have also been developed to provide bandwidths on the order of tens of gigahertz. High RF operating frequency detection is performed by using small-geometry detectors that exhibit maximum power limitations. Limitation in maximum power levels applied to the detector restricts the output signal intensity range. More recent developments in distributed detector elements are extending detector power-handling capabilities.

Dynamic range is a significant fiber optic link metric because the EW sensor system must process low-power signals on the horizon in an environment with high-power local transmissions. Modulator and detector attenuation reductions are technological issues being addressed to enhance the dynamic range performance of fiber optic links.

4.3. Countertargeting

Countertargeting (CTAR) is the technical area that provides the means for protecting the host platform or force from weapons targeting by a hostile force. CTAR functions include obscuration, false-target generation, and confusion. Associated techniques include jamming and onboard and offboard false-target generation.

Countertargeting operates against radars that feature a target, locating or surveillance mode, as shown in the functional sequence of Fig. 10. Airborne surveillance radar is generally used against ship and ground forces because the aircraft altitude provides extended surface target detection range. Conversely, when defending against aircraft with CTAR, the radar could be ground-based. Some radars are designed with the sole purpose of surveillance, whereas others are multimode and can track targets. By using imaging processing, modern surveillance radars that include synthetic aperture, inverse synthetic aperture, high range resolution, and moving target indication processing can accurately determine target location and identify the type of target.

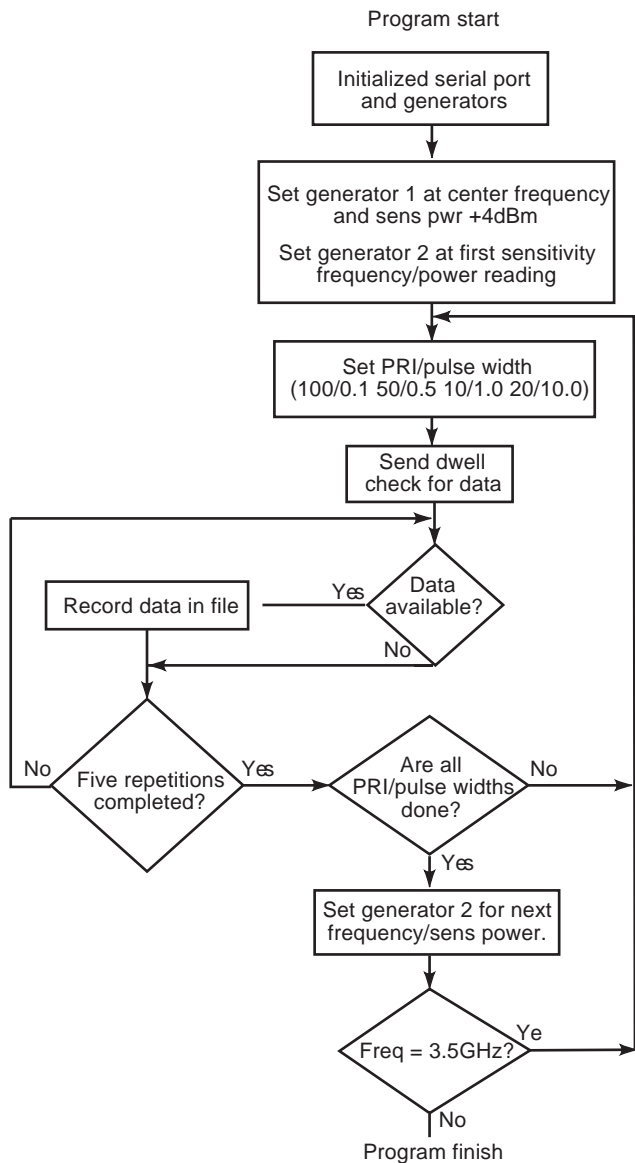

Figure 10. CTAR functional diagram showing sequence used in engaging a surveillance or targeting radar signal.

4.3.1. Countertargeting Techniques. Figure 10 shows the CTAR functional sequence. CTAR EA techniques are categorized as environment obscuration and jamming and false-target signal generation. CTAR provides either confusing or ambiguous data to adversary surveillance and targeting radar displays to confuse the human operators who interpret these presentations. Radar displays include plan position indicators (PPIs), A or B scopes, or combinations of these. Obscuration screens targets over selected portions of the display with a jamming signal power above that of the target signal in environment segments spanning both range and azimuth (see radar articles for descriptions of radar displays). The amplitude of the obscuration CTAR signal exceeds that of any target-reflected signal in the screened sector.

Experienced operators can recognize obscuration and radar jamming and initiate procedures to mitigate its

Figure 11. EA-6B aircraft equipped with the AN/ALQ-99 EA system for airborne CTAR.

effects. The false-target CTAR technique, however, is a more subtle form of EA that is less apparent to the operator. Here, the CTAR signal creates false indications on the radar display that appear as real targets to the operator. When the display is cluttered with false targets, radar operator time is consumed sorting through them. Selecting a false target for missile engagement dissipates an expensive weapon.

CTAR EA systems can be used to protect an entire military force. CTAR force protection systems are generally large and use human operators for system control. An example is the AN/ALQ-99 system installed on the EA-6B (Fig. 11), and EF-111 EW aircraft. Some EA systems, such as the AN/SLQ-32 installed on surface ships (Fig. 12), are for self-protection and support EA functions.

The EA system selects a specific technique from a large EA technique library. Selection is based on knowledge of the threat location, class, electronic parameters, and operating mode. The EA system, using an embedded receiver subsystem, rapidly adapts to threat signal operating mode changes. The threat changes operating mode as either a

Figure 12. Shipboard installation of the AN/SLQ-32 EW equipment used for CTAR.

counter-countermeasures technique to circumvent EA or as part of the hostile targeting and homing sequence. Adaptive EA provides rapid changes in techniques as the threat sequences through operating modes.

Both jamming and deception CTAR techniques may be used. RF jamming techniques are either “barrage” or “spot.” Barrage jamming covers a wider frequency band at lower power density levels and is used to jam either several radars at once or spread-spectrum systems where the precise frequency of the threat is uncertain. Spot jamming concentrates the entire jamming power within the bandwidth of a single threat radar receiver with correspondingly better results. In both cases, a radial jamming strobe will appear on the threat radar PPI scope, as shown in Fig. 13. If the ratio of jamming signal power to the reflected radar signal power (J/S) is insufficient, the real target will “burn through” the jamming signal and become visible within the jamming strobe. For greater jamming effectiveness, it is desirable to have sufficiently large J/S to prevent burn through in the mainbeam and the principal sidelobes (see jam-to-signal calculations later).

Deception techniques are more varied and are generally threat-specific. Many deception techniques are directed against threat-tracking radars or missile-seeker radars. These techniques attack the threat radar target-tracking loops in range, angle, or Doppler. Deception techniques are often used in combinations and can be sequenced as the threat modes vary, or they can sequence according to a programmed pattern. False-target deception techniques are generated to emulate true target returns. The threat-radar operator, in response to deception, may conclude that all detected targets are genuine and simply select false targets for weapons engagement, or, if deception is suspected, time and computational resources must be used to identify the true target prior to engagement. In automated weapons systems, the EA subsystem may create so many false targets that the radar computer becomes overloaded. Because Doppler radar and missile seekers process large numbers of ambiguous radar returns to fix the true target, they are particularly vulnerable to coherent false-target techniques. An effective CTAR approach combines jamming and deception. Jamming creates a radial strobe that obscures the true target, whereas the deceptive CTAR provides false targets that project through the jamming strobe.

Figure 13. PPI radar scope without and with jamming, showing the effects of CTAR jamming on the threat radar display.

4.3.2. Countertargeting Effectiveness. Countertargeting effectiveness is assessed by comparing threat system performance in benign and CM environments. The ability of the threat system to detect, acquire, and target true targets, including parameters, such as target acquisition time and weapon release range, is assessed by evaluating threat performance against live targets on test ranges. Evaluating missile-seeker countermeasure effectiveness presents a more difficult problem. Computer simulations model the missile flyout from an actual or surrogate threat system against a live target. A measure of CTAR effectiveness (MoE) is the ratio of the number of missiles that approach their target outside of the missile lethal range to those missiles that approach the target within lethal range. Software simulates multiunit engagements. U.S. Navy ship EA is evaluated by flying test aircraft carrying captive instrumented seekers against the ships and recording the threat system performance.

A statistical technique to assess CTAR effectiveness compares the number of missiles required to defeat an EA-equipped aircraft versus the number required to defeat a non-EA-equipped aircraft. Similar statistics assess the number of antiradiation missiles fired versus the number of radar systems defeated. Additional effectiveness information can also be gleaned from intelligence sources.

4.3.2.1. Obscuration Burnthrough. A measure of CTAR obscuration effectiveness is the range at which the radar displays the target in the presence of jamming. This is called the *burnthrough* range. At this range, the radar is sufficiently close to the target that the processed target-reflected radar power exceeds the jamming signal display masking. The real target becomes visible superimposed on the jamming signal. Burnthrough is modeled in Eq. (9) by using the radar range equation and free-space propagation. The radar range equation provides the signal power S that is received at the radar after being transmitted to and reflected from the target. The free-space signal propagation equation models the jammer power J that is received at the radar from the jammer. The quotient of jammer to signal power constitutes a figure of merit known as the jam-to-signal (J/S) ratio. This ratio is unique for each radar and depends on radar processing gain and on the display format and screen phosphor. Operator proficiency also plays a significant role. Rearranging the terms of this equation to solve for range yields the burnthrough equation

$$R_b = \sqrt{\frac{J}{S} \left(\frac{P_R \sigma B_J}{P_J 4\pi B_R} \right)} \quad (9)$$

where R_b is the burn through range, J/S is the ratio of jammer-to-signal power required to jam the victim radar, P_R is the effective radiated power of the radar, P_J is the effective radiated power of the jammer, σ is the radar cross section of the target, B_J is the jamming signal bandwidth, and B_R is the processing bandwidth of the radar receiver. This equation models the case with the jammer located on the radar target platform.

4.3.2.2. Jammer-to-Signal-Power Relationships. The J/S power ratio at the threat radar is a concept central to predicting EA effectiveness. To degrade the threat radar, an interfering jammer power J of sufficient strength is required to overcome the target-reflected signal at the radar S . For effective EM noise jamming, the J/S required is 0–6 dB minimum, depending on the noise modulations used and the detailed characteristics of the threat. The minimum J/S ratio required for effective CTAR deception techniques varies from 0 dB for false targets, to 0–6 dB for range deception, to 10–25 dB for angle-tracking deception, and to 20–40 dB for monopulse deception. Equations (10)–(12) are based on two typical EA tactical situations. *Self-protection* CTAR [Eq. (10)] addresses the case with the target in the threat radar mainbeam. *Support* CTAR [Eq. (11)] addresses the case of the target in the threat main radar beam but with the EA jamming emanating from a separate platform and radiating into an arbitrary bearing of the threat radar antenna pattern. In both cases, the radar is assumed monostatic (i.e., the radar receiver and transmitter are collocated):

J/S for self-protection EP CTAR:

$$J/S = \frac{4\pi P_j G_j B_r R^2}{P_r G_r \sigma g^2 B_j} \tag{10}$$

where P_j is jammer power output; G_j is gain of jammer antenna in direction of radar; B_r is radar receiver noise band-width; R is radar-to-jammer range; P_r is radar power output; G_r is gain of radar antenna in target direction; σ is target radar cross section; g^2 is propagation one-way power gain (square of the ratio of field strength to free-space field strength due to direct and reflected ray combination), $0 < g^2 < 4$ (interferometer lobing); and B_j is the jammer noise bandwidth.

J/S for support EA:

$$J/S = \frac{4\pi P_j G_{jr} G_{rj} B_r R_t^4 g_j^2}{P_r G_r^2 \sigma B_j R_j^2 g_t^4} \tag{11}$$

where G_{jr} is the gain of the jammer antenna in the direction of the radar, G_{rj} is the gain of the radar antenna in the direction of the jammer, R_t is the radar-to-target range, g_j is the jammer-to-radar propagation factor, R_j is the radar-to-jammer range, and g_t is the radar-to-target propagation factor. The remaining terms are as defined previously.

Effect of target radar cross-sectional reduction:

$$S = \frac{P_r G_r \sigma \lambda^2 g^4}{(4\pi)^3 R^4} \tag{12}$$

where λ is the wavelength of the radar operating frequency. All the remaining terms are as defined previously.

Equation (12) defines the signal at the receiver of a mono-static radar. Note that the power received at the radar is directly proportional to the target radar cross section σ and inversely proportional to the fourth power of the range R (R is the separation between the target and radar). Therefore, as the radar cross section is reduced, the

signal at the radar is correspondingly reduced. If the cross section is sufficiently reduced, the target becomes indistinguishable from the radar noise and background clutter. Low observable platforms, such as the B-2 and F-117 aircraft, provide sufficiently low radar cross section to make radar detection difficult. The implication of radar cross-sectional reduction technology to CTAR is twofold: first, with sufficiently low radar cross section, EP may not be necessary, and secondly, if the cross section merely lowers the signal power at the radar, then a lower power, low-cost CTAR transmitter becomes sufficient to provide the J/S necessary to achieve the desired level of survivability.

4.3.3. Countermeasure Technology. Countermeasure technology addresses the evolving threat in addition to the need for economic force protection. Significant advances in radar, communications, EO/IR weapons' sensors, and weapons control present heightened challenges to maintaining effective EA capability.

4.3.3.1. Radar Countermeasures Technology. Countertargeting equipment for use against advanced synthetic aperture radar (SAR) or inverse synthetic aperture (ISAR) surveillance and targeting radar requires wide instantaneous bandwidths and high processing speeds. Furthermore, because these radars use coherent processing, CTAR effectiveness consequently requires coherent radar signal storage and reproduction to enhance effectiveness. Digital RF memory (DRFM) technology is being developed to convert the analog radar RF signals into a digital format for convenient storage. As required, the radar signal is retrieved from storage and converted to RF for use in countermeasure waveform generation. Technology limitations and costs constrain currently available DRFM designs, each optimized for a specific application.

Radiofrequency-tapped delay lines provide precise timing between portions of the CTAR waveform. Analog RF-tapped delay lines use surface acoustic wave (SAW) and acoustic charge transport technology. Research is underway to create digital tapped delay lines. Noise modulation is commonly applied to CTAR signals, and high-quality tunable noise sources are required. The output EA stage is the transmitter/antenna combination that generates and radiates the CTAR signal. Antennas for EA applications, once considered a dedicated asset, are currently envisioned as multifunction phased-array antennas with elements fed by solid-state amplifiers.

Radio-frequency isolation between the countermeasures transmitter and the receiver is a common problem of countermeasures-equipped platforms. The countermeasure signal appears at the receiver antenna. When the transmitter and receiver are insufficiently isolated, the countermeasure signal interferes with lower level threat signal reception from the environment. Interference demands careful attention to antenna design, isolation, and platform siting.

4.3.3.2. Radar Countermeasure Signal Source Technology. Electronic attack transmitters require signal sources that can be rapidly switched in azimuth, elevation, frequency, and polarization to generate multiple high-power beams

with low sidelobes over large multioctave bandwidths. CTAR requirements for economical compact transmitters are challenged by the lack of appropriate low-cost EM power sources. Furthermore, few commercial applications exist for wideband EM power source technology. Research and development in this area is limited primarily to EA applications. Original EW power sources, tunable magnetrons, and cross-field amplifiers provided only narrow operating bandwidths. Traveling-wave tubes (TWTs) evolved to fill the need for wide, instantaneous bandwidth. Over time, TWT bandwidths grew from a single-octave 2–4 GHz band to multiple octaves at frequencies beyond 40 GHz. However, TWTs are expensive and unreliable. Although new mini-TWTs and microwave power modules have become available, their basic design remains vacuum-envelope-based. MMIC technology is steadily advancing, and it now provides solid-state chips with multioctave signal generation capability, wide instantaneous bandwidth, and signal power levels approaching 5 W. With MMIC technology, solid-state active aperture arrays become achievable, and such arrays for EA applications are now being developed. Although MMIC active aperture array signal source promises good performance and reliability, the system remains expensive.

4.4. Passive Electrooptic/Infrared Electronic Warfare

Electronic warfare in a passive EO/IR target acquisition and weapons sensors environment applies to a growing threat capability. The open-ocean blue-water scenario requires EO/IR EA and EP ship protection, typically 200 nautical miles or more from shore, against massive and coordinated attack. EO/IR EA applications have more recently focused on littoral scenarios involving amphibious operations in support of peacekeeping operations for regional conflicts, providing humanitarian assistance in politically and militarily unstable regions; evacuating

civilians from regions of conflict, and ensuring safe passage of commerce through disputed littoral waters and choke points.

The traditional EO/IR threat, the long-range antiship missile, has been intensified in the littoral areas by a large variety of air-to-surface, air-to-air, and surface-to-air EO/IR missile weapons. These missiles can inflict severe damage to the smaller craft used for littoral warfare.

Electrooptic system target detection range depends on detector sensitivity and resolution. A target image is defined by contrast with the background. Sensitivity determines whether the contrast is discernible. Resolution depends on the spatial environment angle illuminating the detector, which is a function of detector surface area and focusing optics. The distance at which target features are resolvable determines the maximum operating range of the system.

The target signature detectability is determined not by the absolute temperature of the object but rather by the contrast between the target and background within a given spectral band. Environment backgrounds range from the cold, uniform background of space to thermally cluttered land areas. Solar interaction with the target and background reflection and heating further degrade the background contrast with the target. Typical target contrasts range from about 1 kW/sr (kilowatt per steradian) in the 2–3 μm atmospheric window for an aircraft engine to tens of kilowatts per steradian for ships in the 8–12 μm window. Target aspect, especially the location of hotspots, greatly influences the signature.

4.4.1. Electrooptic/Infrared Countermeasures. Electrooptic/infrared countermeasures are constrained by specular atmospheric propagative characteristics, as is the threat (Fig. 14). The contrast of the target to the background within the weapon sensor’s specular passband, the type of seeker spatial localization processing, and

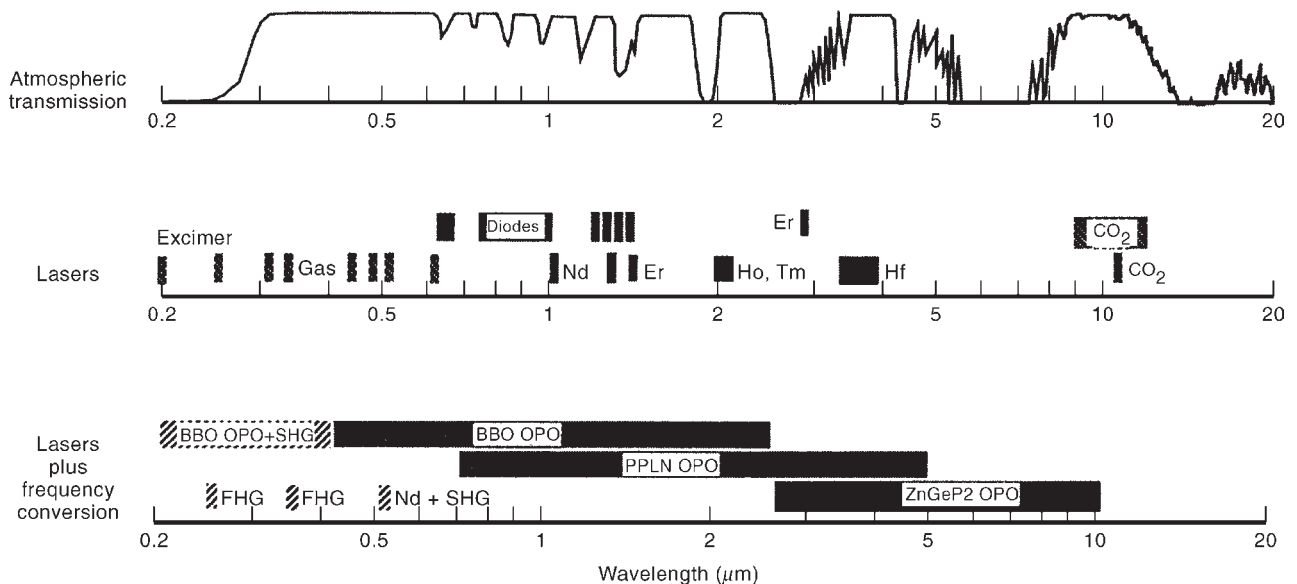

Figure 14. EO/IR atmospheric transmission spectral segments and laser and laser harmonics countermeasures source spectral regions.

available practical radiation sources are also prime considerations.

The missile flyout and CM sequence of events occurs in several seconds. As part of an integrated electronic warfare suite, the EO/IR EA system is designed to engage a large number of missiles launched in a coordinated attack. Figure 15 shows a typical timeline of the CM response to an attack by a subsonic antiship missile. The time line indicates the interaction of EO/IR EA with other ship defense systems.

To preclude detection by a threat EO/IR sensor, target signature can be reduced through a combination of convective, conductive, and radiative mechanisms. Exterior surfaces of ship stacks are cooled by convective air flow between the engine exhaust ports and the outer stacks. Engine plume and exhaust gases from all types of engines can be cooled by dilution with air. Radiation from hotspots can be reduced by spectral emissivity modifications or by obscuring the hot areas from view. On new platforms, low-observability design criteria have led to low-signature aircraft and ships.

Onboard aircraft CM sources initially generated false-target location and/or guidance degradation through weapon automatic gain control (AGC) manipulation. This technique remains highly effective against many threats. The onboard jammer sources can be chemically fueled IR sources or electrically powered incandescent and metal vapor lamps. As the wavelength passbands of anti-air and antiship seekers gradually migrate to longer wavelengths, out to the 8–14 μm window, noncoherent sources will no longer be practical.

Basic spin scan and conical scan (conscan) “hotspot” seekers are vulnerable to flare decoys. Almost universally, these flares are composed of magnesium and polytetrafluoroethylene and are designed with a radiant intensity several times that of the target. In the distraction mode, the decoy is an excellent target; in the seduc-

tion mode, the weapon’s seeker control signal is biased by the decoy or transferred to it. Because pseudoimaging seekers exhibit spatial and temporal processing capabilities, simple flares are relatively ineffective, and simple flares perform even more poorly against imaging sensors. Newer decoys overcome advanced seeker-discriminating processing with improved spectral characteristics that more closely match the target platform spectral emissions. Improved decoy spatial distribution in the form of clouds and multiple hotspots, temporal risetimes, and persistence match target signature increase rates and lifetimes, thus preventing time–history discrimination. Kinematics model realistic target movement.

The small beam divergence of lasers can result in high-radiance, low-power sources that provide the *J/S* power ratios needed for effective EA. Two laser sources, primary lasers and nonlinearly shifted lasers, are available for CM applications. Lasers shifted by nonlinear conversion include harmonic generation and tunable optical parametric oscillators (OPOs). Primary lasers do not produce spectral lines in all the potential threat passbands of interest and are susceptible to notch-filter counter-countermeasure techniques. Although harmonic generating EA techniques provide additional wavelengths, they are also subject to counter-CM. Promising sources for IR/EO CM are tunable OPOs pumped by diode-pumped, solid-state lasers. Two nonlinear materials currently demonstrating the highest potential are periodically poled lithium niobate (PPLN) and zinc germanium phosphide (ZnGeP₂). Figure 14 shows the primary lasers of interest and the wavelength coverage possible with PPLN and ZnGeP₂ OPOs.

Although noncoherent sources provide wide angular protection, high-resolution detection is necessary to point and track the threat system and effectively use laser power. Timely threat detection and warning ES is essential to the success of all nonpreemptive EA.

Figure 15. Missile attack timeline showing launch, acquisition, and homing phases of the missile as well as the CM attack on missile sensors and control circuits.

4.4.2. Electrooptic/Infrared Countermeasure Technology.

Key EO/IR EA technologies required to counter threat performance improvements include higher throughput data processing using more capable algorithms, laser beamsteering, and decoy launcher design. Needed processing improvements include faster signal processing, more efficient image processing, and false alarm reduction. High-performance, high-speed beamsteering, preferably nonmechanical, is required to reduce response time in multiple threat environments. Improved decoy launchers to position decoys quickly and accurately within the scenario are also needed. Low observability technologies are being developed to decrease or mask the IR/EO signatures of targets. Target signature reduction increases the effectiveness of conventional countermeasure responses by reducing the jamming power required to counter the missile system effectively. Low observability enables application of new technologies to IR/EO countermeasures by reducing the size, weight, and power requirements of decoy and laser CM sources. For example, diode laser and diode-pumped nonlinear optical sources can be integrated with unmanned aerial vehicles to produce new classes of CM devices and tactics. Large-area spectrally selective sources and obscurants provide advanced capability against spatially and spectrally discriminating threats. Primary laser and laser-pumped nonlinear sources are important evolving technologies. Launchers and vehicles that provide rapid and precise CM placement with realistic kinematic performance are areas of increasing importance.

4.5. Decoy Countermeasures

Decoys are EW devices, usually expendable, deployed from the platforms to be protected. Decoys generate a jamming response to the threat or false targets. In either case, the decoy lures the threat away from the intended target toward the decoy. A jamming decoy generates a cover signal that masks the target signal. Thereby the threat sensor signal fidelity is degraded, making detection and tracking of the intended target more difficult. A jamming signal may also activate the antijam home-on-jam mode of the weapon system. As false targets, the decoys generate credible target signatures to provide weapon system seduction or distraction. Decoys create confusion that causes weapons to attack false targets.

Decoys may be either passive or active. A passive decoy generates a countermeasure response without the direct, active amplification of the threat signal. Principal examples of passive decoys are chaff and corner reflectors in the RF spectrum and flares in the EO/IR spectrum.

4.5.1. Decoy Operational Employment. Decoys provide EA capability across the entire EW battle timeline. Decoys are used primarily for EP missile defense and self-protection missile defense but also for countersurveillance and countertargeting applications.

Jamming is used in conjunction with decoys to obscure the target signal at the threat radar during decoy deployment. As decoys are deployed, jamming ceases and the threat radar acquires the decoy as a target or transfers radar tracking from the target to the decoy. Threat radar

acquisition of the decoy as a target is probable because decoys present prominent signatures.

Decoys used for missile defense perform either seduction, distraction, or preferential acquisition functions. A single-decoy type may perform multiple functions, depending on deployment geometry with respect to the launch aircraft or ship and the stage of electronic combat.

Decoys are used in a seduction role as a terminal defense countermeasure against missile weapons systems. A seduction decoy transfers the lock of the missile guidance radar or EO/IR sensor from the defending platform onto itself. The decoy that generates a false-target signature is initially placed in the same threat tracking gate, missile sensor range, and/or angle segment as the defending target and is subsequently separated from the launching platform. The decoy signature captures the missile guidance sensor, and the target lock is transferred from the ship or aircraft to the decoy. Typically, the decoy is separated in both range and angle from the defending target to assure target-to-missile physical separation greater than the missile warhead's blast range. The seduction decoy missile interaction is typically initiated within 10 s of deployment. Distraction decoys are deployed prior to missile-seeker acquisition and provide multiple false targets from which the seeker may select. Deployed distraction decoys provide a confusing environment to the missile seeker, causing it to attack a decoy rather than the intended target.

The ALE-129 chaff decoy (Fig. 16) is representative of RF seduction decoys for aircraft defense. The NATO Sea Gnat MK-214 cartridge shown fired from a shipboard launcher in Fig. 17 provides surface defense against radar-guided weapons. Figure 18 shows a TORCH decoy deployed at sea for IR defense.

Distraction decoys are observed for extended periods in the engagement scenario. Consequently, the distraction decoy must generate a credible signature that is sufficient to preclude short-term and extended missile decoy discrimination.

The AN/SLQ-49 inflatable corner reflector (Fig. 19) and the rocket-launched NATO Sea Gnat MK-216 chaff cartridge (Fig. 20) are representative of distraction decoys for surface ship defense. The TALD decoy (Fig. 21) is an example of a distraction decoy used for aircraft defense.

Figure 16. ALE-129 RF chaff round with the bundle of reflector elements partially deployed from the canister.

Figure 17. NATO Sea Gnat MK-214 seduction RF decoy deployed from a shipboard rocket launcher.

Frequently, persistent seduction decoys perform a distraction function after separating sufficiently from the defended platform. This “residual distraction” further minimizes the number of distraction decoys required in an engagement.

An EA preferential acquisition decoy provides a signature to the missile seeker such that during acquisition the missile seeker senses the real target only in combination with the decoy signature. In the endgame, the decoy signature in the missile field of view biases the aim point of the missile tracker away from the intended target.

The preferential acquisition concept requires decoys positioned close to the defending platform. Decoys can be towed behind the target aircraft or tethered to the defending ship. The AN/ALE-50 (Fig. 22) is a towed decoy used for air defense preferential acquisition, and the EAGER decoy (Fig. 23) is being developed for ship defense preferential acquisition.

4.5.2. Chaff Decoys. A chaff decoy is composed of multiple—tens of thousands to millions—of electrically conductive dipole filament elements deployed in the air to reflect and scatter radar signal radiation and create a false-target radar response. Figure 24 shows a typical deployed chaff decoy. The chaff decoy frequency response is determined by the length of the dipole elements, and the chaff radar cross-sectional (RCS) magnitude results from the number of dipoles deployed. Figure 25 shows a radar

Figure 18. TORCH EO/IR decoy deployed at sea.

Figure 19. AN/SLQ-49 inflatable corner reflector decoy deployed at sea.

PPI display of an environment containing numerous chaff clouds.

The RCS of a chaff cloud is tuned for a given frequency (with the dipole length one-half the wavelength of the incident radar signal), and its RCS can be approximated by

$$\text{RCS}(\text{m}^2) = \frac{0.018c^2N}{f^2} \quad (13)$$

where c is the speed of light (3×10^8 m/s), f is the frequency in hertz, and N is the number of dipoles in the cloud.

4.5.3. Corner Reflector Decoys. Corner reflectors are conductive geometric structures that are typically shaped in the form of a perpendicular triangular corner. The shape maximizes the reflection of incident radar signals and provides a large apparent target signature. Figure 26 shows a multifaceted triangular corner reflector that provides wide angular coverage.

The apparent RCS normal to a triangular corner reflector is given by

$$\text{RCS}(\text{m}^2) = \frac{4\pi L^4 f^2}{3c^2} \quad (14)$$

Figure 20. NATO Sea Gnat MK-216 distraction decoy deployed from a rocket launcher.

Figure 21. TALD decoy distraction decoy.

where L is the length from the outside corner to the apex of the reflector, f is the frequency in hertz, and c is the speed of light (3×10^8 m/s). The 3 dB beamwidth of this type of corner reflector is 40° .

4.5.4. Flare Decoys. Flares are typically incendiary devices that produce EO/IR radiation to generate a false target. Figure 27 is an IR image of a magnesium–Teflon flare deployed from an aircraft.

4.5.5. Active Decoys. An active decoy uses direct threat signal amplification to generate the countermeasure response. In the case of RF systems, it is generally an RF amplifier (transistor or tube). In the EO/IR spectrum, a laser or flash tube amplifies the threat signal. Jammer and repeater decoys are active decoys.

Repeater decoys receive, amplify, and retransmit the received signal to generate a false target. Multiple signals may be retransmitted to generate multiple target returns. Modulation techniques (amplitude and frequency) may also be applied to the signal before retransmission to enhance effectiveness. The apparent radar cross section of an active RF decoy is given by

$$RCS(m^2) = \frac{(P_d G_d 4\pi R^2)}{P_r G_r} \quad (15)$$

Figure 22. AN/ALE-50 towed decoy deployed from a tactical aircraft in flight.

Figure 23. EAGER shipboard-tethered decoy in field trials.

Figure 24. Deployed chaff round shown as a burst of reflector elements against a sky background.

Figure 25. Radar PPI display showing target reflections from multiple chaff decoys.

Figure 26. Multifaceted corner reflector deployed on a ship bow to provide a high cross-sectional reflection at several frequencies.

where $P_d G_d$ is the effective radiated power (ERP) of the decoy, R is the range between the decoy and the radar in meters, and $P_r G_r$ is the effective radiated power (ERP) of the radar.

For a decoy operating with linear gain, that is, a decoy whose transmission signal power is directly proportional to the input signal level (up to the signal compression level), the RCS relationship simplifies to the relationship given by

$$\text{RCS}(\text{m}^2) = \frac{(G_t c^2)}{4\pi f^2} \quad (16)$$

where G_t is the combined electronic and antenna gains (receive and transmit) of the decoy, c is the speed of light (3×10^8 m/s), and f is the frequency in hertz.

4.5.6. Decoy Effectiveness. A distraction decoy is deployed at an extended range from the defending platform and provides an alternate target for seeker lockon. Distraction decoys require deployment before seeker lockon to engage the radar in its acquisition process. Usually more than one distraction decoy is used to defend a platform. An estimate of the effectiveness of the distraction decoy is given by

$$P_s = 1 - \frac{1}{N+1} \quad (17)$$

Figure 27. Flare IR decoy deployed from a tactical aircraft in flight.

where P_s is the probability that the missile will be distracted to the decoy and N is the number of distraction decoys deployed.

Equation (17) assumes that all of the distraction decoys exhibit viable target signatures and are equally likely to be acquired by the missile sensor. The number of decoys deployed can be reduced with the same probability of success with knowledge of the seeker acquisition logic, for example, a near-to-far/right-to-left acquisition search.

Seduction decoy effectiveness is primarily determined by the intensity of the decoy signature compared with the target being defended. However, the radar track bias, for example, leading-edge tracker and discrimination algorithms, can significantly impact decoy effectiveness. In some cases, the radar track bias can be exploited to increase decoy seduction effectiveness.

4.5.7. Decoy Countermeasure Technology. Diverse technologies are required to support decoy launch and station-keeping and countermeasure generation. Because most decoys are single-event, short-term items, cost plays a major role in selecting and developing technology for decoy use. Furthermore, because the defending platform must generally deploy a number of decoys throughout an engagement, decoy size and weight criteria also are critical. Attendant decoy platform technologies include aerodynamics, aircraft/projectile design, propulsion systems, avionics, and mechanical structures. Decoy payload technologies that will have significant importance in future systems include broad-bandwidth microwave and millimeter-wave components (e.g., antennas and amplifiers).

Microwave and millimeter-wave output power sources are required with high power, efficiency, and duty cycle to support the projected threat environments. The future RF threat environment is expected to be densely populated with long-pulse radar. Higher decoy radiated power at higher duty cycles will be needed to prevent decoy saturation as the number of simultaneous threat signals in the environment increases.

Ultra-high-speed countermeasure frequency set on circuitry is necessary to queue jammer frequency rapidly. Signals with rapid frequency hopping and frequency chirping require rapid activation for effective countermeasures. Spatially large and efficient spectrally matched IR materials and radiating structures are needed to counter multispectral, imaging IR seekers. Safe, nontoxic, highly opaque, broad-spectrum IR and electrooptical obscuration materials are required to mask targets and confuse image processing seekers. Efficient, primary power sources capable of high peak power and dense energy storage are needed to provide the increasing demand for electrical power used in decoy systems.

1. INTRODUCTION

Real electrical signals are usually composed of an infinite number of components of various frequencies. Each single component occurs at a single frequency has a distinct magnitude and phase. An *electrical filter* will be defined as an electrical network that processes electrical signals on the basis of the individual frequencies of the signals composing that signal. The signal processing can affect both the magnitude and phase of each component. For example, the output signal of an antenna may represent an electrical signal that requires processing by a receiver. The signal may have a fairly wide spectrum, is composed of signals at a wide range of frequencies, but it is often desired that the receiver process a small range of these frequencies, or channel, where important information is contained. One solution is to use a bandpass filter in one of the stages following the antenna. The filter would process the signal so that the range or band of frequencies containing the desired information would pass through to the output, and the signals outside the range would be rejected. From here, signal processing of the desired information may take place. Although this example is greatly simplified in comparison to what actually happens in a receiver, it nonetheless illustrates the general idea of filtering.

Over time, several "standard" types of filters, or signal-processing schemes for filters, have evolved. These are

lowpass, highpass, bandpass, band-reject, and all-pass filters. Lowpass filters strive to allow frequencies below a specific "passband frequency" to pass, while rejecting those frequencies above the passband frequency. Highpass filters strive to allow frequencies above a specific passband frequency to pass, while rejecting those frequencies below the passband frequency. Bandpass filters allow a range or band of frequencies to pass, while rejecting frequencies outside of that band. Band-reject filters reject a band of frequencies, allowing frequencies outside that band to pass. The main objective of these four types of filter is to process the magnitude of the signal as a function of frequency in a particular way. The all-pass filter lets all signals pass through, but selects a band of frequencies for phase angle processing, while not affecting the magnitudes. Time delay of the input to the output is an important consideration for all-pass filters. The overall choice of filter type depends on the application.

Filter design can be broken down into two broad stages. The first stage is the selection of a transfer function possessing the mathematical properties of filtering that will meet a set of specifications that are determined from the particular application. A *transfer function* is a mathematical description that describes the relationship between the input signal and the output signal of a network. We will use it in the sense that for a given input signal, we will have a specific output signal that is determined by the transfer function. Since filters process electrical signals according to the frequency content, the transfer function for a filter is a function of $s = j\omega = j2\pi f$, where ω is the frequency in rad/s (radians per second) and f is the frequency in hertz.

The second stage of filter synthesis is the realization of a circuit that possesses the same transfer function as the mathematical function selected to do the filtering. In general, the circuit may be an analog, digital, or a mixed analog-digital circuit depending on the application. However, to date, most filters used at RF and microwave frequencies are of the analog type.

2. THE APPROXIMATION PROBLEM

When filtering, engineers usually desire ideal filters. For example, when deciding to use a lowpass filter, the engineer typically desires that all frequencies above a specified passband or cutoff frequency be rejected by the filter. An ideal lowpass transfer function magnitude with a passband frequency, $\omega_p = 1$ rad/s, is shown in Fig. 1, and the ideal lowpass transfer function phase characteristics are shown in Fig. 2. For the magnitude-frequency plot, all frequencies below ω_p are passed, with a gain of 1 V/V, and all frequencies above ω_p are rejected. It is a "brick wall" function. It is intuitively obvious that this is an ideal magnitude characteristic for a lowpass filter. The ideal phase characteristics are not so intuitive. The important feature of the ideal phase characteristics are not the values of the phase, but that the phase response is linear. A transfer function that has linear phase characteristics means that a signal composed of two different frequencies applied at the same instant of time at the input of the filter will

Figure 1. Magnitude–frequency plot of the ideal lowpass filter transfer function, showing that all frequencies of a signal below 1 rad/s are passed while those above 1 rad/s are rejected.

arrive, after processing, at the output of the filter at the same time. If the two input signals add together to create a distinct waveform in the time domain, it may be important that they reconstruct together at the output to maintain the “shape” of the input signal. Sometimes this is important, and sometimes it is not. A deviation from the linear phase response results in phase distortion.

The characteristics depicted in Figs. 1 and 2 are for a *normalized* filter; that is, they have passband frequencies ω_p equal to 1 rad/s and the magnitude–frequency characteristics have a maximum gain of 0 dB, or 1 V/V, in the passband. It is conventional to begin a lowpass filter design with a normalized filter. This allows for a common starting point for all lowpass filters, for example, and is also a convenient way of comparing the characteristics of different types of lowpass filter functions with each other. Moreover, numerous tables exist that provide the

Figure 2. The ideal lowpass filter transfer function phase characteristics, which may be summarized as a linear phase response.

coefficients or poles and zeros of filter transfer functions. These tables provide information for normalized filters. Since there is an infinite number of possibilities for passband frequencies, and similar parameters, it would be impractical, if not impossible, to generate tables for all possible cases. Thus, the tables deal only with the normalized case. It is trivial to scale a filter for a desired passband frequency from the normalized frequency of 1 rad/s while retaining all other characteristics of the filter.

The first step in filter design is to find a transfer function having magnitude characteristics similar to those of the magnitude–frequency plot depicted in Fig. 1. Unless a transfer function has an infinite number of terms, it is impossible to devise a transfer function with these characteristics. Although an engineer may desire an ideal response, he/she must live with a nonideal response. Hence, from this simple example arises the *approximation problem*. In other words, may we find a transfer function whose magnitude response comes close enough to the ideal characteristics of Fig. 1 to meet or slightly exceed the filter specifications for a particular application. In general, the higher the order of the filter, the closer the transfer function will approach the ideal case. However, the higher the order of a filter, the more complex the design and the more components that are needed to realize the transfer function. Thus, the concept of tradeoffs and compromises arises. In general, a set of filter specifications must be determined before selecting the transfer function. The specifications may be viewed as to how far the actual filter application may deviate from the ideal case. The ideal filter response provides a metric with which to compare practical transfer functions.

Since it is impossible to come up with an ideal transfer function that is practically realizable, several terms have been defined and have been accepted as conventions that allow the description of the deviation of a practical filter function from the ideal filter function. These terms are depicted in Fig. 3 and may be referred to as filter specifications. The specifications are: the passband, the stopband, the passband ripple (PBR), the stopband ripple (SBR), and the stopband attenuation A . PBR, SBR, and A are usually specified in decibels. There are three distinct regions. The passband is located from 0 rad/s to ω_p rad/s. The second region is the stopband region located from ω_s to infinity. Finally, there is the transition region, composed of the range between ω_p and ω_s . Figure 3 should be interpreted as follows: Signals at or below ω_p will have a gain of at least of G dB and at the most H dB, and signals above ω_s will be attenuated by at least A dB or have a maximum gain of SBR dB. Note that $(G - H)$ dB = PBR in decibels. Filter types other than lowpass filters have similar specifications and the reader is encouraged to investigate these [1,2].

Previous research in network theory has resulted in several classic mathematical approximations to the ideal filter magnitude function. Each of these was designed to optimize a property of the filter function. The lowpass filter approximations are usually of the form

$$|H(j\omega)|^2 = \frac{1}{1 + \varepsilon^2 P^2(\omega)} \quad (1)$$

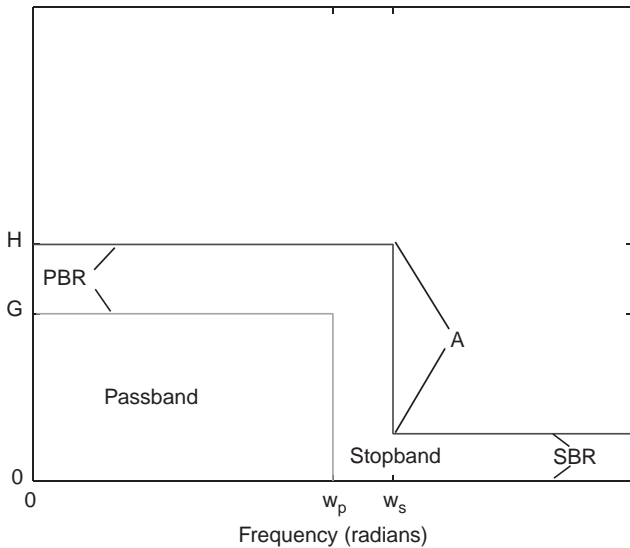

Figure 3. Filter specifications. PBR, SBR, A, passband, and stopband are ways of characterizing an actual filter function’s magnitude versus frequency response to that of an ideal response. For an ideal filter function, PBR = SBR = 0 V/V and ω_s and ω_p are equal.

When $P(\omega)$ is replaced with different types of functions, different approximations to the ideal lowpass filter response arise. The standard approximations to the ideal lowpass magnitude response are the Butterworth approximation, the Chebyshev approximation, the inverse Chebyshev approximation, and the elliptic approximation. Each of these has strong points and weak points. A fifth classic approximation worth mentioning is the Bessel function. This approximation will not be discussed because it strives to approximate the ideal phase response. This article focuses on the elliptic approximation.

3. THE ELLIPTIC APPROXIMATION

Before beginning a mathematical discussion on the elliptic approximation, it is useful to examine a plot of an elliptic filter function. A plot of the magnitude versus frequency of a fifth-order lowpass elliptic filter transfer function is depicted in Fig. 4. The frequency range of the passband is $\omega \leq \omega_p$. The frequency range of the stopband is $\omega \geq \omega_s$. The passband and stopband may be characterized as *equiripple*; that is, the amplitude oscillates between a maximum and minimum throughout each band. If the order of the filter function is even, there are $n/2$ peaks in the passband and $n/2$ minimums or zeros in the stopband. If the order of the filter is odd, there are $(n - 1)/2$ peaks, plus one at $\omega = 0$ in the passband. Also for the odd-order case, there are $(n - 1)/2$ minimums or zeros, plus one at $\omega = \infty$, in the stopband.

In discussing the properties of the elliptic filter, it is beneficial to compare its characteristics with those of the other classic filter types. The magnitude responses for normalized fifth order low pass Butterworth, Chebyshev, and elliptic filter magnitude functions are compared in Fig. 5 and the phases are compared in Fig. 6. Table 1 summarizes the comparisons and the main attributes of

Figure 4. The magnitude characteristics of a fifth-order elliptic filter showing an equiripple passband and stopband, and a zero at $\omega = \infty$.

the elliptic filter may be stated. For a given filter order, the elliptic filter provides the sharpest cutoff characteristics, and thus out of all three filter types, it best approximates the ideal lowpass magnitude function in terms of a sharp transition region. This is very important if filtering is required for frequencies close to each other, if it is desired to pass one of these frequencies and reject the other. The compromise in using the elliptic filter is its very poor phase characteristics.

The theory underlying the mathematics of the elliptic filter is complicated, and beyond the scope of this article. Interested readers may consult Refs. 2 and 3. A summary of the mathematics is discussed in this article. The derivation assumes that $\omega_p = 1$ rad/s and that $\omega_s^{norm} = \omega_s/\omega_p$. This results in *normalized* passband and stopband

Figure 5. Amplitude comparison. The fifth-order elliptic function magnitude characteristics show a much sharper transition for the passband to the stopband than do the Butterworth and Chebyshev function characteristics. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 6. Phase comparison. The fifth-order elliptic function phase characteristics deviate much farther from the desired ideal linear phase characteristics than do the Butterworth and Chebyshev function characteristics. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

frequencies. The normalized stopband frequency ω_s^{norm} is determined by divided the ω_s by ω_p . In a latter stage in the design process, the circuit is then *denormalized*, so the passband and stopband frequencies are those specified by the application.

The general form of the elliptic filter magnitude squared transfer function is given by Eq. (1). For the low-pass elliptic filter function, $P(j\omega)$ is replaced with $R_n(j\omega)$. $R_n(j\omega)$ has two different forms, one for an even-order function and one for an odd-order function. $R_n(j\omega)$ will be described for a normalized lowpass filter. For the even-order case

$$R_n(\omega) = M \prod_{i=1}^{n/2} \frac{\omega^2 - (\omega_s^{norm}/\omega_i)^2}{\omega^2 - \omega_i^2} \tag{2}$$

and for the odd-order case

$$R_n(\omega) = N\omega \prod_{i=1}^{(n-1)/2} \frac{\omega^2 - (\omega_s^{norm}/\omega_i)^2}{\omega^2 - \omega_i^2} \tag{3}$$

where M and N are normalization constants and are chosen so that $R_n(1) = 1$. The ω_i are calculated for the even- or

Table 1. Filter Comparisons

Filter Type	Transition Region	Linear Phase Properties
Butterworth	Poor	Good
Chebyshev	Good	Poor
Elliptic	Best	Very poor

odd-order case. For the former case, we have

$$\omega_i = \frac{\omega_s^{norm}}{sn \left[\frac{(2i-1)K \left(\frac{1}{\omega_s^{norm}} \right)}{n} \right]} \tag{4}$$

and for the latter case

$$\omega_i = \frac{\omega_s^{norm}}{sn \left[\frac{2iK \left(\frac{1}{\omega_s^{norm}} \right)}{n} \right]} \tag{5}$$

where sn is the Jacobian elliptic sine function and $K(k)$ is the complete elliptic integral of the first kind, and is defined as

$$K(k) = \int_0^{\pi/2} (1 - k^2 \sin^2 x)^{-1/2} dx \tag{6}$$

The order of the filter function may be determined by rounding up n to the nearest integer in the expression

$$n = \frac{K \left(\frac{1}{\omega_s^{norm}} \right) K' \left(\frac{1}{L} \right)}{K' \left(\frac{1}{\omega_s^{norm}} \right) K \left(\frac{1}{L} \right)} \tag{7}$$

where L is defined as

$$L = \sqrt{\frac{10^{0.1PBR} - 1}{10^{0.1A} - 1}} \tag{8}$$

and PBR and A are in decibels. Finally

$$K'(k) = K\sqrt{1 - k^2} \tag{9}$$

When $R_n(\omega)$ is found, the substitution $s = \omega/j$ is made, and $R_n(\omega/j)$ may be inserted into Eq. (1). The poles of $H(s)H(s^*) = |H(j\omega)|^2$ are then found. This is a standard synthesis technique [4]. The left half-plane poles and half of the zeros are selected and combined to give the final form of the elliptic filter transfer function. For n even, we obtain

$$H(s) = H \frac{\prod_{i=1}^{n/2} (s^2 + \omega_i^2)}{a_0 + a_1s + \dots + a_{n-1}s^{n-1} + a_ns^n} \tag{10}$$

For the case of n odd, we obtain

$$H(s) = H \frac{\prod_{i=1}^{(n-1)/2} (s^2 + \omega_i^2)}{a_0 + a_1s + \dots + a_{n-1}s^{n-1} + a_ns^n} \tag{11}$$

Note that the even-order transfer function given by Eq. (10) has n poles and zeros and thus no zeros at infinity while the odd-order transfer function of Eq. (11) has n poles and $n - 1$ zeros and thus has a single zero at infinity. It may be convenient to express the denominator in the form of coefficients or in terms of products of poles and zeros, depending on the type and method of realization.

Because of the complexity of the calculations required to find the transfer function, the usual method of finding $H(s)$ is usually either with a computer program, or using one of the numerous tables that have been generated and published [2,5]. Today's simulators allow the filter designer to readily vary zeros to modify the elliptic filter function to take on more specialized tasks.

4. FREQUENCY AND IMPEDANCE SCALING

Frequently, a normalized design is the first step in filter realization. A frequency-normalized filter is designed for a passband frequency of 1 rad/s. A typical normalized realization has component values on the order of ohms, farads, and henries. The design is then frequency-scaled so that the normalized response is *shifted* into place; that is, the passband and stopband frequencies are transformed from normalized values to the design values. The procedure is performed by finding the scaling constant ω_p and replacing s with s/ω_p in the circuit. This results in new values for the capacitances and inductances, while the values for resistances remain unchanged. In certain circumstances it may be desirable to frequency-scale the normalized transfer function first and then do the circuit synthesis.

Frequency scaling usually results in values for capacitors and inductors that are close to practical, but still not practical. Moreover, the impedances of the resistors remain unchanged. The next step in denormalizing a normalized realization is to impedance-scale. Impedance scaling amounts to multiplying each impedance by a specified constant. The constant is picked so that after scaling, the components have reasonable values. If all impedances

are scaled by the same factor, the voltage transfer function of the circuit remains the same. With good selection of the constant, practical values may be achieved.

5. ELLIPTIC FILTERS

5.1. Highpass Filters

In the preceding sections we discussed the properties and applications of lowpass elliptic filters; there is little difference when discussing those of the highpass elliptic filter.

The first step in highpass filter design is to normalize the highpass parameters to the parameters that describe the normalized lowpass filter. The parameters that describe the highpass are identical to those of the lowpass filter. One difference is that $\omega_s < \omega_p$. In general, a lowpass filter transfer function may be transformed into a highpass transfer function by a s -to- $1/s$ transform. This simply means that wherever s appears in the transfer function, $1/s$ is substituted.

Once the normalized lowpass elliptic transfer function has been determined and a normalized circuit has been synthesized, a lowpass-to-highpass transform is applied. This means that everywhere in the circuit, s is replaced with $1/s$. This results in capacitors becoming inductors, and inductors becoming capacitors. If, in an active RC circuit, for example, inductors are not desired, the circuit may be magnitude-scaled by $1/s$. This results in the inductors becoming resistors and the resistors becoming capacitors.

Alternatively, if a normalized lowpass elliptic function has been determined, it is possible to apply the s -to- $1/s$ transform on the transfer function, resulting in a normalized highpass elliptic transfer function. It is now possible to synthesis a circuit from directly from this transfer function.

5.2. Bandpass Filters

Bandpass filters may be classified as wideband or narrowband. A wideband bandpass filter allows a wide range of

Figure 7. Typical n th-order lowpass passive elliptic filters are realized with inductors and capacitors, and include the source and load resistances in the overall design. The circuit in (a) is for the odd-order case and has n capacitors and $(n - 1)/2$ inductors. The circuit in (b) is for the even-order case and has $(n - 1)$ capacitors and $n/2$ inductors. Both have a total of n stages, and n is the order of the filter transfer function.

frequencies to pass with equal magnitude scaling, ideally. A narrowband filter seeks to allow only one frequency or a very small band of frequencies to pass. One definition of narrowband versus wideband filters is given in Ref. 1. This particular definition states that if the ratio of the upper cutoff frequency to the lower cutoff frequency is greater than 1 octave, the filter is considered a wideband filter.

Synthesis of wideband bandpass filters may be performed by a cascade of a highpass filter and a lowpass filter where the cutoff frequency of the lowpass filter is greater than that of the highpass filter. The lower bound of the definition of wideband results in a separation of the highpass and lowpass filters such that there is minimal interaction between the filters. If the ratio of the lowpass cutoff frequency to the highpass cutoff frequency is smaller than 1 octave, the cutoff frequencies are too close together and the filters interact and must be treated as a single filter.

Narrowband filters require alternative synthesis techniques, such as a transformation. Like the highpass filter functions, bandpass filter functions may be synthesized from lowpass filter functions. This is done by performing the transformation

$$s \rightarrow \frac{\omega_0}{\text{BW}} \left(\frac{s}{\omega_0} + \frac{\omega_0}{s} \right) \quad (12)$$

on a normalized lowpass filter function, where ω_0 is the center frequency and BW is the bandwidth of the filter. Equation (12) should be interpreted as s is replaced by the expression on the right. The effect of performing this operation on the lowpass circuit is that inductors are replaced by a series combination of an inductor and a capacitor and capacitors are replaced by a parallel combination of a capacitor and an inductor. This transform may also be used in the design of wideband bandpass filters.

5.3. Band-Reject Filters

Like bandpass filters, band-reject filters may also be classified as wideband or narrowband. A wideband band-reject filter seeks to block a wide range of frequencies while allowing frequencies outside that band to pass with ideally equal magnitude scaling. A narrowband band-reject filter seeks to block only one frequency or a very small band of frequencies. In much the same way that it defines narrowband versus wideband bandpass filters, Ref. 1 defines narrowband versus wideband band-reject filters. The definition is identical to that for the bandpass filter.

Synthesis of wideband band-reject filters may be performed by a cascade of a highpass filter and a lowpass filter where the cutoff frequency of the highpass filter is greater than that of the lowpass filter. The lower bound of the definition of wideband results in a separation of the highpass and lowpass filters such that there is minimal interaction between the filters. If the ratio of the cutoff frequency of the highpass filter to that of the lowpass filter is less than 1 octave, the cutoff frequencies are too close together and the filters interact and must be treated as a single filter.

Narrowband filters require alternative synthesis techniques, such as a transformation. Band-reject filters may also be synthesized from normalized lowpass filter functions by performing a transform of

$$s \rightarrow \frac{\frac{\text{BW}}{\omega_0}}{\left(\frac{s}{\omega_0} + \frac{\omega_0}{s} \right)} \quad (13)$$

on a normalized low-pass filter, where ω_0 is the center frequency and BW is the bandwidth of the filter. The affect of performing this operation on the lowpass circuit is that inductors are replaced by a parallel combination of an inductor and capacitor and capacitors are replaced by a series combination of a capacitor and an inductor. This transform may also be used in the design of wideband bandpass filters.

5.4. Realizations of Elliptic Filters

There are an infinite number of possible synthesis algorithms that may be used. In this section we describe one.

The first step in elliptic filter design is to find a transfer function that will meet a set of specifications that have been determined from the application. The design usually begins with specifying the passband frequency ω_p , PBR, ω_s , and A . If filter tables are to be used, the frequencies of the filter specifications must first be normalized. This is achieved by dividing ω_s and ω_p by ω_p . Other normalizations are possible. This results in a normalized passband frequency of 1 rad/s, and a normalized stopband frequency of ω_s/ω_p rad/s. If a highpass filter is desired, the specifications must be transformed further, by inverting ω_p to $1/\omega_p$. Once the desired transfer function is determined, a method of realization is selected. Presently, most RF and microwave realizations of elliptic filters are analog circuits. Moreover, the greater majority of the analog realizations are passive, although active realizations are achievable at the lower end of the RF frequency spectrum.

5.4.1. Passive Realizations. One may ask if the passive realizations may utilize only discrete elements. There is considerable ongoing research in realizing passive filters in integrated circuit (IC) technologies, and there are published research results of such filters, although this is not yet commonplace. A principal problem with passive LC realizations in an IC technology are low quality factors (Q_s) of the inductors presently available in standard IC technologies. The lower the inductor Q , the more losses in the inductor, and the more difficult it becomes to design high-performance filters. At the time of this writing, there is considerable interest in fabricating high- Q on-chip or on-package inductors in integrated circuit (IC) technologies. If progress in these inductor-technologies continues at today's present rate, it is not inconceivable that passive synthesis could become commonplace in integrated filter design.

Passive realizations utilize capacitors, inductors, and resistors. The source and load resistances are considered part of the realization. Systematic procedures exist for the synthesis of passive filters to realize elliptic transfer

functions. Moreover, normalized passive filters are available as part of table lookup approaches [5]. An example of odd and even passive filter topologies is depicted in Fig. 7.

Even-order passive realizations synthesized from Eq. (10) will have negative elements because they do not have at least a zero at infinity. This problem can be solved by shifting the highest-frequency zero to infinity. The resulting elliptic filter function will have a double zero at infinity, and the passive filter realization will now have positive elements but unequal terminating resistances. This even-order elliptic transfer function is known as *case B*, while the original even-order transfer function given by Eq. (10) is called *case A*. Equal terminating resistances can be obtained by shifting the first maximum to the origin. The resulting even-order elliptic transfer function is known as *case C* [2,5]. The new filter functions will be of the forms given by Eq. (14) for case B and Eq. (15) for case C:

$$H_B(s) = H \frac{\prod_{i=2}^{n/2} (s^2 + \omega_{B,i}^2)}{b_0 + b_1s + \cdots + b_{n-1}s^{n-1} + b_n s^n} \quad (14)$$

$$H_C(s) = H \frac{\prod_{i=2}^{n/2} (s^2 + \omega_{C,i}^2)}{c_0 + c_1s + \cdots + c_{n-1}s^{n-1} + c_n s^n} \quad (15)$$

The magnitude response in for the case B and C filter functions are now slightly modified from the original type A.

5.4.2. Active Realizations. Active realizations of elliptic filters for high-frequency applications tend to be limited to a few types. These types include Gm-C, synthetic-inductor-based, and negative-resistance-based. Gm-C filters utilize transconductors and capacitors to realize elliptic filter functions. Synthetic-inductor-based filters utilize transconductors and capacitors to synthesize an impedance that is inductive. These are often classified as Gm-C filters as well. Negative resistance based utilize active elements to synthesize an impedance that looks like a negative resistor. The “negative resistor” used to cancel out the resistance of an inductor, thereby providing the inductor with a higher “effective Q .” All include realizations in both IC and discrete technologies. However, because of limited bandwidth of active components, the upper end of the frequency range tends to be around 200–400 MHz for practical applications, although there have been reports in the literature demonstrating research results at greater frequency, particularly in monolithic microwave integrated circuit (MMIC) technologies. But the majority of elliptic filters are passive in nature, fabricated using discrete techniques. Pushing active filter synthesis, and in particular higher-order filters such as elliptic filters, into the high MHz and even low GHz ranges appears to be a rich research area.

5.5. Microwave Filters

Elliptic filters are common for microwave filters; typical applications occur after the final power amplifier or before the first low-noise amplifier in a system where insertion losses have direct impact on system performance. Typical

applications include transmit–receive duplexers, multi-band combiners, interference rejection, spurious emission control, and channelized power combining.

The circuits depicted in Fig. 7 are often used as the starting point for a passive elliptic filter regardless of the technology being used to realize the circuit. However, the zeros of elliptic filters are frequently modified from the ideal values to provide design freedoms that can sharpen rejection (at the cost of phase linearity), or can better phase response (at the cost of rejection). The result is a *quasielliptic* filter. In conjunction with appropriate technology and physical layout, elliptic microwave filters realize high performance in compact geometries.

At microwave frequencies, lumped inductors and capacitors are physically large when compared to the wavelengths of the application and seldom perform well (especially inductors) because of parasitic effects. Moreover, the lumped elements must be considered as distributed elements. Microwave filters use stages that consist of distributed elements (e.g., microstrip lines or resonant cavities) and transitions between elements (e.g., coupling slots or impedance steps) that appear inductive or capacitive. Performance depends on the electrical size of elements. There are many ways to realize microwave filters. Choosing the technology to use depends on a variety of factors, some obvious, some subtle, but all with impact on realizing the needed performance.

5.5.1. Tradeoffs. A primary consideration is the placement of the filter used in the system. Filters integrated with MMICs require planar layouts such as with microstrip or coplanar waveguide (CPW). Filters integrated on RF circuit boards may be stripline, surface acoustic wave (SAW), ceramic, or helical, depending on the frequency and space available. If the filter is a separate unit, handles high power, or interfaces with an antenna system, waveguides and coupled cavities are the best choices. Bandpass and band-reject filters are easily realized using resonant elements; lowpass and highpass filters use propagating elements.

Frequency also plays a role in technology selection. Waveguides and waveguide cavities are natural choices above 5 GHz. Waveguides become too large for the wireless bands from 400 MHz to 2.5 GHz; here, combine cavity filters and coaxial line filters are useful, as are planar filters. Helical and SAW filters are useful in the lower-MHz RF bands.

Another consideration is the natural tradeoff that occurs between insertion loss versus quality factor of the components. Each stage in a multistage microwave filter loses power to the finite conductivities of metal and losses in dielectrics (even lumped inductors and capacitors possess parasitic resistances that absorb power). In general, filters composed of a larger number of stages with identical Q values will have higher insertion loss; using higher- Q stages can reduce insertion loss. The Q factor of a filter stage can be increased by increasing unit volume, silver-plating the RF path, or loading with low-loss ceramics. Superconducting filters have extremely high Q values. Dielectric material allows filter size to be physically reduced and Q factors to generally improve; both effects can reduce

insertion loss. Using multimode stages, where one physical element supports multiple electrical stages, also can reduce insertion loss.

There are less obvious considerations to choosing a technology as well. Power handling may be critical, which tends toward using waveguides and cavities and places limits on how small gaps may be. Microwave elements have dispersive propagation effects and support multiple modes; these in turn lead to bandwidth limits and higher-frequency spurious responses in which the stopband begins to resemble the passband. Coupling and tuning methods also have bandwidth limits. Manufacturability is also important; it is possible for unwanted coupling mechanisms to occur and change the filter response, or for production tolerances to change passbands. Last but not least, cost plays a role, especially for commercial applications.

5.5.2. Elliptic Filter Design Concerns Unique to Microwave Frequencies. Microwave filters start with elliptic prototype filters, designed as mentioned previously. The challenge is mapping lumped inductors and capacitors into the correct distributed equivalents for the microwave technology chosen. Fundamental to all microwave filters realization is inclusion of transmission-line effects. A very useful property that follows from this is the ability to invert impedances to more easily realize certain filter topologies; impedance inverters convert impedances to admittances (for e.g., convert a series inductor into a shunt capacitor). A common way of realizing an inverter is to employ the quarter-wave transformer; for cavity filters, an impedance inverter is realized as a shunt inductance in cascade between equal-length negative line lengths. Admittance inverters convert admittances into impedances; they realize as quarter-wave transformers or as series capacitance in cascade between equal-length negative line lengths. The negative line lengths serve to reduce the lengths of the loads on either side, usually resulting in more compact designs. The most limiting transmission-line effect is that the effective L and C values change as frequency deviates from the design center and the response changes.

Transmission lines can be implemented into prototype filters converting lumped impedances, for example, $Z_1 = j\omega L$, to their transmission-line form of $Z_1 = j\Omega L$ using Richard's transformation, $\Omega = \tan \beta 1$. For a lowpass prototype, the passband frequency ω_c of unity results in an electrical length of 45° (or $\lambda/8$). Inductors become a short-circuited stub with characteristic impedance (Z_0) of L ; capacitors become open-circuited stubs with $Z_0 = 1/C$. However, the stub impedance is not the same as the lumped element for frequencies away from passband, and the filter response differs.

The physical elements used in microwave filters have mode structures with cutoff frequencies determined by their geometries; at frequencies below cutoff, the mode rejects energy. As frequencies increase, more modes "turn on" and again, spurious responses can occur. Cutoff frequencies can be changed by small perturbations to the geometries; this allows filter tuning by elements such as screws. Square and circular geometries support degenerate modes that can be coupled to each other; this easily

supports multimode filters but can add limitations to exploiting the design freedom of elliptic zeros.

Discontinuities in transmission lines and cavities have responses that behave inductive or capacitive, depending on whether primarily magnetic or electric energy is being stored at the discontinuity. Microwave resonators have equivalent circuits that look like lumped LC resonators. Intercavity couplings via slots or probes also appear inductive or capacitive, depending on how the modes couple between cavities. All these discontinuities have effects on the electrical lengths of filter sections and adjustments must be made. Slots in cavity walls seem inductive; exploiting this idea and reducing cavity electrical length on either side of the slot will implement an impedance inverter like that mentioned previously. Marcuvitz [7] provides in-depth discussions on finding equivalent circuits for all types of discontinuities, perturbations, and couplings. Another good reference overall for traditional microwave filter synthesis is Matthaei et al. [8].

Today, numerical simulation tools are employed to determine the actual broadband equivalent circuits and their impact on the basic mode behavior of waveguides and cavities. Their use has improved the ability to design filters, reduced design cycle time, and provided insight into building filters. Using these tools effectively still requires an understanding of the underlying basic principles.

6. TECHNOLOGY OVERVIEW

Stripline-type filters are planar in design. This makes them appropriate for use with MMICs and for use on RF and microwave board layouts. While the microstrip filter is most common, filtering structures using coplanar waveguide (CPW), slotguide, and suspended stripline are used as well. These filters generally are small because of the shorter wavelengths of the planar substrates. They also are low- Q filters (200–300), due to etch thickness and substrate losses. Planar filters have limited power-handling capability as well. For microstrip filters, shunt open stubs are commonly used, since short-circuiting elements in microstrips involves extra fabrication steps. Alternating high-impedance/low-impedance stages and coupled-line segments help realize lowpass or highpass filters; microstrip resonators and coupled-line filters allow for realization of bandpass and band-reject filters. Coupled-line filters are generally edge-coupled for microstrip; coupled lines gain an extra design dimension when considering suspended stripline filters, with both vertical and planar separation contributing to the performance. Planar filters also take up board or die space.

Ceramic filters also find use on RF boards and for small devices from 800 MHz and up; a typical application is for duplexers in mobile phones and wireless LAN cards. Ceramic, high-dielectric materials dramatically reduce the physical size of a filter. They have low Q (200–400) and low power handling primarily because of their small size.

Helical filters are used on RF and IF boards. Helical filters use wound wire coils as bandpass resonators; this allows medium- Q performance in compact packaging in the 75–800 MHz range.

Surface acoustic wave (SAW) filters are typically used more at IF frequencies (50–400 MHz). These filters use piezoelectric materials that support acoustic-type leaky waves; typical wavelengths are 10^{-5} those of light. This means that filter dimensions can also be much smaller; SAW filters also achieve brick-wall-type responses. SAW filters have low- Q (50–100) and low power-handling capabilities; more recent developments are pushing SAW performance up into the 1–2 GHz range.

Waveguide filters have high- Q (typically 10,000) and high power-handling capabilities. They are common above 2 GHz, or in low-frequency, high-power applications. Waveguide types used include circular, rectangular, square, ridged, and corrugated, depending on the application. Walls are placed approximately $\lambda/4$ apart to generate resonant cavities within the waveguide, the resonant modes are endwall-coupled to each other. Waveguide filters are large in size and can be quite heavy. As frequencies increase above 50 GHz, mechanical tolerances become extremely critical in the production process.

Coaxial resonator filters (also called *comblines filters* or *TEM filters*) are common from 400 MHz to 6 GHz. They consist of sidewall-coupled cavities whose resonance is controlled by an inductive resonator and a capacitive airgap. They can be realized as interdigital filters, with $\lambda/4$ resonator lengths and airgaps between top and bottom walls. More commonly, they are realized as combline filters where all resonators are on the same wall. This allows for ease of manufacture. The resonator length can be less than $\lambda/4$; this allows freedom to control when cavity harmonic frequencies occur. These are medium- Q (3000–6000) and medium-power devices. Combline resonators may be dielectrically loaded to increase cavity Q (typically 15,000 or higher). The resonators can also be of dielectric material; this increases Q (typically above 10,000) and adds the ability to generate multiple modes.

The highest- Q resonators exist in superconducting filters. These filters use either thin-film or bulk high- T_c (critical temperature) materials, and operate at 77 K. The thin-film resonators are used in planar circuits; bulk materials show up in cavity resonators. Because of the zero resistance of the superconductor, almost no power is lost per stage (some loss occurs because cavity walls are still metal and substrates are still lossy). Consequently, true brick-wall filters, comprising 30, 40, or more stages, are practical with small insertion loss. Superconducting filters require external cooling support to maintain 77 K temperatures; consequently, as a system they are more complicated than other choices. Superconducting filters have found use in situations with severe interference; here, the performance they provide outweighs the added complexity of the system.

The advent of MEMS technology is having an impact on microwave filters as well. MEMS techniques allow realization of lumped inductors with reasonable Q values at microwave frequencies. MEMS switches also have potential to work with tunable filters and switched filterbanks. MEMS processes are generally compatible with IC production and stand to improve stripline filtering. For standalone MEMS parts, packaging is a concern—it is usually packaging that provides most of the parasitics that ruin the performance of lumped elements at microwave frequencies.

7. SUMMARY

Elliptic filters are a class of filters used to shape the magnitude of an electric signal. They may be used in applications for any of the standard magnitude processing filters. In comparisons to other available filters, they provide the sharpest transition from the passband to the stopband for a given order. The magnitude response is equiripple in the passband and the stopband. The drawback of elliptic filters is very poor phase characteristics in comparison to other filter types. Furthermore, evaluation of elliptic filter parameters is considerably more difficult than other filter approximation functions, due to the use of elliptic sine functions and elliptic integrals.

ENHANCEMENTS OF THE FINITE DIFFERENCE TIME DOMAIN METHOD

RAJ MITTRA

University Park, Pennsylvania

1. INTRODUCTION

The fundamentals of the conventional finite-difference time-domain (FDTD) algorithm on a Cartesian grid have been adequately covered by the article FINITE-DIFFERENCE TIME-DOMAIN ANALYSIS, and it has been demonstrated that the algorithm can be used to simulate a wide variety of electromagnetic problems because of its flexibility and

versatility. In this article we discuss some variations and extensions of the method that have been designated to enhance the performance of the algorithm. The first of these deals with the problems of handling conductors or dielectrics with curved surfaces and edges by using a “conformal” FDTD scheme, which mitigates the errors introduced by the staircasing employed in the conventional FDTD. The second, referred to in the literature as the “multiresolution time-domain (MRTD) method,” has been introduced for the purpose of reducing the requirements of both the CPU time and memory.

The conformal FDTD technique has had a long history with many contributors [1–6]. It is beyond the scope of this article to discuss the various proposed approaches in detail. Instead we briefly describe one conformal FDTD technique [7–12], which not only circumvents the need for complex mesh generation but also does not suffer from late-time instability problems that plague many of the proposed schemes.

The method we detail below handles both the PEC and dielectric objects of arbitrary shape, and does not require a significant modification of the Cartesian-type FDTD; hence, it preserves the computational efficiency of the conventional FDTD technique—which is desirable.

2. CONFORMAL FINITE-DIFFERENCE TIME-DOMAIN TECHNIQUE

In order to describe the conformal approach, we first present below two typical difference equations derived from the time-dependent Maxwell’s curl equations (for details, see FINITE-DIFFERENCE TIME-DOMAIN ANALYSIS). As we have seen in the above chapter, the electric fields are located along the edges of cells, while the magnetic fields are positioned at the centers of these cells. Maxwell’s difference equations in this scheme are written as

$$H_x^{n+(1/2)}(i,j,k) = H_x^{n-(1/2)}(i,j,k) + \frac{\Delta t}{\mu_x(i,j,k)} \left(\frac{E_y^n(i,j,k+1) - E_y^n(i,j,k)}{\Delta z(k)} - \frac{E_z^n(i,j+1,k) - E_z^n(i,j,k)}{\Delta y(j)} \right) \quad (1)$$

$$E_y^{n+1}(i,j,k) = \frac{\varepsilon_y(i,j,k) - 0.5 \cdot \Delta t \cdot \sigma_y(i,j,k)}{\varepsilon_y(i,j,k) + 0.5 \cdot \Delta t \cdot \sigma_y(i,j,k)} E_y^n(i,j,k) + \frac{\Delta t}{\varepsilon_y(i,j,k) + 0.5 \cdot \Delta t \cdot \sigma_y(i,j,k)} \times \left(\frac{H_x^{n+(1/2)}(i,j,k+1) - H_x^{n+(1/2)}(i,j,k)}{\Delta z(k)} - \frac{H_z^{n+(1/2)}(i+1,j,k) - H_z^{n+(1/2)}(i,j,k)}{\Delta x(i)} \right) \quad (2)$$

where the superscripts represent the time index and the arguments correspond to spatial sampling locations. The equations for the other field components can also be written similarly. As pointed out by Taflov in FINITE-DIFFERENCE TIME-DOMAIN ANALYSIS, to avoid numerical instabilities, the time increment Δt must satisfy the Courant condition

$$\Delta t \leq \frac{1}{c \sqrt{\left(\frac{1}{\Delta x}\right)^2 + \left(\frac{1}{\Delta y}\right)^2 + \left(\frac{1}{\Delta z}\right)^2}} \quad (3)$$

where $\Delta x, \Delta y, \Delta z$ are the lattice dimensions of the cells.

2.1. Conformal FDTD Technique for a Perfect Electric Conductor (PEC)

If the equations above are used for conductors with curved surfaces and/or edges (see Figs. 1 and 2), the staircasing version of the conventional FDTD may introduce significant errors, unless a very fine discretization is employed at a considerable cost of CPU time and memory. It has been shown [7–9] that this difficulty can be overcome by employing a modification of the conventional FDTD update equations, called the *conformal FDTD* algorithm. A key step in this approach is to assume that both the electric and magnetic fields inside the distorted cell are located at the same positions as those in the conventional FDTD scheme, and that Faraday’s law is applied over the entire FDTD cell, rather than only in the distorted part—thus implying that the contour path follows the edges of the FDTD in its entirety. Since parts of the contour path are located inside the PEC region, we discard their contributions and write the $\oint \vec{E} \cdot d\vec{l}$ contour integral as

Figure 1. Intersection between the FDTD mesh and a PEC surface in the x - z plane.

Figure 2. Contour path of the conformal FDTD in a deformed cell.

follows:

$$\oint \vec{E} \cdot d\vec{l} = \begin{bmatrix} \int_{\Delta x_0(i)} E_x(i,j,k) \cdot dx + \int_{\Delta z_0(k)} E_z(i,j,k) \cdot dz \\ + \int_{\Delta x(i,j,k+1)} E_x(i,j,k+1) \cdot dx \\ + \int_{\Delta z(i+1,j,k)} E_z(i+1,j,k) \cdot dz \end{bmatrix} \quad (4)$$

The definitions of the variables used in this equation are shown in Fig. 1. We note that the E -field representation remains unchanged from that in the conventional FDTD scheme. However, the magnetic fields inside the partially filled cells are updated slightly differently to account for the deformation of the cell, as shown below:

$$H_y^{n+(1/2)}(i,j,k) = \begin{bmatrix} \frac{\Delta z(i,j,k)E_z^n(i,j,k) - \Delta z(i-1,j,k)E_z^n(i-1,j,k)}{\Delta x_0(i) \times \Delta z_0(k)} \\ + \frac{\Delta x(i,j,k-1)E_x^n(i,j,k-1) - \Delta x(i,j,k)E_x^n(i,j,k)}{\Delta x_0(i) \times \Delta z_0(k)} \end{bmatrix} \quad (5)$$

Equations (4) and (5) enable us to handle PEC objects whose geometries do not conform to the Cartesian coordinates.

2.2. Conformal FDTD Technique for Dielectric Objects

For the partially filled cells, the conformal technique for dielectric objects utilizes a modified version of the concept

Figure 3. Conformal dielectric techniques: (a) original problem; (b) after averaging.

of effective dielectric constant (see Figs. 3 and 4). Rather than using a weighted volume average to define the effective dielectric constant, the conformal dielectric algorithm [12] utilizes a weighted-line average concept instead. The calculation of the weighted-line average dielectric constant is carried out on the bold lines in Fig. 5a. The effective dielectric constants $\epsilon_x^{\text{eff}}(i,j,k)$ and $\epsilon_y^{\text{eff}}(i,j,k)$ are defined below:

$$\epsilon_x^{\text{eff}}(i,j,k) = \frac{\Delta x_2(i,j,k)}{\Delta x} \epsilon_2 + \frac{\Delta x - \Delta x_2(i,j,k)}{\Delta x} \epsilon_1 \quad (6)$$

$$\epsilon_y^{\text{eff}}(i,j,k) = \frac{\Delta y_2(i,j,k)}{\Delta y} \epsilon_2 + \frac{\Delta y - \Delta y_2(i,j,k)}{\Delta y} \epsilon_1 \quad (7)$$

We note from the Figs. 5b and 5c that $E_x(i,j+1,k)$ and $E_y(i+1,j,k)$ do not penetrate the dielectric; hence, the dielectric constant ϵ_1 is used in place of the effective dielectric constant in the conformal dielectric FDTD update equations for the electric and magnetic fields. Typical update equations take the form

$$E_x^{n+1}(i,j,k) = E_x^n(i,j,k) + \frac{\Delta t}{\epsilon_x^{\text{eff}}(i,j,k)\Delta y} \times [H_z^{n+(1/2)}(i,j+1,k) - H_z^{n+(1/2)}(i,j,k)] \quad (8)$$

$$- \frac{\Delta t}{\epsilon_x^{\text{eff}}(i,j,k)\Delta z} \times [H_y^{n+(1/2)}(i,j,k+1) - H_y^{n+(1/2)}(i,j,k)]$$

$$E_x^{n+1}(i,j+1,k) = E_x^n(i,j+1,k) + \frac{\Delta t}{\epsilon_1(i,j+1,k)\Delta y} \times [H_z^{n+(1/2)}(i,j+2,k) - H_z^{n+(1/2)}(i,j+1,k)] - \frac{\Delta t}{\epsilon_1(i,j+1,k)\Delta z} \times [H_y^{n+(1/2)}(i,j+1,k+1) - H_y^{n+(1/2)}(i,j+1,k)] \quad (9)$$

where Δy and Δz are the mesh dimensions along the y and z directions, respectively. Note that the effective dielectric constant is used in (8) because the edge on which $E_x(i,j,k)$ lies does penetrate the dielectric. Furthermore, the update equation in (9) has a form that is identical to that used in the conventional FDTD formula, because $E_x(i,j+1,k)$ is located entirely within a single dielectric region, whose

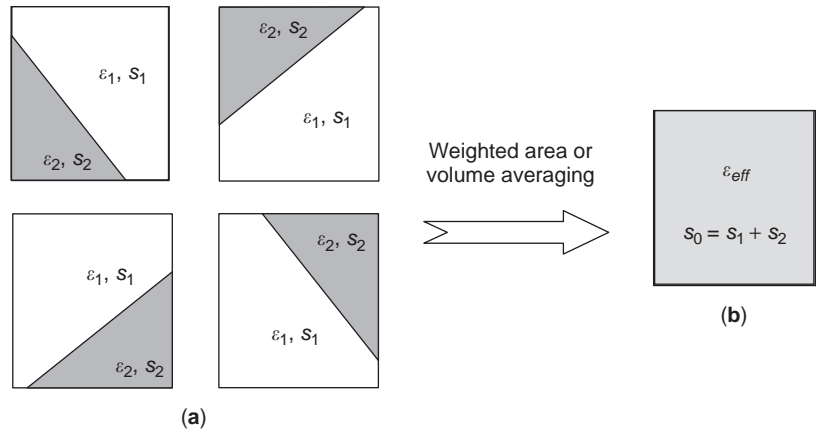

Figure 4. Illustrative examples showing that different material distributions lead to the same effective dielectric constant: (a) original problem; (b) after averaging.

permittivity is ϵ_1 . Similar update equations can also be written for other electric field components.

3. ILLUSTRATIVE EXAMPLES

We now present some examples to illustrate the application of the conformal FDTD method. We use a Gaussian pulse modulated by a sine function for the excitation, and a six-layer unsplit PML [13] to truncate the FDTD domain on the open boundary. On the basis of the Courant condition, the timestep is chosen to be:

$$\Delta t = \frac{0.995}{c \sqrt{\left(\frac{1}{\Delta x}\right)^2 + \left(\frac{1}{\Delta y}\right)^2 + \left(\frac{1}{\Delta z}\right)^2}} \quad (10)$$

which is very close to that dictated by the Courant condition for the undistorted cell.

3.1. Cylindrical Cavity

For the first example, we consider the problem of computing the resonant frequencies of the dominant TE and TM modes of a cylindrical cavity of circular cross section. The results for the resonant frequencies are shown in Table 1, together with the dimensions of the cavities, with R and H representing the radius and height of the cylindrical cavities, respectively. The spatial discretization is chosen to be 0.005 m for each of the four cases studied. We observe good agreement between the conformal FDTD results and those obtained analytically. Furthermore, the CFDTD algorithm, described herein, has been found to be totally stable.

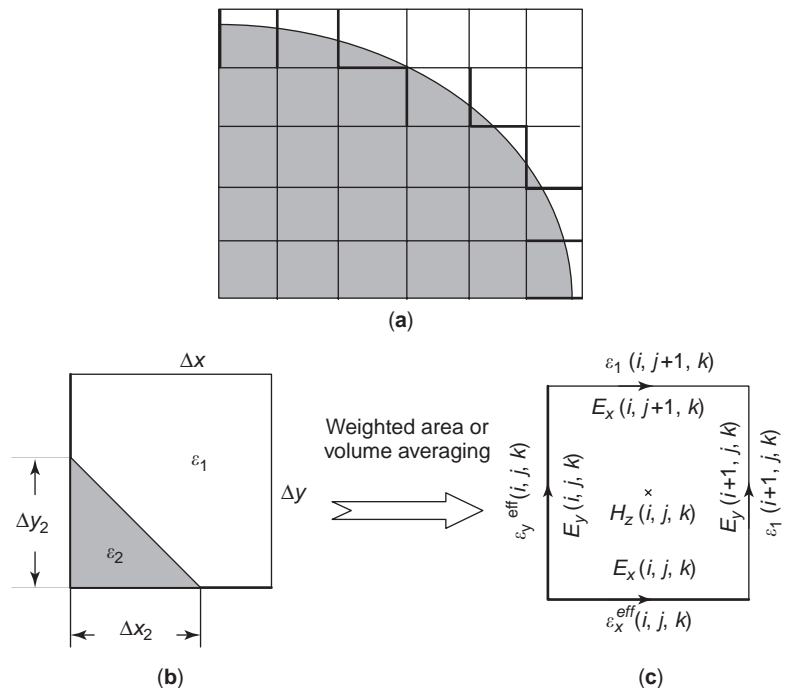

Figure 5. Linear weighted dielectric constant averaging procedure used in the present conformal dielectric FDTD scheme: (a) Intersection between FDTD mesh and curved dielectric surface; (b) original problem; (c) equivalent problem.

Table 1. Comparison of Resonant Frequencies of a Circularly Cylindrical Cavity Derived Using Analytical and CFDTD Techniques

Modes	Methods	Geometry I	Geometry II	Geometry III	Geometry IV

	Analytical	1.889	2.199	2.751	2.897
	Difference (%)	0.48	0.23	0.33	0.86

3.2. Radial Stub

For the next example of the CFDTD simulation, we consider a radial stub whose geometry is shown in Fig. 6. The dimensions of the computational domain are $8.12 \times 8.12 \times 0.889 \text{ mm}^3$, and the domain is discretized into $40 \times 40 \times 7$ cells. In order for the edges of the microstrip lines to coincide with those of the FDTD grid, we choose a nonuniform mesh whose dimensions are $\Delta x(i) = 0.20175 \text{ mm}$, $i = 1, 2, 3, 4$; $\Delta x(i) = 0.203357 \text{ mm}$, $i = 5, \dots, 18$; $\Delta x(i) = 0.203 \text{ mm}$, $i = 19, 20, 21$; $\Delta x(i) = 0.20333 \text{ mm}$, $i = 26, \dots, 36$; and $\Delta x(i) = 0.20175 \text{ mm}$, $i = 37, 38, 39, 40$. A uniform mesh is used in the z direction with a cell dimension of $\Delta z(k) = 0.127 \text{ mm}$. A voltage source between the ground plane and the left microstrip line is placed at a distance of 5 cells away from the domain boundary ($y = 0$), while the observation point is located at a distance of 10 cells away from the boundary ($y = y_{\max}$) in the y direction. The 3 dB cutoff frequency of the excitation source is 25 GHz, and the timestep is $\Delta t = 0.3146 \text{ ps}$. The scattering parameter S_{21} versus frequency is shown in Fig. 7. Good agreement with the experimental data reported in Ref. 14 is observed.

3.3. Microstrip Patch Antenna of Circular Shape

Next, we compute the scattering parameter of a microstrip patch antenna of circular shape, as shown in Fig. 8. The dimensions of the computational domain are $0.11 \times 0.088 \times 0.00795 \text{ m}^3$ and are subdivided into $55 \times 44 \times 10$ cells. The cell dimensions are chosen to be 0.002, 0.002, and 0.000795 m, in the x , y , and z directions, respectively. The simulation was run with a timestep of $\Delta t = 2.29847 \text{ ps}$, and no stability problems were encountered. The reflection plot of the circular patch antenna as a function of frequency is shown in Fig. 9. The results reported in Ref. 2 via the application of the symmetric and asymmetric

planar generalized Yee (PGY) approaches, with a timestep of 0.725 ps [2], and those obtained using the MoM (method of moments) [15] are also plotted in the same figure for comparison. The CFDTD results are seen to compare quite favorably with those obtained via the MoM.

3.4. Dielectric-Loaded Cavity

Finally, we turn to an example pertaining to a curved dielectric structure, namely, rectangular cavity loaded with a cylindrical dielectric rod (see Fig. 10) [16].

The relative dielectric constant of the rod is 38, while it is 1 for the pedestal below. The computational domain is discretized in to $48 \times 44 \times 47$ cells, and the Δx and Δy are chosen to be 0.519112 mm inside, and 0.549275 and 0.563033 mm outside the dielectric rod. Also Δz is 0.537307, 0.5537, and 0.53658 mm below, inside, and above the dielectric resonator, respectively. For the other structures listed in Table 2, the discretizations are chosen in a similar manner.

The simulation results, shown in Table 1, demonstrate that the results agree well with both the mode-matching values and the measured data, thus validating the accuracy of the CFDTD algorithm, even for these narrowband structures.

4. SUMMARY OF CFDTD

In this section, we have described a conformal FDTD approach, designated for both PEC and dielectric objects without the use of staircasing and the need for complex mesh generation techniques. We have shown, by comparison with analytical and experimental results, that the CFDTD algorithm is both accurate and computationally efficient. For further information, the reader may refer to Refs. 17 and 18.

Figure 7. Transmission coefficient of the microstrip line with a radial stub comparison of CFDTD and experimental results.

5. INTRODUCTION TO MRTD

The multiresolution time-domain (MRTD) scheme for solving electromagnetic field problems, introduced by Krumpholz and Katehi [19,20], is based on expansions of unknown fields in terms of scaling or wavelet functions. It has been shown that the use of the MRTD improves the computational capacity and efficiency over those of the conventional finite-difference time-domain (FDTD) method [19–23].

The MRTD approach, described in this section, retains the philosophy of the leapfrog algorithm employed in the conventional FDTD, and places the MRTD scheme in the context of the FDTD, although it differs considerably in detail, as we will see below.

To illustrate the application of MRTD, we analyze a two-layer, dielectric-loaded cavity, and develop a systematic formulation for constructing the constitutive relations; then update equations in the MRTD transform domain by utilizing only the field quantities defined in the real structures. We introduce the concepts of the multiple-image technique (MIT) and present a criterion for determining the number of images needed along each side of the structure that is based on the localization properties of the scaling basis functions.

In this section, we also present a two-dimensional (2D) version of the MRTD, in conjunction with the unsplit anisotropic perfectly matched layer (APML), for the analysis of printed transmission lines. We apply the MIT

Figure 8. Microstrip-coupled circular patch antenna. The microstrip line is located on a 1.59-mm substrate ($\epsilon_r = 2.62$) backed by a ground plane, and the patch antenna is printed on the same dielectric at a height of 1.59 mm, above the microstrip line.

Figure 9. Comparison of reflection loss of the microstrip-coupled circular patch antenna computed by using the CFDTD, the MoM, and the PGY techniques.

APML concept for the analysis of microwave structures with inhomogeneous materials, including different dielectrics and conductors with infinite conductivity. Such imaging is needed to handle the boundaries in the MRTD formulation.

6. MIT MRTD METHOD FOR PEC-SHIELDED STRUCTURES

6.1. MRTD Update Equations

By using the generalized differential matrix operators (GDMOs) [24], the two curl relations of the Maxwell’s equations can be expressed as

$$\begin{bmatrix} 0 & -\partial_z & \partial_y \\ \partial_z & 0 & -\partial_x \\ -\partial_y & \partial_x & 0 \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ H_z \end{bmatrix} = \frac{\partial}{\partial t} \begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix} \quad (11)$$

$$\begin{bmatrix} 0 & -\partial_z & \partial_y \\ \partial_z & 0 & -\partial_x \\ -\partial_y & \partial_x & 0 \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} = -\mu_0 \frac{\partial}{\partial t} \begin{bmatrix} H_x \\ H_y \\ H_z \end{bmatrix} \quad (12)$$

where, for generality, we assume that the relative permittivity is a biaxial tensor. Then the associated constitutive

Figure 10. Dielectric resonator comprising a cylindrical rod in a rectangular cavity. The pedestal below is assumed to be free space in this work.

relation in the space domain becomes

$$\begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix} = \epsilon_0 \begin{bmatrix} \epsilon_{xx}(\vec{r}) & 0 & 0 \\ 0 & \epsilon_{yy}(\vec{r}) & 0 \\ 0 & 0 & \epsilon_{zz}(\vec{r}) \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} \quad (13)$$

In the MRTD domain, the local relationship between the \mathbf{D} and \mathbf{E} fields shown above is no longer valid; hence, we must work simultaneously with both the \mathbf{D} and \mathbf{E} fields.

As a first step in the MRTD formulation, we begin by representing all the field quantities in terms of the scaling function in space and pulse function in time as follows

$$\begin{aligned} D_x(\vec{r}, t) &= \sum_{i,j,k,n=-\infty}^{\infty} \phi_x D_{i+(1/2),j,k}^n \phi_{i+(1/2)}(x) \phi_j(y) \phi_k(z) h_n(t) \end{aligned} \quad (14)$$

$$\begin{aligned} H_x(\vec{r}, t) &= \sum_{i,j,k,n=-\infty}^{\infty} \phi_x H_{i+(1/2),k+(1/2)}^n \phi_i(x) \phi_{j+(1/2)}(y) \\ &\times \phi_{k+(1/2)}(z) h_{n+(1/2)}(t) \end{aligned} \quad (15)$$

where $\phi(x)$ denotes the cubic spline *Battle-Lemarie* scaling function [25,26] and $h_n(t)$ is a rectangular pulse function. Substitution of these field expansions into the Maxwell equations, followed by the application of the Galerkin method [27], leads us to the following set of update equations

$$\begin{aligned} \phi_x D_{i+(1/2),j,k}^{n+1} &= \phi_x D_{i+(1/2),j,k}^n + \sum_{\nu} a(\nu) \\ &\times \left[\phi_z H_{i+(1/2),j+\nu+(1/2),k}^{n+(1/2)} \frac{\Delta t}{\Delta y} \right. \\ &\left. - \phi_y H_{i+(1/2),j,k+\nu+(1/2)}^{n+(1/2)} \frac{\Delta t}{\Delta z} \right] \end{aligned} \quad (16)$$

$$\begin{aligned} \phi_x H_{i,j+(1/2),k+(1/2)}^{n+(1/2)} &= \phi_x H_{i,j+(1/2),k+(1/2)}^{n-(1/2)} + \frac{1}{\mu_0} \sum_{\nu} a(\nu) \\ &\times \left[\phi_y E_{i,j+(1/2),k+\nu+1}^n \frac{\Delta t}{\Delta z} \right. \\ &\left. - \phi_z E_{i,j+\nu+1,k+(1/2)}^n \frac{\Delta t}{\Delta y} \right] \end{aligned} \quad (17)$$

where the quantities being updated are the expansion coefficients in the field expansions, and their corresponding superscripts and subscripts represent the discretized time and space positions, respectively. The coefficient $a(\nu)$, appearing in (16) and (17), may be derived by utilizing a nonorthogonal relationship [19,22]. Although the summation index ν in (16) and (17) spans from positive to negative infinity, it is usually sufficient to truncate it at 9, by taking advantage of the localized nature of the *Battle-Lemarie* scaling function.

6.2. MIT for Derivation of the Constitutive Relationship

The constitutive relationship in the transform domain of the MRTD is considerably more involved than its counterpart in the spatial domain presented in (13). This is because the MRTD-transformed \mathbf{D} field at a particular point is determined not only by the \mathbf{E} field at the same location but also by the distribution of the \mathbf{E} field in its neighborhood. To solve for the constitutive relation in the MRTD domain, we once again represent the \mathbf{E} fields as expansions in terms of the same basis functions as (14), and substitute the above expansion into (13). Next, an application of the Galerkin's method leads us to the constitutive relationships in the MRTD domain that

Table 2. Comparison of Different Methods for a Dielectric Rod in a Rectangular Cavity^a

Size (in.)	t	Resonant Frequencies (GHz)			
		Present	Kaneda's [11]	Mode Matching [17]	Measured [17]
0.654	0.218	4.388	4.40	4.3880	4.382
0.689	0.230	4.163	4.17	4.1605	4.153
0.757	0.253	3.725	3.78	3.721	3.777

^a $a = 1.0$ in., $b = 1.0$ in., $e = 0.92$ in., $h = 0.275$ in., $r = 0$ in.; $\epsilon_r = 38$.

read

$$\phi_x D_{i+(1/2),j,k}^n = \epsilon_0 \sum_{i',j',k'=-\infty}^{+\infty} (\epsilon_{xx})_{ii',jj',kk'} \phi_x E_{i'+(1/2),j',k'}^n \quad (18)$$

where

$$\begin{aligned} (\epsilon_{xx})_{ii',jj',kk'} &= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \phi_{i+(1/2)}(x) \phi_j(y) \phi_k(z) \epsilon_{xx}(\vec{r}) \\ &\quad \times \phi_{i'+(1/2)}(x) \phi_{j'}(y) \phi_{k'}(z) \frac{dx dy dz}{\Delta x \Delta y \Delta z} \\ &= \delta_{i,i'} \delta_{j,j'} \delta_{k,k'} + \sum_{p=1}^P [\epsilon_{xx}(p) - 1] \zeta_{ii',jj',kk'}(p) \end{aligned} \quad (19a)$$

$$\begin{aligned} \zeta_{ii',jj',kk'} &= \alpha_{i,i'}(p) \beta_{j,j'}(p) \gamma_{k,k'}(p) \\ &= \int_{x_1(p)}^{x_2(p)} \phi_{i+(1/2)}(x) \phi_{i'+(1/2)}(x) \frac{dx}{\Delta x} \\ &\quad \times \int_{y_1(p)}^{y_2(p)} \phi_j(y) \phi_{j'}(y) \frac{dy}{\Delta y} \int_{z_1(p)}^{z_2(p)} \phi_k(z) \phi_{k'}(z) \frac{dz}{\Delta z} \end{aligned} \quad (19b)$$

where we assume that all dielectric objects are rectangular and P is the total number of dielectric objects.

We now present an example of deriving the constitutive relationship for a two-layer, dielectric-loaded cavity shown in Fig. 11. By expressing

$$\begin{aligned} \epsilon_{xx} &= \epsilon_{xx}(y) \\ &= \begin{cases} \epsilon_r(p), & y_1(p) \leq y \leq y_2(p) \\ 1, & \text{otherwise} \end{cases} \quad (p = 1, 2) \end{aligned} \quad (20)$$

Figure 11. Geometry of a two-layer, dielectric-loaded cavity.

we can write the x component of the constitutive relation in the MRTD domain

$$\phi_x D_{i+(1/2),j,k}^n = \epsilon_0 \sum_{j'=j-M}^{j+M} (\epsilon_{xx})_{jj'} \phi_x E_{i+(1/2),j',k}^n \quad (21)$$

with

$$\begin{aligned} (\epsilon_{xx})_{jj'} &= \delta_{j,j'} + \sum_{p=1}^P [\epsilon_r(p) - 1] \\ &\quad \times \int_{y_1(p)}^{y_2(p)} \phi_j(y) \phi_{j'}(y) \frac{dy}{\Delta y} \end{aligned} \quad (22)$$

where M is the number of the sampled E fields in the MRTD domain. It is usually set equal to a number slightly greater than 9, by taking advantage of the localization of the scaling function.

It is very important to note that the summations in (21) cover not only the original computation domain but also the entire image regions, as shown in Fig. 12. In fact, for a PEC-shielded structure, all the field quantities in the image regions can be expressed in terms of the ones inside the original cavity structure. Toward this end, we employ the principle that the tangential components of the image E fields (parallel to the PEC mirror wall) or the normal components of the image H fields (normal to the PEC mirror wall) are always odd symmetric about the original fields, whereas the normal components of the image E fields and the tangential components of the image H fields are even symmetric. Using these above guidelines we can express all the image field quantities in terms of the fields in the original region, and this leads to a degeneration of the summation index in (21) to N_y , the grid number along the y direction, defined only inside the original cavity structure. Consequently,

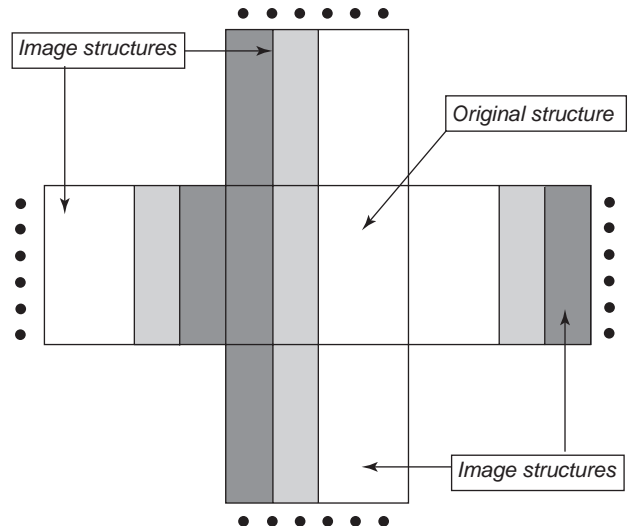

Figure 12. Original structure and multiple images in the y - z plane.

(21) can be simplified to read

$$\phi_x D_{i+(1/2),j,k}^n = \varepsilon_0 \sum_{j'=0}^{N_y} (\hat{\varepsilon}_{xx})_{jj'} \phi_x E_{i+(1/2),j',k}^n \quad (23)$$

where we define the equivalent permittivity matrix in the MRTD domain as follows

$$\begin{aligned} \sum_{j'=0}^{N_y} (\hat{\varepsilon}_{xx})_{jj} &= \sum_{j'=0}^{N_y} (\varepsilon_{xx})_{jj'} - \sum_{j'=-1}^{-N_y} (\varepsilon_{xx})_{jj'} \\ &\quad - \sum_{j'=N_y+1}^{2N_y} (\varepsilon_{xx})_{jj'} - \dots \\ &\quad + (-1)^m \sum_{j'=(m-1)N_y-1}^{j-M} (\varepsilon_{xx})_{jj'} \\ &\quad + (-1)^m \sum_{j'=mN_y+1}^{j+M} (\varepsilon_{xx})_{jj'} \end{aligned} \quad (24a)$$

or in a matrix form as

$$\begin{aligned} [\hat{\varepsilon}_{xx}] &= [\varepsilon_{xx}]_{\text{orig}} - [\varepsilon_{xx}]_{\text{Im}g(-1)} - [\varepsilon_{xx}]_{\text{Im}g(-1)} \\ &\quad - \dots + (-1)^m [\varepsilon_{xx}]_{\text{Im}g(-m)} + (-1)^m [\varepsilon_{xx}]_{\text{Im}g(+m)} \end{aligned} \quad (24b)$$

where the m is the number of images. The first term in (24b) corresponds to the original structure, and the rest are associated with the images.

Next, we present a criterion for determining the number of image m along the y direction (positive or negative). The criterion is derived from knowledge of the effective range of the basis functions at the PEC boundary locations

$$m = \begin{cases} \text{INT} \left[\frac{M}{N_y} \right] + 1, & \text{if } \frac{M}{N_y} \text{ is not an integer} \\ \frac{M}{N_y}, & \text{if } \frac{M}{N_y} \text{ is an integer} \end{cases} \quad (25)$$

where INT is the integer-converting function that truncates all the decimal parts of a number. For example, if $M = 10, N_y = 5$, then $m = \text{INT}(2.5) + 1 = 3$, this implies that we need three images in both sides of the $+y$ and $-y$ directions.

We will now illustrate the procedure for deriving the equivalent permittivity matrix in the MRTD domain. We consider a cavity with the discretization grid number $N_y = 6$ in the y direction. To simplify the notation, we omit the subscript x , and write $(\varepsilon_{xx})_{jj}$ simply as ε_{jj} . In this

example we choose $M = 9$ and $m = 2$. We then have

$$\begin{aligned} &\begin{bmatrix} \phi_x D_{i+(1/2),0,k}^n \\ \phi_x D_{i+(1/2),1,k}^n \\ \phi_x D_{i+(1/2),2,k}^n \\ \phi_x D_{i+(1/2),3,k}^n \\ \phi_x D_{i+(1/2),4,k}^n \\ \phi_x D_{i+(1/2),5,k}^n \\ \phi_x D_{i+(1/2),6,k}^n \end{bmatrix} = \varepsilon_0 \begin{bmatrix} \hat{\varepsilon}_{0,0} & \hat{\varepsilon}_{0,1} & \hat{\varepsilon}_{0,2} & \hat{\varepsilon}_{0,3} & \hat{\varepsilon}_{0,4} & \hat{\varepsilon}_{0,5} & \hat{\varepsilon}_{0,6} \\ \hat{\varepsilon}_{1,0} & \hat{\varepsilon}_{1,1} & \hat{\varepsilon}_{1,2} & \hat{\varepsilon}_{1,3} & \hat{\varepsilon}_{1,4} & \hat{\varepsilon}_{1,5} & \hat{\varepsilon}_{1,6} \\ \hat{\varepsilon}_{2,0} & \hat{\varepsilon}_{2,1} & \hat{\varepsilon}_{2,2} & \hat{\varepsilon}_{2,3} & \hat{\varepsilon}_{2,4} & \hat{\varepsilon}_{2,5} & \hat{\varepsilon}_{2,6} \\ \hat{\varepsilon}_{3,0} & \hat{\varepsilon}_{3,1} & \hat{\varepsilon}_{3,2} & \hat{\varepsilon}_{3,3} & \hat{\varepsilon}_{3,4} & \hat{\varepsilon}_{3,5} & \hat{\varepsilon}_{3,6} \\ \hat{\varepsilon}_{4,0} & \hat{\varepsilon}_{4,1} & \hat{\varepsilon}_{4,2} & \hat{\varepsilon}_{4,3} & \hat{\varepsilon}_{4,4} & \hat{\varepsilon}_{4,5} & \hat{\varepsilon}_{4,6} \\ \hat{\varepsilon}_{5,0} & \hat{\varepsilon}_{5,1} & \hat{\varepsilon}_{5,2} & \hat{\varepsilon}_{5,3} & \hat{\varepsilon}_{5,4} & \hat{\varepsilon}_{5,5} & \hat{\varepsilon}_{5,6} \\ \hat{\varepsilon}_{6,0} & \hat{\varepsilon}_{6,1} & \hat{\varepsilon}_{6,2} & \hat{\varepsilon}_{6,3} & \hat{\varepsilon}_{6,4} & \hat{\varepsilon}_{6,5} & \hat{\varepsilon}_{6,6} \end{bmatrix} \\ &\quad \times \begin{bmatrix} \phi_x E_{i+(1/2),0,k}^n \\ \phi_x E_{i+(1/2),1,k}^n \\ \phi_x E_{i+(1/2),2,k}^n \\ \phi_x E_{i+(1/2),3,k}^n \\ \phi_x E_{i+(1/2),4,k}^n \\ \phi_x E_{i+(1/2),5,k}^n \\ \phi_x E_{i+(1/2),6,k}^n \end{bmatrix} \end{aligned} \quad (26)$$

with

$$[\varepsilon_{xx}]_{\text{orig}} = \begin{bmatrix} \varepsilon_{0,0} & \varepsilon_{0,1} & \varepsilon_{0,2} & \varepsilon_{0,3} & \varepsilon_{0,4} & \varepsilon_{0,5} & \varepsilon_{0,6} \\ \varepsilon_{1,0} & \varepsilon_{1,1} & \varepsilon_{1,2} & \varepsilon_{1,3} & \varepsilon_{1,4} & \varepsilon_{1,5} & \varepsilon_{1,6} \\ \varepsilon_{2,0} & \varepsilon_{2,1} & \varepsilon_{2,2} & \varepsilon_{2,3} & \varepsilon_{2,4} & \varepsilon_{2,5} & \varepsilon_{2,6} \\ \varepsilon_{3,0} & \varepsilon_{3,1} & \varepsilon_{3,2} & \varepsilon_{3,3} & \varepsilon_{3,4} & \varepsilon_{3,5} & \varepsilon_{3,6} \\ \varepsilon_{4,0} & \varepsilon_{4,1} & \varepsilon_{4,2} & \varepsilon_{4,3} & \varepsilon_{4,4} & \varepsilon_{4,5} & \varepsilon_{4,6} \\ \varepsilon_{5,0} & \varepsilon_{5,1} & \varepsilon_{5,2} & \varepsilon_{5,3} & \varepsilon_{5,4} & \varepsilon_{5,5} & \varepsilon_{5,6} \\ \varepsilon_{6,0} & \varepsilon_{6,1} & \varepsilon_{6,2} & \varepsilon_{6,3} & \varepsilon_{6,4} & \varepsilon_{6,5} & \varepsilon_{6,6} \end{bmatrix} \quad (27a)$$

$$[\varepsilon_{xx}]_{\text{Im}g(-1)} = \begin{bmatrix} 0 & \varepsilon_{0,-1} & \varepsilon_{0,-2} & \varepsilon_{0,-3} & \varepsilon_{0,-4} & \varepsilon_{0,-5} & \varepsilon_{0,-6} \\ 0 & \varepsilon_{1,-1} & \varepsilon_{1,-2} & \varepsilon_{1,-3} & \varepsilon_{1,-4} & \varepsilon_{1,-5} & \varepsilon_{1,-6} \\ 0 & \varepsilon_{2,-1} & \varepsilon_{2,-2} & \varepsilon_{2,-3} & \varepsilon_{2,-4} & \varepsilon_{2,-5} & \varepsilon_{2,-6} \\ 0 & \varepsilon_{3,-1} & \varepsilon_{3,-2} & \varepsilon_{3,-3} & \varepsilon_{3,-4} & \varepsilon_{3,-5} & \varepsilon_{3,-6} \\ 0 & \varepsilon_{4,-1} & \varepsilon_{4,-2} & \varepsilon_{4,-3} & \varepsilon_{4,-4} & \varepsilon_{4,-5} & 0 \\ 0 & \varepsilon_{5,-1} & \varepsilon_{5,-2} & \varepsilon_{5,-3} & \varepsilon_{5,-4} & 0 & 0 \\ 0 & \varepsilon_{6,-1} & \varepsilon_{6,-2} & \varepsilon_{6,-3} & 0 & 0 & 0 \end{bmatrix} \quad (27b)$$

$$[\hat{\epsilon}_{xx}]_{\text{Im}g(+1)} = \begin{bmatrix} 0 & 0 & 0 & \epsilon_{0,9} & \epsilon_{0,8} & \epsilon_{0,7} & 0 \\ 0 & 0 & \epsilon_{1,10} & \epsilon_{1,9} & \epsilon_{1,8} & \epsilon_{1,7} & 0 \\ 0 & \epsilon_{2,11} & \epsilon_{2,10} & \epsilon_{2,9} & \epsilon_{2,8} & \epsilon_{2,7} & 0 \\ \epsilon_{3,12} & \epsilon_{3,11} & \epsilon_{3,10} & \epsilon_{3,9} & \epsilon_{3,8} & \epsilon_{3,7} & 0 \\ \epsilon_{4,12} & \epsilon_{4,11} & \epsilon_{4,10} & \epsilon_{4,9} & \epsilon_{4,8} & \epsilon_{4,7} & 0 \\ \epsilon_{5,12} & \epsilon_{5,11} & \epsilon_{5,10} & \epsilon_{5,9} & \epsilon_{5,8} & \epsilon_{5,7} & 0 \\ \epsilon_{6,12} & \epsilon_{6,11} & \epsilon_{6,10} & \epsilon_{6,9} & \epsilon_{6,8} & \epsilon_{6,7} & 0 \end{bmatrix} \quad (27c)$$

$$[\hat{\epsilon}_{xx}]_{\text{Im}g(-2)} = \begin{bmatrix} 0 & 0 & 0 & \epsilon_{0,-9} & \epsilon_{0,-8} & \epsilon_{0,-7} & 0 \\ 0 & 0 & 0 & 0 & \epsilon_{1,-8} & \epsilon_{1,-7} & 0 \\ 0 & 0 & 0 & 0 & 0 & \epsilon_{2,-7} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (27d)$$

$$[\hat{\epsilon}_{xx}]_{\text{Im}g(+2)} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \epsilon_{4,13} & 0 & 0 & 0 & 0 & 0 \\ 0 & \epsilon_{5,13} & \epsilon_{5,14} & 0 & 0 & 0 & 0 \\ 0 & \epsilon_{6,13} & \epsilon_{6,14} & \epsilon_{6,15} & 0 & 0 & 0 \end{bmatrix} \quad (27e)$$

where (27a) is associated with the original structure, whereas (27b)–(27e) are contributed by the image regions. As seen from the above, these latter contributions to the equivalent permittivity matrix decrease dramatically with the increase in the number of image regions. Since the elements of the equivalent permittivity matrix depend only on the basis functions and the material properties of the structure, both the $[\hat{\epsilon}_{xx}]$ and its inverse $[\hat{\epsilon}_{xx}]^{-1}$ can be computed in advance and saved in the MRTD Maxwell solver for the update equations. Consequently, the E field can be updated as follows

$$\phi_x E_{i+(1/2),j,k}^n = \frac{1}{\epsilon_0} \sum_{j'=0}^{N_y} ([\hat{\epsilon}_{xx}]^{-1})_{j,j'} \phi_x D_{i+(1/2),j',k}^n \quad (28)$$

where, apparently, we need to compute the product of only two small matrices, whose dimensions are typically 6 or less in this work, to update the E fields at each timestep.

6.3. MIT in Update Equations

Although, in principle, (16) and (17) can be employed to update the fields, they are numerically inefficient and somewhat impractical for coding and computation, because the summations in these update expressions include both the original and image regions. In this section, we truncate the summations in these update equations by

excluding some of the image field quantities. This is accomplished by carrying out the following two steps: (1) expressing all the field quantities in terms of those defined in the original structure by the MIT technique described in the previous section and, (2) maintaining the values and positions of the coefficients $a(v)$ unchanged for all of the terms, but expressing them only by using the grid indices inside the structure. Following this procedure, we can rewrite the update equations for the x components using the MIT as follows

$$\begin{aligned} & \phi_x D_{i+(1/2),j,k}^n \\ &= \phi_x D_{i+(1/2),j,k}^n + \left\{ \sum_{v=0}^{N_y-1} a(v-j)_{\phi_z} H_{i+(1/2),v+(1/2),k}^{n+(1/2)} \right. \\ &+ \left[\sum_{\text{Im}g=\text{even}} \left(\sum_{v=0}^{N_y-1} a(-\text{Im}g-2) \cdot N_y - v - j - 1 \right) \right. \\ &+ \left. \left. \sum_{v=0}^{N_y-1} a(\text{Im}g \cdot N_y + v - j) \right) \phi_z H_{i+(1/2),v+(1/2),k}^{n+(1/2)} \right] \\ &+ \left[\sum_{\text{Im}g=\text{odd}} \left(\sum_{v=0}^{N_y-1} a(-\text{Im}g \cdot N_y - v - j - 1) \right) \right. \\ &+ \left. \sum_{m=0}^{N_y-1} a(\text{Im}g \cdot N_y + v - j) \right] \\ &\times \left. \phi_z H_{i+(1/2),N_y-v-1+(1/2),k}^{n+(1/2)} \right\} \frac{\Delta t}{\Delta y} \\ &+ \left\{ \sum_{v=0}^{N_z-1} a(v-k)_{\phi_y} H_{i+(1/2),j,v+(1/2)}^{n+(1/2)} \right. \\ &+ \left[\sum_{\text{Im}g=\text{even}} \left(\sum_{v=0}^{N_z-1} a(-\text{Im}g-2) \cdot N_z - v - k - 1 \right) \right. \\ &+ \left. \sum_{v=0}^{N_z-1} a(\text{Im}g \cdot N_z + v - k) \right] \\ &\times \left. \phi_y H_{i+(1/2),j,v+(1/2)}^{n+(1/2)} \right] \\ &+ \left[\sum_{\text{Im}g=\text{odd}} \left(\sum_{v=0}^{N_z-1} a(-\text{Im}g \cdot N_z - v - k - 1) \right) \right. \\ &+ \left. \sum_{v=0}^{N_z-1} a(\text{Im}g \cdot N_z + v - k) \right] \\ &\times \left. \phi_y H_{i+(1/2),j,N_z-v-1+(1/2)}^{n+(1/2)} \right\} \frac{\Delta t}{\Delta z} \end{aligned} \quad (29a)$$

$$\begin{aligned}
 & H_{ij+(1/2),k+(1/2)}^{n+(1/2)} \\
 &= \phi_x H_{ij+(1/2),k+(1/2)}^{n-(1/2)} + \frac{1}{\mu_0} \left\{ \sum_{v=0}^{N_z} \alpha(v-k-1) \phi_y E_{ij+(1/2),v}^n \right. \\
 &+ \left[\sum_{\text{Im}g=\text{even}} \left(-\sum_{v=0}^{N_z-1} \alpha(-\text{Im}g-2) \cdot N_z - v - k - 2 \right) \right. \\
 &+ \left. \left. \sum_{m=0}^{N_z-1} \alpha(\text{Im}g \cdot N_z + v - k) \right) \phi_y E_{ij+(1/2),v+1}^n \right] \\
 &+ \left[\sum_{\text{Im}g=\text{odd}} \left(\sum_{v=0}^{N_z-1} \alpha(-\text{Im}g \cdot N_z - v - k - 2) \right) \right. \\
 &- \left. \sum_{v=0}^{N_z-1} \alpha(\text{Im}g \cdot N_z + v - k) \right) \\
 &\times \phi_z E_{ij+(1/2),N_z-v-1}^{n+(1/2)} \left. \right\} \frac{\Delta t}{\Delta z} \\
 &- \frac{1}{\mu_0} \left\{ \sum_{v=0}^{N_y} \alpha(v-j-1) \phi_z E_{i,v,k+(1/2)}^n \right. \\
 &+ \left[\sum_{\text{Im}g=\text{even}} \left(-\sum_{v=0}^{N_y-1} \alpha(-\text{Im}g-2) \cdot N_y - v - j - 2 \right) \right. \\
 &+ \left. \sum_{v=0}^{N_y-1} \alpha(\text{Im}g \cdot N_y + v - j) \right) \\
 &\times \phi_z E_{i,v+1,k+(1/2)}^n \left. \right] \\
 &+ \left[\sum_{\text{Im}g=\text{odd}} \left(\sum_{v=0}^{N_y-1} \alpha(-\text{Im}g \cdot N_y - v - j - 2) \right) \right. \\
 &- \left. \sum_{v=0}^{N_y-1} \alpha(\text{Im}g \cdot N_y + v - j) \right) \\
 &\times \phi_z E_{i,N_y-v-1,k+(1/2)}^n \left. \right\} \frac{\Delta t}{\Delta y} \quad (29b)
 \end{aligned}$$

where N_y and N_z are the numbers of cells along the y and z directions inside the structure, respectively, and the summation indexes, “odd” (1,3, ...) and “even” (2,4, ...), denote the contributions to the updated field quantities from the specified odd or even image regions, respectively.

Before closing this section, it would be worthwhile to point out that although the (29a) and (29b) are quite lengthy, they are actually quite efficient in terms of coding and computation. Because all the field quantities usually have small dimensions, the coefficients $\alpha(v)$ can be

computed in advance and saved in the MRTD solver for later use.

7. 2D MRTD ANALYSIS FOR PRINTED TRANSMISSION LINES

7.1. Field Construction

Following the procedure described in Refs. 28 and 29, we develop a two-dimensional (2D) MRTD analysis by deriving a set of governing equations for the problem at hand, specifically, a lossless guided-wave structure shown in Fig. 13. We begin by expanding the field quantities as

$$\begin{aligned}
 & \left\{ \begin{array}{l} E_x(x,y,z,t), E_y(x,y,z,t), E_z(x,y,z,t) \\ H_x(x,y,z,t), H_y(x,y,z,t), H_z(x,y,z,t) \end{array} \right\}^t \\
 &= \left\{ \begin{array}{l} jE_x(x,y,t), jE_y(x,y,t), E_z(x,y,t) \\ H_x(x,y,t), H_y(x,y,t), jH_z(x,y,t) \end{array} \right\}^t e^{-j\beta z} \quad (30)
 \end{aligned}$$

where β is the propagation constant for the structure. Next, we use the GDMOs to obtain the following governing equations from the Maxwell's curl equations

$$\begin{aligned}
 & \begin{bmatrix} 0 & j\beta & \partial_y \\ -j\beta & 0 & -\partial_x \\ -\partial_y & \partial_x & 0 \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ 0 \end{bmatrix} \\
 &= \left(\varepsilon_0 \frac{\partial}{\partial t} \begin{bmatrix} \varepsilon_{xx} & 0 & 0 \\ 0 & \varepsilon_{yy} & 0 \\ 0 & 0 & \varepsilon_{zz} \end{bmatrix} + \begin{bmatrix} \sigma_x^e & 0 & 0 \\ 0 & \sigma_y^e & 0 \\ 0 & 0 & \sigma_z^e \end{bmatrix} \right) \begin{bmatrix} jE_x \\ jE_y \\ E_z \end{bmatrix} \quad (31a)
 \end{aligned}$$

$$\begin{aligned}
 & \begin{bmatrix} 0 & j\beta & \partial_y \\ -j\beta & 0 & -\partial_x \\ -\partial_y & \partial_x & 0 \end{bmatrix} \begin{bmatrix} jE_x \\ jE_y \\ E_z \end{bmatrix} \\
 &= \left(-\mu_0 \frac{\partial}{\partial t} \begin{bmatrix} \mu_{xx} & 0 & 0 \\ 0 & \mu_{yy} & 0 \\ 0 & 0 & \mu_{zz} \end{bmatrix} + \begin{bmatrix} \sigma_x^m & 0 & 0 \\ 0 & \sigma_y^m & 0 \\ 0 & 0 & \sigma_z^m \end{bmatrix} \right) \\
 &\times \begin{bmatrix} H_x \\ H_y \\ jH_z \end{bmatrix} \quad (31b)
 \end{aligned}$$

In practice, we set $\sigma_x^m = 0$. Note that a printed planar transmission line is usually inhomogeneous in the vertical

direction, but homogenous in the horizontal direction, which leads to $\varepsilon_{\alpha\alpha} = \varepsilon_{\alpha\alpha}(y)$, ($\alpha = x, y, z$).

7.2. 2D MRTD Algorithm

Next, we represent all the field quantities by using scaling functions in space and pulse functions in time. For instance, for the x component of the fields we write

$$E_x(x, y, t) = \sum_{n, i, j = -\infty}^{+\infty} \phi_x E_{i+(1/2)j}^n \phi_{i+(1/2)}(x) \phi_j(y) h_n(t) \quad (32)$$

$$H_x(x, y, t) = \sum_{n, i, j = -\infty}^{+\infty} \phi_x H_{i+(1/2)j}^{n+(1/2)} \phi_i(x) \phi_{j+(1/2)}(y) h_{n+(1/2)}(t) \quad (33)$$

Substitution of the field expansions into Maxwell's equations, followed by application of Galerkin's method, leads us to obtain a set of field update equations. For instance, the x components of the update equations are given by

$$\begin{aligned} \phi_x H_{i+(1/2)j}^{n+(1/2)} &= \phi_x H_{i+(1/2)j}^{n-(1/2)} + \frac{\Delta t}{\mu_0 \mu_x} \\ &\times \left[\beta_{\phi_y} E_{i+(1/2)j}^n - \sum_v a(v) \phi_z E_{i+(1/2)j+v+1}^n \frac{1}{\Delta y} \right] \end{aligned} \quad (34)$$

$$\begin{aligned} &\sum_{i', j' = -\infty}^{+\infty} (\sigma_x^e)_{i'i', j'j'} \frac{\Delta t}{2} \left(\phi_x E_{i'+(1/2)j'}^{n+1} + \phi_x E_{i'+(1/2)j'}^n \right) \\ &+ \varepsilon_0 \sum_{j' = -\infty}^{+\infty} (\varepsilon_{xx})_{j'j'} \left(\phi_x E_{i+(1/2)j'}^{n+1} - \phi_x E_{i+(1/2)j'}^n \right) \\ &= \Delta t \left[\beta_{\phi_y} H_{i+(1/2)j}^{n+(1/2)} + \sum_m a(m) \phi_z H_{i+(1/2)j+m+1}^{n+(1/2)} \frac{1}{\Delta y} \right] \end{aligned} \quad (35)$$

where the coefficient $a(v)$ is as given in Ref. 19. Assuming that the conducting strip is infinitely thin, we can express its conductivity as

$$\sigma_x^e = \begin{cases} \sigma, & i_1 \Delta x \leq x \leq i_2 \Delta x, \left(j_0 \Delta y - \frac{\tau}{2} \right) < y < \left(j_0 \Delta y + \frac{\tau}{2} \right) \\ 0, & \text{otherwise} \end{cases} \quad (\Delta = x, y) \quad (36)$$

Thus, we can express $(\varepsilon_{xx})_{j'j'}$ and $(\sigma_x^e)_{i'i', j'j'}$ as

$$(\varepsilon_{xx})_{j'j'} = \int_{-\infty}^{+\infty} \phi_j(y) \varepsilon_{xx}(y) \phi_{j'}(y) \frac{dy}{\Delta y} \quad (37a)$$

$$\begin{aligned} (\sigma_x^e)_{i'i', j'j'} &= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \phi_{i+(1/2)}(x) \phi_j(y) \sigma \phi_{i'+(1/2)} \\ &\times (x) \phi_{j'}(y) \frac{dx dy}{\Delta x \Delta y} \end{aligned} \quad (37b)$$

By including the image contributions and using the first-order approximation, we can derive

$$(\sigma_x^e)_{i'i', j'j'} = \sigma_{i,i'} \delta_{i,i'} \zeta_{j,j'} \delta_{j,j'} (\delta_{j,j_0} + \delta_{j,-j_0} + \delta_{j,2j_0} + \dots) \quad (38)$$

where $\delta_{i'i'}$ is the Kronecker symbol, which is 1 for $i = i'$, otherwise 0. Then, we further rewrite the discretized time-domain equation as

$$\begin{aligned} &(\phi_x E_{i+(1/2)j}^{n+1} + \phi_x E_{i+(1/2)j}^n) \frac{\sigma^e (\delta_{j,j_0} + \delta_{j,-j_0} + \delta_{j,2j_0} + \dots) \Delta t}{2} \\ &+ \varepsilon_0 \sum_{j' = -\infty}^{+\infty} (\varepsilon_{xx})_{j'j'} (\phi_x E_{i+(1/2)j'}^{n+1} - \phi_x E_{i+(1/2)j'}^n) \\ &= \Delta t \left[\beta_{\phi_y} H_{i+(1/2)j}^{n+(1/2)} + \sum_v a(v) \phi_z H_{i+(1/2)j+v+1}^{n+(1/2)} \frac{1}{\Delta y} \right] \end{aligned} \quad (39)$$

The summation index v in (39) includes not only the regions in the interior of the original structure but also the image regions. Two types of boundary are frequently used for truncating the grids: the absorbing boundary condition for open structures and the perfect electric conductor (PEC) for shielded ones. Usually, the PEC boundary is handled by using the MIT described earlier. Figure 13 shows the original structures: shielded and open microstrip lines, as well as their images.

$$\begin{aligned} &(\phi_x E_{i+(1/2)j}^{n+1} + \phi_x E_{i+(1/2)j}^n) \frac{\sigma^e \delta_{j,j_0} \Delta t}{2} \\ &+ \varepsilon_0 \sum_{j' = 0}^{N_y} (\hat{\varepsilon}_{xx})_{j'j'} (\phi_x E_{i+(1/2)j'}^{n+1} - \phi_x E_{i+(1/2)j'}^n) \\ &= \Delta t \left[\beta_{\phi_y} H_{i+(1/2)j}^{n+(1/2)} + \sum_v a(v) \phi_z H_{i+(1/2)j+v+1}^{n+(1/2)} \frac{1}{\Delta y} \right] \end{aligned} \quad (40)$$

By taking an inverse of (30), we can obtain the update equation for the x component of the E field as

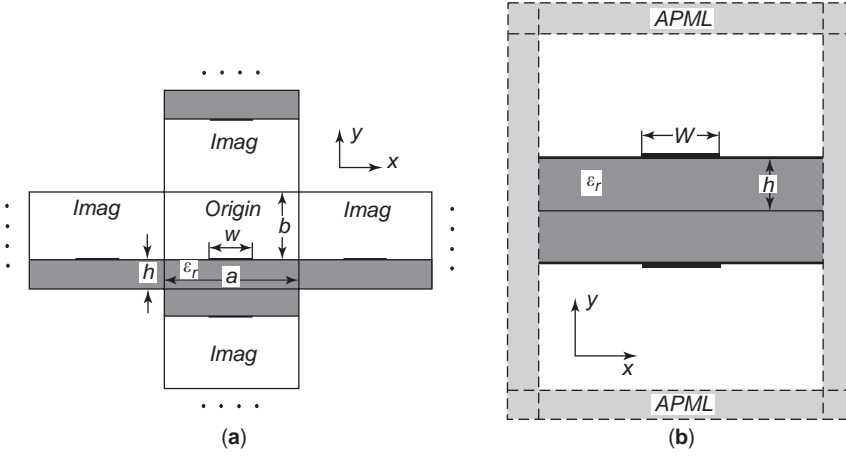

Figure 13. Cross section of printed transmission lines and their images: (a) shielded microstrip line; (b) open microstrip line.

follows

$$\begin{aligned} \phi_x \mathbf{E}_{i+(1/2),j}^{n+1} &= \sum_{j'=0}^{N_y} ([A])_{j,j'} \phi_x \mathbf{E}_{i+(1/2),j'}^n \\ &+ \frac{1}{\varepsilon_0} \sum_{j'=0}^{N_y} ([B])_{j,j'} \left[\beta_{\phi_y} \mathbf{H}_{i+(1/2),j'}^{n+(1/2)} \Delta t \right. \\ &\left. + \sum_m a(m)_{\phi_z} \mathbf{H}_{i+(1/2),j'+m+1}^{n+(1/2)} \frac{\Delta t}{\Delta y} \right] \end{aligned} \quad (41)$$

with

$$[A] = \left[[\hat{\varepsilon}_{xx}]_{j,j'} + [I] \frac{\sigma^e \delta_{j,j_0} \Delta t}{2\varepsilon_0} \right]^{-1} \cdot \left[[\hat{\varepsilon}_{xx}]_{j,j'} - [I] \frac{\sigma^e \delta_{j,j_0} \Delta t}{2\varepsilon_0} \right] \quad (42a)$$

$$[B] = \left[[\hat{\varepsilon}_{xx}]_{j,j'} + [I] \frac{\sigma^e \delta_{j,j_0} \Delta t}{2\varepsilon_0} \right]^{-1} \quad (42b)$$

For a shielded structure, we need to employ the MIT for constructing the $[\hat{\varepsilon}_{xx}]$ matrix. Since the matrix $[A]$ and $[B]$ depend only on the basis functions and the material properties of the structure, they can be computed in advance and saved in the MRTD Maxwell solver for the update equations.

7.3. Application of APML

In this section we address the problem of mesh truncation for open structures. We find that the 2D version of the lossy, uniaxial, anisotropic PML (APML) [30] medium is well suited for this purpose. Since the APML is applied only in the x and y directions, the frequency-domain Maxwell curl equation in the APML medium can be

written as

$$\begin{bmatrix} j \frac{\partial H_z}{\partial y} + j \beta H_y \\ -j \beta H_x - j \frac{\partial H_z}{\partial x} \\ \frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} \end{bmatrix} \quad (43a)$$

$$= j \omega \varepsilon_0 \begin{bmatrix} \frac{\varepsilon_{xx} s_y}{s_x} & 0 & 0 \\ 0 & \frac{\varepsilon_{yy} s_x}{s_y} & 0 \\ 0 & 0 & \varepsilon_{zz} s_x s_y \end{bmatrix} \begin{bmatrix} j E_x \\ j E_y \\ E_z \end{bmatrix}$$

$$\begin{bmatrix} \frac{\partial E_z}{\partial y} + \beta E_y \\ \beta E_x - \frac{\partial E_z}{\partial x} \\ j \frac{\partial E_y}{\partial x} - j \frac{\partial E_x}{\partial y} \end{bmatrix} \quad (43b)$$

$$= -j \omega \mu_0 \begin{bmatrix} \frac{\mu_{xx} s_y}{s_x} & 0 & 0 \\ 0 & \frac{\mu_{yy} s_x}{s_y} & 0 \\ 0 & 0 & \mu_{zz} s_x s_y \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ j H_z \end{bmatrix}$$

with

$$s_\alpha = \begin{cases} 1 + \frac{\sigma_\alpha}{j \omega \varepsilon_0}, & \text{for absorption in } \alpha \text{ direction} \\ 1, & \text{elsewhere} \end{cases} \quad (\alpha = x, y) \quad (44)$$

Depending on combination of the values of s_x and s_y , the equations above are applicable to all of the APML regions, which include two side edges, the top wall, as well as the two corners. By expanding these equations for the case of the corners, we immediately obtain the x components of the governing equations given below:

$$\frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} = j\omega D_x + \frac{\sigma_y}{\varepsilon_0} D_x \quad (45)$$

$$\frac{\partial E_z}{\partial y} - \frac{\partial E_y}{\partial z} = -j\omega B_x - \frac{\sigma_y}{\varepsilon_0} B_x \quad (46)$$

We use a two-step update approach to timestepping fields inside APML regions. Following the MRTD discretization procedure, described previously, we obtain the desired E -field update equations:

$$\begin{aligned} \phi_x D_{i+(1/2)j}^{n+1} &= \frac{1 - \frac{\sigma_y \Delta t}{2\varepsilon_0}}{1 + \frac{\sigma_y \Delta t}{2\varepsilon_0}} \phi_x D_{i+(1/2)j}^n + \frac{1}{1 + \frac{\sigma_y \Delta t}{2\varepsilon_0}} \\ &\times \left(\beta_{\phi_y} H_{i+(1/2)j}^{n+1} \Delta t \right. \\ &\left. + \sum_m a(m)_{\phi_z} H_{i+(1/2)j+m+1}^{n+1} \frac{\Delta t}{\Delta y} \right) \end{aligned} \quad (47)$$

$$\begin{aligned} \phi_x E_{i+(1/2)j}^{n+1} &= \phi_x E_{i+(1/2)j}^n + \frac{1}{\varepsilon_0} \sum_{j'} ([\varepsilon_x]^{-1})_{jj'} \\ &\times \left[\left(1 + \frac{\sigma_x \Delta t}{2\varepsilon_0} \right) \phi_x D_{i+(1/2)j'}^{n+1} \right. \\ &\left. - \left(1 - \frac{\sigma_x \Delta t}{2\varepsilon_0} \right) \phi_x D_{i+(1/2)j'}^n \right] \end{aligned} \quad (48)$$

We can employ the same procedure to obtain the remaining E and H -field update equations.

In applying the MRTD method, we chose the time step Δt to satisfy the stability and limit condition [19] in all simulations. Starting from the convergence condition of the update equations of D fields given above, it can be shown that, to obtain good absorption, the APML parameters may be chosen as

$$\sigma_\alpha = \sigma_{\max} \left| \frac{\alpha - \alpha_0}{N_p \Delta \alpha} \right|^p = \gamma \frac{\varepsilon_0}{\Delta t} \left| \frac{i - i_0}{N_p} \right|^p, \quad (\alpha = x, y) \quad (49)$$

where α_0 is the starting position in the α direction, d is the thickness of the APML, and N_p is the number of cells within the APML region. In principle, it can be shown that this relationship is consistent with the standard form, which can be derived from a plane wave, normally incident on a PML region. We found that we can minimize the reflection error, and have good absorption, if we choose $p = 2$ and $\gamma = 0.8-1.6$.

7.4. Computation of the Propagation Characteristics

Typically, for the printed transmission lines, the two parameters of interest are the effective dielectric constant ε_{eff} , and the characteristic impedance Z_0 , which can, in general, be derived from the MRTD calculated field quantities. For example, the time-domain voltage V defined as an integral from the PEC ground to the stripline can be calculated as follows

$$\begin{aligned} V &= - \int_0^h E_y(x_0, y, t_0) dy \\ &= - \sum_{l=0}^{N_s} \int_{l\Delta y}^{(l+1)\Delta y} E_y(x_0, y, t_0) dy \\ &= - \sum_{l=0}^{N_s} \int_{l\Delta y}^{(l+1)\Delta y} \left[\iint E_y(x, y, t) \delta(x - x_0) \delta(t - t_0) dx dt \right] dy \\ &= - \sum_{l=0}^{N_s} \left[\sum_{i,j=-\infty}^{\infty} \phi_y E_{i,j-l+(1/2)}^n \phi_i(x_0) b(j) \Delta y \right] \end{aligned} \quad (50)$$

where N_s is the number of the cells from the bottom ground to the PEC strip and the indices i and j of the summation span the original microstrip line and its image regions. The integral coefficient $b(j)$ forms a localized distribution with even symmetric $b(j) = b(-j)$ listed in Table 3. We can apply a similar procedure to solve for all required field quantities.

7.5. BHW Function Truncation and Modulation

To eliminate the Gibb phenomenon that results from an abrupt truncation of the time-domain response, the Blackman-Harris (BH) window function is used to truncate and modulate the time domain [29]. We write

$$\begin{aligned} [E_\kappa^W(t_n), H_\kappa^W(t_n)] &= [E_\kappa(t_n), H_\kappa(t_n)] \\ W_{\text{BH}}(t_n) \quad (\kappa = x, y, z) \end{aligned} \quad (51)$$

where $[E_\kappa(t_n), H_\kappa(t_n)]$ represent the original time-domain electromagnetic fields defined in the MRTD algorithm, and $[E_\kappa^W(t_n), H_\kappa^W(t_n)]$ are the windowed versions. Since the frequency-domain response is the convolution of the frequency-domain signature and its window function, the

Table 3. Integral Coefficient $b(j)$

j	$b(j)$
0	0.9143952
1	0.0385998
2	0.0095740
3	-0.0086579
4	0.0050629
5	-0.0027034
6	0.0014053
7	-0.0007203
8	0.0000695

choice of the window function can significantly affect the accuracy of the propagation characteristics. Extremely low sidelobe levels (-92 dB) of the BH window ensures the accuracy of the extracted frequency domain signals, whereas the use of the conventional rectangular window function, which has a much higher sidelobe level (-13 dB), can seriously corrupt the frequency signatures, especially for a resonant structure.

8. NUMERICAL RESULTS

8.1. MIT MRTD Application

We have applied the MRTD scheme in conjunction with the MIT to analyze a number of dielectric-loaded cavities, *viz.*, an empty cavity, two partially filled (25% and 50%) cavities containing a single dielectric medium, and two different two-layer, dielectric-filled cavities. The dimensions of the cavity were set to be $1 \times 2 \times 1.5$ m³, in the $x, y,$ and z directions, respectively, in all these cases.

We begin with an empty cavity that is discretized with $2 \times 4 \times 3$ cells. The frequency spectrum of E_x sampled at the gridpoint [1,3,1] is displayed in Fig. 14, and the extracted resonant frequencies for the dominant and higher-order modes are summarized in Table 4, along with the discretization parameters. It is evident that the results obtained with the MRTD scheme show good agreement with both the analytical results and those derived using the FDTD. However, the MRTD scheme demands only 0.8% of the computational resources needed in the conventional FDTD technique. In addition, we have investigated the required CPU time for conventional MRTD and the MIT MRTD schemes. For a total timestep of $N_t = 10^4$, it was found that the CPU time for the conventional MRTD was about 19.27 s, whereas of the MIT MRTD required about 27.08 s on a 500-MHz Alpha digital workstation. Obviously, this increase in the CPU time is

^a $V = 1 \times 2 \times 1.5$ m³; $\Delta x = \Delta y = \Delta z = \frac{1}{2}$ m.

due to the use of additional images in the process of implementing the MIT MRTD technique. Specially, we use five images along the positive and negative x directions, and three in the remaining directions. By comparison, the conventional MRTD uses only a single image irrespective of the direction. We also note that the introduction of the MIT in the MRTD scheme enhances the accuracy of the results.

The MRTD analysis of the half- and quarter-filled dielectric cavities, with $\epsilon_{r1} = \epsilon_{r2} = 64$ and $\epsilon_{r1} = 64, \epsilon_{r2} = 1$, respectively, also yields excellent results, as is evident from Figs. 15 and 16 and Tables 5 and 6. Once again, the MRTD scheme is found to be highly efficient when compared to the conventional FDTD method, since it requires only 0.8% and 1.2% of the CPU memory for the two cases described above. In general, the accuracy of the MRTD technique is again improved when it is combined with the multiple-image technique.

Next, we consider a two-layer, dielectric-filled cavity, using only $2 \times 6 \times 3$ cells to discretize the computational domain. We investigate the following two cases: (1) $\epsilon_{r1} = 64, \epsilon_{r2} = 8$ and (2) $\epsilon_{r1} = 8, \epsilon_{r2} = 64$, with $N_{y1} = N_{y2} = 1.5$ cells. The structure dimensions still remain

$V = 1 \times 2 \times 1.5 \text{ m}^3$. We also analyze the same problem using the traditional FDTD mesh with a discretization of $\Delta x = \Delta y = 2.5 \text{ cm}$ and $\Delta z = 3 \text{ cm}$, specifically, $40 \times 40 \times 50$ cells. As seen from Figs. 17 and 18 and from Table 7, the two sets of computed results agree very well with each other and the percentage differences are 0.038% and 0.343%, for cases 1 and 2, respectively. However, the MIT MRTD scheme uses only 0.045% of the computational resources relative to the conventional FDTD algorithm.

8.2. Application of 2D MRTD

We consider a shielded microstrip line shown in Fig. 13a, whose trace is assumed very thin and perfectly conducting. Figure 19 shows that the propagation characteristics derived from an application of the present 2D MRTD scheme agree quite well with those derived from the spectral-domain approach (SDA) [31].

Next, we study the propagation characteristics of a shielded microstrip line, shown in Fig. 13a, whose dimensions and substrate material are given in the caption of Fig. 20. We observe, from Fig. 20, that the MRTD-computed results are in good agreement with those published in the literature, derived by using the FDTD [29]. For this case, the distance from the air-dielectric interface of the

^a $N_{y1} = N_{y2} = 1.5$; $V = 1 \times 2 \times 1.5 \text{ m}^3$; $\Delta x = \Delta z = \frac{1}{2} \text{ m}$; $\Delta y = \frac{1}{3} \text{ m}$.

structure to the inner surface of the APML is seven cells. The corresponding discretization parameters employed in the FDTD and the MRTD methods are summarized in Table 8, and a comparison of the total number of cells needed in the MRTD and FDTD technique is presented in Table 8, and the relative advantage of the former is evident from the table.

Finally, we investigate an open microstrip line, whose geometry is specified in Fig. 13b. Once again, from Fig. 21 we observe good agreement between the computed results and those derived by using the FDTD [29,32], as well as the empirical approach [33,34]. The corresponding discretization parameters employed in the FDTD and MRTD methods are summarized Table 9. We note that the memory required in the 2D MRTD method is only about 6.25% or 7.64% of the 2D FDTD scheme for the same shielded and open microstrip lines, respectively. We further notice that, to ensure computational accuracy, we must employ at least two cells along the width of the narrow PEC strip.

9. SUMMARY OF MRTD

In this section we have presented an adjustable multiple-image technique, which can be incorporated in the multi-resolution time-domain (MRTD) scheme for the boundary truncation of PEC-shielded. We have also developed a 2D version of the MRTD, and have applied it in conjunction with an APML mesh truncation technique, for the analysis of both shielded and open microstrip lines. We have developed a systematic technique for constructing the multiple images, extracting the constitutive relations,

Figure 20. Frequency dependence of propagation characteristics of a shielded microstrip line with $w = h = 1.5 \text{ mm}$, $a = 6.5 \text{ mm}$, $b = 3.5 \text{ mm}$; $\epsilon_{xx} = \epsilon_{zz} = 9.4$, $\epsilon_{yy} = 11.6$: (a) ϵ_{eff} ; (b) magnitude of Z_0 in ohms. (Tong and Chan [29].)

deriving the update equations, and determining the number of images in the transform domain of the MRTD. The propagation characteristics computed via the MRTD have been shown to be in good agreement with those obtained by using other numerical techniques. The computational resources needed in the MRTD scheme are only a small fraction of those of the FDTD algorithm, albeit the computational complexity is higher in the MRTD. Although we have presented only a few representative examples of the application of the MRTD, its scope is wider, as is evident from a variety of problem to which it has been applied.

10. CONCLUSION

In this article we have briefly discussed two techniques for enhancing the FDTD algorithm: the conformal method and the MRTD algorithm. Space does not permit us to include two other approaches that are also quite important: the pseudospectral time-domain (PSTD) method and the multiscale analysis for dealing with geometries requiring a fine discretization in a subregion of the computational domain. We have simply chosen, as a compromise, to include some selected set of references on these two topics. The references on the multiscale analysis have been limited to those related to the FDTD/ADI algorithm and do not include a vast array of literature dealing with the problem of subgridding in FDTD.

FABRY–PEROT RESONATORS

RONAN SAULEAU
University of Rennes
Rennes, France

1. THE PLANE-PARALLEL FABRY–PEROT INTERFEROMETER

1.1. Historical Background and Generalities

Two French physicists (Alfred Perot and Charles Fabry) developed the classical Fabry–Perot interferometer (FPI) or *etalon* at the beginning of the twentieth century. This novel form of interference device was based on multiple reflections of waves between two closely spaced and highly reflecting mirrors (the original thinly silvered *plane* glass mirrors were adjusted to be as flat and parallel to each other as possible). Alternative but conceptually equivalent elements are (1) the “solid” etalon made from some low-loss materials (e.g., fused quartz or sapphire) or (2) the Fabry-Perot (FP) cavity whose reflectors are partially transparent metal mirrors (e.g., perforated plates) or multilayer dielectric coatings (e.g., Bragg mirrors). The modal analysis of resonators with *spherical* mirrors is beyond the scope of this article. Nevertheless, all the abovementioned topologies are widely used at microwave frequencies; their choice depends on the envisaged applications, as described in Section 3.

The general concepts and theoretical analysis of these resonant optical cavities were published by George Airy about the middle of the nineteenth century. As we will see, plane-parallel FPIs have sharp resonances or transmission passbands at discrete frequencies. They thus behave as *narrowband frequency filters*. Their main characteristics (standing-wave resonance conditions, resonant frequencies, fringe contrast, free spectral range, half-power bandwidth, Q factor, reflectivity finesse) can be found in any general textbook dealing with optical resonators e.g., [1,2]. However, for consistency, these parameters are voluntarily derived in Section 1.2 using a *ray* approach. Although approximate, this analytical treatment reveals itself very fruitful for the analysis of FP-based devices operating at *microwave* and *millimeter-wave* frequencies (Section 2).

In their original form, FPIs used only flat reflecting surfaces, and the spacing between the mirrors was usually smaller than, or at most on the same scale as, the transverse diameters of the mirrors. Moreover, the FP interferometers were usually illuminated with a converging or diverging beam having a spread of angular directions, which resulted in “Fabry–Perot rings” transmitted through the interferometer in given discrete angular directions. Thus FPIs are also *spatial filters*. In particular, we will show in Section 3 that the high directivity of FP-based resonator antennas originates from this property.

Since its invention, the FPI has continued to evolve and find many new fields of applications, ranging, for instance, from astronomy, astrophysics, atomic spectroscopy, optics,

and similar applications to metrology, optical bistability, infrared, sensors, and plasma physics. A detailed and well-documented description of the FPI is given by Vaughan [3] at optical wavelengths. Here we concentrate only on radio-frequency and microwave implementations of FP resonators, such as quasioptical frequency filters, highly directive antennas, open resonators, or power combiners (Section 3).

1.2. Ray Analysis

The simplest way to define the basic properties of plane-parallel FPI is to use an infinite plane-wave model, with the plane waves assumed to be arriving at either normal or oblique incidence. The standard formulas developed here describe the transmission properties of FP etalons as a function of (1) the operating frequency and (2) the mirror spacing and reflectivity (the oblique incidence case is introduced in Section 3.1). The Gaussian beam optics [2] or full-wave methods (Section 2.1.3) should be applied to account for (1) the transverse width or shape of the two mirrors, (2) the transverse field variations, or (3) the complex geometry of reflectors.

The geometry of a plane-parallel FPI, depicted in Fig. 1, consists of two semitransparent plane mirrors, M_1 and M_2 , separated by a lossy medium of thickness D and refractive index n ($n = \epsilon_r^{1/2}$). As the mirrors are not confined by an aperture, diffraction is negligible and beam propagation inside the FPI can be described using geometric optics. Losses generated by scattering and absorption are incorporated in our model using the absorption coefficient α . A monochromatic plane wave illuminates the FPI under an incident angle θ . Its amplitude and angular frequency are labeled E_i and $\omega = 2\pi f$, respectively ($f = c_0/\lambda_0$ is the operating frequency; c_0 and λ_0 are the speed of light and wavelength in vacuum). The incident light is partially reflected and partially transmitted by the input mirror M_1 . The transmitted field travels to the output mirror M_2 , where it is again partially reflected and transmitted. The many reflected components add to produce a total field traveling in each direction. Consequently *multiple-beam interference*

Figure 1. Schematic diagram of a plane-parallel Fabry–Perot interferometer (FPI) illuminated by a slightly off-axis incident plane wave. The two partially reflective mirrors M_i are characterized by their reflection and transmission coefficients r_i and t_i ($i = 1, 2$).

occurs. Two important points should be kept in mind: (1) the reflection and transmission coefficients at the interfaces are not the same for rays traveling in different directions; and (2) at optical wavelengths, highly reflecting mirrors of modern FPI are coated with multi-layer dielectric thin films, whereas they often consist of metallic grids (Section 2) from microwave to submillimeter wavelengths. Hence their reflection and transmission coefficients are in general complex quantities (Section 2.1.4), unlike the case of simple dielectric slabs for which the phase shift is either 0° or 180° depending on the dielectric contrast 1:n.

For convenience, we now assume that the mirrors are located in free space (n = 1). {r₁, t₁} and {r₂, t₂} denote the (frequency-dependent) reflection and transmission coefficients of M₁ and M₂, respectively. With these notations, the reflected and transmitted fields, E_r and E_t, at normal incidence (θ = 0) are given by

$$E_r = E_i \{ r_1 + r_2 t_1^2 \exp(-j2\varphi) \exp(-\alpha 2D) + r_1 r_2^2 t_1^2 \exp(-j4\varphi) \exp(-\alpha 4D) + \dots \} \tag{1}$$

$$E_t = E_i \{ t_1 t_2 \exp(-j\varphi) \exp(-\alpha D) + t_1 t_2 r_1 r_2 \exp(-j3\varphi) \exp(-\alpha 3D) + t_1 t_2 (r_1 r_2)^2 \exp(-j5\varphi) \exp(-\alpha 5D) + \dots \} \tag{2}$$

where φ = (2π/λ₀)D represents the phase change due to the optical path through the device.

Since the magnitude of the factor exp(-j2φ) exp(-α2D) is less than unity, both summations (1) and (2) are convergent geometric progressions

$$\frac{E_r}{E_i} = \left\{ r_1 + \frac{t_1^2 r_2 \exp(-j2\varphi) \exp(-2\alpha D)}{1 - r_1 r_2 \exp(-j2\varphi) \exp(-2\alpha D)} \right\} \tag{3}$$

$$\frac{E_t}{E_i} = \left\{ \frac{t_1 t_2 \exp(-j\varphi) \exp(-\alpha D)}{1 - r_1 r_2 \exp(-j2\varphi) \exp(-2\alpha D)} \right\} \tag{4}$$

The total power transmitted by the interferometer T_{FPI} is written

$$T_{FPI} = \left[\frac{E_t}{E_i} \right] \left[\frac{E_t}{E_i} \right]^* = \frac{T_1 T_2 \exp(-2\alpha D)}{1 - 2(R_1 R_2)^{1/2} \cos(2\varphi - \rho_1 - \rho_2) \exp(-2\alpha D) + R_1 R_2 \exp(-4\alpha D)} \tag{5}$$

where t_i = T_i^{1/2} exp(jτ_i) and r_i = R_i^{1/2} exp(jρ_i), i = 1, 2. T_i and R_i are known as the power transmittance and reflectance of mirrors M_i, respectively.

Neglecting all absorption processes (α = 0, T_i = 1 - R_i, i = 1, 2), we obtain

$$T_{FPI} = \frac{(1 - R_1)(1 - R_2)}{1 - 2(R_1 R_2)^{1/2} \cos(2\varphi - \rho_1 - \rho_2) + R_1 R_2} \tag{6}$$

Using the identity

$$1 - \cos \Psi = 2 \sin^2 \left(\frac{\Psi}{2} \right) \tag{7}$$

T_{FPI} can now be written

$$T_{FPI} = \frac{(1 - R_1)(1 - R_2)}{(1 - (R_1 R_2)^{1/2})^2 + 4(R_1 R_2)^{1/2} \sin^2 \left(\frac{2\varphi - \rho_1 - \rho_2}{2} \right)} \tag{8}$$

Equation (8) is known as the *Airy formula*.

Similarly, the power reflectance R_{FPI} of the FPI can be computed by multiplying the reflection coefficient E_r/E_i (3) by its complex conjugate. If absorption losses are negligible, we get

$$R_{FPI} = \frac{R_1 - 2(R_1 R_2)^{1/2} \cos(2\varphi - \rho_1 - \rho_2) + R_2}{1 - 2(R_1 R_2)^{1/2} \cos(2\varphi - \rho_1 - \rho_2) + R_1 R_2} \tag{9}$$

As our discussion has assumed for simplicity that any coating or gap absorption may be neglected (A_{FPI} = 0), it is left as an exercise to show that Eqs. (8) and (9) must add to unity

$$R_{FPI} + T_{FPI} = 1 \tag{10}$$

since energy must be conserved (A_{FPI} + R_{FPI} + T_{FPI} = 1).

Let us return to the interferometer transmission and assume that the reflectivities R₁ and R₂ are frequency-independent. In that case, inspection of relation (8) shows that a maximum of transmission occurs whenever the sine term becomes zero. This happens for

$$\frac{\Phi}{2} = \frac{2\varphi - \rho_1 - \rho_2}{2} = q\pi \tag{11}$$

where q = 0, 1, 2, ... is an integer referred to as the *longitudinal* (or *axial*) *mode number*.

Equation (11) corresponds exactly to the familiar *standing-wave condition* of multiple interference filters for which the total transmitted field is maximum whenever the round-trip phase shift Φ is an integer multiple of 2π [to account for the incidence angle and the dielectric constant of the substrate, D should be replaced by D(n² - sin² θ)^{1/2} in the definition of φ].

From (11) we deduce the expression of the *resonant frequency* $f_{\text{res},q}$ of the q th interference mode

$$f_{\text{res},q} = \frac{c_0}{2D} \left(q + \frac{\rho_1 + \rho_2}{2\pi} \right) \quad (12)$$

For full metal reflectors: $\rho_1 = \rho_2 = \pi$ and $f_{\text{res},q} = f_{\text{res},q,\text{metal}} = (q+1)(c_0/2D)$. As is well known, this corresponds to a gap spacing equal to an integer number of half-wavelengths at resonance [$D = (q+1)(\lambda_0/2)$]. At microwave frequencies, frequency-selective surfaces (FSSs) [4] are often employed as semitransparent mirrors (Section 2). Therefore, compared to the ideal case, two main differences appear:

- $\rho_1 < \pi$ and $\rho_2 < \pi \Rightarrow f_{\text{res},q} < f_{\text{res},q,\text{metal}}$.
- The frequency response of the mirrors is dispersive and $f_{\text{res},q}$ has to be computed numerically by solving the following equation

$$f_{\text{res},q} = \frac{c_0}{2D} \left(q + \frac{\rho_1(f_{\text{res},q}) + \rho_2(f_{\text{res},q})}{2\pi} \right) \quad (13)$$

This relation assumes that the frequency variations of ρ_1 and ρ_2 are known and the mutual coupling between mirrors is negligible (this hypothesis is false for thin FP resonators with capacitive mirrors; see Section 2.1.5).

At resonance, according to Eqs. (8) and (11), the maximum value $T_{\text{FP,max}}$ of T_{FP} is given by

$$T_{\text{FP,max}} = \frac{(1 - R_1)(1 - R_2)}{(1 - (R_1 R_2)^{1/2})^2} \quad (14)$$

whereas a minimum appears in the transmission curve if the sine term in (8) is unity

$$T_{\text{FP,min}} = \frac{(1 - R_1)(1 - R_2)}{(1 + (R_1 R_2)^{1/2})^2} \quad (15)$$

The q th *antiresonance frequency* $f_{\text{antires},q}$ is deduced from

$$\frac{\Phi}{2} = \frac{2\varphi - \rho_1 - \rho_2}{2} = (2q+1)\frac{\pi}{2} \quad (16)$$

and is equal to

$$f_{\text{antires},q} = \frac{c_0}{2D} \left(q + \frac{1}{2} + \frac{\rho_1 + \rho_2}{2\pi} \right) \quad (17)$$

The ratio of maximum to minimum transmission at normal incidence is called the *fringe contrast*

$$\frac{T_{\text{FP,max}}}{T_{\text{FP,min}}} = \frac{(1 + (R_1 R_2)^{1/2})^2}{(1 - (R_1 R_2)^{1/2})^2} \quad (18)$$

When mirrors are identical and lossless ($r_i = r$, $t_i = t$, $R_i = R$, $T_i = T = 1 - R$ for $i = 1, 2$), the maximum and minimum lev-

els of transmission become

$$T_{\text{FP,max}} = 1, \forall R \quad (19)$$

$$T_{\text{FP,min}} = \frac{(1 - R)^2}{(1 + R)^2} \quad (20)$$

Equation (19) implies that all the light impinging on the interferometer is transmitted and none is reflected; the FPI is matched and is analogous to a transmission line terminated by its characteristic impedance. Moreover, as the power transmittance of M_2 is $(1 - R)$, the intensity of the incident field on M_2 (inside the cavity) must be $[1/(1 - R)]|E_i|^2$. For instance, if $R = 99\%$, the incident intensity on M_2 must be 100 times larger than the intensity used to excite the cavity. Although the running-wave intensities on the inside of the resonator can be much larger than those on the outside, we have not violated conservation of energy. Rather, the intensity enhancement is a manifestation of the energy storage capabilities of a cavity with highly reflecting mirrors. As demonstrated in Section 3.2, the high directivity of FP-based antennas and their small bandwidth originate from this startling fact. Finally, we can account for the effect of the dielectric substrate in Eqs. (12), (13), and (17) if we substitute nD for D .

The variations of T_{FP} are represented in Fig. 2 as a function of frequency (or single-pass phase change φ) for symmetric lossless fused-quartz cavities ($\epsilon_r = 3.80$, $D = 3$ mm). These curves confirm that the fringe sharpness and contrast increase with R , while maintaining the transmission peak at unity. For asymmetric resonators (i.e., $R_1 \neq R_2$), $T_{\text{FP,max}} < 1$ (even for an ideal FPI). This issue and the influence of dielectric and conductor losses will be discussed in Section 2.2.2.

According to Eq. (12), the frequency interval Δf_{res} between two successive resonances (known as the *free spectral range*) is given by (21) or (22) (for grid or full metal

Figure 2. Influence of the reflectivity R of the mirrors on the transmittance T_{FP} [Eq. (8)] of a lossless FPI ($D = 3$ mm, $n = 1.95$, $\rho_1 = \rho_2 = \pi$, $\alpha = 0$). R varies between 20 and 99%. Curves (1) $R = 20\%$; (2) $R = 50\%$; (3) $R = 80\%$; (4) $R = 90\%$; (5) $R = 96\%$; (6) $R = 99\%$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

mirrors, respectively)

$$\Delta f_{\text{res}} = \frac{c_0}{2D} \left(\frac{\rho_1 + \rho_2}{2\pi} \right) \quad (21)$$

$$\Delta f_{\text{res,metal}} = \frac{c_0}{2D} \quad (22)$$

The *half-power bandwidth* $\Delta f_{1/2}$ quantifies the sharpness of the transmission peaks ($\Delta f_{1/2}$ is referred to as the *resolution* at optical frequencies). Defining f_q^+ as the higher frequency at which the transmission has dropped to half its maximum value around the q th resonance, we have

$$\Delta f_{1/2} = 2(f_q^+ - f_{\text{res},q}) \quad (23)$$

f_q^+ is deduced from Eqs. (8) and (14)

$$\sin\left(\frac{2\varphi_q^+ - \rho_1 - \rho_2}{2}\right) = \frac{1 - (R_1 R_2)^{1/2}}{2(R_1 R_2)^{1/4}} \quad (24)$$

with $\varphi_q^+ = (2\pi D/c_0)f_q^+$. Substituting for f_q^+ from Eq. (23) and assuming that the angular variable $(\pi D/c_0)\Delta f_{1/2}$ is very small (which is true for narrow resonances), we obtain

$$\Delta f_{1/2} = \frac{c_0}{\pi D} \frac{1 - (R_1 R_2)^{1/2}}{2(R_1 R_2)^{1/4}} \quad (25)$$

This relation shows that the -3 dB bandwidth of a FPI whose mirrors are *nondispersive* depends only on the mirror reflectivities. Inspection of Eqs. (12) and (25) suggests that it seems possible to design a FPI with a prescribed resonant frequency and resolution. This will be discussed in Section 2.3 for the case of dispersive mirrors.

The frequency selectivity of the resonator is usually characterized by the *Q factor* of the q th longitudinal mode

$$Q_q = \frac{f_{\text{res},q}}{\Delta f_{1/2}} = \frac{(R_1 R_2)^{1/4}}{1 - (R_1 R_2)^{1/2}} \left[q\pi + \frac{\rho_1 + \rho_2}{2} \right] \quad (26)$$

$$Q_{q,\text{metal}} = \frac{f_{\text{res},q,\text{metal}}}{\Delta f_{1/2}} = \frac{\pi D}{\lambda_0/2} \frac{(R_1 R_2)^{1/4}}{1 - (R_1 R_2)^{1/2}} \quad (27)$$

Figure 3 represents the variations of Q for the first three resonances. At microwave frequencies, typical values of Q vary between 10 and 500 for antenna applications and can easily exceed 10^5 for highly resonant structures such as open resonators (Section 3.3). Unfortunately, at optical wavelengths, the Q values are astronomical, primarily because of the smallness of λ_0 (if $D = 1$ m, $n = 1$, $R_1 = R_2 = 99\%$, and $\lambda_0 = 0.6 \mu\text{m}$, then $Q_0 = 3.3 \times 10^8$). To avoid such large numbers and yet provide a measure of the frequency-filtering properties of the cavity, we may introduce a figure of merit known as the *reflectivity finesse* F_R and

Figure 3. Variation of the Q factor of the q th longitudinal mode of a lossless FPI ($D = 3$ mm, $n = 1.95$, $\rho_1 = \rho_2 = \pi$, $\alpha = 0$) as a function of R . Q values are computed from Eq. (8). They are also compared to Eq. (26) for $q = 1$. Key: \times , $q = 0$ [Eq. (8)]; \square , $q = 1$ [Eq. (8)]; \triangle , $q = 2$ [Eq. (8)]; ∇ , $q = 1$ [Eq. (26)]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

defined as

$$F_R = \frac{\Delta f_{\text{res}}}{\Delta f_{1/2}} = \frac{\rho_1 + \rho_2}{2\pi} \frac{\pi(R_1 R_2)^{1/4}}{1 - (R_1 R_2)^{1/2}} \quad (28)$$

For the numbers used above, this yields a more reasonable value ($F_R = 312$). The finesse is a dimensionless quantity depending only on the mirror reflectivities and gives the width of the resonance as a fraction of the spacing between the resonances for an ideal monochromatic source. As it is independent of the free spectral range, this is a measure of the resolving power of the FPI.

2. GEOMETRY, METHODS OF ANALYSIS, PERFORMANCE, AND DESIGN OF MICROWAVE FABRY-PEROT CAVITIES

In the previous section, the basic properties of *optical* FP resonators have been established using a ray model. In particular, it has been shown that the reflection and transmission coefficients of the mirrors play a crucial role in the frequency response of a FPI. For this reason the first part of this section deals exclusively with the analysis and the performance of *periodic* metal grid mirrors that are often used at *microwave* frequencies. Although we do not voluntarily delve deep into the details, this introduction appears essential for a coherent presentation of the characteristics and design rules of *plane-parallel* FP cavities (Sections 2.2 and 2.3). Finally, we investigate briefly the performance of multilayer semitransparent structures (Section 2.4) and compare them to stacked dielectric slabs (Section 2.5). Applications involving all these devices are discussed in Section 3, where we also summarize the properties of *convex* resonators.

2.1. Geometry, Modeling, and Characteristics of Metallic Reflecting Mirrors

For most applications, it is often desirable to obtain a high value of Q in an order as low as possible ($1 - R \ll 1$) and low

absorption losses ($A \ll 1-R$). These requirements cannot be fulfilled simultaneously by thin homogeneous metal layers in the far-infrared and at microwave and (sub) millimeter-wave frequencies. In that frequency range, two kinds of mirrors are mainly used: (1) partially reflective metal grids [or frequency-selective surfaces (FSSs)] and (2) multilayer dielectric mirrors (or Bragg mirrors). The latter are briefly described in Section 2.5.

FSSs have an extremely broad range of applications (e.g., laser technologies, quasioptical components diplexers, interference filters, polarizers, etc., FPIs, dichroic reflectors and subreflectors, high-gain antennas), and a very abundant literature is available on that subject¹ [4].

For the sake of coherence and concision, and for the purpose of this discussion, only the basic principles of FSS operation are reviewed. After a preliminary introduction about the modeling of infinite periodic structures (Section 2.1.1), we will start with devices that can be treated as simple transmission-line elements operating in the long-wavelength regime and can be analyzed using the transmission-line matrix techniques (Section 2.1.2). In particular, this includes one-dimensional (1D) and two-dimensional (2D) inductive and capacitive metal grids. Alternative global electromagnetic approaches are also discussed in Section 2.1.3. The frequency response of such mirrors is finally presented in Sections 2.1.4 and 2.1.5.

2.1.1. Preliminaries. Let us consider a 2D planar periodic infinite array illuminated by a linearly polarized homogeneous plane wave of incident wavevector \vec{k}^i (Fig. 4). The spatial periods are labeled d_x and d_y in x and y directions, respectively. By analogy with Fourier decomposition of periodic signals, it can be demonstrated that the electric field \vec{E}_s scattered by the array is an infinite sum of Floquet space harmonics [5]

$$\vec{E}_s(\vec{r}) = \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} \vec{E}_{s, nm} e^{-j\vec{k}_{nm} \cdot \vec{r}} \quad (29)$$

The wavevector \vec{k}_{nm} of each harmonic can be decomposed in transverse (to z direction) and longitudinal components

$$\vec{k}_{nm} = \vec{k}_{t, nm} + k_{z, nm} \cdot \vec{e}_z$$

With

$$\vec{k}_{t, nm} = k_{x, n} \cdot \vec{e}_x + k_{y, nm} \cdot \vec{e}_y$$

$$k_{x, n} = k_x^i + \frac{2\pi n}{d_x} = -k \sin(\theta) \cos(\varphi) + \frac{2\pi n}{d_x}$$

$$k_{y, nm} = k_y^i + \frac{2\pi m}{d_y} = -k \sin(\theta) \sin(\varphi) + \frac{2\pi m}{d_y}$$

¹For further information, refer also to the articles entitled FREQUENCY-SELECTIVE SURFACES AND PERIODIC STRUCTURES published in that Encyclopedia.

Figure 4. Incident plane wave illuminating a 2D planar periodic array.

And with

$$k_{z, nm} = \sqrt{k^2 - k_{x, n}^2 - k_{y, nm}^2}, \quad \text{if } k^2 > k_{x, n}^2 + k_{y, nm}^2 = k_{t, nm}^2$$

or

$$k_{z, nm} = -j\sqrt{-k^2 + k_{x, n}^2 + k_{y, nm}^2}, \quad \text{if } k^2 < k_{x, n}^2 + k_{y, nm}^2$$

respectively.

The effective direction of propagation (\vec{k}_{nm}) of each mode depends on (1) the order (n, m) of the mode under consideration, (2) the geometry of the unit periodic cell, and (3) the frequency, polarization, and directions (θ, φ) of the incident plane wave.

If $k_{t, nm}^2 > k^2$, then $k_{z, nm}$ is a pure imaginary number; the scattered field is evanescent along (Oz) and is propagating along the plane of the periodic array ($\theta_{nm} = 90^\circ$). It interacts with the metallic patterns and contributes to the *inductive* or *capacitive* behavior of the screen. On the contrary, if $k_{z, nm}$ is real, the wave is propagating outside the structure, and grating lobes may appear, depending on the operating frequency and angles of incidence.

According to Eq. (29), each component of \vec{E}_s can be written as

$$X(\vec{r}) = e^{-j\vec{k}^i \cdot \vec{r}_T} \sum_{n=-\infty}^{+\infty} \sum_{m=-\infty}^{+\infty} X_{nm} e^{-j(n\vec{k}_1 + m\vec{k}_2) \cdot \vec{r}_T} e^{-jk_{z, nm} z} \quad (30)$$

where $\vec{r}_T = x\vec{e}_x + y\vec{e}_y$, $\vec{r} = x\vec{e}_x + y\vec{e}_y + z\vec{e}_z$, $\vec{k}_1 = -(2\pi/A)\vec{e}_z \times \vec{d}_y$, $\vec{k}_2 = (2\pi/A)\vec{e}_z \times \vec{d}_x$; $A = d_x d_y$ is the area of the unit periodic cell. The factor

$$e^{-j\vec{k}^i \cdot \vec{r}_T} = e^{-j[k \sin(\theta) \cos(\varphi)x + k \sin(\theta) \sin(\varphi)y]} \quad (31)$$

is referred to as the *Floquet phase factor*.

To conclude: (1) the field distributions from one periodic cell to another are identical, except to a phase factor; and (2) the computation of the scattering matrix of the infinite array requires to model only *one single unit cell*.

2.1.2. Transmission-Line Matrix Approach. The transmission-line (TL) matrix method is a very convenient

one for the analysis or design of multilayer systems including layers of different dielectric permittivities and planar geometries. It has been described in details elsewhere [e.g., 6]. We present only the fundamental concepts: (1) *ABCD* matrix, (2) modeling of dielectric slabs, and (3) modeling of periodic metallic mirrors.

2.1.2.1. ABCD matrix. We assume that only a single mode is propagating. The various elements of the system affect only the complex amplitude of the reflected and transmitted waves. Let us consider a linear two-port device. The input and output currents and voltages, defined in Fig. 5a, are related by the following matrix equation

$$\begin{bmatrix} V_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} V_2 \\ I_2 \end{bmatrix} \quad (32)$$

The elements of the matrix are called the *ABCD parameters*, and the matrix itself is referred to as the *transmission-line matrix* or *ABCD matrix*.

When considering N cascading elements (Fig. 5b), the convention for the currents and voltages is such that the output current and voltage for a given element are equal to the input current and voltage for the following element. As a result, the *ABCD* matrix of the whole system is simply the product of the individual matrices

$$\begin{bmatrix} V_{in,1} \\ I_{in,1} \end{bmatrix} = \begin{bmatrix} A_1 & B_1 \\ C_1 & D_1 \end{bmatrix} \begin{bmatrix} A_2 & B_2 \\ C_2 & D_2 \end{bmatrix} \begin{bmatrix} A_3 & B_3 \\ C_3 & D_3 \end{bmatrix} \begin{bmatrix} V_{out,3} \\ I_{out,3} \end{bmatrix} \quad (33)$$

The scattering matrix [S] of the two-port junction is easily deduced from the *ABCD* coefficients [6]

$$S_{11} = \frac{A + B/Z_c - CZ_c - D}{A + B/Z_c + CZ_c + D} \quad (34)$$

$$S_{12} = \frac{2(AD - BC)}{A + B/Z_c + CZ_c + D} \quad (35)$$

$$S_{21} = \frac{2}{A + B/Z_c + CZ_c + D} \quad (36)$$

$$S_{22} = \frac{-A + B/Z_c - CZ_c + D}{A + B/Z_c + CZ_c + D} \quad (37)$$

Figure 5. (a) Definition of the *ABCD* parameters of a linear two-port device modeled by the transmission-line matrix approach; (b) cascading transmission-line elements ($N=3$).

where Z_c is the normalization characteristic impedance. Note that the *ABCD* matrix has the following properties: (1) for reciprocal elements, $AD-BC=1$ ($S_{12}=S_{21}$); (2) $A=D$ for symmetric devices.

2.1.2.2. Modeling of Dielectric Slabs. The TL matrix of a dielectric slab of thickness D and refractive index $n = \epsilon_r^{1/2}$ ($\epsilon_r = \epsilon' - j\epsilon''$) is

$$\begin{bmatrix} \cosh \gamma D & Z \sinh \gamma D \\ \frac{1}{Z} \sinh \gamma D & \cosh \gamma D \end{bmatrix} \quad (38)$$

where γ is the propagation constant in the dielectric material; the wave impedance Z differs for the parallel ($||$) and perpendicular (\perp) polarizations

$$\gamma = j \left(\frac{2\pi n}{\lambda_0} \right) \cos \theta \quad (39)$$

$$Z_{||} = \frac{Z_0(\epsilon' - \sin^2 \theta_i)^{1/2}}{\epsilon'} \quad (40)$$

$$Z_{\perp} = \frac{Z_0}{(\epsilon' - \sin^2 \theta_i)^{1/2}} \quad (41)$$

Here, θ_i and θ are the angles of incidence of the plane wave illuminating the slab and the propagation angle relative to normal incidence in this material, respectively. Both angles are related by Snell's law. For low-loss materials, $n \approx (\epsilon')^{1/2} [1 - j(\tan \delta/2)]$, and for lossless materials, Eq. (38) becomes

$$\begin{bmatrix} \cos \beta D & jZ \sin \beta D \\ \frac{j}{Z} \sin \beta D & \cos \beta D \end{bmatrix} \quad (42)$$

$\beta = (2\pi/\lambda_0)(\epsilon' - \sin^2 \theta_i)^{1/2}$ is the imaginary part of γ .

Other TL matrices are given in the literature [e.g. 6,7].

2.1.2.3. Modeling of Periodic Metallic Mirrors. The extremely extensive literature on metallic periodic structures includes many elaborate analytical treatments as well as numerical methods (Section 2.1.3). We restrict ourselves to the simplest cases, referring the reader to specific publications for detailed information [4,5,8-10]. Figure 6a represents typical geometries of 1D and 2D metallic grids (of thickness t and conductivity σ) commonly used in microwave applications involving FP cavities. 1D grids are also called ("strip") gratings; and 2D grids, "meshes". These grids are located at the interface between two semiinfinite dielectric materials $(\epsilon_{r,i}, \tan \delta_i)_{i=1,2}$ and are assumed illuminated by a normally incident ($\theta_i=0$) linearly polarized plane wave \mathbf{E}_i (Fig. 6b). As suggested in the preliminaries, they are typically classified into two categories (*inductive* or *capacitive*) depending on their geometry and the orientation of \mathbf{E}_i . This terminology is

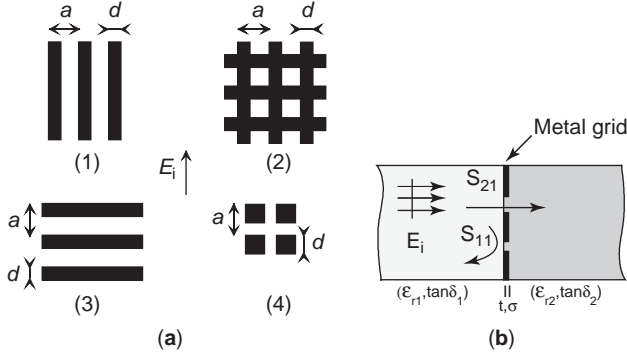

Figure 6. (a) Traditional geometries of metallic periodic grids employed as reflecting mirrors of FP cavities. The grid is illuminated by an incident electric field \mathbf{E}_i . The general terminology qualifying these grids is the following: (1) 1D inductive; (2) 2D inductive; (3) 1D capacitive; (4) 2D capacitive. (b) Metallic grid located at the interface between two semiinfinite dielectric media $(\epsilon_{r,i}, \tan \delta_i)_{i=1,2}$.

justified later on. Their spatial period is labeled a ; d denotes the width of the metallic patterns.

At long wavelengths regime ($a \ll \lambda_0$), only the fundamental mode $(n,m) = (0,0)$ is propagating. The other modes are evanescent (Section 2.1.1) and decay exponentially away from the grid. Consequently such structures reflect and transmit in zero order only in specular directions (no grating lobes appear in the visible region [4,5]). They can be modeled by an impedance Z shunting a transmission line (Fig. 6b) whose $ABCD$ matrix is given by Eq. (43)

$$\begin{bmatrix} 1 & 0 \\ Y & 1 \end{bmatrix} \quad (43)$$

$$Z = \frac{1}{Y} = R_\sigma + jX \quad (44)$$

The real part R_σ accounts for conductor losses inside finite conductivity grids. Ulrich [11] found a good agreement with experience if $(R_\sigma/Z_0) = (a/d)[\pi f(\epsilon_0/\sigma)]^{1/2}$, where f is the operating frequency and $Z_0 = (\mu_0/\epsilon_0)^{1/2}$ is the wave impedance in free space.

The reactance X depends on λ_0 and grid parameters (a,d) . Surveying literature on that subject is well beyond the scope of this article and would require much more space; a well-documented description of equivalent circuits is given elsewhere [e.g., 12, Chap. 9]. Their range of validity is also discussed in Refs. 13 and 14. Here we present only general principles for the purpose of discussion.

Historically, Marcuvitz [8] was probably one of the first authors to propose explicit expressions of Z for inductive (Fig. 6a, grid 1) and capacitive (Fig. 6a, grid 3) strip gratings illuminated by a TM/TE incident plane wave. The reactance of a freestanding ($\epsilon_{r,1} = \epsilon_{r,2} = 1$) zero-thickness inductive grid ($X = X_i$, $Z = Z_i$) has the following form [8]

$$\frac{X_i}{Z_{fs}} = \omega \ln \frac{1}{\sin\left(\frac{\pi d}{2a}\right)} \quad (45)$$

where $\omega = (a/\lambda_0)$ is the normalized frequency and Z_{fs} is the characteristic transmission-line impedance. Z_{fs} is given by Eqs. (40) and (41) for TM and TE polarizations, respectively. At normal incidence ($Z_{fs} = Z_0$), a more accurate expression is available [8]

$$\begin{aligned} \frac{X_i}{Z_0} = \omega \left\{ \ln\left(\frac{1}{\sin(\beta)}\right) \right. \\ \left. + \frac{Q_2 \cos^4(\beta)}{1 + Q_2 \sin^4(\beta)} + \frac{1}{16} \omega^2 (1 - 3 \sin^2(\beta))^2 \cos^4(\beta) \right\} \end{aligned} \quad (46)$$

with $\beta = (\pi d/2a)$ and $Q_2 = (1 - \omega^2)^{-1/2} - 1$. Equation (46) is deduced from an integral formulation in which only the first two diffraction modes are taken into account.

According to Eqs. (34), (36), (43), and (44), the reflection and transmission coefficients of zero-thickness grids are equal to

$$r = S_{11} = \frac{-1}{1 + 2\frac{Z}{Z_{fs}}} \quad (47)$$

$$t = 1 + r = S_{21} = \frac{1}{1 + \frac{2Z}{Z_{fs}}} \quad (48)$$

The power reflectivity $R = |r|^2$ and the phase $\arg(r)$ of the reflection coefficient are represented as a function of ω in Figs. 7a and 7b for a strip grating modeled by Eq. (46). As expected, for a given frequency, R and $\arg(r)$ are decreasing functions of the filling factor d/a . Similarly, they decrease with ω for given values of a and d/a . Keeping in mind these evolutions is important to understand and interpret the influence of the grid geometry on the frequency response of FP cavities (Section 2.2.2).

It is advisable to mention that the equivalent circuits of grids should be applied cautiously [14]. As an illustration, Figs. 8a and 8b quantify the range of validity and the accuracy of Marcuvitz model (46) in the nondiffraction region for a wide range of grid geometries ($a = 1$ mm, $5\% < d/a < 75\%$). For that purpose, two indicators are defined

$$\Delta R = R - R_{\text{FDTD}} \quad (49)$$

$$\Delta \arg(r) = \arg(r) - \arg(r)_{\text{FDTD}} \quad (50)$$

R and R_{FDTD} [resp. $\arg(r)$ and $\arg(r)_{\text{FDTD}}$] are the reflectivities (resp. the phases of r) computed with the TL method and the finite-difference time-domain (FDTD) technique (Section 2.1.4).

Ulrich [11] later developed equivalent models for freestanding 2D grids; at long wavelengths, inductive meshes (Fig. 6a, grid 2) reflect most of the incident power. Their frequency response is thus very similar to that of inductive strip gratings. Nevertheless they present a resonance around $\lambda_0 \approx a$, where they are totally transparent. This single-pole highpass behavior can be represented by an oscillatory equivalent circuit (L,C) whose reactance X_i has

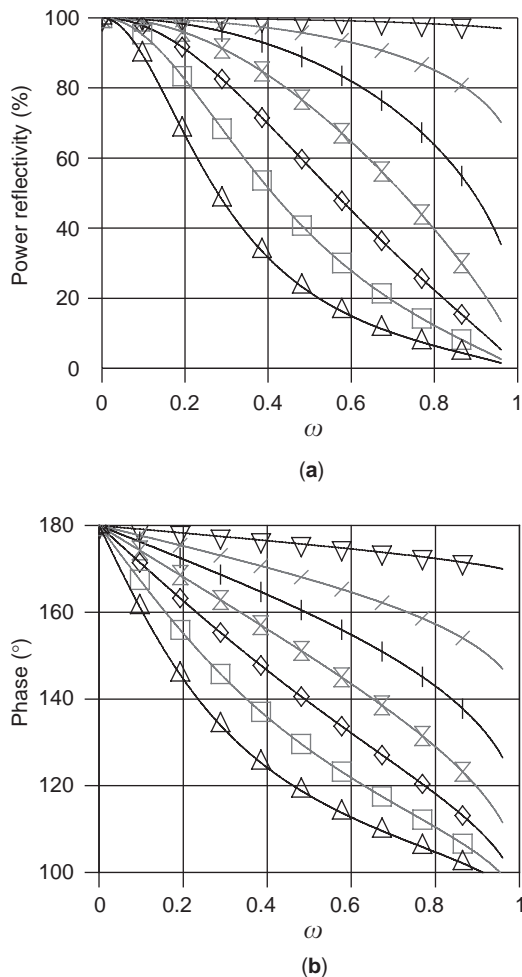

Figure 7. Reflection properties of freestanding 1D inductive strip gratings ($a = 1$ mm) illuminated by a normally incident plane wave. Their geometry is represented in Fig. 6a, grid 1. The grid is assumed lossless ($\sigma = \infty$, $R_s = 0$) and infinitely thin ($t \ll \lambda_0$). Its equivalent reactance is given by Eq. (46). (a) Power reflectivity R ; (b) phase of the reflection coefficient $\arg(r)$. Key: \triangle , $d/a = 11.07\%$; \square , $d/a = 20.7\%$; \diamond , $d/a = 30.7\%$; \times , $d/a = 40.7\%$; $+$, $d/a = 50.7\%$; --- , $d/a = 60.7\%$; ∇ , $d/a = 75.7\%$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the following expression

$$X_i = -\omega_0 \ln \left\{ \frac{1}{\sin\left(\frac{\pi d}{2a}\right)} \right\} \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right)^{-1} \quad (51)$$

$$\omega_0 = 1 - 0.27 \frac{d}{2a} \quad (52)$$

where ω_0 defines the position of the resonance (52) and was obtained by fitting experimental data and calculation [11]. More accurate expressions for X_i and ω_0 have been proposed [14] over a very wide frequency band.

The interested reader will find more details about (1) other equivalent models and (2) the influence of (a) the

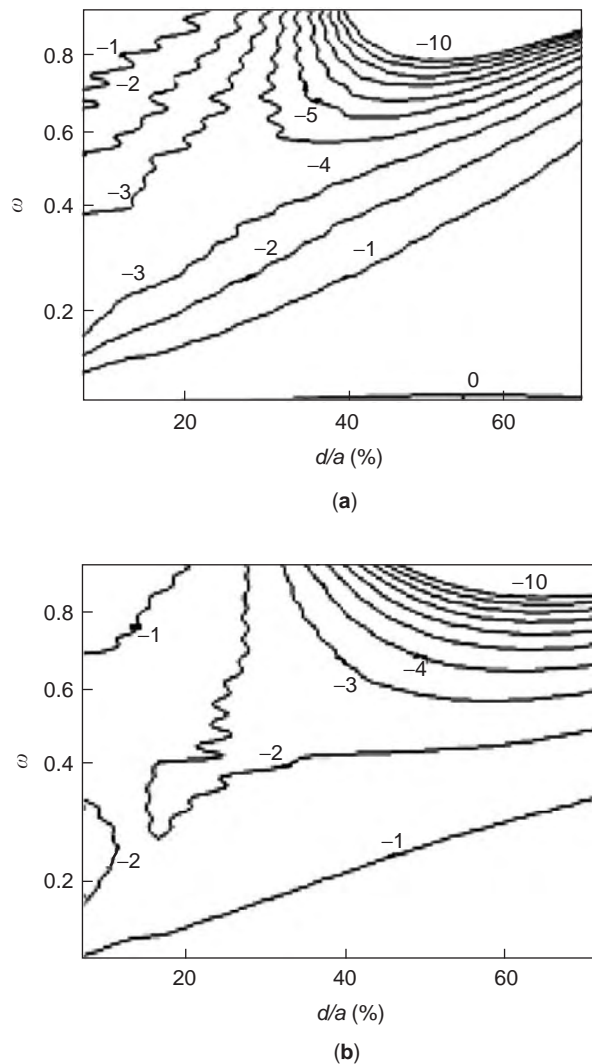

Figure 8. Validity and accuracy of the equivalent circuit [Eq. (46)] proposed by Marcuvitz [8]. ΔR (a) and $\Delta \arg(r)$ (b) are defined by Eqs. (49) and (50), respectively. The equiamplitude contours show that Marcuvitz formulation is accurate ($|\Delta R| < 3\%$ and $|\Delta \arg(r)| < 2^\circ$) in the nondiffraction region ($\omega < 1$) for $d/a < 35\%$, and for any d/a if $\omega < 0.6$. (From Ref. 14; copyright Kluwer Academic/Plenum Publishers, reproduced by permission).

oblique incidence illumination, (b) the dielectric substrates supporting the mirrors, or (c) the finite conductivity and thickness of the grids in the literature [8–10,13–22]. A very interesting discussion about periodic grids is also provided in the bibliographic notes [12, pp. 307–312].

2.1.3. Electromagnetic Modeling. Many modeling approaches have been developed to predict the scattering properties of multilayer periodic structures. They could be applied for the analysis of complex FP cavities coupled to real feeds. The following references might be consulted for further information.

Analytical treatments, including the homogenization technique and the averaged boundary conditions, are explained in detail in Refs. 9, 10, and 23. Generally

sophisticated numerical methods can also be implemented, such as (1) the equivalent multimode network method [24,25]; (2) the modal expansion method in which the diffracted and aperture fields are decomposed in space harmonics and waveguide modes, respectively [16,19,26]; (3) the spectral domain approach [27]; (4) the generalized scattering matrix theory [27,28]; (5) the finite-element method [29,30]; (6) the boundary element method [31]; or (7) the finite-difference techniques applied either in the time domain (FDTD) [32] or in the frequency domain (FDFD) [33].

2.1.4. Frequency Response of 2D Inductive Metal Meshes. The complex reflection coefficient of freestanding perfectly conducting meshes ($\epsilon_{r,i}=1$, $\tan \delta_i=0$, $i=1,2$; $a=1$ mm; $\sigma=\infty$, $t=0$) is represented in Figs. 9a and 9b for a normally incident plane wave and for various filling factors d/a [34]. These curves confirm the highpass filter behavior of inductive meshes. The reflectivity and phase increase with d/a but decrease with the normalized frequency ω . Comparison with the frequency response of 1D grids (Fig. 7) provides evidence of the resonance of 2D grids appearing for $0.9 < \omega < 1$, as suggested by Eq. (52).

2.1.5. Complementary and capacitive grids. Impact on FP resonators. The grids discussed so far correspond to the commonly used geometry of semitransparent mirrors of microwave FP cavities. They are oriented parallel to the direction of the incident electric field in order to obtain a high reflectivity (for $a \ll \lambda_0$), and thus high- Q resonators.

According to the Babinet principle, if we interchange the perfectly conducting and empty parts of infinitely thin ($t=0$) grids and rotate by 90° the polarization direction of the incident plane wave, then the reflection and transmission coefficients of the original and *complementary* grids, labeled $\{r,t\}$ and $\{r_c,t_c\}$, respectively are related as follows [11]

$$\begin{aligned} t + t_c &= 1 \\ t_c &= -r \\ r_c &= -t \end{aligned} \quad (53)$$

The shunt impedance Z_c of the complementary grid is deduced from Eqs. (47), (48), and (53)

$$\frac{Z_c}{Z_{fs}} = \frac{Z_{fs}}{4Z_i} \quad (54)$$

As Z_c is inversely proportional to frequency, these structures are called *capacitive grids*. Their reflection coefficient, computed with the FDTD technique, is represented in Figs. 10a and 10b for various values of d/a . As expected, their reflectivity naturally increases with frequency (dual behavior of inductive grids).

Transmission line models of capacitive grids have been also proposed by several authors [8, pp. 218–219, 280–284] [11,15,18–20,102]. Their accuracy and range of validity have been defined recently [103] over the whole visible region ($\lambda_0 > a$) by comparison with the FDTD results given in Figs. 10a and 10b (the methodology implemented is

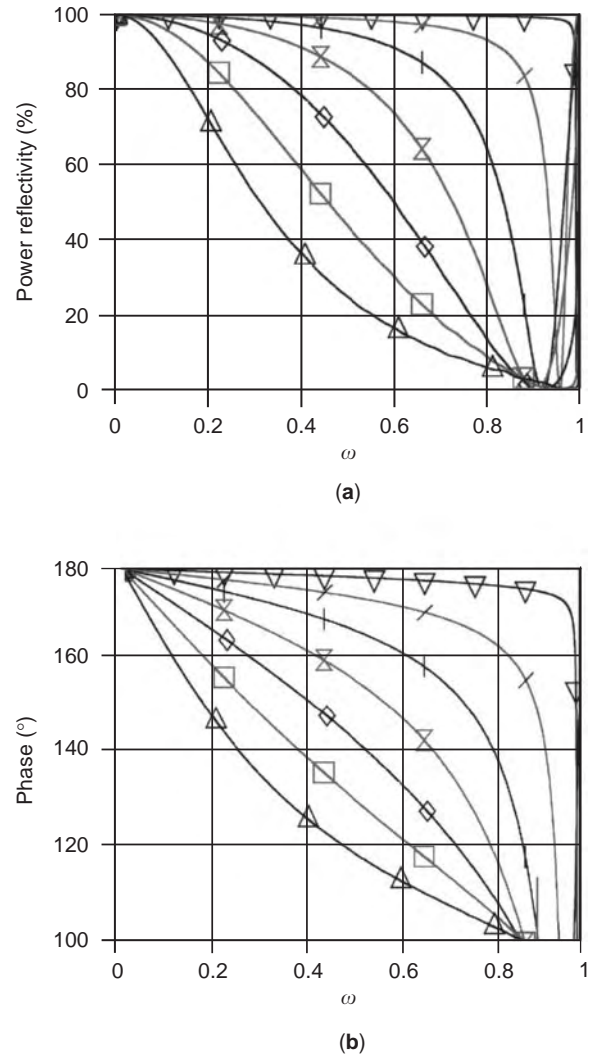

Figure 9. Theoretical frequency response of perfectly conducting 2D inductive meshes computed with the FDTD method: (a) power reflectivity R ; (b) phase of the reflection coefficient $\arg(r)$. The geometry of the mesh is represented in Fig. 6a, grid 2. Key: \triangle , $d/a=11.07\%$; \square , $d/a=20.7\%$; \diamond , $d/a=30.7\%$; \times , $d/a=40.7\%$; $+$, $d/a=50.7\%$; $-$, $d/a=60.7\%$; ∇ , $d/a=72.7\%$. (From Ref. 34; copyright Kluwer Academic/Plenum Publishers, reproduced by permission.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

similar to the one associated with Eqs. (49) and (50)). By analogy with inductive meshes [14], very accurate and ultra-wideband explicit formulations are also introduced in [103] for the wave reactances.

To obtain a high- Q cavity, both capacitive grids should be highly reflecting [Eq. (26)]. This implies

- $\omega > 0.85$ and $d/a \approx 1$ (Fig. 10a).
- $-160^\circ < \arg(r) < -180^\circ$ (Fig. 10b).
- The first resonant frequency is defined for $q=1$ [Eq. (12)].

Consequently the gap D is very thin [35], and such cavities are at least 10 times more *compact* than resonators with inductive grids. This peculiar property is interesting for

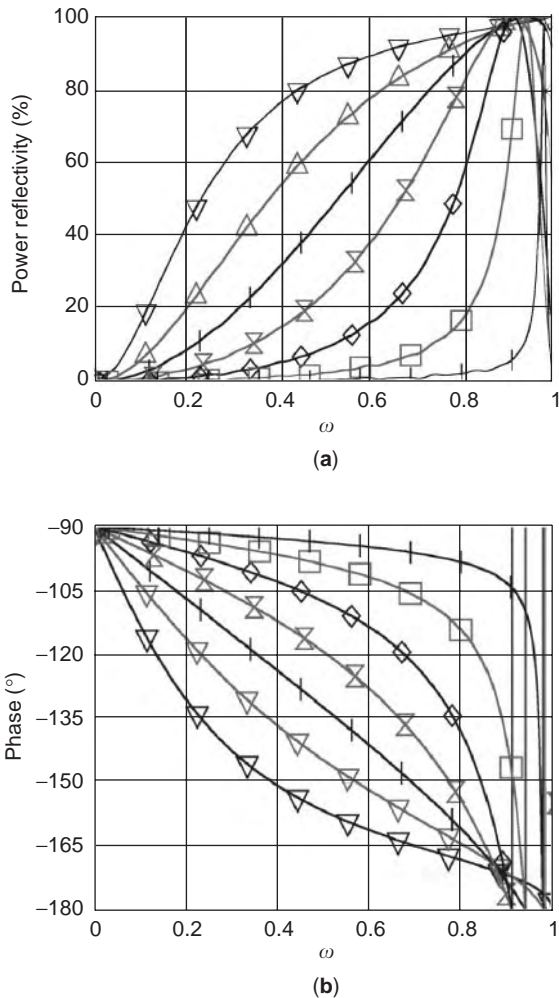

Figure 10. Theoretical frequency response of perfectly conducting 2D capacitive meshes computed with the FDTD method: (a) power reflectivity R ; (b) phase of the reflection coefficient $\arg(r)$. The geometry of the mesh is represented in Fig. 6a, grid 4. Key: --- , $d/a = 30.7\%$; \square , $d/a = 40.7\%$; \diamond , $d/a = 50.7\%$; \times , $d/a = 60.7\%$; --- , $d/a = 70.7\%$; \triangle , $d/a = 80.7\%$; ∇ , $d/a = 90.7\%$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the design of liquid crystal tunable frequency filters (Section 3.1).

2.2. Performance of Microwave FP Resonators

2.2.1. Modeling. The modeling techniques discussed in Sections 2.1.2. and 2.1.3 can be directly applied to study FP resonators of infinite size in extent. As an example, Figs. 11 and 12 represent the equivalent circuit and the FDTD computational domain of a FP cavity analyzed with the TL matrix method and with the FDTD technique [36], respectively. In Fig. 11, the mirrors are identical and modeled by a shunt impedance $Z_m = 1/Y_m$. They are fabricated on both faces of a dielectric slab ($\epsilon_r, \tan \delta$) of thickness D , as depicted in Fig. 1. The transmission coefficient S_{21} of the cavity excited under normal incidence is deduced from

Figure 11. Transmission-line model of a symmetric FP cavity. The semitransparent mirrors are modeled by an impedance Z_m shunting a transmission line whose characteristic impedance and propagation constant depend on the thickness D of the substrate and its electrical properties ($\epsilon_r, \tan \delta$) [13].

Eqs. (33), (36), (38) and (43)

S_{21}

$$= \frac{2}{2(1+Z_0 Y_m) \cosh(\gamma D) + \left(\frac{2Z_0 Y_m}{n} + \frac{1}{n} + n + \frac{(Z_0 Y_m)^2}{n} \right) \sinh(\gamma D)} \quad (55)$$

where $n = \epsilon_r^{1/2}$ is the refractive index of the substrate.

2.2.2. Frequency Response and Parametric Study. The FDTD frequency response of a FP resonator is given in Fig. 13 for the first five transmission peaks ($q = 0, \dots, 4$). Comparison with the transmission coefficient of an ideal FPI [Eq. (8)] demonstrates that

- The theoretical FDTD resonant frequencies are systematically lower than those predicted by Eq. (8); besides, this discrepancy increases with frequency. These particularities are due to the phase of an

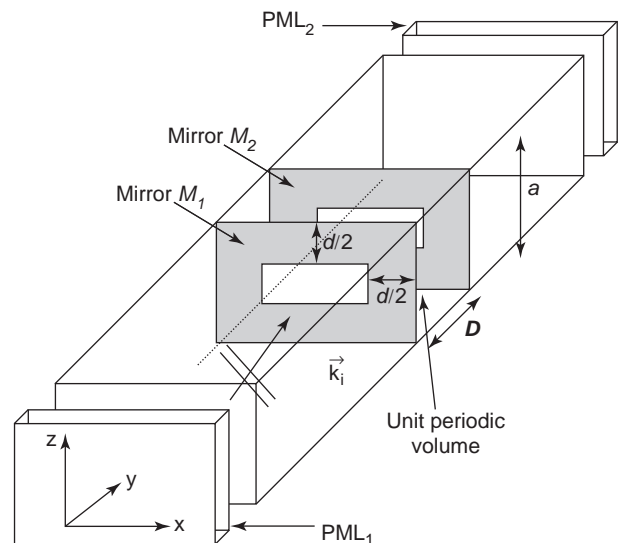

Figure 12. FDTD computational domain for the modeling of plane-parallel FP cavities. Periodic boundary conditions (PBC) are applied in the transverse directions, and perfectly matched layers (PML) are oriented in the direction of propagation (y axis) of the incident plane wave.

Figure 13. Comparison between the frequency responses of an ideal FPI (Section 1.2) and a FP cavity ($\epsilon_r = 3.80$, $\tan \delta = 10^{-4}$, $D = 5.106$ mm) whose inductive mesh mirrors are identical ($a = 1100$ μm , $d/a = 50\%$, $\sigma = \infty$, $t = 0$). Key: \square , Ideal FPI; $-$, FP cavity with mesh mirrors (FDTD). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

inductive grid, which is always smaller than 180° and decreases with frequency (Fig. 9b).

- The fringe contrast decreases with the interference order q , while it remains constant for an ideal FPI. This comes from the frequency variation of the mirror reflectivity (Fig. 9a).

This example demonstrates unambiguously that the *dispersive* characteristics of the reflectors must be taken into account to accurately predict the scattering parameters of a FP cavity with grid mirrors.

Let us now consider the influence of the mesh parameters (a, d) on the frequency response [resonant frequency f_{res} , -3 dB bandwidth (BW) and insertion losses (IL)] of fused-quartz half-wavelength cavities ($\epsilon_r = 3.80$, $D \approx \lambda_0/2\epsilon_r^{1/2}$). This material is ideal as a dielectric holder because of its low loss ($\tan \delta < 5 \times 10^{-4}$ at 60 GHz) and good temperature stability, particularly for the design of open resonators (Section 3.3) and oscillators (Section 3.4) with semitransparent mirrors. The samples studied here (Fig. 14) have been fabricated using a precise liftoff process (± 2 μm) of sputtered-copper film ($t = 1.2$ μm , $\sigma_{\text{Cu}} = 5.8 \times 10^7$ S/m) with a thin chromium adhesion layer ($t = 0.1$ μm , $\sigma_{\text{Cr}} = 7.5 \times 10^6$ S/m). Two cases are considered [37]: symmetric ($R_1 = R_2 = R$) and asymmetric ($R_1 \neq R_2$) resonators.

2.2.2.1. Symmetric Resonators. Figures 15a and 15b show the theoretical and experimental variations of f_{res} and BW as a function of (a, d) for two sets of cavities ($D = 1.263 \pm 0.003$ mm): the mirrors of set 1 have a constant spatial period ($a = 0.6$ mm) and a variable filling factor d/a ($17.7\% < d/a < 46.2\%$); for set 2, $d/a = 50\%$ and a varies between 0.5 and 2.1 mm with a constant step equal to 0.2 mm; a scale indicating the value of the mirror reflectivity R of each sample is also inserted in Fig. 15a. The transmission coefficients S_{21} have been computed with the FDTD and TL methods (Section 2.2.1). They were measured in far field under normal incidence between two V-band standard horn

Figure 14. Fused-quartz FP resonator operating in the 60-GHz band. The highly reflecting mirrors are 2D sputtered-copper meshes ($\epsilon_r = 3.80$, $D = 5.105$ mm \pm 0.003 mm, diameter = 50 mm, $a = 1500$ $\mu\text{m} \pm 3$ μm , $d/a = 50\%$). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

antennas. As expected [relations (12) and (25)], f_{res} (BW) increases (resp. decreases) with R . The theoretical resonant frequencies computed with the FDTD and TL [19] methods are in very good agreement; this is due to the range of validity of the equivalent reactance of the mesh (Ref. 14 and Section 2.1.2, above). Moreover, the discrepancy between the values of f_{res} measured and computed by FDTD is lower than 600 MHz (Fig. 15a). The larger deviation observed for the bandwidth (Fig. 15b) comes from the diffraction losses (substrates of finite diameter) that are not taken into account in the modeling. These losses can be reduced significantly using focusing planoconvex cavities (Section 3.2, below and Ref. 36, Table 4). Finally, Fig. 15c shows that the insertion losses (IL) due to the finite conductivity of the meshes increase exponentially with R . Comparison with the IL due only to the dielectric loss ($\sigma = \infty$, $\tan \delta = 10^{-4}$) demonstrates that metal losses contribute, for the most part, to the IL of millimeter-wave FP cavities. In particular, this explains the moderate radiation efficiencies of FP-based Gaussian beam antennas (Section 3.2.1).

2.2.2.2. Asymmetric Resonators. Relations (12) and (25) suggest that f_{res} and BW of asymmetric devices can be adjusted by a convenient choice of the complex reflection coefficient of each mirror, but at the price of a slight increase of their transmission loss [$R_1 \neq R_2$, relation (14)]. FDTD simulations are used to determine accurately the variations of f_{res} , BW, and IL with the width d_2 of the metal strips of M_2 . The grid parameters of M_1 remain unchanged ($a_1 = 1.3$ mm, $d_1/a_1 = 50.7\%$). Figure 16a represents the theoretical transmission coefficients of several cavities ($D = 1.259$ mm, $\sigma_{\text{Cu}} = 5.8 \times 10^7$ S/m, $t = 1.2$ μm) for which

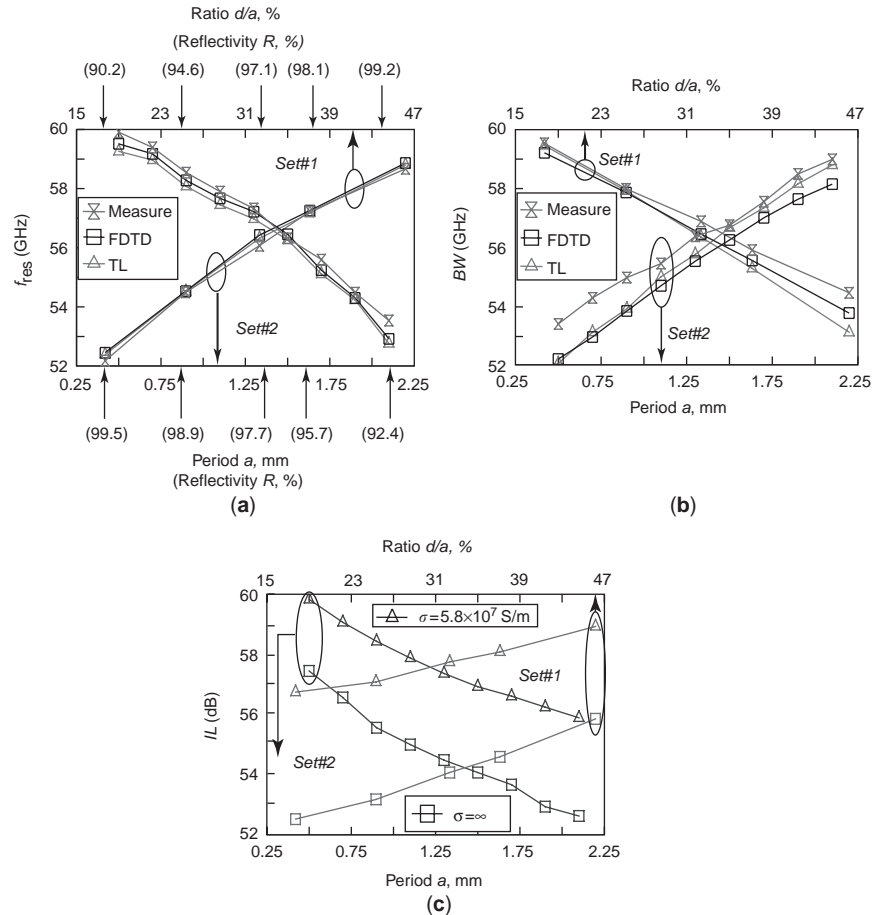

Figure 15. Variations of (a) the resonant frequency f_{res} ; (b) the half-power bandwidth BW, and (c) the insertion losses IL, as a function of the mesh parameters of symmetric resonators. Metal meshes are perfectly conducting ($\sigma = \infty$) or in copper ($\sigma = \sigma_{Cu}$). (From Ref. 37; copyright John Wiley & Sons, Inc., reproduced by permission.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

$32.7\% < d_2/a_2 < 74.7\%$ ($a_2 = a_1 = 1.3$ mm, $87.10\% < R_2 < 99.95\%$), and Fig. 16b shows the resulting change in f_{res} , BW, and IL as a function of R_2 . As expected, IL is minimum ($IL_{min} = 1.3$ dB) for $R_2 = R_1 = 97.8\%$ ($d_2/a_2 = d_1/a_1 = 50.7\%$) and increases very rapidly for $R_2 > R_1$. Besides, we notice that f_{res} can be tuned between 55.4 and 57.6 GHz if we tolerate an increase in IL of 1 dB above IL_{min} . Controlling the complex reflection coefficient of a mirror then constitutes a possible solution for the design of tunable FP devices using active grids or MEMS (micro-electromechanical system) technologies (Section 3.1).

2.3. Design of Microwave FP Resonators

In the previous section, we have quantified the influence of the mirror properties on the performance of FP cavities. However, from a design perspective, the *inverse* problem should be solved.

For that purpose, *approximate* or *purely numerical* synthesis methods can be implemented. In the first case, the simplest way to describe the frequency response of the device is to use the theory of multilayer structures in which each individual layer is described by its own scattering matrix (Section 2.1.2 above). This approach is typically applied to design FP cavities operating at a given frequency; it basically consists in graphically solving

Eq. (13) [38]. From the resonance condition (11), we have

$$\frac{\rho_1 + \rho_2}{2} = k_0 D - q\pi, \quad \text{with} \quad k_0 = \frac{2\pi}{\lambda_0} \quad (56)$$

When plotted as a function of frequency, the right-hand side of this equation is a set of straight lines, representing the ray pathlength with a slope depending on D (and eventually on θ_i and ϵ_r). These are referred to as *phase lines*. The left-hand side is the average reflection phase of both mirrors. Equation (56) is satisfied when the phase lines intersect this curve (Fig. 17a); transmission peaks appear then in the frequency response of the structure. These plots are useful guides to systematically adjust the resonant frequency of cascaded layers, by appropriate adjustment of the dielectric spacer parameters and $[\rho_1(f) + \rho_2(f)]/2$.

Nevertheless, this technique does not account for mutual coupling and evanescent waves, and fails when the mirror spacing is smaller than half the spatial period of each grid [9] [which is dramatically the case for resonators with capacitive strip gratings (Section 3.1)]. Moreover, the choice of grid geometries is necessarily limited because their frequency characteristics must be known a priori [Eq. (56)]. These are the reasons why global electromagnetic

Figure 16. (a) Influence of the reflectivity R_2 of mirror M_2 on the transmission coefficient S_{21} of asymmetric resonators ($a_1 = 1.3$ mm, $d_1/a_1 = 50.7\%$); (b) variations of the resonant frequency f_{res} , the half-power bandwidth BW , and the insertion losses IL , as a function of R_2 ($a_1 = 1.3$ mm, $d_1/a_1 = 50.7\%$). (From Ref. 37; copyright John Wiley & Sons, Inc., reproduced by permission.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

analysis tools combined with optimization procedures, such as simulated annealing or genetic algorithms [39], may be required for accurate and innovative designs. A simplified example of FDTD-based methodology is schematized in Fig. 17b, in which a very wide range of grid geometries is explored [37]. In this work, it has been shown in particular that an infinite number of 2D metal meshes can be used to design a symmetric resonator with prescribed values of f_{res} and BW . However, all the solutions are not equivalent in terms of insertion losses.

2.4. Multilayer FP Resonators

Multilayer FP cavities are of particular interest for the design of interference filters (Section 3.1) or frequency beam scanning antennas (Section 3.2.2). Their frequency response can be computed using the $ABCD$ formalism (Section 2.1.2) or full-wave methods (Section 2.1.3). To minimize the number of degrees of freedom and for the purpose of discussion, we assume that the device comprises N identical 2D meshes separated by air slabs ($\epsilon_r = 1$) of thickness D (Fig. 18a). Each mesh is characterized by its complex reflection and transmission coefficients $\{r_1, t_1\}$.

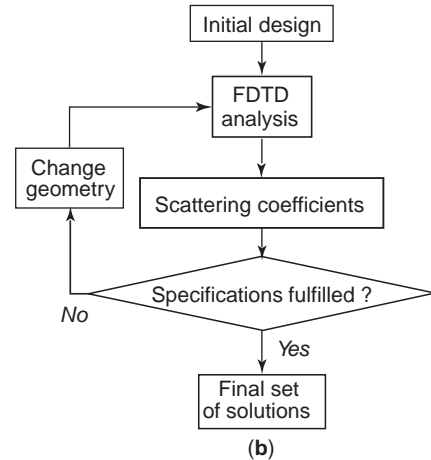

Figure 17. (a) Graphical procedure for the approximate design of FP cavities whose mirrors are dispersive. The resonant frequencies are given by the intersection points of the phase lines ($k_0 D - q\pi$) with the average reflection phase of both mirrors (\square). These points (\bullet) are in very good agreement with the transmission peaks of the FDTD frequency response of the cavity (\triangle) ($a = 1$ mm, $d/a = 11.4\%$, $D = 2.52$ mm, $\epsilon_r = 1$). (b) FDTD-based synthesis algorithm. (From Ref. 37; copyright John Wiley & Sons, Inc., reproduced by permission.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Under normal incidence, it can be easily shown that the scattering parameters $\{r_N, t_N\}$ of the whole structure are given by the following recursive relations

$$t_N = \frac{t_{N-1} t_1 \exp(-jk_0 D)}{1 - r_{N-1} r_1 \exp(-j2k_0 D)} \quad (57)$$

$$r_N = r_{N-1} + \frac{t_{N-1}^2 r_1 \exp(-j2(N-1)k_0 D)}{1 - r_{N-1} r_1 \exp(-j2k_0 D)} \quad (58)$$

In the forbidden band, the minimum level of transmission is equal to

$$|t_N|_{\min} = \frac{2\{(1 - |r_1|)/(1 + |r_1|)\}^{N/2}}{1 + \{(1 - |r_1|)/(1 + |r_1|)\}^{N/2}} \quad (59)$$

Typical transmission coefficients are represented in Fig. 18b for $N \leq 3$. In each transmission band (1) the number of propagation peaks equals $N-1$ and (2) the intersection points between $|t_1|$ and $|t_{N-1}|$ correspond to the case $|t_N|=1$. Further details can be found in general textbooks dealing with infinite periodic structures and electromagnetic bandgap (EBG) materials.

2.5. Dielectric FP Resonators

Highly directive FP-based antennas (Section 3.2.1) may be obtained from resonators comprising N stacked identical freestanding dielectric slabs (Fig. 18c) behaving as Bragg mirrors ($D_s = \lambda_0/4\epsilon_r^{1/2}$, $D_a = \lambda_0/4$). Their transmission coefficient is represented in Fig. 18d for alumina slabs ($N \leq 3$). As expected, the forbidden band is all the deeper as the number of layers and the dielectric contrast (1: ϵ_r) increase. High-performance reflecting mirrors based on this concept are very popular at optical wavelengths. Comparison between Figs. 18b and 18d reveals the dual behavior of multilayer metallic and dielectric mirrors (the positions of the forbidden bands and passbands are inverted). Metal meshes usually lead to lower profile structures and are compatible with the integration of active circuits. Nevertheless, as frequency increases, ohmic losses of partially reflective mirrors may significantly reduce the Q factor of the resonator (Section 2.2.2) and justify the use of Bragg mirrors, especially for high-gain antennas (Section 3.2.1).

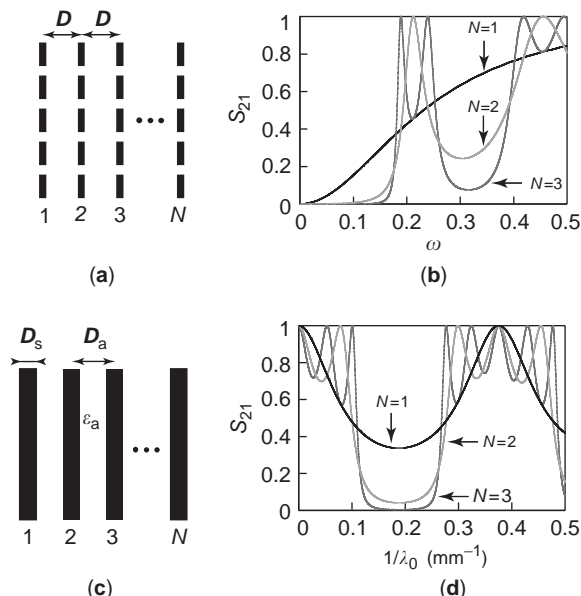

Figure 18. (a) Generalized FP resonator comprising N identical freestanding partially reflective mirrors; (b) theoretical transmission coefficients for $N \leq 3$ (inductive mesh, [Fig. 6a, grid 2], $a = 1$ mm, $d/a = 5.40\%$, $D = 1.8$ mm, $\epsilon_r = 1$); (c) generalized FP resonator comprising N cascaded identical dielectric slabs (D_s, ϵ_r) separated by air gaps (D_a, ϵ_a); (d) theoretical transmission coefficients of a Bragg mirror for $N \leq 3$. The alumina and air sections have a quarter-wave electrical thickness at 56.8 GHz ($D_s = 0.42$ mm, $D_a = 1.32$ mm, $\epsilon_r = 9.87$, $\epsilon_a = 1$). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

3. APPLICATIONS OF FABRY-PEROT CAVITIES AT MICROWAVE FREQUENCIES

FP cavities are employed in many microwave applications, such as quasioptical circuits and systems [filters, diplexers (Section 3.1), oscillators and power combiners (Section 3.4)], directive, multibeam, and beam scanning antennas (Section 3.2), or dielectric measurement systems (Section 3.3). A series of three review articles [40–42] reviews the concepts of FP resonators and describes some possible applications from microwave to infrared wavelengths (open resonators for characterization of gases, or liquid, solid, anisotropic and magnetic materials; laser output couplers; plasma diagnostics, etc.).

3.1. Frequency Filters and Diplexers

FP resonators are widely used not only as bandpass frequency filters [11,13,18,19,36–38], but also as diplexers [43,44]. The simple plane-parallel devices described in Section 2 suffer from two disadvantages:

1. It seems impossible to design filters with both broad bandwidth and high attenuation in the stopband, since these parameters are not independent [Eqs. (15) and (25)]. However alternative ways have been proposed in the literature, [e.g., 45–47]; these filters are constructed either from more than two grids (Section 2.4), or from capacitive grid arrays (Section 2.1.5) deposited on a dielectric substrate. Note that any interference filter may be discussed in terms of only two effective interfaces (Section 2.1.2), which may themselves consist of many interfaces (Sections 2.4 and 2.5) [48].
2. The second drawback is the transmission level at higher orders. Here again, the use of capacitive reflectors might solve this problem [11] because the bandwidth of capacitive FP filters decreases with frequency (Section 2.1.5); higher modes no longer lie at harmonics of the fundamental mode.

The rapid variation of bandwidth [roughly as f^3 according to Eqs. (25), (45), and (47)] limits performance when scanning over a wide range of frequencies. One solution might to use a hybrid FP, with one inductive mesh and one capacitive mesh [11]. This kind of configuration has also been investigated by Lockyer et al. [49] for the design of low-profile filters (Fig. 19a) presenting two narrow highly stable passbands separated by a distinct null (Fig. 19b).

Reflecting mirrors may also be built from photonic crystals [50]. In that case, they consist of multilayer metallodielectric 1D, 2D or 3D periodic structures (see Sections 2.4 and 2.5 for the 1D and 2D cases). Conceptually, the gap between the (composite) mirrors can be interpreted as the creation of a defect inside the periodicity of the electromagnetic crystal. An example of devices is schematized in Fig. 19c, where each mirror is constructed from a square lattice of lossy dielectric rods [51].

McCleary et al. [52] has reported improved filter performance by slot coupling to higher-order Gaussian beam modes [53] in concave resonators; these results include

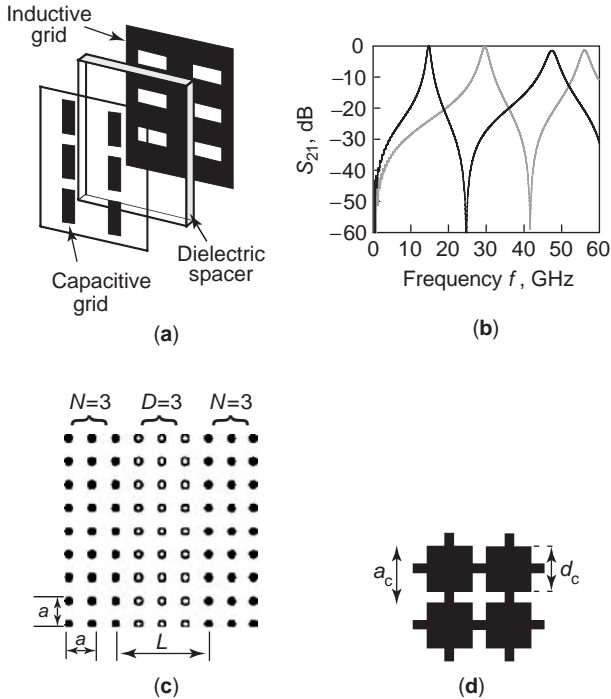

Figure 19. (a) FP filter constructed from complementary frequency-selective surfaces (CP FSS) [49]; (b) theoretical transmission coefficient of CP FSS FP filters for two different lengths of dipoles; (c) top view of a FP resonator operating in the 4–8-GHz band. The mirrors, of adjustable reflectivity and thickness, are built from square lattice ($a = 2.08$ cm) 2D photonic crystals constituting N layers of lossy dielectric rods of radius 3.175 mm ($11 < \epsilon_r < 13$, $\tan \delta \approx 0.004$). They are separated by an airgap of varying thickness L (from Ref. 51; copyright 2003 IEEE, reproduced by permission); (d) mirror geometry of tunable nematic liquid crystal FP filters operating at 27 GHz [$a_c = 5$ mm, $d_c/a_c = 98.75\%$, $D = 110$ μm ($\approx \lambda_0/100$)] [54].

mechanically tunable (20%) X-band filters with insertion losses less than 1 dB and unloaded Q values ranging from 1000 to 7000. Electronically tunable filters can also be built from liquid crystal (LC) materials [54–56], Barium strontium titanate (BSTO) ferroelectric films [57], or active grids [58]. Note that an efficient low-voltage driving (< 10 V) of microwave LC-FPI requires ultrathin substrates ($D \ll \lambda/2$) [35] to ensure covering of the whole anisotropic spectrum of nematic crystals [54]. As suggested in Section 2.1.5, this can be achieved using interconnected capacitive grids serving simultaneously as reflecting mirrors and driving electrodes (Fig. 19d). Tunable filters based on MEMS technologies have been reported at optical wavelengths [59], but not yet at microwave frequencies due to the large-scale technological challenges.

3.2. Fabry-Perot-Based Antennas

3.2.1. Highly Directive Antennas

3.2.1.1. Spatial Filtering. Partially reflective surfaces (PRSs) have been studied [60–62] for the design of spatial filters. To demonstrate the focusing ability of PRS, let us

consider an ideal isotropic electromagnetic source S located on a perfect electromagnetic screen, inside a FP cavity of thickness D (Fig. 20a). The reflection coefficient of the output mirror is labeled $r = R^{1/2} \exp(j\rho)$. The sum of all outgoing waves yields the following expression for the far-field power pattern [61]

$$P(\theta) = \frac{1 - R(\theta)}{1 + R(\theta) - 2(R(\theta))^{1/2} \cos\left(\rho(\theta) - \pi - \frac{4\pi D}{\lambda_0} \cos(\theta)\right)} \quad (60)$$

The variations of $|P(\theta)|$ are represented in Fig. 20b as a function of θ and $R_0 = R(\theta = 0^\circ)$ at resonance

$$f_{r,q} = \frac{c_0}{4D} \left(2q - 1 + \frac{\rho(0)}{\pi} \right) \quad (61)$$

with $q \leq 0$ (or 1) for capacitive (or inductive) grids. Figure 20b shows that

- $|P(\theta)|$ decreases with θ for a given value of R_0 .
- The maximum directivity of the antenna (for $\theta = 0^\circ$) increases with the broadside reflectivity R_0 .

This simple model also enables us to establish an analytical relation between *frequency* and *angular* selectivities. For highly reflecting mirrors ($R \approx 1$), simple algebra shows that the half-power beamwidth $\theta_{3 \text{ dB}}$ is minimum for the fundamental mode ($q = 0$) and is written at resonance [63] as follows

$$\theta_{3 \text{ dB}} \approx 2 \arccos \left(1 - \frac{1}{2Q_0} \right) \approx \frac{2}{Q_0^{1/2}} \quad (62)$$

As a consequence, highly directive FP-based antennas are necessarily narrowband. For real applications, the exact value of $\theta_{3 \text{ dB}}$ can be obtained from the dispersion diagram of Bloch modes [64].

3.2.1.2. Radiating Structures and Applications. PRS and FP resonators are specific electromagnetic bandgap (EBG) materials [50,65]. With the exception of antennas based on ultrarefractive metamaterials [66], most of them can be considered as photonic crystals operating in a defect mode [67] (e.g., Fig. 19c).

In that context, a very wide variety of geometries of primary feeds and focusing devices has been proposed. To excite the structure, we can use waveguide apertures [61,62,68], horn antennas [60,68], dipole and monopole antennas [63,69], or printed patches and arrays fed by a coaxial probe, a microstrip transmission line, or coupling slots [70–73]. As a first approximation, for PRS mirrors, the thickness D of the cavity is chosen to maximize the broadside directivity (Fig. 20b) at the operating frequency. Nevertheless, we should keep in mind that when the cavity is excited by a real primary source, a slight difference ($< 1\%$) appears between the frequency maximizing the antenna directivity and the quasioptical resonant frequency of the FP cavity alone.

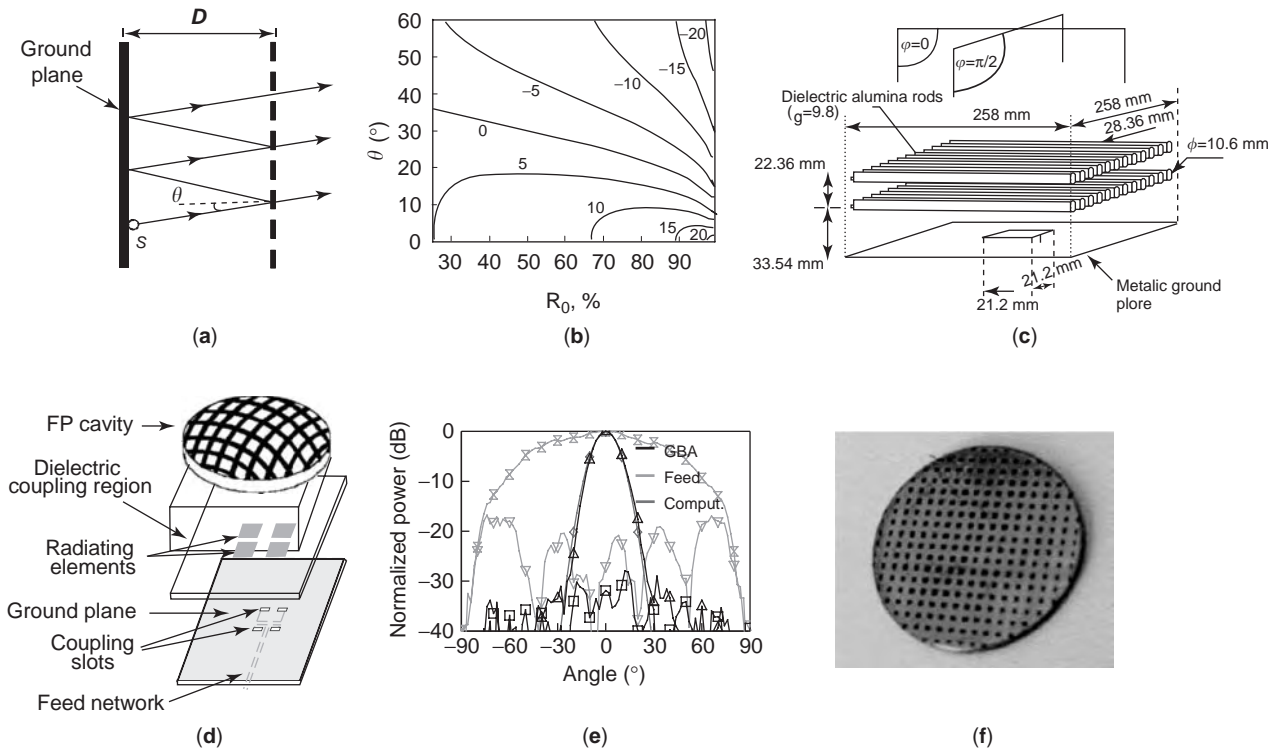

Figure 20. (a) Multiple reflections between a ground plane and a semi-transparent sheet; (b) variation of the antenna directivity (equimagnitude contours in dB) as a function of the broadside reflectivity R_0 of the output mirror and elevation angle θ (inductive grid, $q = 1$, $D = 2.5$ mm); (c) directive antenna using a Bragg mirror (4.75 GHz), where each reflecting surface of the superstrate is built from one layer of alumina rods (from Ref. 73; copyright 2003 IEEE, reproduced by permission); (d) general architecture of multilayer Gaussian beam antennas (GBAs): a planoconvex FP cavity with periodic mirrors is fed by a printed primary radiator through a dielectric coupling region. (from Ref. 72; copyright John Wiley & Sons, Inc., reproduced by permission); (e) measured and computed radiation patterns of a GBA in H plane at 56.6 GHz [the primary source is a patch antenna printed on a 150 μm -fused-quartz substrate; the mirrors of the quartz ($\epsilon_r = 3.80$) FP resonator are inductive metal meshes ($a = 600 \mu\text{m}$, $d/a = 46\%$; see grid 2 in Fig. 6a); the thickness and the radius of curvature of the cavity equal 1.310 mm and 2595 mm, respectively]; (f) FP resonator with nonuniform mesh operating in V band.

The focusing elements can be classified in three main categories:

- A single PRS [61,62,74,75] (in that case, we may consider that the source is located *in the middle* of a FP cavity defined by the actual PRS and its electrical image with respect to the ground plane (Fig. 20a)).
- Two cascaded PRS arranged in a plane-parallel [70,76,77] or planoconvex [68,71,72] configuration—by analogy with open resonators (Section 3.3), the planoconvex structure generates a symmetric Gaussian beam and minimizes the sidelobe level.
- Reflecting mirrors constructed from multilayer 1D, 2D or 3D dielectric [63,69,73,78] (e.g., alumina plates or rods) or metallic (e.g., crossed wires, strip gratings) [70] EBG materials, as emphasized in Sections 2.4, 2.5 and 3.1.

This antenna technology usually leads to low-profile high-gain (≤ 32 dB today) radiating structures. Despite

their narrow bandwidth ($< 0.5\%$ for 30 dB gain), they might be competitive for (1) applications requiring medium-gain antennas (< 25 dB), (2) fixed wireless access [e.g., local multipoint distribution services (LMDS)] and satellite reception [76], (3) high-data-rate indoor 60-GHz WLANs [68,77], or (4) interleaved feeds of focal array-fed reflector (FAFR) antennas that simultaneously need an efficient illumination of the reflector and a low rollover between the beams [79].

Two examples of directive antennas based on the FP concept are represented in Figs. 20c and 20d. In both cases, the distance separating the printed source from the input mirror of the superstrate is near $\lambda/2$; this opens a defect mode inside the forbidden band of the periodic structure [72, Fig. 4; 73, Fig. 10]. The input impedance of the antenna and its radiation performance (gain, efficiency, co- and cross-polarization levels) have been investigated as a function of the Q factor of the FP cavity, the topology of the feed, and the mutual coupling between the feed and the resonator [71,72,80]. Figure 20e compares the radiation patterns of the primary source alone and the

FP-based antenna. It clearly demonstrates the focusing effect induced by the cavity, thereby confirming the ability of a FPI to spread the electromagnetic energy over its whole surface (i.e., to increase significantly the directivity of an elementary feed). Design rules have been proposed [71,78] for Gaussian beam antennas and EBG resonator antennas, respectively. Finally, let us mention the possibility to further reduce the total height of the antenna by a factor two by virtue of employing a planar artificial magnetic conductor (AMC) [65,104] as a ground plane [105].

The PRS that we have considered until now were *periodic*; when the FP approach applies, their geometry is determined according the antenna specifications [directivity, Eqs. (26) and (62); bandwidth, Eq. (25); resonant frequency, Eq. (13)]. Several authors have proposed *nonuniform* PRS (1) to shape the beam radiated by horn antennas [106] and printed antennas [77] (Fig. 20f), or (2) to increase the radiation purity and bandwidth usually altered by phase aberrations of the aperture electric field around sharp resonance [75].

3.2.2. Frequency Beam Scanning Antennas and Multi-beam Antennas. Frequency beam scanning antennas rely simultaneously on the angular (Section 3.2.1) and frequency (Section 1.2) selectivities of FP cavities. According to Eq. (60), the radiated power is maximum in the direction $\theta_s = \arccos(f_{r,q}/f)$ where f is the operating frequency and $f_{r,q}$ is given by Eq. (61). Frequency beam scanning is thus possible if $f_{r,q}$. To minimize the variation of the maximum directivity during scanning, periodic arrays insensitive to oblique incidence are of particular interest.

On the other hand, we have seen in Section 2.4 that multiple propagation peaks appear in each passband if the FP resonator comprises more than two PRSs (e.g., Fig. 18b). Therefore several beams can be radiated by the antenna, depending on the operating frequency, that is, the cavity mode chosen. These multilayer FP cavities may be excited by linear [81] or printed [82] antennas.

Adjusting the radiation characteristics by frequency tuning may prove constraining for many applications. An alternative solution consists in combining astutely and simultaneously two *independent* modes of reconfiguration; the first one uses agile materials as substrates (e.g., liquid crystals or ferroelectric thin films), and the second one controls the reflection/transmission properties of capacitive grids by integrating varactor diodes or MEMS switches in the PRS [82].

3.3. Open Resonators and Concave Mirrors

Accurate knowledge of the complex permittivity of dielectric materials² is crucial for the design of microwave circuits and antennas. The most widely used techniques in the microwave region are cavity resonators; free-space, open-ended coaxial probes; and wideband transmission lines based on one- or two-port measurements. Although

²For further information, refer also to the article entitled “DIELECTRIC MEASUREMENTS” in this encyclopedia.

narrowband, the open-resonator (OR) technique has established itself as a powerful and precise tool for measuring the permittivity of *low-loss* dielectric materials [40,41,83,84]. A very extensive literature is available on that subject since interest in OR was generated in the 1960s by the invention of the laser and the need for resonators with large volume and low loss.

In its most general form, an OR comprises two axially aligned spherical mirrors of radii of curvature R_1 and R_2 and separated by a distance D (Fig. 21a). The sample S is located in the middle of the structure. Compared to the plane-parallel FPI, the use of (at least) one *concave* mirror has the advantage to focus the field into a smaller volume and thus remove diffraction and alignment problems provided the mirrors are of sufficiently large aperture [85,86]. An additional advantage is gained if one (or both) of the mirrors is (are) *spherical*; in the paraxial approximation, the orthogonal modes are the well-known *Gaussian beam* modes, as in laser and maser cavities. In that case, no sophisticated numerical methods [31,87,88] is required for an accurate analysis of the OR:

- Kogelnik and Li [89] provided a very clear scalar analysis of these modes and determined a criterion ensuring stability for the beam resonances: $0 \leq (1 - D/R_1)(1 - D/R_2) \leq 1$. Three particular configurations, located at the limit between the stable and unstable regions, appear from the stability diagram: the symmetric confocal resonator ($R_1 = R_2 = D$), the plane-parallel resonator ($R_1 = R_2 = \infty$) discussed in Section 1.2, and the concentric resonator ($R_1 = R_2 = D/2$) for which the centers of the two mirrors coincide.
- Rigorous vector theory has been proposed later by Yu and Cullen [90].

Detailed treatments about optics of Gaussian beams and resonant cavities can be found in textbooks [e.g., 2, Chaps. 4 and 5; 53]. We just state that the resonant modes are quasi- TEM_{plq} (or TEM_{mnq}) modes, where q denotes the longitudinal mode number (Section 1.2) and pl (or mn) describes the transverse variations of the electromagnetic fields in terms of Laguerre–Gaussian beams in cylindrical coordinates (or Hermite–Gaussian beams in Cartesian coordinates). The resonant frequency of the

Figure 21. (a) FP open resonator for dielectric measurement—the sample of dielectric material S is located in the middle of the device and the shaded area symbolizes the transverse extent of the Gaussian beam mode; (b) hemispherical open resonator.

TEM_{plq} mode is given by [89]

$$f_{\text{res},plq} = \frac{c_0}{2D} \left(q + 1 + \frac{2p+l+q}{\pi} \arccos \left\{ \left(1 - \frac{D}{R_1} \right) \left(1 - \frac{D}{R_2} \right) \right\}^{1/2} \right) \quad (63)$$

This equation is consistent with relation (12), that provides the q th resonant frequency of an ideal plane-parallel FPI with full metal mirrors ($\rho_1 = \rho_2 = \pi$).

The resonator technique relies on perturbation of the electric field distribution by a sample of the material into the resonant structure. The resulting shift of resonant frequency and change in Q factor are analyzed to determine the material properties. The relevant theory is described in a number a review articles, (e.g., see Refs. 84 and 90). There are two basic procedures. In the first, the resonant frequency is measured with and without the sample under test, in a FP cavity of fixed length [91,92]. In the second, the frequency is fixed and the length of the resonator is adjusted to establish resonance with and without the sample [83,92]. Accurate measurements are facilitated by using a high Q for the resonator (up to 2×10^5 in Ref. 93; 6×10^5 in Ref. 94). Experimental errors depend on a number of factors, but the fractional uncertainties obtained in determining the index of refraction have been on the order of 10^{-4} . Loss-tangent measurements are considerably less precise, with fractional uncertainties in the range 0.01–0.1. Among the various OR geometries already employed, configurations with one plane mirror (Fig. 21b), namely, the hemispherical ($D \approx R$) and semiconfocal ($D \approx R/2$) resonators, are convenient because (1) they are unconditionally stable, (2) the boundaries of flat materials conform closely to the phase fronts of the field distribution in the resonator, and (3) they enable the characterization of liquid specimen. Small samples can also be studied with hemispherical structures because the beam radius is very small at the plane mirror.

Coupling energy in and out of the device must perturb as little as possible the configuration of the resonant Gaussian beam modes. A commonly employed method utilizes small apertures in the reflectors to couple energy from waveguides. This approach may significantly increase the insertion losses since small holes radiate energy into a large solid angle. An alternative solution consists in coupling to a quasioptical beam using partially reflecting surfaces, such as grid mirrors [93], as discussed in Section 2.

3.4. Oscillators and Quasioptical Power Combiners

There is a strong need for high-power, solid-state sources at microwave and millimeter wavelengths. At microwave frequencies, waveguide or cavity combiners have been successful; but at higher frequencies, problems appear in terms of loss, combining efficiency, power output, and dimensional tolerances. Spatial or quasioptical techniques³ could provide a possible solution since they are able to integrate many active devices, minimize signal distribution

³For further information, refer to the article entitled SPATIAL AND QUASI-OPTICAL POWER COMBINING in this encyclopedia.

Figure 22. Quasioptical power combiner using a semiconfocal open resonator.

and combining losses, and maintain desired amplitude and phase relationships.

An enhanced RF efficiency is achieved with quasioptical power combiners by coupling a planar array of active devices to a propagating Gaussian beam in free space (and vice versa). Compared to circuit-combining structures, these systems have low losses because (1) energy is distributed or combined in free space and ohmic losses are minimized and (2) the use of beams with large beam waist size enables to integrate a lot of devices in a *single* stage of combining (causing them to operate in parallel). Most of the losses are associated with coupling efficiency from active devices to the beam, and with the coupling to a power collection port.

This concept was suggested in the 1980s [95,96]. The classic paper published by Mink [96] is generally credited with providing the impetus for the increased research activity that followed. In that work, Mink analyzed theoretically a power combiner based on an array of negative resistance devices located inside a semiconfocal open resonator (Fig. 22).

Practical considerations include (1) the choice of solid-state components themselves (Gunn diodes [97,98], HEMT transistors [99,100], operating from X band to V band), (2) coupling of the individual devices to the cavity (for instance using grooved mirrors [97–99] and (3) coupling to the outside of the cavity via waveguides [97–99] or partially reflecting surfaces fabricated on quartz substrates [100]. A more complete summary of this technique is given by York and Popovic [101].

FAST FOURIER TRANSFORMS AND NUFFT

QING HUO LIU
Duke University
Durham, North Carolina

1. INTRODUCTION

The Fourier transform has been an essential analytical tool for many fields. The discretized version of the Fourier transform, the discrete Fourier transform (DFT), on the other hand, is an important numerical tool for ubiquitous applications in every branch of science and engineering. The fast Fourier transform (FFT) algorithm, as an efficient way of calculating DFT, has become an indispensable part of modern numerical computation since the pioneering work of Cooley and Tukey [18], although some related earlier FFT concepts can be dated back to Gauss in 1805 [32] and Danielson and Lanczos in 1942 [21].

The FFT algorithms have found widespread applications in engineering and sciences. In this article we will discuss only its application in numerical solution of Maxwell's equations. Within this important area, the FFT has been widely applied in solving both time-domain and frequency-domain partial-differential equations and integral equations.

Over the decades since the invention of the FFT algorithms, there has been increasing demand for nonuniform discrete Fourier transform (NUFFT), where data are sampled at nonuniform points in either the spectral or physical domain, or both. Although the need for such nonuniform discrete Fourier transform has been recognized for a long time, fast transform algorithms were developed as recently as the mid-1990s. This article includes the latest developments in these nonuniform fast Fourier transform (NUFFT) algorithms [5,24,52,65].

This article is organized as follows. In Section 2, we will introduce the Fourier transform and its properties. In Section 3, the discrete Fourier transform (DFT) will be given in detail, followed by the fast Fourier transform (FFT) algorithms in Section 4. Applications of the FFT algorithms will be briefly summarized in Section 5. Finally, the nonuniform fast Fourier transform (NUFFT) will be discussed in Section 6.

2. FOURIER TRANSFORMS

2.1. One-Dimensional Fourier Transform

Given a complex function $s(x)$ in terms of a real variable x , its Fourier transform is defined by

$$S(k) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} s(x)e^{-jkx} dx \equiv \mathcal{F}[s(x)] \tag{1}$$

where x may be a time or space coordinate, k is the corresponding angular frequency or wavenumber (spatial frequency), and $S(k)$ is in general a complex function. The inverse Fourier transform can be defined as

$$\frac{1}{2}[s(x+0) + s(x-0)] = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} S(k)e^{jkx} dk \tag{2}$$

The inverse Fourier transform involves the average of left and right limits of function $s(x)$ because the function may be discontinuous. In the special case where the function is continuous, the left-hand side of (2) simply reduces to $s(x)$:

$$s(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} S(k)e^{jkx} dk \tag{3}$$

In what follows, unless otherwise stated, we will assume that function $s(x)$ is continuous; the transform of discontinuous functions will be discussed in Section 6. Thus, Eqs. (1) and (2) form a Fourier transform pair. Note in this article that a factor of $1/\sqrt{2\pi}$ is used for both the forward and inverse Fourier transforms (and similarly a factor of $1/\sqrt{N}$ for the forward and inverse discrete Fourier transform) to make them symmetric; other choices of such factors are possible but will not be described in detail here.

If $s(x)$, $s_1(x)$, and $s_2(x)$ have the corresponding Fourier transforms $S(k)$, $S_1(k)$, and $S_2(k)$, respectively, the Fourier transform has the following basic properties:

- *Linearity*—for any complex constants c_1 and c_2 , the Fourier transform of function $s(x) = c_1s_1(x) + c_2s_2(x)$ is

$$S(k) = \mathcal{F}[c_1s_1(x) + c_2s_2(x)] = c_1S_1(k) + c_2S_2(k) \tag{4}$$

where \mathcal{F} denotes the Fourier transform.

- *Symmetry*—the Fourier transform of $S(x)$ is

$$s(-k) = \mathcal{F}[S(x)] \tag{5}$$

- *Spatial (temporal) scaling*—for any nonzero real constant a , we have

$$\frac{1}{|a|} S\left(\frac{k}{a}\right) = \mathcal{F}[s(ax)] \tag{6}$$

- *Spectral (frequency) scaling*—for any nonzero real constant a , we have

$$S(ak) = \mathcal{F}\left[\frac{1}{|a|} s\left(\frac{x}{a}\right)\right] \tag{7}$$

- *Spatial (temporal) shifting*—if the spatial function is shifted by a constant value x_0 , the Fourier transform of the shifted function is

$$e^{-jkx_0} S(k) = \mathcal{F}[s(x - x_0)] \tag{8}$$

- *Spectral (frequency) shifting*—a constant shift k_0 in the spectral function corresponds to the Fourier transform of the modulated function $s(x)e^{jk_0x}$:

$$S(k - k_0) = \mathcal{F}[s(x)e^{jk_0x}] \tag{9}$$

- *Alternative inverse Fourier transform*—the inverse Fourier transform can be written in two ways:

$$s(x) = \mathcal{F}^{-1}[S(k)] = \{\mathcal{F}[S^*(k)]\}^* \tag{10}$$

- *Even function*—for an even function $s_e(x) = s_e(-x)$, the Fourier transform

$$S_e(k) = S_e(-k) \tag{11}$$

is also an even function.

- *Odd function*—for an odd function $s_o(x) = -s_o(-x)$, its Fourier transform

$$S_o(k) = -S_o(-k) \tag{12}$$

is also an odd function.

- *Convolution theorem*—the Fourier transform of the convolution between $s_1(x)$ and $s_2(x)$ is the product of $S_1(k)$ and $S_2(k)$,

$$\begin{aligned} \sqrt{2\pi} S_1(k) S_2(k) &= \mathcal{F}[s_1(x) * s_2(x)] \\ &= \mathcal{F}\left[\int_{-\infty}^{\infty} s_1(\tau) s_2(x - \tau) d\tau\right] \end{aligned} \tag{13}$$

where $*$ denotes the convolution.

- *Correlation theorem*—the Fourier transform of the correlation between $s_1(x)$ and $s_2(x)$ is the product of $S_1(-k)$ and $S_2(k)$

$$\begin{aligned} \sqrt{2\pi} S_1(-k) S_2(k) &= \mathcal{F}[s_1(x) \otimes s_2(x)] \\ &= \mathcal{F}\left[\int_{-\infty}^{\infty} s_1(\tau) s_2(x + \tau) d\tau\right] \end{aligned} \tag{14}$$

where \otimes denotes the correlation.

These Fourier transform properties are important in applications. Corresponding properties are found in discrete Fourier transform (see Section 3).

2.2. Multidimensional Fourier Transform

Multidimensional Fourier transform is a straightforward extension of one-dimensional Fourier transform. Given an M -dimensional function $s(\mathbf{r})$, where $\mathbf{r} = (x_1, x_2, \dots, x_M)$ is the position vector, its Fourier transform in terms of the M -dimensional spectral vector $\mathbf{k} = (k_1, k_2, \dots, k_M)$ is defined as

$$S(\mathbf{k}) = (2\pi)^{-M/2} \int_{-\infty}^{\infty} s(\mathbf{r}) e^{-j\mathbf{k} \cdot \mathbf{r}} d\mathbf{r} \quad (15)$$

and its inverse is defined as

$$s(\mathbf{r}) = (2\pi)^{-M/2} \int_{-\infty}^{\infty} S(\mathbf{k}) e^{j\mathbf{k} \cdot \mathbf{r}} d\mathbf{k} \quad (16)$$

where $s(\mathbf{r}) = [s(\mathbf{r} - 0) + s(\mathbf{r} + 0)]/2$ is understood for discontinuous functions. The properties of the multidimensional Fourier transform can be summarized easily as given in Table 1.

3. DISCRETE FOURIER TRANSFORM

Although many functions have closed-form Fourier transforms, for applications in signal processing and numerical analysis, many more functions have no closed-form Fourier transforms. Thus, numerical computation of Fourier transform is necessary for most applications. As the computer can deal only with discrete numbers, one has to convert the continuous Fourier transform into a discrete Fourier transform. Below we first define the discrete Fourier transform pairs, and then make the connection between the continuous and discrete Fourier transforms. The development here follows closely the book by Brigham [9].

3.1. Definition of 1-D DFT

Consider a 1-D periodic, discrete array $\{h(n)\}$ having a period of N , i.e., $h(n+rN) = h(n)$ for any integer r . The 1-D forward discrete Fourier transform of $\{h_n\}$ is defined as

$$H(m) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} h(n) e^{-j2\pi mn/N}, \quad m = 0, 1, \dots, N-1 \quad (17)$$

Table 1. Properties of Fourier Transform

Property	Inverse FT	Forward FT
Linearity	$c_1 s_1(\mathbf{r}) + c_2 s_2(\mathbf{r})$	$c_1 S_1(\mathbf{k}) + c_2 S_2(\mathbf{k})$
Symmetry	$S(\mathbf{r})$	$s(-\mathbf{k})$
Spatial shifting	$s(\mathbf{r} - \mathbf{r}_0)$	$S(\mathbf{k}) e^{-j\mathbf{k} \cdot \mathbf{r}_0}$
Spectral shifting	$s(\mathbf{r}) e^{j\mathbf{k}_0 \cdot \mathbf{r}}$	$S(\mathbf{k} - \mathbf{k}_0)$
Conjugation	$S^*(\mathbf{r})$	$s^*(\mathbf{k})$
Even function	$s_e(\mathbf{r})$	$S_e(\mathbf{k})$
Odd function	$s_o(\mathbf{r})$	$S_o(\mathbf{k})$
Convolution	$s_1(\mathbf{r}) * s_2(\mathbf{r})$	$(2\pi)^{M/2} S_1(\mathbf{k}) S_2(\mathbf{k})$
Correlation	$s_1(\mathbf{r}) \otimes s_2(\mathbf{r})$	$(2\pi)^{M/2} S_1(-\mathbf{k}) S_2(\mathbf{k})$
Parseval's theorem	$\int_{-\infty}^{\infty} s(\mathbf{r}) ^2 d\mathbf{r}$	$\int_{-\infty}^{\infty} S(\mathbf{k}) ^2 d\mathbf{k}$

Due to the periodic nature of $\exp(-j2\pi mn/N)$, it is easy to show that the DFT array $\{H(m)\}$ is also periodic with a period N , namely, $H(m+rN) = H(m)$, where r is any integer.

The inverse DFT can be shown to be given by

$$h(n) = \frac{1}{\sqrt{N}} \sum_{m=0}^{N-1} H(m) e^{j2\pi mn/N}, \quad n = 0, 1, \dots, N-1 \quad (18)$$

3.2. Properties of DFT

The properties of the DFT are analogous to those of the continuous Fourier transform, as summarized in Table 2.

Of particular importance are the convolution and correlation theorems. Cyclic convolution between $h_1(n)$ and $h_2(n)$ is defined as

$$h(n) = \sum_{p=0}^{N-1} h_1(p) h_2(n-p) \quad (19)$$

while their correlation is defined as

$$g(n) = \sum_{p=0}^{N-1} h_1(p) h_2(n+p) \quad (20)$$

It is important to note that all the arrays involved, $h_1(n)$, $h_2(n)$, $h(n)$, and $g(n)$, are periodic arrays with period N . The cyclic convolution and correlation theorems in Table 2 are based on this important property. The DFT is a simple way to perform these cyclic convolution and correlation. Later we will discuss how to use the DFT to perform linear convolution and correlation when the arrays are non-periodic.

3.3. Relationship between FT and DFT

Discrete Fourier transform can be considered as a tool entirely independent of continuous Fourier transform. However, the application of the DFT is primarily in the approximation of continuous Fourier transform. Therefore, we must establish the connection between the DFT and continuous FT. As will be seen below, the question of this approximation is entirely dependent on the function

Table 2. Properties of DFT

Property	Inverse DFT	Forward DFT
Linearity	$c_1 h_1(n) + c_2 h_2(n)$	$c_1 H_1(m) + c_2 H_2(m)$
Symmetry	$H(n)$	$h(-m)$
Time shifting	$h(n-p)$	$H(m) e^{-j2\pi mp/N}$
Frequency shifting	$h(n) e^{j2\pi np/N}$	$H(m-p)$
Conjugation	$H^*(n)$	$h^*(m)$
Even array	$h_e(n)$	$H_e(m)$
Odd array	$h_o(n)$	$H_o(m)$
Convolution	$h_1(n) * h_2(n)$	$\sqrt{N} H_1(m) H_2(m)$
Correlation	$h_1(n) \otimes h_2(n)$	$\sqrt{N} H_1(m) H_2(N-m)$
Parseval's theorem	$\sum_{n=0}^{N-1} h(n) ^2$	$\sum_{m=0}^{N-1} H(m) ^2$

and its sampling. For a bandlimited function, the DFT can be designed to completely capture the information of the underlying function without any error, while for other functions the DFT will provide an approximate representation of the functions.

3.3.1. General Complex Waveforms. Consider a general complex-valued function $s(x)$ having an infinite support; thus, the function is nonzero even at $x \rightarrow \pm \infty$. In order to convert the Fourier transform into a discrete Fourier transform, the following steps are taken:

1. This function $s(x)$ is first truncated to the function

$$\tilde{s}(x) = s(x)[U(x - x_{\min}) - U(x - x_{\max})] \quad (21)$$

with a finite support $x \in [x_{\min}, x_{\max}]$, where $U(x)$ is the Heaviside step function.

2. The truncated function is then made periodic by repeating this function with a period equal to $T = x_{\max} - x_{\min}$. Mathematically, this is equivalent to convolving $\tilde{s}(x)$ with a delta function train:

$$\delta_1(x) = \sum_{k=-\infty}^{\infty} \delta(x - kT) \quad (22)$$

The resulting periodic function of this convolution is given by

$$s_T(x) = \tilde{s}(x) * \delta_1(x) = \sum_{k=-\infty}^{\infty} \tilde{s}(x - kT) \quad (23)$$

3. Now, since $s_T(x)$ is a periodic function, one can find its Fourier series

$$s_T(x) = \sum_{m=-\infty}^{\infty} S_m e^{j2\pi mx/T} \quad (24)$$

where the Fourier coefficients $\{S_m\}$ are given by

$$S_m = \frac{1}{T} \int_{x_{\min}}^{x_{\max}} s(x) e^{-jmk_0 x} dx \quad (25)$$

where $k_0 = 2\pi/T$, and we have made use of the fact that $s_T(x) = s(x)$ within the period.

4. Using the trapezoidal rule (or other integration rules) to approximate the integral in step 3 in terms of the function values at some sampling points, we have

$$S_m = \frac{1}{N} \sum_{n=0}^{N-1} s\left(x_0 + \frac{nT}{N}\right) e^{-jmk_0 x_0} e^{-j2\pi mn/N} \quad (26)$$

where $x_0 = x_{\min} + T/2N$ is the first sampling point.

5. Finally, we truncate the Fourier series to N terms by keeping $m = -N/2, \dots, N/2 - 1$.

Therefore, the inverse Fourier series in (24) becomes

$$s_T(x) = \sum_{m=-N/2}^{N/2-1} S_m e^{j2\pi mx/T} \quad (27)$$

In particular, at the sample points, we have

$$s\left(x_0 + \frac{nT}{N}\right) = \sum_{m=-N/2}^{N/2-1} S_m e^{j2\pi mx_0/T} e^{j2\pi mn/N} \quad (28)$$

In general, these steps give rise to approximation errors; the only exception is the bandlimited function. The approximation errors associated with these steps are the spatial truncation error (step 1), aliasing error (integration error) due to inadequate sampling density (step 4), and spectral truncation error (step 5). From these steps, it is obvious that the relationship between the continuous Fourier transform and DFT is

$$h(n) \approx \frac{1}{\sqrt{N}} s\left(x_0 + \frac{nT}{N}\right), \quad H(m) \approx S_m e^{j(2\pi mx_0/T)} \quad (29)$$

These are only approximate because of the errors introduced in the above steps. Note that in the preceding equations, we intentionally express the forward and inverse DFT to contain a factor of $1/\sqrt{N}$ to make the forward and inverse transforms symmetric; it is not a necessary, but a convenient, choice of the multiplication factor.

3.3.2. Bandlimited Nonperiodic Functions. The *bandwidth* of a function is defined as the frequency band $k_{\min} \leq k \leq k_{\max}$ beyond which the spectrum is zero. In the preceding equations for a general complex function, we note that the bandwidth of the function is usually infinite; its spectrum is nonzero even when the frequency approaches $\pm \infty$. However, there is one special class of functions that are bandlimited; that is, their spectra are zero beyond a finite frequency. Such bandlimited functions have some special properties, as given by the Nyquist sampling theorem.

3.3.2.1. Nyquist Sampling Theorem. If function $s(x)$ is bandlimited, that is, if

$$S(k) = 0, \quad \text{for } |k| > k_{\max} \quad (30)$$

then under the condition that $\Delta x \leq \pi/k_{\max}$, the function can be uniquely determined by the sample points at $x = n\Delta x$ ($n = -\infty, \dots, \infty$)

$$s(x) = \sum_{n=-\infty}^{\infty} s(n\Delta x) \text{sinc}\left[\pi\left(\frac{x}{\Delta x} - n\right)\right] \quad (31)$$

where the sinc function is defined as

$$\text{sinc}(x) = \frac{\sin x}{x} \quad (32)$$

However, bandlimited functions have infinite support. In other words, the truncation in Eq. (21) (step 1) will cause errors.

3.3.3. Bandlimited Periodic Functions. It is only for bandlimited periodic functions that an exact relationship between FT and DFT can be established. For a bandlimited function $s_T(x)$, by definition its spectrum is nonzero only within $|k| \leq k_{\max}$, where k_{\max} is a finite real number, representing the maximum angular frequency where the spectrum is nonzero. If the period of the function is T , we can sample the function at an increment

$$\Delta x = \frac{T}{N} \quad (33)$$

Since this function is already periodic, the truncation in Eqs. (21) (step 1) and (23) (step 2) are no longer necessary. We can directly perform the Fourier series in Eq. (23).

Furthermore, in the spectral truncation step, that is, the last step in Eq. (28), if

$$\Delta x = \frac{T}{N} \leq \frac{\pi}{k_{\max}} \quad (34)$$

then according to Nyquist sampling theorem there is no spectral truncation error. Therefore, under this Nyquist sampling rate (34), the equations in (29) are exact. Moreover, the reconstruction formula for $s(x)$ in Eq. (31) reduces to

$$s(x) = \sum_{n=0}^{N-1} s(n\Delta x) \text{sinc} \left[\pi \left(\frac{x}{\Delta x} - n \right) \right] \quad (35)$$

In Eqs. (34) and (35), we consider that the truncation interval is exactly equal to the period T . Note that if this truncation is integer number of periods, the conclusion given above still applies, namely, that there is no approximation error between the continuous Fourier transform and DFT, and the original function can be reconstructed perfectly using discrete Fourier transform. However, if the truncation interval is not equal to an integer number of periods, a discontinuity is present at the two end truncation points because the function is no longer continuous (i.e., it has nonsmooth function value or derivatives) at the truncation point when the function is made periodic. Such discontinuities make Eq. (26) (step 4) inexact because the trapezoidal rule is approximate for this discontinuous function. In other words, a result of this truncation is that the function is no longer bandlimited. This effect is called ‘‘leakage.’’

4. FAST FOURIER TRANSFORM

Now that we have established the relationship between FT and DFT, we can use DFT to calculate the exact FT for bandlimited periodic functions, or approximate FT for other more general functions. Our objective is to calculate

efficiently the sum in (17), rewritten here for convenience:

$$H(m) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} h(n) e^{-j2\pi mn/N}, \quad m = 0, 1, \dots, N-1 \quad (36)$$

However, we note that the straightforward summation in (36) requires N^2 complex multiplications and $N(N-1)$ complex additions. Our goal is to evaluate equation (36) more efficiently than the direct summation so that these numbers of arithmetic operations will be reduced to $O(N \log N)$.

There are many variations of FFT algorithms. In this section, we will discuss only the Cooley–Tukey FFT algorithm for arbitrary factors. Then we will discuss the applications of FFT in fast convolution and correlation, and in fast methods in computational electromagnetics.

4.1. The Cooley–Tukey FFT Algorithm without Twiddle Factors

First, following Brigham [9] we summarize the derivation of Cooley–Tukey FFT algorithm for arbitrary factors as extended by Bergland [3]. We assume the number of points N can be factored as

$$N = \prod_{i=1}^I r_i \quad (37)$$

where r_i ($i = 1, \dots, I$) are positive integers.

To present the FFT algorithm, it is more convenient to express indices m and n in (36) in a variable radix representation

$$m = m_{I-1}(r_1 r_2 \cdots r_{I-1}) + m_{I-2}(r_1 r_2 \cdots r_{I-2}) + \cdots + m_1 r_1 + m_0 \quad (38)$$

$$= \sum_{k=0}^{I-1} m_k \prod_{l=0}^k r_l$$

$$n = n_{I-1}(r_2 r_3 \cdots r_I) + n_{I-2}(r_3 r_4 \cdots r_I) + \cdots + n_1 r_I + n_0 = \sum_{p=0}^{I-1} n_p \prod_{q=I-p+1}^{I+1} r_q \quad (39)$$

where $r_0 = r_{I+1} = 1$ and

$$m_i = 0, 1, 2, \dots, r_{i+1} - 1, \quad 0 \leq i \leq I-1$$

$$n_i = 0, 1, 2, \dots, r_{I-i} - 1, \quad 0 \leq i \leq I-1$$

Then (36) can be rewritten as

$$H(m_{I-1}, m_{I-2}, \dots, m_1, m_0) = \frac{1}{\sqrt{N}} \sum_{n_0=0}^{r_1-1} \sum_{n_1=0}^{r_2-1} \cdots \sum_{n_{I-1}=0}^{r_I-1} h(n_{I-1}, n_{I-2}, \dots, n_0) W_N^{mn} \quad (40)$$

where $W_N = \exp(-j2\pi/N)$. This may seem to make the new DFT summation even more complicated than the original equation (36), but we will see that this factorization actually saves some arithmetic operations. We will carry out this factorization in several stages allowed by the radix factorization:

Stage 1. Noting that $W_N^{\prod_{i=1}^I r_i} = W_N^N = 1$, we can rewrite the first terms of $W_N^{mn} = W_N^{m[n_{I-1} \prod_{i=1}^I r_i + \dots + n_0]}$ as

$$W_N^{mn_{I-1} \prod_{i=2}^I r_i} = W_N^{m_0 n_{I-1} \prod_{i=2}^I r_i} \tag{41}$$

Therefore

$$H(m_{I-1}, m_{I-2}, \dots, m_1, m_0) = \sum_{n_0=0}^{r_I-1} \sum_{n_1=0}^{r_{I-1}-1} \dots \left[\sum_{n_{I-1}=0}^{r_1-1} x_0(n_{I-1}, n_{I-2}, \dots, n_0) \cdot W_N^{m_0 n_{I-1} \prod_{i=2}^I r_i} \right] \cdot W_N^{m[n_{I-2} (\prod_{i=3}^I r_i) + \dots + n_0]} \tag{42}$$

where $x_0 = h/\sqrt{N}$. We define the item inside the square brackets as x_1 :

$$x_1(m_0, n_{I-2}, \dots, n_0) = \sum_{n_{I-1}=0}^{r_1-1} x_0(n_{I-1}, n_{I-2}, \dots, n_0) W_N^{m_0 n_{I-1} \prod_{i=2}^I r_i} \tag{43}$$

Note that this stage for calculating (43) requires Nr_1 operations (one complex multiplication and one complex addition), without considering the symmetries of the complex exponential. Then, equation (42) can then be written as

$$H(m_{I-1}, m_{I-2}, \dots, m_1, m_0) = \sum_{n_0=0}^{r_I-1} \sum_{n_1=0}^{r_{I-1}-1} \dots \sum_{n_{I-2}=0}^{r_2-1} x_1(m_0, n_{I-2}, \dots, n_0) \times W_N^{m[n_{I-2} (\prod_{i=3}^I r_i) + \dots + n_0]} \tag{44}$$

Stage 2. Similar to equation (41), we can now show that

$$W_N^{mn_{I-2} \prod_{i=3}^I r_i} = W_N^{(m_1 r_1 + m_0) n_{I-2} \prod_{i=3}^I r_i} \tag{45}$$

Hence, by defining

$$x_2(m_0, m_1, n_{I-3}, \dots, n_0) = \sum_{n_{I-2}=0}^{r_2-1} x_1(m_0, n_{I-2}, \dots, n_0) W_N^{(m_1 r_1 + m_0) n_{I-2} \prod_{i=3}^I r_i} \tag{46}$$

we can rewrite (44) as

$$H(m_{I-1}, m_{I-2}, \dots, m_1, m_0) = \sum_{n_0=0}^{r_I-1} \sum_{n_1=0}^{r_{I-1}-1} \dots \sum_{n_{I-3}=0}^{r_3-1} x_2(m_0, m_1, n_{I-3}, \dots, n_0) \times W_N^{m[n_{I-3} (\prod_{i=4}^I r_i) + \dots + n_0]} \tag{47}$$

This stage requires Nr_2 arithmetic operations without considering the symmetries of the complex exponential.

Stage p. In the same manner, if we continue reducing (47), we will obtain a set of recursive equations of the form

$$x_p(m_0, m_1, \dots, m_{p-1}, n_{I-p-1}, \dots, n_0) = \sum_{n_{I-p}=0}^{r_p-1} x_{p-1}(m_0, m_1, \dots, m_{p-2}, n_{I-p}, \dots, n_0) \tag{48}$$

$$\cdot W_N^{[m_{p-1}(r_1 r_2 \dots r_{p-1}) + \dots + m_1 r_1 + m_0] n_{I-p} \prod_{i=p+1}^I r_i},$$

$$p = 1, 2, \dots, I$$

where we have defined $(r_{p+1} \dots r_I) = 1$ for $p > I - 1$ and $n_{-1} = 0$. This stage requires Nr_p arithmetic operations without considering the symmetries of the complex exponential.

The Complete FFT Algorithm. The final results are given by

$$H(m_{I-1}, m_{I-2}, \dots, m_1, m_0) = x_I(m_0, \dots, m_{I-1}) \tag{49}$$

from which the total number of multiplications is

$$M = N \sum_{p=1}^I r_p$$

In the special case where the radix representation is constant, $r_1 = r_2 = \dots = r_I = r$, $I = \log_r N$, we have the total number of multiplications $M = Nr \log_r N$, without considering the symmetries of the complex exponential. Thus, the FFT algorithm requires only $O(N \log N)$ operations.

4.2. The Cooley–Tukey FFT Algorithm with “Twiddle” Factors

As discussed above, in the Cooley–Tukey FFT algorithm without “twiddle” factors, the p th stage calculation in (48) requiring Nr_p operations. However, recognizing that one factor in (48) can be rewritten as

$$W_N^{m_{p-1}(r_1 r_2 \cdots r_{p-1})n_{I-p}} \prod_{i=p+1}^I r_i = W_N^{m_{p-1}n_{I-p}N/r_p} = W_{r_p}^{m_{p-1}n_{I-p}} \quad (50)$$

we can rewrite the p th stage equation (48) as

$$\begin{aligned} & x_p(m_0, m_1, \dots, m_{p-1}, n_{I-p-1}, \dots, n_0) \\ &= \left[\sum_{n_{I-p}=0}^{r_p-1} x_{p-1}(m_0, m_1, \dots, m_{p-2}, n_{I-p}, \dots, n_0) W_{r_p}^{m_{p-1}n_{I-p}} \right] \\ & \cdot W_N^t = [DFT_{r_p}\{x_{p-1}\}] \cdot W_N^t \end{aligned} \quad (51)$$

where

$$t = [m_{p-1}(r_1 r_2 \cdots r_{p-2}) + \cdots + m_1 r_1 + m_0]n_{I-p} \prod_{i=p+1}^I r_i$$

It is obvious that the summation inside the brackets in Eq. (51) is an r_p -point DFT (denoted by $DFT_{r_p}\{x_{p-1}\}$); the factor W_N^t outside the bracket is called the twiddling factor. Thus, the p th stage in the FFT algorithm can be computed by the r_p -point DFT followed by the twiddling operation (i.e., by the referencing operation of W_N^t).

Because of the symmetries in $W_{r_p}^{m_{p-1}n_{I-p}} \equiv W_{r_p}^d$, it is important to recognize that this r_p -point DFT can be computed very efficiently, with much fewer operations than r_p^2 . For example, if $r_p = 2$ (i.e., a base 2 transform), the W_2^d factor takes only ± 1 , and there is no need for multiplications; the total number of complex multiplications is

$$M_2 = \frac{1}{4}[2 \log_2 N - 4]N + 1$$

If $r_p = 4$ (i.e., a base 4 transform), there is no need for multiplications in the DFT since the W_2^d factor takes only ± 1 and $\pm j$; the total number of complex multiplications is

$$M_4 = \frac{1}{4}[1.5 \log_2 N - 4]N + 1$$

If $r_p = 8$ (i.e., a base 8 transform), there are only four real multiplications in the DFT since the W_2^d factor takes only ± 1 , $\pm j$, $\pm e^{j\pi/4}$; and $\pm e^{j3\pi/4}$; the total number of complex multiplications is

$$M_8 = \frac{1}{4}[1.333 \log_2 N - 4]N + 1$$

For more details, the reader is referred to Ref. 9.

5. APPLICATIONS OF FFT IN ELECTROMAGNETICS

The FFT algorithm is one of the most important developments in numerical analysis. Its applications are ubiquitous. Here we will only summarize its applications in fast computational methods for electromagnetics, including the pseudospectral time-domain (PSTD) methods and the integral equation methods.

5.1. Fast Derivatives and the Pseudospectral Time-Domain (PSTD) Methods

The finite-difference time-domain (FDTD) method has become a standard technique to solve transient electromagnetic problems by solving time-domain Maxwell equations [82]. However, the major difficulty with the FDTD method is the required high sampling density (≥ 20 cells per wavelength) because of its low-order accuracy. It is known that the accuracy of the FDTD method is second-order in a homogeneous medium, but only first order in a discontinuous medium.

In order to improve the FDTD method, many researchers have proposed various techniques. One class of such techniques is pseudospectral time-domain methods, which use trigonometric functions or Chebyshev polynomials to approximate spatial derivatives [27,36,49–51,79–81,86,87]. These PSTD methods have been developed for unbounded and bounded media, and have been shown to greatly outperform the FDTD methods, especially for large-scale problems.

The key to the PSTD methods lies in the fast and accurate spatial derivatives by using either the FFT or the Chebyshev polynomials. Consider a 1D function $u(x, t)$. In the regular FDTD method, the spatial (and temporal) derivatives are approximated by the central finite-difference scheme, which has a second-order accuracy. In contrast, in the PSTD methods, the spatial derivatives are approximated by either trigonometric functions or by Chebyshev polynomials.

5.1.1. The Fourier PSTD Method. In the Fourier PSTD method, we consider a spatially periodic function $u(x, t)$ in x ($0 \leq x \leq L$), where L is the period. If $\Delta x = L/N$ is used as the cell size and $x_n = n\Delta x$, $n = 0, 1, \dots, N-1$, the approximation of the spatial derivative can be in general written as

$$\frac{\partial u(x, t)}{\partial x} \approx \mathcal{D}_x\{u(x, t)\} \quad (52)$$

where the derivative operator is given by

$$\mathcal{D}_x f(x) = \mathcal{F}_x^{-1}\{jk_x \mathcal{F}_x[f(x)]\} \quad (53)$$

where \mathcal{F} and \mathcal{F}^{-1} denote the forward and inverse Fourier transforms that are achieved by an FFT algorithm with the number of operations $O(N \log N)$. Such an approximation in (53) has a spectral accuracy; that is, the error

decreases exponentially as N increases, given that $u(x, t)$ is analytic.

In contrast to the FDTD method, which uses a staggered grid, the Fourier PSTD method uses a centered grid where all field components are located at the cell centers. In addition to its simplicity, this centered grid provides an important advantage over the FDTD algorithm since the material properties are not altered by the presence of the staggered grid. Furthermore, the centered grid is more advantageous for anisotropic media [51], and removes the singularity problem for EM waves in cylindrical coordinates [55].

Since the Fourier PSTD method assumes periodicity in the wave fields, in order to apply this method to unbounded media, the perfectly matched layer (PML) absorbing boundary condition should be used at the computational edge to remove the so-called wraparound effect caused by the periodicity [49].

5.1.1.1. Time Integration. The temporal grid, however, is staggered since the central differencing is used for time-stepping. Therefore, the time integration is exactly the same as in the regular Yee scheme. The dispersion analysis and stability condition of the FDTD and Fourier PSTD algorithm has been formulated for a homogeneous, lossless medium [49,50]. The Courant-Friedrichs-Lewy (CFL) stability conditions can be written compactly as

$$\frac{c\Delta t}{\Delta x} \leq \frac{1}{\alpha\sqrt{D}} \quad (54)$$

for a problem of dimensionality D , where $\alpha = 1$ for FDTD, and $\alpha = \pi/2 \approx 1.5708$ for PSTD [51]. Higher-order time-integration methods such as the fourth-order Runge-Kutta method can be used to further improve the time integration accuracy.

The Fourier PSTD method is easy to implement and requires only two points per minimum wavelength, but the medium under study needs to be homogeneous or smoothly varying to ensure the exponential accuracy.

The Fourier PSTD method, originally proposed in Refs. 49 and 50, has been applied to the simulation of many engineering problems [31,41–44,56,74]. This method provides spectral accuracy when the medium is very smooth. However, its major limitation is that it is not applicable to problems with perfect conductors; theoretically, it has the spectral accuracy only for smoothly varying inhomogeneous media, although numerical examples show that it is much more efficient and accurate than the FDTD method. One way to deal with strongly inhomogeneous media is to use a nonuniform grid to account for the material variation, by using the nonuniform fast Fourier transform (NUFFT) [56] or the nonuniform grid mapping [43]; a hybrid of PSTD and FDTD techniques has also been suggested [42,44]. However, all these remedies still cannot remove the staircasing error associated with the Kröner product grid (i.e., the mesh is parallel to coordinate directions). An alternative method for perfect conductors and discontinuous inhomogeneous media is the multidomain Chebyshev PSTD method discussed below.

5.1.2. The Multidomain Chebyshev PSTD Method. The Fourier PSTD method discussed above is applied for both periodic problems (such as the frequency-selective surfaces and photonic crystals), and for unbounded media with the PML absorbing boundary condition. For bounded media, on the other hand, one can develop a single-domain Chebyshev PSTD method [74]. However, the single-domain Chebyshev PSTD method, similar to the Fourier PSTD method, has spectral accuracy only for smoothly varying media.

In order to apply the PSTD method to perfect conductors and discontinuous media with spectral accuracy, it is necessary to develop a multidomain PSTD method [36,79,80]. Examples of multidomain Chebyshev PSTD method have been shown for perfect conductors and for discontinuous inhomogeneous lossy media, including the applications in GPR (ground penetrating radar) sensing [27], waveguides [86], and scattering problems [87]. It has demonstrated the great flexibility of dealing with complex objects, with a slightly increased computational burden because it requires π cells per minimum wavelength.

In order to develop a multidomain Chebyshev PSTD method, the problem domain is divided into hexahedron subdomains naturally conformal to the geometry. In general, each subdomain has curved boundaries in the (x, y, z) coordinates, but can be mapped into a cube in the curvilinear coordinates (ξ, η, ζ) with $\xi, \eta, \zeta \in [-1, 1]$. In each direction ξ, η, ζ , the spatial derivative can be found by using Chebyshev polynomials. For example, in the ξ direction, for $\xi \in [-1, 1]$, the region can be discretized by $N + 1$ Gauss-Chebyshev-Lobatto points (or simply called the Chebyshev points) defined at

$$\xi_i = -\cos\frac{i\pi}{N}, \quad i = 0, 1, \dots, N \quad (55)$$

Then function $u(\xi, t)$ can be represented as

$$u(\xi, t) = \sum_{n=0}^N a_n(t) T_n(\xi) \quad (56)$$

where $T_n(\xi) = \cos[n \cos^{-1}(\xi)]$ is the n th-order Chebyshev polynomial. Equivalently

$$u(\xi, t) = \sum_{i=0}^N u(\xi_i, t) \phi_i(\xi) \quad (57)$$

where

$$\phi_i(\xi) = \frac{(1 - \xi^2) T'_N(\xi) (-1)^{i+1+N}}{c_i N^2 (\xi - \xi_i)} \quad (58)$$

and $c_i = 1 + \delta_{i,0} + \delta_{i,N}$. With the interpolation in (56), the spatial derivative of $u(\xi, t)$ with respect to ξ is approximated as

$$\frac{\partial u(\xi_i, t)}{\partial \xi} = \sum_{k=0}^N D_{ik}^{(\xi)} u(\xi_k, t) \quad (59)$$

where the differential matrix elements are given by

$$D_{ik} = \phi'_k(\xi_i) \quad (60)$$

and the explicit expressions can be found in Refs. 10 and 87.

Alternatively, using (56), one can obtain the derivative of $u(\xi, t)$ as

$$\frac{\partial u(\xi, t)}{\partial \xi} = \sum_{n=0}^N b_n(t) T_n(\xi) \quad (61)$$

where the coefficients $\{b_n\}$ can be derived through the recursion relations of the Chebyshev polynomials

$$\begin{cases} b_N = 0 \\ b_{N-1} = 2Na_N \\ b_{N-2} = 2(N-1)a_{N-1} \\ b_{i-1} = b_{i+1} + 2ia_i, \quad i = N-2, N-3, \dots, 2 \\ b_0 = a_1 + b_2/2 \end{cases} \quad (62)$$

Obviously, the choice of the gridpoints in (55) makes (56) a cosine transform; thus, the coefficients $\{a_n\}$ in (56) can be found from $\{u(\xi_i)\}$ by using the fast cosine transform (FCT) algorithm, which can be derived from the FFT algorithm. The derivative coefficients $\{b_n\}$ are then obtained by the recursion relation (62); then the derivative can be obtained by the fast cosine transform using equation (61). In general, if $N > 16$, it is more efficient to obtain the derivative by using the CFT than the direct matrix-vector multiplication [10].

Once the spatial derivatives have been found accurately, the fields inside each subdomain can be updated by a time integration method such as the fourth-order Runge–Kutta method. Then, the fields between adjacent subdomains must be reconciled by a patching procedure so that the boundary conditions between subdomains are satisfied. For details of the multidomain PSTD method, the reader is referred to Refs. 27, 36, 79, and 86–88 and a review paper [59].

5.2. Fast Convolution, Correlation, and k -Space Methods for Integral Equations

In addition to the PSTD methods discussed above, the FFT algorithm is an essential ingredient in modern computational methods for electromagnetics, in the areas of fast forward and inverse problems involving integral equations.

The use of the FFT to accelerate the solution of integral equations dates back to the k -space method proposed by Bojarski in the early 1980s [6]. In general, to solve an integral equation in electromagnetics with the conventional method of moments (MoM) [35], one uses some basis functions to express the unknown field (or unknown current density); after tested by some weighting functions, the integral equation can be converted into N algebraic equations with N discrete unknowns. Solving this problem involves the inversion of the $N \times N$ matrix, which can be a prohibitive task as the memory requirement is $O(N^2)$, and the CPU time is $O(N^3)$ (if a direct method is used for the matrix inversion) or $O(KN^2)$ (if an iterative method is used, where K denotes the number of iterations).

The original k -space method [6] was proposed for objects in a homogeneous background medium. In this case, the k -space method utilizes the fact that the scattered field from an object can be written as a convolution integral between the background Green function and the induced current in the scatterer. Therefore, after discretization with a uniform grid, the operation of the Green's function onto the induced current (called "Green's operation") can be carried out by using the FFT with only $O(N \log N)$, rather than $O(N^2)$ arithmetic operations in the MoM. The integral equation has to be solved iteratively; within each iteration Green's operation and its adjoint operation are accelerated by the FFT, thus resulting in an algorithm requiring only $O(KN \log N)$ CPU time, where K is the number of iterations required. Furthermore, the memory requirement has been greatly reduced from $O(N^2)$ in MoM to $O(N)$ in the k -space method as the MoM matrix is no longer needed. The idea of the k -space method was later improved by the CG-FFT (conjugate-gradient fast Fourier transform) methods. Early works include Refs. 8, 12, 39, 68, 69 and 75; 3D CG-FFT-type methods include Refs. 37, 73, 77, 83, 84, and 90; see Ref. 13 for more complete references. In the CG-FFT method, the conjugate-gradient method is used as the iterative method to improve the convergence of the original k -space method. The k -space and the CG-FFT methods can be applied to a wide variety of integral equations, including volume integral equations and surface integral equations with planar geometries. They are not applicable to surface equations with arbitrary geometries where the shift invariance of Green's function no longer holds along the scatterer surface.

Traditionally, the k -space and CG-FFT methods have been applied to objects in a homogeneous background. The CG-FFT method has been further improved by the biconjugate-gradient (BCG-FFT) method [37, 83] and stabilized biconjugate-gradient (BCGS-FFT) method [77]. Since all these iterative methods solve the integral equation using the FFT, we categorize them as the general k -space method for integral equations.

The k -space method has also been applied to planar conductor structures in a multilayered medium where the scatterer is parallel to the layer interfaces. In this case, the shift-invariance of the Green function again ensures that the FFT can be used to accelerate the convolution integral along the parallel planar directions [13, 46, 66, 89]. More recently, the k -space method has been applied to acoustic scattering in a layered medium [76], electromagnetic scattering in a half-space [19, 20], and a multilayered medium [63, 64, 78], by penetrable inhomogeneous objects. The major difference between the multilayered background medium and the homogeneous background medium is that the Green function is no longer shift-invariant in the direction perpendicular to the layer interfaces; thus, the Green operation is no longer a convolution integral. However, it has been shown that if the objects are located within one single layer in the multilayered medium, one can split the Green's operation into a convolution integral and a correlation integral, making the FFT algorithm still applicable to accelerate the Green's operation [19, 20, 63, 64, 76, 78].

To illustrate these important applications of the FFT in computational electromagnetics, we summarize the latest development in the solution of electromagnetic scattering by penetrable objects embedded in a multilayered medium [63,64,78]. As shown in Fig. 1, if an inhomogeneous dielectric object of arbitrary shape is completely embedded in the i th layer, the scattered magnetic vector potential in the m th layer, then $A^{mi}(\mathbf{r})$, due to the induced current source \mathbf{J} inside the inhomogeneous object embedded in the i th layer, is given by

$$\begin{aligned} \mathbf{A}^{mi}(\mathbf{r}) &= \mu_m \int_V \mathbf{G}^{mi}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') d\mathbf{r}' \\ &= j\omega\mu_m \int_V \mathbf{G}^{mi}(\mathbf{r}, \mathbf{r}') \cdot \chi(\mathbf{r}') \mathbf{D}(\mathbf{r}') d\mathbf{r}' \end{aligned} \quad (63)$$

where \mathbf{G}^{mi} is the dyadic Green function for the magnetic vector potential, V is the volume of the scattering object, $\chi(\mathbf{r}) = [\tilde{\epsilon}(\mathbf{r}) - \tilde{\epsilon}_i]/\tilde{\epsilon}_i$ is the contrast function, $\tilde{\epsilon}(\mathbf{r}) = \epsilon(\mathbf{r}) + \sigma(\mathbf{r})/j\omega$, $\mathbf{D}(\mathbf{r}) = \tilde{\epsilon}(\mathbf{r})\mathbf{E}(\mathbf{r})$ is the unknown electric flux density inside the object, and $\tilde{\epsilon}_i$ is the complex permittivity of the i th layer. We can form the integral equation for the unknown electric flux density inside the object as

$$\mathcal{L}[\mathbf{D}_i(\mathbf{r})] = \mathbf{E}_i^{\text{inc}}(\mathbf{r}), \quad \mathbf{r} \in V \quad (64)$$

where \mathcal{L} is a linear operator defined as

$$\mathcal{L}[\cdot] = \left[\frac{\cdot}{\tilde{\epsilon}} - (k_i^2 + \nabla\nabla \cdot) \right] \frac{1}{\tilde{\epsilon}_i} \int_V \mathbf{G}^{ii}(\mathbf{r}, \mathbf{r}') \cdot \chi[\cdot] d\mathbf{r}', \quad \mathbf{r} \in V \quad (65)$$

and $k_i = \omega\sqrt{\tilde{\epsilon}_i\mu_i}$ is the wavenumber of the i th layer. Solving Eq. (64), the electric flux density $\mathbf{D}_i(\mathbf{r})$ is obtained for $\mathbf{r} \in V$. The relationship $\mathbf{J} = j\omega\chi\mathbf{D}$ can be used to calculate the induced current inside the scattering object, and thus the electric field at any location.

The volume EFIE (electric field integral equation) has been formulated with the electric flux density as the unknown because the continuity of the normal component of electric flux density can be easily enforced by choosing the rooftop basis functions for \mathbf{D} . On the other hand, if the electric/magnetic fields are chosen as the unknown, implementation of the boundary conditions is not trivial. Furthermore, the ‘‘weak form’’ discretization process proposed in Ref. 90 for the scattering of objects in a homoge-

Figure 1. Typical configuration of an inhomogeneous object in a planar layered medium.

neous background can be extended to layered media to reduce the singularity of the problem. To make use of the FFT to accelerate the solution, the integral equation in (64) is usually solved iteratively by Krylov subspace methods such as the conjugate-gradient, biconjugate-gradient, or stabilized biconjugate-gradient methods, as summarized in Table 3.

When solving the integral equation in (64) iteratively, we need to calculate the interactions of the dyadic Green function $\mathbf{G}^{ii}(\mathbf{r}, \mathbf{r}')$ with the induced current density $\mathbf{J} = j\omega\chi\mathbf{D}$ for every testing function within the object. If the object is discretized into N unknowns, the straightforward computation of these interactions requires $O(N^2)$ arithmetic operations. In free space, this computation can be accelerated by using the fast Fourier transform (FFT) algorithm because the Green function there is shift-invariant.

As a result of the inhomogeneity along the z direction, however, the dyadic Green function for a layered medium is no longer shift-invariant; thus the integral kernel of the volume EFIE (64) is not convolutional. For example, in the spectral domain, we obtain

$$\begin{aligned} \tilde{\mathbf{G}}_{xx}^{ii}(k_\rho, z, z') &= \frac{1}{2jk_{z,i}} \left[e^{-jk_{z,i}|z-z'|} \right. \\ &+ \frac{1}{D_i^{\text{TE}}} \{ \bar{R}_i^{\text{TE}} e^{-jk_{z,i}[(z+z')-2z_i]} + \bar{R}_{i-1}^{\text{TE}} e^{-jk_{z,i}[2z_{i-1}-(z+z')] } \\ &\left. + 2\bar{R}_i^{\text{TE}} \bar{R}_{i-1}^{\text{TE}} e^{-j2\psi_i} \cos k_{z,i}(z-z') \} \right] \end{aligned} \quad (66)$$

Table 3. Three Krylov Subspace Methods

CG Method	BCG Method	BCGSTAB Method
$\mathbf{r}_0 = \mathbf{E}^{\text{inc}} - \mathcal{L}\mathbf{D}_0$ $\mathbf{p}_0 = \mathbf{r}_0$	$\mathbf{r}_0 = \mathbf{p}_0 = \mathbf{E}^{\text{inc}} - \mathcal{L}\mathbf{D}_0$ $\tilde{\mathbf{r}}_0 = \tilde{\mathbf{p}}_0 = \mathbf{r}_0^*$	$\mathbf{r}_0 = \mathbf{E}^{\text{inc}} - \mathcal{L}\mathbf{D}_0$ Choose $\tilde{\mathbf{r}}_0$ so that $(\tilde{\mathbf{r}}_0, \mathbf{r}_0) \neq 0$ $\rho_0 = \alpha = \omega_0 = 1$, $\mathbf{v}_0 = \mathbf{p}_0 = 0$
$\alpha_k = \frac{\langle \mathbf{r}_{k-1}, \mathbf{r}_{k-1} \rangle}{\langle \mathbf{p}_k, \mathbf{p}_k \rangle}$	$\alpha_k = \frac{\langle \mathbf{r}_k, \tilde{\mathbf{r}}_k \rangle}{\langle \mathcal{L}\mathbf{p}_k, \tilde{\mathbf{p}}_k \rangle}$	$\rho_k = \langle \tilde{\mathbf{r}}_0, \mathbf{r}_{k+1} \rangle$
$\beta_k = -\frac{\langle \mathbf{r}_k, \tilde{\mathbf{r}}_k \rangle}{\langle \mathbf{r}_{k-1}, \tilde{\mathbf{r}}_{k-1} \rangle}$	$\beta_k = \frac{\langle \mathbf{r}_{k+1}, \tilde{\mathbf{r}}_{k+1} \rangle}{\langle \mathbf{r}_k, \tilde{\mathbf{r}}_k \rangle}$	$\beta = \alpha\rho_k/(\omega_{k-1}\rho_{k-1})$
$\mathbf{D}_{k+1} = \mathbf{D}_k + \alpha_k \mathbf{p}_k$	$\mathbf{D}_{k+1} = \mathbf{D}_k + \alpha_k \mathbf{p}_k$	$\mathbf{p}_k = \mathbf{r}_{k-1} + \beta(\mathbf{p}_{k-1} - \omega_{k-1}\mathbf{v}_{k-1})$
$\mathbf{r}_{k+1} = \mathbf{r}_k - \alpha_k \mathcal{L}\mathbf{p}_k$	$\mathbf{r}_{k+1} = \mathbf{r}_k - \alpha_k \mathcal{L}\mathbf{p}_k$	$\mathbf{v}_k = \mathcal{L}\mathbf{p}_k$, $\alpha = \rho_k/(\tilde{\mathbf{r}}_0, \mathbf{v}_k)$
$\mathbf{p}_{k+1} = \mathbf{r}_{k+1} + \beta_k \mathbf{p}_k$	$\tilde{\mathbf{r}}_{k+1} = \tilde{\mathbf{r}}_k - \alpha_k^* \mathcal{L}^* \tilde{\mathbf{p}}_k$	$\mathbf{s} = \mathbf{r}_{k-1} - \alpha \mathbf{v}_k$, $\mathbf{t} = \mathcal{L}\mathbf{s}$
	$\mathbf{p}_{k+1} = \mathbf{r}_{k+1} + \beta_k \mathbf{p}_k$	$\omega_k = \langle \mathbf{t}, \mathbf{s} \rangle / \langle \mathbf{t}, \mathbf{t} \rangle$
	$\tilde{\mathbf{p}}_{k+1} = \tilde{\mathbf{r}}_{k+1} + \beta_k^* \tilde{\mathbf{p}}_k$	$\mathbf{D}_k = \mathbf{D}_{k-1} + \alpha \mathbf{p}_k + \omega_k \mathbf{s}$
		$\mathbf{r}_k = \mathbf{s} - \omega_k \mathbf{t}$

where \vec{R}_i^{TE} and $\vec{R}_{i-1}^{\text{TE}}$ define some global reflection coefficients, $\psi_i = k_{z,i}(z_{i-1} - z_i)$, and $D_i^{\text{TE}} = 1 - \vec{R}_i^{\text{TE}} \vec{R}_{i-1}^{\text{TE}} e^{-j2\psi_i}$ [60–62]. Obviously, this Green function is not shift-invariant in the z direction, even though it is still shift-invariant in the x and y directions. Consequently, unlike the scattering problem in free space, the integral in (65) is no longer convolutional; thus, the convolutional theorem cannot be used directly to arrive at the FFT acceleration in the CG-FFT, BCG-FFT, and BCGS-FFT methods as in the case of a homogeneous background.

Fortunately, we are able to develop a splitting technique to rewrite the dyadic Green function into two terms, one is shift-invariant in all directions, the other is shift-invariant in the x and y directions, but as a function of $z + z'$ in the z direction ([19,20,63,64,76,78]). More specifically, as indicated in (66), the dyadic Green's function in a layered medium can be written as the summation of two terms:

$$\mathbf{G}^{ii}(\mathbf{r}, \mathbf{r}') = \mathbf{G}_1^{ii}(|\bar{\rho} - \bar{\rho}'|, z - z') + \mathbf{G}_2^{ii}(|\bar{\rho} - \bar{\rho}'|, z + z') \quad (67)$$

As a result, in Eq. (65), the interaction between $\mathbf{G}_1^{ii}(\mathbf{r}, \mathbf{r}')$ and $\chi(\mathbf{r}')\mathbf{D}(\mathbf{r}')$ is a convolution in all (x, y, z) directions, and that between $\mathbf{G}_2^{ii}(\mathbf{r}, \mathbf{r}')$ and $\chi(\mathbf{r}')\mathbf{D}(\mathbf{r}')$ is a convolution in x and y directions, but a correlation in z direction. In other words, the integral kernel in the EFIE is convolutional in the x and y directions and convolutional or correlational in the z direction after the splitting. Consequently, the FFT can be applied to these two operations separately through the convolution and correlation theorems, reducing CPU time of the ‘‘Green’s operation’’ from $O(N^2)$ to $O(N \log N)$.

5.2.1. Linear convolution and correlation. In order to make use of the FFT algorithm to achieve discrete convolution and correlation for non-periodic, finite functions $\{h_1(n)\}$ of length N_1 and $\{h_2(n)\}$ of length N_2 , one needs to pad zeros to these arrays and assume that the new arrays are periodic. These new arrays must have a length at least equal to $N = N_1 + N_2 - 1$ to avoid the overlap in the resulting circular convolution and correlation. Furthermore, the convolution and correlation integrals in the volume integral equations actually involve discrete convolution and correlation of a non-periodic array $h(n)$ of finite duration M with a non-periodic function $g(n)$, namely the Green’s function, of infinite support but truncated to length N . In this case, since both functions must be made periodic of length N , to avoid the end effect one must choose the total number $N \geq 2M - 1$ to obtain the correct result for the M points within the scatterer.

5.2.2. Fast Multipole Method. The FFT algorithm is also an important component in the fast multipole method (FMM) [17,70] that has significantly reduced the computational complexity of the numerical solution of integral equations, especially surface integral equations. For more details of this FMM algorithm, the reader is referred to Ref. 16.

5.3. Fast Inverse Scattering Methods

Electromagnetic waves have widespread applications in areas such as medical diagnosis, geophysical exploration,

nondestructive evaluation, and other areas of imaging. In such applications, one needs to solve the inverse problem, that is, to infer the characteristics of the target from the observed electromagnetic fields. The inverse scattering problems can be classified into two types: (1) approximate, linear inverse problems and (2) nonlinear inverse scattering methods. The FFT plays an important role in both types of electromagnetic inverse scattering problems.

Electromagnetic inverse problems are inherently nonlinear because of the multiple scattering within different parts of the scatterer. However, in the low-frequency regime, one can approximately neglect the multiple scattering; such an approximation is known as the *Born approximation* [7]. Similarly, in the high-frequency regime, one can use Rytov approximation or Kirchhoff approximation to make the inverse problem linear. Such linear inverse methods include the low-frequency diffraction tomography [22], high-frequency synthetic aperture radar (SAR) processing [72], and the related migration processing. For example, in a SAR processing scheme, the principal idea is to synthesize the effect of a large-aperture radar whose physical construction is infeasible. In three-dimensional SAR, the antennas move along a 2D trajectory in the 3D space. Denote the location of the antenna as $(0, u, v)$, where (u, v) are the azimuthal and elevation coordinates of the radar, and the wideband signal emitted by the antenna as $p(t)$. We may assume for simplicity an omnidirectional radar radiation pattern. Then, the SAR signal [72] can be expressed as

$$s(t, u, v) = \sum_n f_n p \left(t - 2\sqrt{x_n^2 + (y_n - u)^2 + (z_n - v)^2} / c \right) \quad (68)$$

where c is the velocity of light (or sound) and f_n is the normalized reflectivity of the n th point scatterer. Taking the Fourier transform of (68) in (t, u, v) yields the reconstruction equation for the unknown reflectivity

$$f(x, y, z) = \frac{\mathcal{F}_{k_x, k_y, k_z}^{-1} S(\omega, k_u, k_v)}{P(\omega)} \quad (69)$$

where \mathcal{F}^{-1} denotes the inverse Fourier transform and $[k_x, k_y, k_z]$ are governed by the SAR (SAS) spatial frequency mapping

$$\begin{aligned} k_x(\omega, k_u, k_v) &= \sqrt{4\omega^2/c^2 - k_u^2 - k_v^2}, \\ k_y(\omega, k_u, k_v) &= k_u, \quad k_z(\omega, k_u, k_v) = k_v \end{aligned} \quad (70)$$

The image of the object can thus be found by using the FFT algorithm from (69).

To address the high-contrast problems where the electrical properties of the object are very different from the background, nonlinear inverse scattering methods in 2D [11,14,15,38] and 3D [1,2,85] have been developed. For more recent developments in this area, the reader is referred to the references cited in Refs. 45 and 85.

6. NONUNIFORM FAST FOURIER TRANSFORM (NUFFT)

As illustrated above, the FFT has been enjoying widespread applications in numerical analysis and other areas of applied mathematics since the work of Cooley and Tukey [18] in the 1960s. However, the requirement for using FFT algorithms is that the input data must be equally sampled. In many practical situations, however, the input data are not equally spaced either by error or by design, and hence the regular FFT does not apply. To overcome this limitation Dutt and Rokhlin [24] studied the problem of FFT for nonuniform (unequally spaced) data. Later, the fast FFT for nonuniform data has been termed (*nonuniform fast Fourier transform*) (NUFFT) [52,65].

6.1. Nonuniform Discrete Fourier Transforms (NUDFTs)

The nonuniform discrete Fourier transform (NUDFT) is an extension of the regular (uniform) DFT. This extension has widespread applications because many measurements, ranging from synthetic aperture radar (SAR), ground penetrating radar (GPR), to biomedical imaging using magnetic resonance imaging (MRI) and X-ray computerized tomography (CT), are sampled nonuniformly in a given space. First, we define the temporal sampling point locations $\{t_n, n = 0, \dots, N - 1\} \in [0, N)$, and frequency sampling point locations $\{\omega_m, m = 0, \dots, N - 1\} \in [0, N)$, where periodicity is implied with a period of N in both domains. There are three basic types of NUDFT as given below. The complex sequence and its spectrum are defined as $h = \{h(t_0), \dots, h(t_{N-1})\}$ and $H = \{H(\omega_0), \dots, H(\omega_{N-1})\}$, respectively:

1. *NUDFT-1*. Nonuniform temporal sampling points $\{t_n\} \in [0, N)$, but uniform frequency sampling points $\omega_m = 0, \dots, N - 1$. This NUDFT is termed NUDFT-1 here and is defined as the sum

$$H(m) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} h(t_n) e^{-j t_n m (2\pi/N)}, \quad (71)$$

$$m = 0, \dots, N - 1$$

2. *NUDFT-2*. Uniform temporal sampling points $t_n = 0, \dots, N - 1$, but nonuniform frequency sampling points $\{\omega_m\} \in [0, N)$. This NUDFT is termed *NUDFT-2* here and is defined as the sum

$$G(\omega_m) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} g(n) e^{-j \omega_m n (2\pi/N)}, \quad (72)$$

$$m = 0, \dots, N - 1$$

3. *NUDFT-3*. Nonuniform temporal sampling points $t_n \in [0, N)$, and nonuniform frequency sampling points $\omega_m \in [0, N)$. This NUDFT is termed *NUDFT-3*

here and is defined as the sum

$$F(\omega_m) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} f(t_n) e^{-j \omega_m t_n (2\pi/N)}, \quad (73)$$

$$m = 0, \dots, N - 1$$

The corresponding fast algorithms for these sums are designated NUFFT-1, NUFFT-2, and NUFFT-3, respectively.

As shown in Ref. 24, once the solution to NUFFT-1 is found, NUFFT-2 and NUFFT-3 algorithms follow analogously. Therefore, here we will only discuss the NUFFT-1 algorithm for the fast solution of (71). Furthermore, the nonuniform inverse transforms corresponding to (18) can be defined similarly, and the algorithms are analogous to (71)–(73).

Now let's focus on the NUDFT-1 given by (71). The properties of the NUDFT-1 are largely analogous to those of the regular DFT, as summarized in Table 4.

6.2. The Forward NUFFT Algorithm

The aim of the NUFFT is to find a fast way to evaluate the sums in (71)–(73). Note that the direct summation in these equations requires $O(N^2)$ operations, much more than the FFT algorithm that requires only $O(N \log N)$ operations. The NUFFT algorithms developed by various groups [5,24,29,52,65] can provide approximate solutions to the NUDFT summations with $O(N \log N)$ operations. We will describe the algorithms reported in Refs. 52, 57, and 65 below.

We now consider the NUDFT-1 defined in (71). Instead of interpolating the input data $\{h(t_n)\}$, we will interpolate the exponential function $\exp(-j2\pi t m/N)$ for each $t = t_n$ ($n = 0, \dots, N - 1$). In applications, we only need to consider a discrete sequence

$$f(m) = s_m e^{-j2\pi t m/N}, \quad m \in \{0, \dots, N - 1\} \quad (74)$$

where t is real, $0 \leq s_m \leq 1$ for $m = 0, \dots, N - 1$ are called the “scaling factors,” and are chosen to minimize the error, and q an even positive integer. Denoting $w = e^{-j(2\pi t/N)}$, we will now interpolate $f(m)$ using the exponential function at $q + 1$ points on a unit circle

$$s_m w^{mvt} = \sum_{k=-q/2}^{q/2} x_k(t) w^{m(vt+k)}, \quad m = 0, \dots, N - 1 \quad (75)$$

Table 4. Properties of NUDFT-1

Property	Inverse NUDFT-1	Forward NUDFT-1
Linearity	$c_1 h_1(t_n) + c_2 h_2(t_n)$	$c_1 H_1(m) + c_2 H_2(m)$
Symmetry	None	None
Timeshifting	$h(t_n - T_0)$	$H(m) e^{-j2\pi m T_0/N}$
Frequency shifting	$h(t_n) e^{j2\pi t_n p/N}$	$H(m - p)$
Time reversal	$h(-t_n)$	$H(-m)$
Conjugation	$h^*(t_n)$	$H^*(-m)$
Even array	$h_e(t_n)$	$H_e(m)$
Odd array	$h_o(t_n)$	$H_o(m)$

where $[a]$ denotes the integer nearest to a , and $x_{-q/2}(t), \dots, x_{q/2}(t)$ are some unknown interpolation coefficients to be determined.

The unknown interpolation coefficients $x(t) = [x_{-q/2}(t), \dots, x_{q/2}(t)]^T$ can be determined by the least-squares method. Remarkably, this solution can be written almost analytically as

$$x(t) = F^{-1}y(t) \quad (76)$$

where for $i, k = 0, \dots, q$ we have

$$F_{ik}(v, N, q) = \begin{cases} N & i = k \\ \frac{w^{(i-k)N/2} - w^{(k-i)N/2}}{1 - w^{(k-i)}}, & i \neq k \end{cases} \quad (77)$$

$$y_k(t) = \sum_{m=0}^{N-1} s_m w^{(vt) + q/2 - km} \quad (78)$$

Observe that while $y(t)$ depends on t , matrix $F(v, N, q)$ is completely independent of t and is uniquely determined by v, N , and q . This remarkable property of this interpolation is important because it reduces the number of operations required by the NUFFT algorithms. The matrix $F(v, N, q)$ is called the *regular Fourier matrix*; it is a $(q+1) \times (q+1)$ Hermitian matrix, $F(v, N, q)^\dagger = F(v, N, q)$. These formulas make sense for any $q \in \mathcal{N}$, and therefore $F(v, N, q)$ can be defined for any $v, N, q \in \mathcal{N}$.

In the equations above, the coefficients $0 < s_m \leq 1$, for $m = 0, \dots, N-1$, called the *scaling factors*, are chosen to minimize the errors. Two scaling factors have been investigated:

- *Cosine scaling factors* $s_m = \cos(\pi m/vN)$ for $m = 0, \dots, N-1$.
- *Gaussian scaling factors* $s_m = e^{-b(2\pi m/vN)^2}$ for $m = 0, \dots, N-1$.

For the cosine scaling factors $s_m = \cos(\pi j/vN)$ for $j = 0, \dots, N-1$, it turns out that $y_k(t)$ can be written in a closed form by

$$y_k(t) = j \sum_{\gamma=-1,1} \frac{\sin\left[\frac{\pi}{2v}(2k - \gamma - q - 2\{vt\})\right]}{1 - e^{j(\pi/vN)(2\{vt\} + q - 2k + \gamma)}} \quad (79)$$

Unfortunately, for the Gaussian scaling factor, we are unable to find a closed-form expression for $y_k(t)$.

The NUFFT-1 algorithm consists of following steps:

1. Compute $y_k(t_n)$ by (79) for $k = 0, \dots, q$ and $n = 0, \dots, N-1$. The complexity is $O(Nq)$.
2. Compute $P_{\text{in}} = \sum_{k=0}^q [F^{-1}]_{ik} y_k(t_n)$, where the inverse regular Fourier matrix F^{-1} is precomputed. The complexity is $O(Nq^2)$.
3. Find the inverse of the scaling factor s_m^{-1} . For the cosine scaling factors $s_m^{-1} = \sec(\pi m/vN)$ for $m = 0, \dots, N-1$. The complexity is $O(N)$.

4. Calculate Fourier coefficients

$$\tau_l = \sum_{i, n, [vt_n] + i = l} h(t_n) \cdot P_{\text{in}}$$

The complexity is $O(Nq)$.

5. Use uniform FFT to evaluate

$$T_m = \sum_{l=-vN/2}^{vN/2-1} \tau_l \cdot e^{-j2\pi ml/vN}$$

The complexity is $O(vN \log N)$.

6. With a complexity of $O(N)$, scale the values to arrive at the approximated nonuniform FFT:

$$\tilde{H}(m) = T_m \cdot s_m^{-1}$$

The total complexity is $O(N \cdot q^2 + vN \log N)$, noting that $q \sim \log(1/\epsilon)$ where ϵ is the precision, and $v^2 \ll N$ (usually $v = 2$).

6.3. The Inverse NUFFT Algorithm

The inverse NUFFT algorithm is to find $h(t_n)$ from known $H(m)$ in Eq. (71). We first rewrite the NUFFT-1 in (71) and NUFFT-2 in (72) as

$$H(m) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} h(n) e^{-jt_n m 2\pi/N} \quad (80)$$

$$\equiv \sum_{n=0}^N A_{mn} h(t_n), \quad A_{mn} = \frac{1}{\sqrt{N}} e^{-jt_n m 2\pi/N}$$

$$G(\omega_m) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} g(n) e^{-jn\omega_m 2\pi/N} \quad (81)$$

$$\equiv \sum_{n=0}^{N-1} B_{mn} g(n), \quad B_{mn} = \frac{1}{\sqrt{N}} e^{-jn\omega_m 2\pi/N}$$

These forward NUFFT summations can be evaluated by NUFFT-1 and NUFFT-2 algorithms with $O(vN \log N)$ arithmetic operations (v is the oversampling rate).

For the regular, uniformly sampled data where both $\{t_k\}$ and $\{\omega_j\}$ are uniform, the inverse FFT (IFFT) can share the same algorithm as the FFT simply because $A^{-1} = A^\dagger$ and $B^{-1} = B^\dagger$ in these special cases (the superscript \dagger denotes the complex conjugate and transpose of a matrix). Unfortunately, this is no longer true for matrices A and B for nonuniformly sampled data. Hence, the inverse NUFFT can no longer share the same algorithm as the forward NUFFT. Obviously, the direct inversion of (80) and (81) to obtain $h(n)$ and $g(n)$ is prohibitively expensive as it requires $O(N^3)$ arithmetic operations. In Refs. 24 and 52, the inverse NUFFT algorithms have been developed.

We first rewrite (80) using a matrix notation $H = Ah$. From elementary matrix identities we observe that

$A^{-1} = A^\dagger(AA^\dagger)^{-1}$. Therefore the inverse DFT solution of (80) is

$$h = A^\dagger f, \quad f = (AA^\dagger)^{-1}H \quad (82)$$

The advantage of rewriting the solution in the form of (82) is clear because matrix AA^\dagger is a Toeplitz matrix. That is, $(AA^\dagger)_{kl} = a_{k-l}$, where

$$a_k = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} e^{-jt_n 2\pi k/N}, \quad k = -N+1, \dots, N-1 \quad (83)$$

Observe that there are only N independent elements in the array a since $a_{-k} = (a_k)^*$. Furthermore, these N elements in (83) can be obtained by the NUFFT-1 algorithm

$$a_k = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} e^{-jt_n 2\pi k/N}, \quad k = 0, \dots, N-1 \quad (84)$$

with $O(vN \log N)$ arithmetic operations.

Since AA^\dagger is a Toeplitz matrix, the vector f in (82) can be obtained efficiently using the conjugate-gradient FFT (CG-FFT) method [24]. In the CG-FFT method, the solution of f in (82) is obtained iteratively. Each iteration involves operations such as $y = (AA^\dagger)x$, which can be written as a discrete convolution

$$y_n = \sum_l a_{n-l} \cdot x_l = \{\text{FFT}^{-1}[\text{FFT}(a)\text{FFT}(x_p)]\}_j \quad (85)$$

and has been calculated by the regular FFT algorithm through the convolution theorem. Note that in (85), the size of the FFT's is $2N$, and x_p is the array x padded with N zeros. After f is solved by the above CG-FFT method, we can obtain h from (82) by

$$h(t_n) = \sum_{m=0}^{N-1} A_{mn}^* f_m = \frac{1}{\sqrt{N}} \left[\sum_{m=0}^{N-1} f_m^* e^{-jmt_n 2\pi/N} \right]^* \quad (86)$$

which can be achieved by the NUFFT-2 algorithm.

In summary, the procedures for the inverse NUFFT-1 algorithm for Eq. (80) is

1. *Preprocessing*—use the NUFFT-1 to obtain array $\{a_j\}$ through Eq. (84), and use the FFT algorithm to find $[\text{FFT}(a)]$.
2. *Inversion*—use the CG-FFT method for the solution f in (82).
3. *Transposition*—apply the NUFFT-2 to the transposed problem in Eq. (86).

In these steps, since NUFFT-1 and NUFFT-2 require $O(vN \log N)$ arithmetic operations, the most expensive step is the CG-FFT solution. It requires $O(KN \log N)$ arithmetic operations, where the number of iterations K in the CG method is proportional to the condition number of AA^\dagger . In most applications K is rather small as the points $\{t_m\}$ are fairly uniformly spaced. A similar algorithm has been developed for the inverse NUFFT of equation (81).

6.4. FFT for Discontinuous Functions—the DFFT Algorithm

The NUFFT algorithms presented above have been developed for nonuniform discrete Fourier transform. However, in practice, we often need to consider the continuous functions. In many applications in antennas, scattering, and computational electromagnetics, as well as in signal and image processing and other areas of computational science and engineering, one often needs to compute the Fourier transform of discontinuous functions. For example, in the well-known conjugate-gradient fast Fourier transform (CG-FFT)-type methods for integral equations (see Ref. 13 and references cited therein), one needs to find the Fourier transform of the unknown fields; in discontinuous media, some components of these unknown fields are discontinuous functions across the interfaces between different materials. In the conventional CG-FFT methods, discrete Fourier transforms (DFT) of these discontinuous functions are calculated through FFT algorithms. However, it is known that the conventional DFT cannot give accurate results for discontinuous function. This approach has a poor accuracy of $O(N^{-1})$, where N is the number of sample points. This large error is a result of the trapezoidal rule for the Fourier integration; in comparison, if the function is smooth and periodic, the DFT has exponential accuracy. A highly accurate fast Fourier transform algorithm for discontinuous functions, called the *discontinuous fast Fourier transform* (DFFT) algorithm, was proposed by Fan and Liu [25,28], based on the previous work for piecewise constant functions [71].

An accurate and efficient FFT algorithm for discontinuous data include two basic steps:

1. A highly accurate quadrature for improving the accuracy of integration
2. The standard FFT for efficiently evaluating the discretized summation of the integration

To combine these two steps, we need to resort to an interpolation procedure. Since the FFT algorithm requires uniformly sampled points while the function to be transformed has discontinuities at potentially nonuniform points, the interpolation procedure should interpolate such nonuniform data points to the uniform FFT data points. Unfortunately, many existing interpolation algorithms are either not directly applicable or cannot be utilized in this problem. Previously, two algorithms for discontinuous data were found in the literature [5,71]. Sorets proposed a fast Fourier transform algorithm for piecewise constant functions via the Gaussian quadrature and Lagrange interpolation, together with an application of the standard FFT [71], but the algorithm cannot be directly applied to piecewise smooth functions. The FFT of functions with similar singularities has also been treated by Beylkin [5] using piecewise polynomial splines, although numerical results are yet to be given for piecewise smooth functions.

The DFFT reported by Fan and Liu [26,28] considers the Fourier transform of a periodic piecewise smooth

function $f(x)$ defined in a period $T = 1$

$$\hat{f}(n) = \int_0^1 f(x) e^{-j2\pi nx} dx \quad -\frac{N}{2} < n \leq \frac{N}{2} - 1 \quad (87)$$

where n is an integer. We divide the integration interval $[0,1]$ into L subdivisions within which $f(x)$ is a smooth function. Step discontinuities are allowed at the boundaries of these subdivisions. In subdivision l ($l = 1, \dots, L$), there are at most p^l uniformly or nonuniformly sampling points, where p^l is referred to as the order of interpolation as shown later. Then (87) can be written as

$$\hat{f}(n) = \sum_{l=1}^L \int_{x_{l-1}}^{x_l} f(x) e^{-j2\pi nx} dx \quad (88)$$

where $\{x_l\}$ ($l = 1, \dots, L$) are the endpoints of the subdivisions. Using the change of variables

$$x = a^l + b^l t = \frac{x_l + x_{l-1}}{2} + \frac{x_l - x_{l-1}}{2} t \quad (89)$$

and the Gaussian Legendre quadrature

$$\int_{-1}^1 f(t) dt \cong \sum_{k=1}^q f(t_k) \omega_k \quad (90)$$

where t_k and ω_k ($k = 1, \dots, q$) are the Gaussian-Legendre nodes and weights, respectively, we obtain

$$\hat{f}(n) \cong \sum_{l=1}^L b^l \sum_{k=1}^q \omega_k^l f(t_k^l) e^{-j2\pi n t_k^l} \quad (91)$$

In this expression, the values of both function $f(x)$ and the exponential function $\exp(-j2\pi nx)$ at the nonuniform distributed points $\{t_k^l\}$ can be obtained via the Lagrange interpolation

$$g(x) = \sum_{m=1}^p g(x_m) \delta_m(x) \quad (92)$$

where

$$\delta_m(x) = \prod_{\substack{n=1 \\ n \neq m}}^p \frac{x - x_n}{x_m - x_n} \quad (93)$$

Here we perform this interpolation separately for $f(x)$ with order $p = p_1$ and $\exp(-j2\pi nx)$ with order $p = p_2$. Note that p_1 and p_2 can vary for different subdivisions; thus, they take p_1^l and p_2^l , respectively. (However, to simplify the presentation, we take the same p value in the following discussion.)

Note that we use this double-interpolation scheme because these two functions to be interpolated have different properties. The former, $f(x)$, is a piecewise function, while the latter, $\exp(-j2\pi nx)$, is a periodic analytic function but highly oscillating when n becomes large. Therefore we normally interpolate the two functions with different sets

of sampling points and orders of interpolation. For the exponential function, we use a uniform grid in order to apply the uniform FFT for the discrete summation; furthermore, we always place the interpolated points at the center of the interpolation region to obtain the highest accuracy for a p th-order Lagrange interpolation. With this double interpolation, (90) becomes

$$\hat{f}(n) = \sum_{l=1}^L b^l \sum_{k=1}^q \omega_k^l \left(\sum_{m_1=1}^{p_1} f(t_{m_1}^l) \delta_{m_1}(t_k^l) \right) \left(\sum_{m=1}^{p_2} e^{-j2\pi n t_m^l} \delta_m(t_k^l) \right) \quad (94)$$

Transforming the local coordinate into a global coordinate and changing the order of summation, we finally obtain

$$\hat{f}(n) = \sum_{i=1}^{vN} g_i e^{-j2\pi n x_i} \quad (95)$$

where

$$g_i = \sum_{l=1}^L \sum_{k=1}^q F_{lk} \sum_{m=1}^{p_2} \delta_m(t_k^l) |_{x(t_m^l)=x_i}, \quad (96)$$

$$F_{lk} = b^l \omega_k^l \sum_{m_1=1}^{p_1} f(t_{m_1}^l) \delta_{m_1}(t_k^l)$$

and v is the oversampling factor. Note that F_{lk} can be calculated independently and stored in a temporary vector of size $N \approx L \times q$, and all g_i values can be obtained by performing only once the triple summations over l, k, m , only for the terms with $x(t_m^l) = x_i$. Hence the calculation of g_i is very efficient with $O(vNp_2)$ complexity. Finally, (95) can be efficiently evaluated via a standard uniform FFT algorithm since $\{x_i\}$ are now on a uniform grid in $[0,1]$.

Furthermore, note that taking $L = 1$, the above formulas are directly reduced to the FFT algorithm for nonuniformly sampled continuous functions. In such a nonuniform fast Fourier transform (NUFFT) algorithm, however, it is desirable to further subdivide the domain (i.e., to increase L) when N is large, since this can reduce the computational cost in the Lagrange interpolation, resulting a more effective NUFFT algorithm for continuous functions. Such an NUFFT algorithm by itself is very useful in many engineering applications.

It is worth pointing out that compared with a single interpolation procedure, the double-interpolation procedure described above has several advantages:

- Double interpolation can ensure that the interpolation points for the exponential function are always located at the center of the interpolation region, leading to the highest accuracy for a given Lagrange interpolation order. In contrast, if a single interpolation were applied to the product of these two functions, the resulting function would not have the periodicity.

As a result, the locations of the interpolated points would not be always located at the center of the interpolation region, especially for those points near a function discontinuity point. Therefore, the accuracy of the interpolation for the product, and thus the accuracy of the FT, would be significantly reduced, especially when n becomes large.

- Since the Lagrange interpolation allows for nonuniform sampling, the algorithm described above can be applied to both uniform and nonuniform sampled data with the same number of arithmetic operations. Hence, it provides an FFT algorithm for nonuniformly sampled data. In contrast, a single interpolation allows only uniformly sampled data in order to use uniform FFT to evaluate the summation.
- Double interpolation allows for a lower-order interpolation, that is, a lower sample density, for $f(x)$ if it is a slowly varying function within each subdivision.
- Double interpolation allows other efficient algorithms, such as the fast multipole method (FMM) [23], to be incorporated readily into the interpolation procedure.

Implementation of the algorithm includes the following steps:

Step 1. Initialization of $\delta_{m_1}(t_k^l)$ and $\delta_m(t_k^l)$. This preprocessing step is needed only once and has a complexity of $O(Np^2)$, taking $q = p = \max(p_1, p_2)$.

Step 2. Calculation of F_{lk} and g_i in (96). The complexities are $O(vNp_1)$ and $O(vNp_2)$, respectively.

Step 3. Calculation of $\hat{f}(n)$ in (95) by a standard FFT. The complexity is $O(vN \log N)$.

The total complexity is $O(vNp + vN \log N)$ for steps 2 and 3. The preprocessing step needs to be done only once, and its computation time is negligible for repeated applications.

The DFFT algorithm has been utilized in several applications in computational electromagnetics, including the CG-FFT method [26] and the precorrected FFT solution [33].

7. CONCLUSIONS

The fast Fourier transform algorithm is a fundamental numerical computation tool in electrical engineering. It reduces the number of arithmetic operations in the discrete Fourier transform from $O(N^2)$ to $O(N \log N)$. More recent efforts have extended the FFT algorithm to nonuniform sampled data (NUFFT), and to discontinuous functions (DFFT). These algorithms have played and are continuing to play a central role in many modern applications in electromagnetics.

FEEDBACK AMPLIFIERS

THOMAS F. SCHUBERT Jr.
University of San Diego
San Diego, California

Feedback is the process of combining a portion of the output of a system with the system input to achieve modified performance characteristics. Found in a multitude of engineering applications, the process has become the foun-

dition several disciplines such as feedback control systems, feedback receivers, feedback oscillators, and feedback amplifiers. It has become particularly pervasive in amplifier design since the advent of transistors that can provide high gain cheaply, but cannot provide stable gain.

Negative feedback was originally applied by Harold S. Black in 1927 at Bell Labs to valve (vacuum tube) amplifiers to reduce distortion. In 1957 Black's work was described by Mervin Kelly, president of Bell Labs, as one of the two inventions of broadest scope and significance in electronics and communications is the first half of the century. Negative feedback is the process of mixing an inverted portion of the output of a system with the input to alter system performance characteristics. The process of negative feedback has become especially important in linear amplifier design and is characterized by several significant *benefits*:

- The gain of the amplifier is stabilized against variation in the characteristic parameters of the active devices due to voltage or current supply changes, temperature changes, or device degradation with age. Similarly, amplifier gain is stabilized within a group of amplifiers that have active devices with somewhat different characteristic parameters.
- Nonlinear signal distortion is reduced.
- The frequency range over which there is constant linear amplification (the midband region) is increased.
- The input and output impedance of the amplifier can be selectively increased or decreased.

It is a rare occurrence when benefits come without a price. In the case of negative feedback, the listed above benefits are accompanied by two primary *drawbacks*:

- The gain of the circuit is reduced. In order to regain the losses due to feedback, additional amplification stages often must be included in the system design. Complexity, size, weight, and cost may be added to the final amplifier design.
- There is a possibility for oscillation to occur. Should oscillation occur, the basic gain properties of the amplifier are destroyed.

This article considers the benefits of negative feedback on amplifier design. Basic definitions are followed by a general discussion of the properties of a feedback system. Amplifiers are divided into four categories of feedback topology, and the specific properties of each topological type are stated. While the emphasis of discussions must focus on circuit analysis techniques, a clear understanding of feedback in general, and effects of circuit topology in particular, is a necessity for good feedback amplifier design.

1. BASIC FEEDBACK CONCEPTS

Electronic amplifiers are fundamentally characterized by four properties:

- The gain of the amplifier. *Gain* is defined as the ratio of the output signal to the input signal. Each signal may be either a voltage signal or current signal.
- The range of frequencies over which the gain is essentially constant. This range of frequencies is identified as the midband region. It is bounded by the frequencies at which the output power is halved: the high and low 3-dB frequencies.
- The midband input impedance. Defined as the ratio of input voltage to input current.
- The midband output impedance. Defined as the Thévenin impedance seen at the amplifier output terminals.

The application of feedback to an amplifier alters each of these fundamental properties.

The basic topology of a feedback amplifier is shown in Fig. 1. An input signal X_i enters a summing (or *mixing*) junction, symbolized by a circular symbol. At the summing junction, the feedback signal X_f is subtracted from the input signal and the resultant signal X_δ is passed on to a linear amplifier, shown as a triangular symbol, of gain A . The output of the linear amplifier X_o forms the output of the feedback system. The rectangular symbol indicates a feedback network that samples the output signal, scales it by a feedback factor f and passes it forward to the input of the system. Each signal can take the form of either a voltage or a current, and ideally travels only in the direction of the indicated arrows. Subtraction of the two inputs at the summing junction is the key factor in negative feedback systems.

Feedback systems can be mathematically modeled with a set of simple relationships. The output X_o of the amplifier is related to the input signal X_δ by a linear amplification factor (gain) A , often called the *forward* or *open-loop gain*:

$$X_o = A(X_\delta) \quad (1)$$

Since the quantities X_o and X_δ can be either voltage or current signals, the forward gain A can be a voltage gain, a current gain, a transconductance, or a transresistance. *Voltage gain* is the ratio of output voltage to input voltage. Similarly, *current gain* relates output and input currents. *Transresistance* is the ratio of output voltage to input current and *transconductance* is the ratio of output current to input voltage. The feedback signal X_f (a fraction of the output signal X_o) is then subtracted from the input signal

Figure 1. Basic negative feedback topology.

X_i to form the difference signal X_δ

$$X_\delta = (X_i - X_f) = (X_i - fX_o) \quad (2)$$

where f is the *feedback ratio* defining the relationship between X_f and X_o :

$$X_f = fX_o \quad (3)$$

As is the case with the amplifier gain, the feedback ratio f is either a ratio of voltages, a ratio of currents, a transconductance, or a transresistance. The product fA , called the *loop gain*, must be a positive, dimensionless quantity in order to have stable negative feedback. Thus it is necessary, for negative feedback, that the mathematical sign of f be the same as that of A within the midband region. The input–output relationship for the overall feedback system can be derived from Eqs. (1) and (2):

$$X_o = \frac{A}{1+fA} X_i = A_f X_i \quad (4)$$

The overall gain of the system including the effects of feedback is then written as

$$A_f = \frac{X_o}{X_i} = \frac{A}{1+fA} \quad (5)$$

The overall feedback amplifier gain A_f has the same dimensions as the forward gain A . Equation (5) has special significance in the study of feedback systems and is typically identified as the *basic feedback equation*. The denominator of the basic feedback equation is identified as the *return difference D* but is also commonly referred to as “the amount of feedback”:

$$D = 1 + fA \quad (6)$$

The return difference, for negative-feedback systems, has magnitude larger than unity (in the midband frequency region) and is often specified in decibels:

$$D_{\text{dB}} = 20 \log_{10} |1 + fA| \quad (7)$$

The return difference quantifies the reduction in gain due to the addition of feedback to the system. It also plays a significant role in quantifying changes in frequency bandwidth and input and output impedance. Specifically, the high and low 3-dB frequencies are increased and decreased, respectively, by approximately a factor of D , and the input and output impedance are increased or decreased by a factor of D depending on the sampling and mixing circuit topologies.

Derivation of the basic feedback equation is based on two basic assumptions:

- The reverse transmission through the amplifier is negligible (a signal at the output produces essentially no signal at the input) compared to the reverse transmission through the feedback network.

- The forward transmission (left to right in Fig. 1) through the feedback network is negligible compared to the forward transmission through the amplifier.

In most feedback amplifiers, the amplifier is an active device with significant forward gain and near-zero reverse gain: the feedback network is almost always a passive network. Thus, in the forward direction, the large active gain will exceed the passive attenuation significantly. Similarly, in the reverse direction, the gain of the feedback network, albeit typically small, is significantly greater than the near-zero reverse gain of the amplifier. In almost every electronic application, the above-stated requirements for the use of the basic feedback equation are easily met by the typical feedback amplifier.

2. ANALYSIS OF FEEDBACK AMPLIFIER PROPERTIES

The analysis and design of electronic amplifiers is typically a multistep process. Complete, analytic characterization of an amplifier is a complex process whose results are in a form that often masks the individual amplifier properties. Amplifier designers therefore investigate the amplifier gain, frequency response, and impedance properties separately, carefully balancing system requirements to converge on a successful design. In addition to simplifying the process, separate investigation of the amplifier properties often leads to greater insight into design improvement. When a successful design is apparent, final fine tuning is accomplished with the aid of a computerized circuit simulator [i.e., System Program with Integrated Circuit Emphasis (SPICE)] and a prototype.

Essentially all of the drawbacks and benefits of feedback systems can be investigated on a simple level by looking at the properties of the basic feedback equation [Eq. (5)]. Gain stabilization, the reduction in nonlinear signal distortion, the increase in the frequency range over which there is linear amplification, the reduction in gain, and the possibility of oscillation all can be investigated on a simple level. The change in the input and output impedances cannot be investigated at this level: it is necessary to specify the nature (voltage or current) of the input and output quantities and the circuit topology in order to investigate these impedance changes.

2.1. Amplifier Gain

In Section 1, it was shown that feedback reduces amplifier gain by a factor of the return difference D . While reduction of gain can be a significant drawback, the ancillary gains are significant. Primary among those benefits is the stabilization of the amplifier gain against variation in the characteristic parameters of the active devices. It is well known that the forward gain A of an electronic amplifier is highly dependent on the parameters of the active devices contained within that amplifier. These parameters are typically dependent on temperature, bias conditions, and manufacturing tolerances. In order to maintain consistent amplifier performance it is desirable to design amplifiers that are reasonably insensitive to the variation of the device parameters.

The relationship between the differential change in gain due to device parameter variation with and without feedback is obtained by differentiating Eq. (5):

$$dA_f = \frac{1}{(1+fA)^2} dA \quad (8)$$

Stable negative-feedback amplifiers require that the return difference have magnitude greater than unity:

$$1 \quad (9)$$

Thus the absolute variation in gain is reduced by a factor of the return ratio squared. Another measure of the change in gain variation can be found by regrouping terms:

$$\left| \frac{dA_f}{A_f} \right| = \left| \frac{1}{(1+fA)} \right| \left| \frac{dA}{A} \right| \quad (10)$$

The factors in this equation more realistically describe the benefits: Equation (10) demonstrates the change in the percentage of gain variation about the nominal value. It can be seen that the percentage variation of the overall amplifier gain A_f is reduced by a factor of the return ratio when compared to the percentage variation of the gain A of the forward amplifier.

For example, if a feedback amplifier is constructed with an amplifier that is subject to a 3% variation in gain as its fundamental forward-gain element and it is desired that the feedback amplifier have no more than 0.1% variation in its overall gain due to the variation in this element. The necessary return difference to achieve this design goal can be obtained as follows:

Equation (10) is the significant relationship in determining the gain variation:

$$\left| \frac{dA_f}{A_f} \right| = \left| \frac{1}{(1+fA)} \right| \left| \frac{dA}{A} \right|$$

The significant properties are

$$0.001 \geq \left| \frac{1}{(1+fA)} \right| 0.03 \Rightarrow D = 1 + Af \geq 30$$

The minimum necessary return ratio is 30, more often identified as its decibel equivalent, $D_{dB} = 20 \log_{10} D \geq 29.54$ dB

Equation (10) is extremely useful for small changes in amplification due to parameter variation but is inaccurate for large changes. If the change in amplification is large, the mathematical process must involve differences rather than differentials:

$$\Delta A_f = A_{2f} - A_{1f} = \frac{A_2}{1+fA_2} - \frac{A_1}{1+fA_1} \quad (11)$$

In order to put this into the same format as Eq. (10), it is necessary to divide both sides of the equation by A_{1f}

$$\left| \frac{\Delta A_f}{A_{1f}} \right| = \left| \frac{A_2}{1+fA_2} \left(\frac{1+fA_1}{A_1} \right) - 1 \right| = \left| \frac{(A_2 - A_1)}{1+fA_2} \left(\frac{1}{A_1} \right) \right| \quad (12)$$

or

$$\left| \frac{\Delta A_f}{A_{1f}} \right| = \left| \frac{1}{1+fA_2} \right| \left| \frac{\Delta A}{A_1} \right| = \left| \frac{1}{1+f(A_1 + \Delta A)} \right| \left| \frac{\Delta A}{A_1} \right| \quad (13)$$

The results are similarly a reduction in gain sensitivity by a factor of the form of the return difference.

The differential change in feedback amplifier gain due to variation in the feedback ratio f can be obtained by differentiating Eq. (5) with respect to the feedback ratio. Appropriate mathematical manipulation leads to the desired results:

$$\frac{dA_f}{A_f} = \frac{-fA}{1+f} \frac{df}{Af} \Rightarrow \left| \frac{dA_f}{A_f} \right| = \frac{fA}{1+fA} \left| \frac{df}{f} \right| \quad (14)$$

It is easily seen that the percentage variation of the overall amplifier gain A_f is of approximately the same magnitude (actually it is slightly lesser) as the percentage variation of the feedback ratio f . Since electronic feedback amplifiers typically employ a feedback network constructed entirely with passive elements (usually resistors), variation in the feedback ratio can be kept relatively small through the utilization of precision elements in the feedback network. In good amplifier designs, the variation of amplifier gain due to variability in the feedback network is usually of lesser significance than that due to variability of the basic forward amplifier gain.

2.2. Nonlinear Signal Distortion

Stabilization of gain with parameter variation suggests that amplifier gain will be stabilized with respect to other gain-changing effects. One such effect is nonlinear distortion. Nonlinear distortion is a variation of the gain with respect to input signal amplitude. A simple example of non-linear distortion is demonstrated in Fig. 2. Here the transfer characteristic of a simple amplifier is approximated by two regions, each of which is characterized by

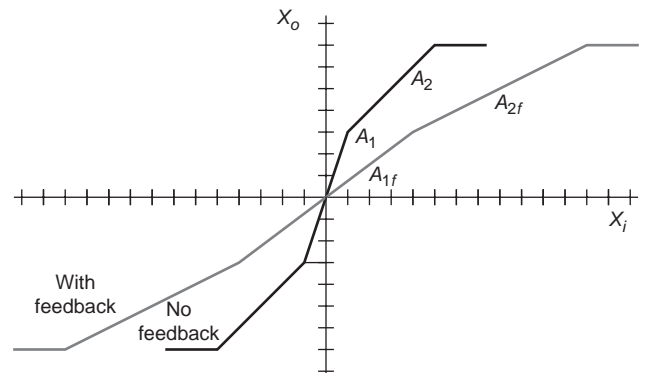

Figure 2. The effect on feedback on an amplifier transfer characteristic.

different amplification, A_1 and A_2 . To this transfer characteristic, a small amount of feedback is applied so that $fA_1 = 1$, and the resultant feedback transfer characteristic is shown. As can be easily seen, the overall feedback transfer characteristic also consists of two regions with overall amplification A_{1f} and A_{2f} . In this demonstration, the amplification ratios are:

$$\frac{A_1}{A_2} = 3, \quad \frac{A_{1f}}{A_{2f}} = 1.5$$

Feedback has significantly improved the linearity of the system and consequently has reduced the nonlinear distortion. Larger amounts of feedback (increasing the feedback ratio f) will continue to improve the linearity. For this example, increasing the feedback ratio by a factor of 5 will result in a ratio of overall gain in the two regions of 1.067 (as compared to 1.5, above). It should be noted that the saturation level of an amplifier is not significantly altered by the introduction of negative feedback. Since the incremental gain in saturation is essentially zero, the incremental feedback difference is also zero. No significant change to the input occurs and the output remains saturated.

Another viewpoint on gain stabilization comes from a limiting form of the basic feedback equation:

$$A_f = \frac{A}{1+fA} = \frac{1}{f} \left(1 - \frac{1}{1+fA} \right) \approx \frac{1}{f} \quad (15)$$

For large return difference ($D = 1 + Af$) the overall gain with feedback is dominated by the feedback ratio f and is therefore virtually independent of the forward gain A and any variations in A .

2.3. Frequency Response

Typical linear amplifiers have a range of frequencies over which the gain is essentially constant: this frequency range is called the *midband*. As frequencies increase, the performance parameters of an amplifier degrade. Similarly, coupling and bypass capacitors internal to the amplifier, when present, will degrade low-frequency performance. Using feedback to broaden the frequency range over which gain is relatively constant can be considered a special case of the stabilization of gain due to variation in amplifier performance characteristics. Feedback reduces the effects of these frequency-dependent degradations and thereby increases the frequency band over which the amplifier has stable gain.

A more exact description of the increase in the width of the midband region can be obtained through a frequency-domain analysis. It is common practice to use the frequencies at which the output power is reduced by 50% (the high and low 3-dB frequencies) as descriptors of the limits of the midband region. Discussion focuses on the change in these 3-dB frequencies.

It can be shown that the basic forward amplifier gain A is described as the midband gain A_0 , divided by a polynomial in frequency (written as s or $j\omega$)

$$A(s) = \frac{A_0}{P(s)} \quad (16)$$

The locations of the first few poles of $A(s)$ (or the zeroes of $P(s)$) closest to the midband region are the dominant predictors of amplifier frequency response; specifically, their location controls the 3-dB frequencies.

The application of feedback to an amplifier alters the gain expression through the basic feedback equation so that the total gain A_f is described by:

$$A_f(s) = \frac{\frac{A_0}{P(s)}}{1 + f \frac{A_0}{P(s)}} = \frac{A_0}{P(s) + fA_0} \quad (17)$$

Application of feedback to the basic forward amplifier has the effect of vertically shifting the denominator polynomial by a constant, fA_0 (see Fig. 3). This shift upward causes movement in the zeros of the denominator, thereby changing the location of the poles of the frequency response. Any movement of the poles nearest the region of constant gain (the midband region) equates into a change in the width of the midband region. Observation of the consequences of the result in graphical format is a great aid to understanding pole migration.

For example, when the high-frequency response is described by a single pole p_1 , Eq. (17) takes the following form:

$$\begin{aligned} A_f(s) &= \frac{A_0}{P(s) + fA_0} = \frac{A_0}{\left(1 + \frac{s}{p_{H1}} \right) + fA_0} \\ &= \frac{1}{1 + fA_0} \frac{A_0}{\left(1 + \frac{s}{p_{H1}(1 + fA_0)} \right)} \end{aligned} \quad (18)$$

It can easily be seen that the gain has been reduced by a factor of the return difference D and the pole frequency has been increased by the same factor. Similarly, if the low-frequency response is described by a single pole p_{L1} , the pole frequency will be reduced (i.e., divided by) by a factor of D . Since, in single-pole systems, the 3-dB frequency coincides with the pole frequencies, the high and low 3-dB frequencies, ω_H and ω_L , are shifted by a factor of the return ratio:

$$\omega_{Hf} = (1 + fA_0)\omega_H = D\omega_H \quad \text{or} \quad \omega_{Lf} = \frac{\omega_L}{1 + fA_0} = \frac{\omega_L}{D} \quad (19)$$

Figure 3. Pole migration due to feedback.

As the number of poles increases, description of the bandwidth increase with the application of feedback increases in complexity. When the high or low frequency response can be described by two poles, the damping coefficient due to the application of feedback is function ratio of the initial pole locations k and the return difference. The damping coefficient can be calculated to be

$$\zeta = \frac{1+k}{2\sqrt{k(1+fA_0)}} = \frac{1+k}{2\sqrt{kD}} \quad (20)$$

where k is defined as the ratio of the larger pole to the smaller pole at high or low frequencies:

$$k_H = \frac{\omega_{2H}}{\omega_{1H}} \quad \text{or} \quad k_L = \frac{\omega_{1L}}{\omega_{2L}} \quad (21)$$

This simple expression for the damping coefficient is a particularly important result in that it can tell the circuit designer the flatness of the frequency response in relation to the amount of feedback applied; a flat frequency response requires overdamped pole pairs ($\zeta \geq 0.707$).

Once the damping coefficient is determined, the exact expression for the high or low 3-dB frequency shift with the application of feedback takes a form similar to the single-pole case with an additional factor

$$\omega_{Hf} = K(\zeta_H, k_H) \cdot D \cdot \omega_{1H} \quad \text{or} \quad \omega_{Lf} = \frac{\omega_{1L}}{K(\zeta_L, k_L) \cdot D} \quad (22)$$

where k is the ratio of the initial pole spacing ($k \geq 1$), ζ is the pole pair damping coefficient, ω_{1H} and ω_{1L} are the poles closest to the midband, and the factor, $K(\zeta, k)$, is given by

$$K(\zeta, k) = \frac{2k\zeta}{k+1} \sqrt{1 - 2\zeta^2 + \sqrt{(1 - 2\zeta^2)^2 + 1}} \quad (23)$$

This relationship is shown in Fig. 4 for a variety of initial pole spacing ratios k . In most amplifier applications, $0.9 < K(\zeta, k) < \sqrt{2}$; some designers use a $K(\zeta, k) \approx 1$ as a first-order approximation.

For amplifiers where the frequency response must be described by more than two poles, description of the fre-

quency shift is even more complicated. Fortunately, amplifiers with a high or low frequency response that is described by more than two poles are reasonably modeled by considering them to be two-pole systems [13]: Eq. (22) adequately approximates the change in bandwidth for these higher-order systems.

For example, if an amplifier has a midband gain $A_0 = 1000$ and has frequency response described by one low-frequency pole, $f_L = 10$ kHz and two high-frequency poles, $f_{H1} = 1$ MHz and $f_{H2} = 10$ MHz and feedback is applied so that the midband gain is reduced to $A_{of} = 140$. The new low and high 3-dB frequencies can be determined as follows:

The return difference is the ratio of the two gains:

$$D = \frac{A_0}{A_{of}} = \frac{1000}{140} = 7.14286$$

The low-frequency response is described by a single pole; thus the low 3-dB frequency is changed by a factor of D :

$$f_{Lf} = \frac{f_L}{D} = \frac{10 \text{ kHz}}{7.14286} = 1.4 \text{ kHz}$$

The high-frequency response is described by two poles with ratio k :

$$k = \frac{\omega_{2H}}{\omega_{1H}} = \frac{f_{2H}}{f_{1H}} = \frac{10 \text{ MHz}}{1 \text{ MHz}} = 10$$

The damping coefficient for the two poles are found to be

$$\zeta_H = \frac{1+k}{2\sqrt{k(1+fA_0)}} = \frac{1+10}{2\sqrt{10(7.14286)}} = 0.6508$$

Note that the high poles of the feedback amplifier are slightly underdamped and that there will be a small “bump” (≈ 0.1 dB for this case) in the frequency response as a result. The high 3-dB frequency f_{Hf} is then found from

Figure 4. High 3-dB frequency as a function of ζ and nonfeedback pole spacing.

$K(\zeta_H, k)$, D , and f_1 :

$$f_{Hf} = K(\zeta_H, k)Df_1 = (1.277)(7.14286)(1 \text{ MHz}) = 9.12 \text{ MHz}$$

The resultant frequency response plots are shown in Fig. 5.

2.4. Input and Output Impedance

The input and output impedance of a feedback amplifier can be selectively increased or decreased through the application of feedback. As has been seen in the previous sections, general discussions provide great insight into many of the properties of feedback systems. In order to consider the design of electronic feedback amplifiers, it is necessary, however, to specify the details of the feedback sampling and mixing processes and the circuits necessary to accomplish these operations. The sampling and mixing processes have a profound effect on the input impedance, the output impedance, and the definition of the forward gain quantity that undergoes *quantified* change due to the application of feedback. This section will characterize the various idealized feedback configurations: the following section looks at practical feedback configurations.

The mixing and the sampling process for a feedback amplifier utilize either voltages or currents. Voltage mixing (subtraction) implies a series connection of voltages at the input of the amplifier; current mixing implies a shunt connection. Voltage sampling implies a shunt connection of the sampling probes across the output voltage; current sampling implies a series connection so that the output current flows into the sampling network. Either type of mixing can be combined with either type of sampling. Thus, a feedback amplifier may have one of four possible combinations of the mixing and sampling processes. These

Figure 5. An example of the effect of feedback on frequency response.

four combinations are commonly identified by a hyphenated term: mixing topology–sampling topology. The four types are

- *Shunt–shunt feedback* (current mixing and voltage sampling)
- *Shunt–series feedback* (current mixing and current sampling)
- *Series–shunt feedback* (voltage mixing and voltage sampling)
- *Series–series feedback* (voltage mixing and current sampling).

These four basic feedback amplifier topologies are shown schematically in Fig. 6. A source and a load resistance have been attached to model complete operation. In each diagram the input, feedback, and output quantities are shown properly as voltages or currents. Forward gain A must be defined as the ratio of the output sampled quantity divided by the input quantity that undergoes mixing.

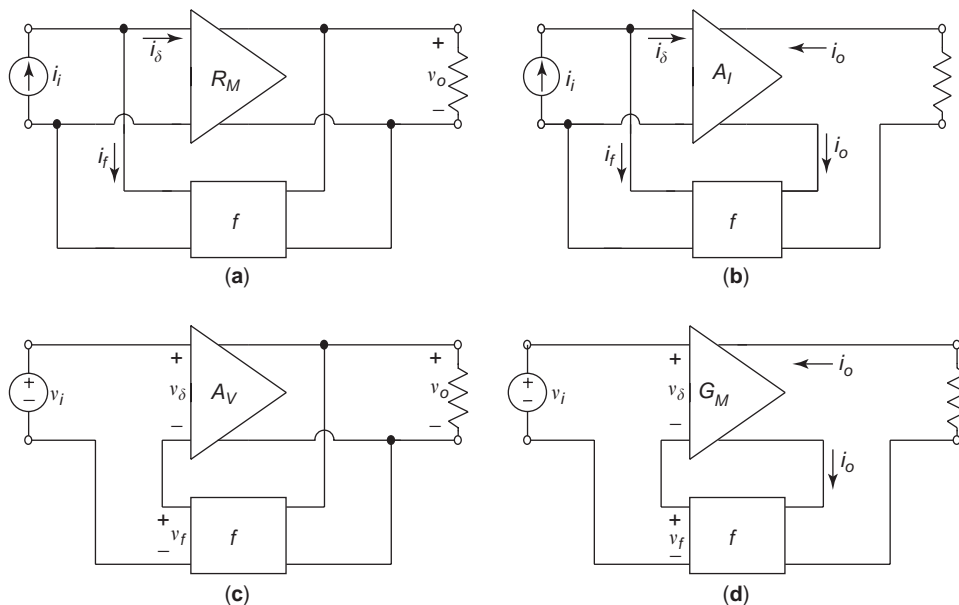

Figure 6. Feedback amplifier topologies: (a) shunt–shunt feedback; (b) shunt–series feedback; (c) series–shunt feedback; (d) series–series feedback.

Table 1. Feedback Amplifier Topology Parameters

Parameter	Shunt–Shunt	Shunt–Series	Series–Shunt	Series–Series
Input quantity X_i	Current i_s	Current i_s	Voltage v_s	Voltage v_s
Output quantity X_o	Voltage v_o	Current i_o	Voltage v_o	Current i_o
Forward gain A	Transresistance R_M	Current gain A_I	Voltage gain A_V	Transconductance G_M
Feedback ratio f	i_f/v_o	i_f/i_o	v_f/v_o	v_f/i_o

As such, it is a transresistance, current gain, voltage gain, or transconductance. The feedback network, as described by the feedback ratio (f), must sample the output quantity and present a quantity to the mixer that is of the same type (current or voltage) as the input quantity. As such it is a transconductance, current gain, voltage gain, or transresistance. Table 1 lists the appropriate quantities mixed at the input, the output sampled quantity, the forward gain, and the feedback ratio for each of the four feedback amplifier topologies. It is important to remember that the product fA must be dimensionless and, in the midband region of operation, positive.

In the previous section, all benefits of feedback were discussed *except* the modification of input–output impedance. The specific definitions of the four feedback amplifier topologies allow for that discussion to begin here. The *mixing process alters the input impedance* of a negative-feedback amplifier. Heuristically, one can see that subtraction of a feedback quantity at the mixing junction increases the input quantity necessary for similar performance. Thus, subtracting current (shunt mixing) requires an increase in overall input current and decreases the input impedance. Similarly, subtracting voltage (series mixing) requires an increase in overall input voltage and increases input impedance.

Although it can be easily shown that in each case, the change in resistance is proportional to the return difference D , it is important to note that the measurement point of the input and output resistance changes with each circuit topology. Two amplifier types are shown as examples: a *shunt–shunt* feedback amplifier (Fig. 7) and a *series–series* feedback amplifier (Fig. 8). Similarly, the return difference D is calculated using different gain and feedback parameters for each topology. The changes due to feedback on each feedback amplifier topology are summarized in Table 2.

Figure 7. Input–output resistance for shunt–shunt feedback.

3. PRACTICAL FEEDBACK CONFIGURATIONS

Previous discussions of feedback and feedback configurations have been limited to idealized systems and amplifiers. The four idealized feedback schematic diagrams of Fig. 6 identify the forward-gain amplifier and the feedback network as two-port networks with a very specific property—each is a device with one-way gain. Realistic electronic feedback amplifiers can only approximate that idealized behavior. In addition, in practical feedback amplifiers there is always some interaction between the forward-gain amplifier and the feedback network. This interaction most often takes the form of input and output resistive loading of the forward-gain amplifier. The division of the practical feedback amplifier into its forward-gain amplifier and feedback network is also not always obvious. These apparent obstacles to using idealized feedback analysis can be resolved through the use of two-port network relationships in the derivation of practical feedback amplifier properties. Once amplifier gain and impedance relationships have been derived, the utility of the two-port representations becomes minimal and is typically discarded.

3.1. Identification of the Feedback Topology

Feedback topology is determined through careful observation of the interconnection of the feedback network and forward-gain amplifier. Shunt mixing occurs at the input terminal of the amplifier. Thus, *shunt mixing* is identified by a connection of feedback network and the forward-gain amplifier at the input terminal of first active device within the amplifier, in one of the following locations:

- At the base of a bipolar junction transistor (BJT) for a common-emitter or common-collector first stage

Figure 8. Input–output resistance for series–series feedback.

Table 2. Feedback Amplifier Analysis

Characteristic	Topology			
	Shunt–Shunt	Shunt–Series	Series–Shunt	Series–Series
Input X_i	Current i_s	Current i_s	Voltage v_s	Voltage v_s
Output X_o	Voltage v_o	Current i_o	Voltage v_o	Current i_o
Signal source	Norton	Norton	Thévenin	Thévenin
Input circuit ^a	Include shunting resistances; set $v_o = 0$	Include shunting resistances; set $i_o = 0$	Exclude all shunt resistances; set $v_o = 0$	Exclude all shunt resistances; set $i_o = 0$
Output circuit ^a	Include shunting resistances; set $v_i = 0$	Exclude all shunt resistances; set $v_i = 0$	Include shunting resistances; set $i_i = 0$	Exclude all shunt resistances; set $i_i = 0$
Feedback ratio f	i_f/v_o	i_f/i_o	v_f/v_o	v_f/i_o
Forward gain A	Transresistance R_M	Current gain A_I	Voltage gain A_V	Transconductance G_M
Input resistance ^b	$R_{if} = \frac{R_i}{1 + f R_M}$	$R_{if} = \frac{R_i}{1 + f A_I}$	$R_{if} = R_i(1 + f A_V)$	$R_{if} = R_i(1 + f G_M)$
Output resistance ^b	$R_{of} = \frac{R_o}{1 + f R_M}$	$R_{of} = R_o(1 + f A_I)$	$R_{of} = \frac{R_o}{1 + f A_V}$	$R_{of} = R_o(1 + f G_M)$

^aInput–output circuit: These procedures give the basic forward amplifier without feedback but including the effects of loading due to the feedback network.
^bResistance: The resistance modified at *shunted* ports will include all shunting resistances that were included in the basic forward amplifier. The resistance modified at *series* ports will include only the resistances included in the basic forward amplifier. The true amplifier input–output impedance must be modified to reflect the point of measurement desired.

- At the emitter of a BJT for a common-base first stage
- At the gate of a field-effect transistor (FET) for a common-source or common-drain first stage
- At the source of a FET for a common-gate first stage

Series mixing occurs in a loop that contains the input terminal of the forward-gain amplifier and the controlling port of the first active device. The controlling port of a BJT in the forward-active region is the base–emitter junction; a FET in the saturation region is controlled by the voltage across the gate–source input port. *Series mixing* is characterized by a circuit element or network that is *both* connected to the output *and* in series with the input voltage and the input port of the first active device.

Identification of the sampling is derived from direct observation of the connection of the output of the basic forward amplifier and the feedback network. *Shunt sampling* is typically characterized by a direct connection of the feedback network to the output node; *series sampling* implies a series connection of the amplifier output, the feedback network, and the load. Two tests performed at the feedback amplifier output can aid in the determination of sampling topology:

- If the feedback quantity vanishes for a short-circuit load, the output voltage must be the sampled quantity. Thus zero feedback for a short-circuit load implies *shunt sampling*.
- If the feedback quantity vanishes for an open-circuit load, the output current must be the sampled quan-

ity. Thus zero feedback for an open-circuit load implies *series sampling*.

After the topological type has been identified, each amplifier must be transformed into a form that allows for the use of the idealized feedback formulations. This transformation includes modeling the amplifier and the feedback network with a particular two-port representation that facilitates combination of elements. Once the transformations are accomplished, the amplifier performance parameters are easily obtained using the methods previously outlined. The particular operations necessary to transform each of the four feedback amplifier topological types require separate discussion. Only the shunt–shunt topology is discussed in detail; the other three topologies use similar techniques that lead to the results shown in Fig. 11 and described in Table 2.

3.1.1. Shunt–Shunt Feedback: A Detailed Derivation.

Figure 9 is a small-signal model representation of a typical shunt–shunt feedback amplifier. In this representation, the forward-gain amplifier and the feedback network have been replaced by their equivalent *y*-parameter two-port network representations so that parallel parameters can be easily combined. A resistive load has been applied to the output port; and, since shunt–shunt feedback amplifiers are transresistance amplifiers, a Norton equivalent source has been shown as the input. It should also be noted that

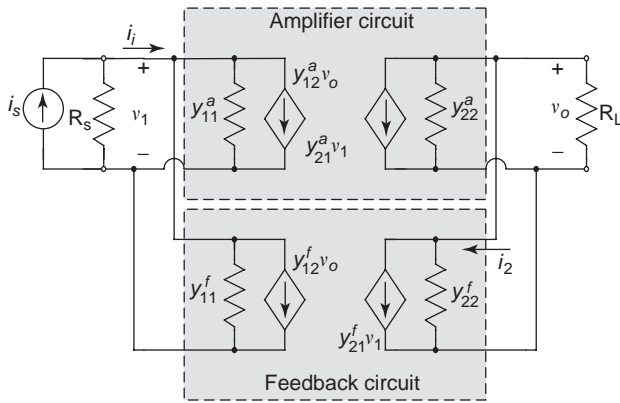

Figure 9. Two-port realization of a shunt–shunt feedback amplifier.

the forward-gain parameter of each two-port y_{21} is the transadmittance.

The basic feedback equation for a transresistance amplifier takes the form

$$R_{Mf} = \frac{R_M}{1 + R_{Mf}} \quad (24)$$

The application of the basic feedback equation to this circuit in its current form is not immediately clear. It is necessary to transform the feedback amplifier circuit into a form that allows for easy application of the basic feedback equation, [Eq. (24)]. Such a transformation must meet the previously stated feedback requirements:

- The forward-gain amplifier is to be a forward transmission system only—its reverse transmission must be negligible.
- The feedback network is to be a reverse transmission system that presents a feedback current, dependent on the output voltage, to the amplifier input port.

While a mathematically rigorous derivation of the transformation is possible, greater insight to the process comes with a heuristic approach.

The two-port y -parameter representation, in conjunction with the shunt–shunt connection, is used to describe the two main elements of this feedback amplifier so that all the input port elements of both two-port networks are in parallel. Similarly, all output port elements are in parallel. It is well known that circuit elements in parallel may be rearranged and, as long as they remain in parallel, the circuit continues to function in an identical fashion. Hence, it is possible, *for analysis purposes only*, to *conceptually* move elements from one section of the circuit into another (from the feedback circuit to the amplifier circuit or the reverse). The necessary conceptual changes made for the transformation are

- The source resistance, the load resistance, and all input and output admittances, y_{11} and y_{22} , are placed in the modified amplifier circuit. While inclusion of the source and load resistance in the amplifier seems, at first, counterproductive, it is necessary, however, to

include these resistances so that the use of the feedback properties produces correct results for input and output resistance (after appropriate transformations).

- All forward transadmittances y_{21} (represented by current sources dependent on the input voltage v_1) are placed in the modified amplifier circuit.
- All reverse transadmittances y_{12} (represented by current sources dependent on the output voltage v_o) are placed in the modified feedback circuit.

The dependent current source can be easily combined:

$$y_{12}^t = y_{12}^a + y_{12}^f \quad (25)$$

$$y_{21}^t = y_{21}^a + y_{21}^f \quad (26)$$

In virtually every practical feedback amplifier the reverse transadmittance of the forward-gain amplifier is much smaller than that of the feedback network ($y_{12}^a \ll y_{12}^f$) and the forward transadmittance of the feedback network is much smaller than that of the forward-gain amplifier ($y_{21}^f \ll y_{21}^a$). Thus, approximate simplifications of the amplifier representation can be made:

$$y_{12}^t = y_{12}^a + y_{12}^f \approx y_{12}^f \quad (27)$$

$$y_{21}^t = y_{21}^f + y_{21}^a \approx y_{21}^a \quad (28)$$

The shunt–shunt feedback amplifier circuit of Fig. 9 is, with these changes and approximations, thereby transformed into the circuit shown in Fig. 10.

This transformed circuit is composed of two simple elements:

- The original amplifier with its input shunted by the source resistance and the feedback network short-circuit input admittance y_{11}^f and its output shunted by the load resistance and the feedback network short-circuit output admittance y_{22}^f .
- A feedback network composed solely of the feedback network reverse transadmittance y_{12}^f .

It is also important to note that the input resistance R_{if} of this circuit includes the source resistance R_s ; as such, *it is*

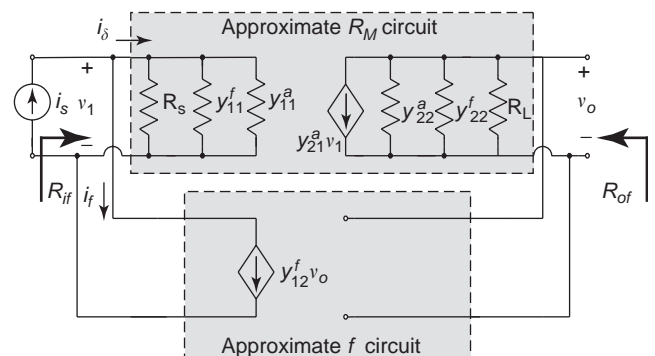

Figure 10. Redistributed shunt–shunt realization.

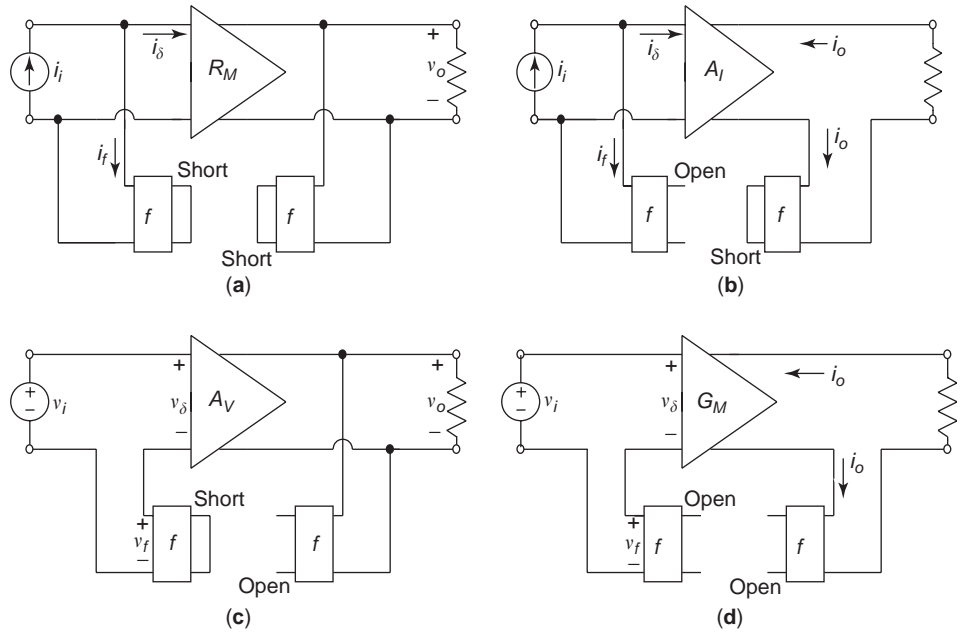

Figure 11. Feedback network loading of a basic forward amplifier: (a) shunt–shunt feedback; (b) shunt–series feedback; (c) series–shunt feedback; (d) series–series feedback.

not the same as the input resistance of the true amplifier R_{in} . The input resistance of the true amplifier can be obtained as

$$R_{in} = \left(\frac{1}{R_{if}} - \frac{1}{R_s} \right)^{-1} \quad (29)$$

Similarly, the output resistance R_{of} of this circuit includes the load resistance R_L ; similar operations may be necessary to obtain the true output resistance of the amplifier.

The y parameters of the feedback network can be obtained

$$y_{11}^f = \left. \frac{i_f}{v_1} \right|_{v_o=0}, \quad y_{22}^f = \left. \frac{i_2}{v_o} \right|_{v_1=0}, \quad y_{12}^f = \left. \frac{i_f}{v_o} \right|_{v_1=0} \quad (30)$$

where i_2 is the current entering the output port of the feedback network (see Fig. 8). With the determination of these two-port parameters, the circuit has been transformed into a form that is compatible with all previous discussions. The forward-gain parameter (in this case, G_M) of the loaded basic amplifier must be calculated, while the feedback ratio has been determined from the two-port analysis of the feedback network:

$$f = y_{12}^f \quad (31)$$

In the case of totally resistive feedback networks, the shunting resistances can be found in a simple fashion:

- $r_{in} = (y_{11}^f)^{-1}$ is found by setting the output voltage to zero value $v_o = 0$ and determining the resistance from the input port of the feedback network to ground.

- $r_{out} = (y_{22}^f)^{-1}$ is found by setting the input voltage to zero value $v_i = 0$ and determining the resistance from the output port of the feedback network to ground.

The feedback ratio f is simply the ratio of the feedback current i_f to the output voltage when the input port of the feedback network v_i is set to zero value. All idealized feedback methods can be applied to this transformed amplifier, and all previously derived feedback results are valid.

The other three feedback amplifier topologies can be similarly analyzed using various two-port parameters for analysis:

- Shunt–series: g parameters
- Series–shunt: h parameters
- Series–series: z parameters

Such analysis leads to a characterization of the loading of the basic forward amplifier as is described in Fig. 11. As is the case with the shunt–shunt topology, individual elements within the feedback network may appear more than one in the loaded basic forward-amplifier equivalent circuit. Table 2 summarizes the analysis of feedback amplifier properties:

4. STABILITY IN FEEDBACK AMPLIFIERS

Under certain conditions, feedback amplifiers have the possibility of being unstable. This instability stems from the frequency-dependent nature of the forward gain of the basic amplifier, A and the feedback factor f . The frequency dependence is exhibited in the changes in magnitude and phase of the product fA as a function of frequency.

Instability can be visualized by studying the basic feedback equation as a function of frequency:

$$A_f(j\omega) = \frac{A(j\omega)}{1 + f(j\omega)A(j\omega)} \quad (32)$$

It is important that an amplifier be designed so that stability is present at all frequencies, not only those in the midband region. If the product $-f(j\omega)A(j\omega)$ approaches unity at any frequency, the denominator of Eq. (32) approaches zero value; the total gain of the amplifier approaches infinity. This condition represents an output that is truncated only by power supply limitations regardless of input magnitude and is an unstable condition that is intolerable in amplifiers. In order to avoid this instability, it is necessary to avoid a simultaneous approach of $|f(j\omega)A(j\omega)| = 1$ and $\angle f(j\omega)A(j\omega) = \pm 180^\circ$. Since each pole can provide a phase shift ranging from 0° and -90° only, the second condition is possible only for amplifiers that have high or low frequency responses described by three or more poles. Simultaneously satisfying both conditions can be avoided if the magnitude of fA is always less than unity when the phase angle of fA is $\pm 180^\circ$. Designers of feedback amplifiers typically verify that this is the case through the use of amplifier frequency response plots.

4.1. Gain Margin and Phase Margin

A frequency response plot of the loop gain fA for a typical amplifier is shown in Fig. 12. The frequency at which $|f(j\omega)A(j\omega)| = 1$ is identified as ω_m , and the frequency at which $\angle f(j\omega)A(j\omega) = -180^\circ$ is identified as ω_p . Since $\omega_m \neq \omega_p$, it is apparent that this is a stable amplifier; that is, the two instability conditions are not simultaneously met. It is, however, important to ensure that the two conditions are not met simultaneously with a margin of safety. The *margin of safety* is defined by the gain margin and the phase margin of the feedback amplifier.

Gain margin is defined as the difference in the loop gain magnitude (in decibels) between 0 dB (unity gain) and the loop gain magnitude at frequency ω_p :

$$\text{Gain margin} = -20 \log |f(j\omega_p)A(j\omega_p)| \quad (33)$$

Figure 12. Gain margin and phase margin.

Phase margin is the difference between the loop gain phase angle at frequency ω_m and -180° :

$$\text{Phase margin} = \angle f(j\omega_m)A(j\omega_m) + 180^\circ \quad (34)$$

Each safety margin is shown in Fig. 12. It is common to specify the design of feedback amplifiers with gain and phase margins greater than 10 dB and 50° , respectively. These margins ensure stable amplifier operation over component parameter variation, temperature change, and other variations found in typical amplifiers.

4.2. Compensation Networks

Two fundamental techniques are available for ensuring amplifier stability:

- Reducing the midband loop gain fA of the amplifier
- Adding a compensation network to the amplifier to shape the loop gain frequency response so that the phase and gain margins are positive and in an acceptable range

Careful design is required in each of these cases to ensure stable amplifier operation over typical performance conditions.

In many cases, decreasing the loop gain to achieve stability is not an acceptable design possibility. Additionally, as is often the case in operational amplifier circuits, the feedback quantity f may be determined by the user rather than the amplifier designer and can range widely. In such cases, compensation networks are added within the feedback loop of the amplifier to increase the gain and phase margins. Such compensation networks add poles or a combination of poles and zeros to the loop gain characteristic. The most commonly used compensation techniques are

- Dominant pole compensation
- Lag-lead (pole-zero) compensation
- Lead compensation

Each technique modifies the gain and phase profiles of the basic forward amplifier through pole and zero manipulation.

In dominant-pole compensation, the amplifier is modified by adding a dominant pole that is much smaller in magnitude than all other poles in the amplifier gain function; typically it is chosen so that the gain reaches 0 dB at the frequency of the next pole (the first pole of the uncompensated amplifier). Consequently, the modified loop gain falls below 0 dB before the nondominant poles shift the total phase shift near 180° and the circuit is inherently stable. Dominant-pole compensation will typically result in a phase margin of approximately 45° .

The location of the new compensation pole can be determined by modeling the loop gain response with a single pole and setting its value to 0 dB at the first pole of the uncompensated amplifier:

$$20 \log |fA_0| - 20 \log \left| 1 + \frac{j\omega_c}{\omega_{p1}} \right| = 0 \text{ dB} \quad (35)$$

Solving Eq. (35) for the compensation pole frequency ω_c , results in

$$\omega_c \approx \frac{\omega_{p1}}{fA_0} \tag{36}$$

If the design goals of the feedback amplifier includes a range of feedback ratios, the frequency of the compensation pole is determined by the maximum value of the feedback ratio; that is, ω_c is chosen to be the smallest value predicted by Eq. (36).

An example of dominant-pole compensation is shown in Fig. 13 in the frequency domain. For clarity, the gain plots are represented by straight-line Bode approximations, while the exact phase plots are retained. The example amplifier is described by a midband gain of 60 dB with poles at 1, 5, and 50 MHz; the feedback ratio is $f=0.1$.

The possibility of feedback amplifier instability is focused at the frequency where $|fA|=1$ or equivalently where $|A|_{dB} = -20 \log(f)$. For this particular three-pole example, instability may occur at $\omega_m \approx 21$ MHz. Here the phase margin is very small and negative ($\approx -7^\circ$). After compensation, the focus is again centered where the gain plot (now compensated) intersects the negated feedback ratio plot. Addition of the compensation pole ω_c shifts this intersection to the frequency of the first uncompensated pole ω_{p1} . For this example, the compensation pole is placed at 10 kHz and yields a phase margin of $\approx 43^\circ$ and a gain margin of ≈ 14 dB.

Dominant-pole compensation reduces the open-loop bandwidth drastically. In this example the 3-dB frequency was lowered by two decades to 10 kHz. Still, it is common in many circuits with inherently large gain; internally compensated operational amplifiers often utilize dominant-pole compensation.

Lead-lag (or pole-zero) compensation is similar to dominant-pole compensation with one major exception. In addition to a dominant pole, a higher-frequency zero is added. This zero is used to cancel the first pole of the uncompensated amplifier. The added dominant pole can then be chosen so that the gain reaches 0 dB at the frequency of the next pole (the second pole of the uncompensated amplifier). Lead-lag compensation has a distinct bandwidth advantage over dominant-pole compensation.

Figure 13. Bode diagram for a dominant-pole-compensated amplifier.

The location of the new compensation pole can be determined in a method similar to the method utilized under dominant-pole compensation with the exception that the loop gain (without the first original pole) is to reach 0 dB at the second pole of the uncompensated amplifier. Solving Eq. (35) for the compensation pole frequency ω_c results in

$$\omega_c \approx \frac{\omega_{p2}}{fA_0} \tag{37}$$

As with dominant-pole compensation, design goals including a range of feedback ratios lead to the determination of frequency of the compensation pole by the maximum value of the feedback ratio; that is, ω_c is chosen to be the smallest value predicted by Eq. (37).

The uncompensated amplifier described previously, is compensated with a lag-lead pole-zero pair, and the frequency domain results are displayed in Fig. 14. The possibility of feedback amplifier instability is again focused at the intersection of the gain and the negated feedback ratio plots. After compensation, the focus is centered where the gain plot (now compensated) intersects the negated feedback ratio plot. The addition of the compensation pole ω_c and a zero at the first uncompensated pole ω_{p1} shifts this intersection to the frequency of the second uncompensated pole ω_{p2} . The previously identified amplifier parameters lead to a compensation pole at 50 kHz (also the 3-dB frequency), a positive phase margin of $\approx 48^\circ$, and a gain margin of ≈ 20 dB.

Lead compensation can lead to the largest bandwidth of the three most common compensation networks. Here, as in lead-lag compensation, a pole and a zero are added. The zero is used to cancel the *second* pole of the uncompensated amplifier, and the added pole is positioned at a frequency higher than the zero. The objective is to reduce the phase shift of the uncompensated amplifier at the frequency where the loop gain reaches 0 dB (ω_m). It can be extremely effective in feedback amplifiers where there are two or three dominant poles in the uncompensated amplifier.

The uncompensated amplifier described above is compensated with a lead pole-zero pair, and the frequency-domain results are displayed in Fig. 15. After compensation, the focus is again centered where the gain plot (now compensated) intersects the negated feedback ratio plot.

Figure 14. Bode diagram for a lag-lead-compensated amplifier.

Figure 15. Bode diagram for a lead-compensated amplifier.

The addition of a zero at the second uncompensated pole ω_{p2} and a high-frequency compensation pole ω_c , shifts this intersection to a frequency beyond the second uncompensated pole ω_{p2} . For this example, the high-frequency pole was chosen at 500 MHz. This design choice leads to a positive phase margin of $\approx 35^\circ$ and a gain margin of ≈ 15 dB. Note that with lead compensation there is no significant reduction in the frequency response of the feedback amplifier; the 3 dB frequency for this example is 999.6 kHz (0.04% reduction).

A passive component circuit implementation of each of the three compensation techniques is schematically shown in Fig. 16. For the circuit of Fig. 16a, the compensation network component values are chosen so that

$$(R_p + R_o)C_p = \frac{fA_0}{\omega_{p1}} \quad (38)$$

where A_0 , R_o , and ω_{p1} are the midband gain, the output resistance, and the first pole frequency, of the basic forward amplifier, respectively. For the circuit of Fig. 16b, the compensation network component values are chosen so that

$$R_b C_c = \frac{1}{\omega_{p1}} \quad (39)$$

and

$$(R_a + R_b + R_o)C_c = \frac{fA_0}{\omega_{p2}} \quad (40)$$

For the circuit of Fig. 16c, the compensation network component values are chosen so that

$$R_a C_c = \frac{1}{\omega_{p2}} \quad (41)$$

$$(R_a // R_b)C_c \ll \frac{1}{\omega_{p1}} \quad (42)$$

While the placement of a compensation network at the output of the basic forward amplifier is an effective technique for feedback topologies with shunt sampling, other

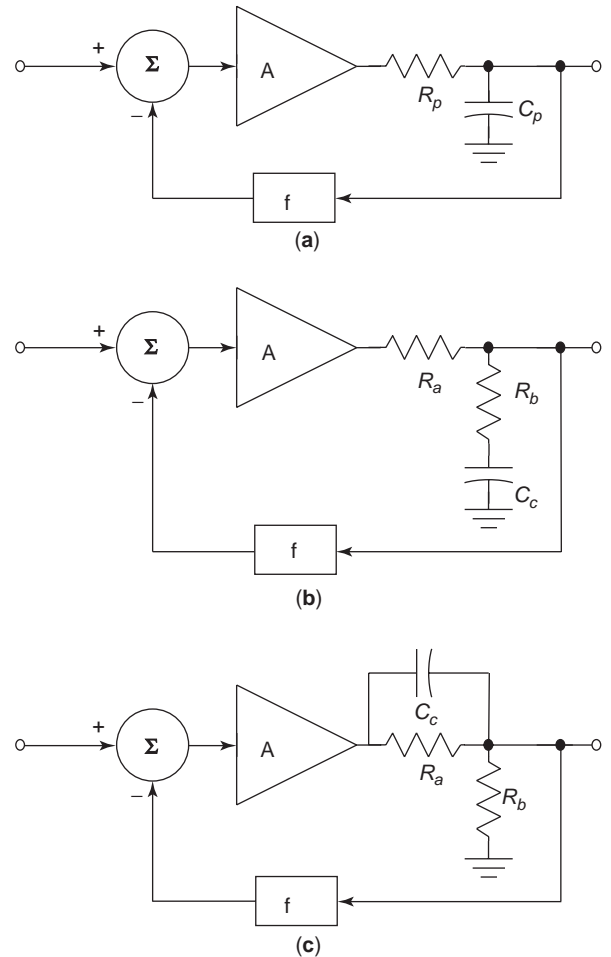

Figure 16. Compensation networks: (a) dominant-pole compensation; (b) lag-lead (pole-zero) compensation; (c) lead compensation.

placement may be necessary. In particular, connections at the output of a feedback amplifier with series sampling are *not within the feedback loop* and are therefore invalid. In such cases, alternate placement of the compensation is necessary; one common placement intersperses the compensation network between individual gain stages of the amplifier. Similarly, it is possible to compensate a feedback amplifier within the feedback network rather than the basic forward amplifier. Unfortunately, analysis of compensation within the feedback network is often extremely complex because of the loading of the basic forward amplifier by feedback network components.

FEEDBACK OSCILLATORS

JIANYI ZHOU
WEI HONG
Southeast University
Nanjing, China

1. INTRODUCTION

An oscillator is a type of circuit that converts DC power to AC signals automatically without external excitation, and has been widely used as a key component in various electronic products, such as communication systems, measurement instruments, and computers. In communication systems, oscillators are ubiquitous, generating carrier signals in both the transmitter and the receiver [1–3]. In many digital systems, oscillators provide the clock for CPUs, A/D converters, D/A converters, frequency synthesizers, and other devices.

Most oscillators are sinusoidal, generating a steady-state sinusoidal signal; some oscillators generate other types of waveform such as square and triangular waves. The sinusoidal oscillators are the basic type of oscillator because many other kinds of waveform can be obtained with the sinusoidal oscillator and waveshaping circuits.

There are two fundamental concerns in a sinusoidal oscillator—one is the purity of the output sinusoidal signal, and the other is the frequency stability. Actually, all oscillators are not perfect, and the output signal is always the superposition of the desired sinusoidal signal and

many undesired harmonics and noise. The power contained in the harmonics should be small relative to the desired fundamental signal. The noise accompanying the output signal of an oscillator will be the factor that limits system performance in many communication systems. There are two kinds of noise: amplitude noise and phase noise. Because amplitude fluctuations are usually greatly attenuated in many systems, the phase noise generally dominates [4,5]. The output signal frequency of an oscillator varies inevitably with the parameters of components in the oscillator because of the temperature variation. In many applications, especially in communication systems and electronic clocks, the frequency drift is required to be as small as possible [6].

In general, either the positive feedback or the negative resistance in a circuit can generate oscillation. Therefore, from the physical mechanism of oscillation, there are two kinds of oscillators: feedback oscillators and negative-resistance oscillators.

2. PRINCIPLE OF FEEDBACK OSCILLATORS

The basic method of generating sinusoidal oscillation electronically is to insert a positive-feedback circuit in an amplifier. The basic topology for a feedback oscillator, shown in Fig. 1, consists of three fundamental parts: the amplifier or active device, the feedback circuit, and the output load [1–3].

In Fig. 1, the feedback loop is broken at “×” for analysis. The input voltage of the amplifier is V_i , and the output voltage of the amplifier is

$$V_o(j\omega) = A(j\omega)V_i(j\omega) \tag{1}$$

where $A(j\omega)$ is the transfer function or gain of the amplifier, ω denotes the angular frequency, and $j = \sqrt{-1}$ is an imaginary unit.

The output voltage of the feedback circuit is

$$V_f(j\omega) = \beta(j\omega)V_o(j\omega) = A(j\omega)\beta(j\omega)V_i(j\omega) \tag{2}$$

and the loop gain is defined as

$$T(j\omega) = \frac{V_f(j\omega)}{V_i(j\omega)} = A(j\omega)\beta(j\omega) \tag{3}$$

For the closed loop, the closed-loop gain is defined as

$$G_{CL}(j\omega) = \frac{A(j\omega)}{1 - A(j\omega)\beta(j\omega)} \tag{4}$$

Figure 1. Block diagram of a feedback oscillator.

Because there is no input signal for an oscillator (i.e., $V_i = 0$) to maintain a nonzero output voltage, the denominator of the closed-loop gain (4) should be equal to zero. This is the Barkhausen criterion [1–3,7,8]

$$T(j\omega_0) = A(j\omega_0)\beta(j\omega_0) = T(\omega_0)e^{j\varphi_T(\omega_0)} = 1 \quad (5)$$

where ω_0 is the oscillation frequency.

Note that the Barkhausen criterion really implies two conditions for oscillation:

1. The magnitude of the loop gain must be 1, which termed the *magnitude-balanced condition*.
2. The phase of the loop gain must be 0 (or an integral multiple of 2π), which is termed the *phase-balanced condition*.

The Barkhausen criterion requires the magnitude of the loop gain $T(\omega_0)$ to be exactly 1 at the oscillation frequency. If $T(\omega_0) < 1$, the oscillation will be decaying. On the other hand, if $T(\omega_0) > 1$, the oscillation amplitude will continue to increase until it is limited by the nonlinearity of the active devices in the amplifier. In fact, this nonlinearity is an essential feature of practical oscillators.

Suppose that the oscillator satisfies the Barkhausen criterion when $V_i = V_{iA}$ other than $V_i = 0$, i.e., the magnitude of the loop gain $T(\omega_0)$ equates to 1. As the circuit characteristics drift, $T(\omega_0)$ may be either smaller or larger than 1. For the former case, the oscillation will decay to stop; for the latter case it increases until limited by the nonlinearity of the amplifier. Therefore, in order to initially establish an oscillation, $T(\omega_0)$ must be larger than 1. The phase-balanced condition and the startup condition for a feedback oscillator are as follows [1,7,8]:

$$T(\omega_0)|_{t=t_0} > 1 \quad (6a)$$

$$\varphi_T(\omega_0)|_{t=t_0} = 2n\pi \quad (n = 0, 1, 2, \dots) \quad (6b)$$

Moreover, in order to maintain a steady oscillation, nearby V_{iA} , $T(\omega_0)$ must decrease when V_i increases; in other words, the derivative of $T(\omega_0)$ at $V_i = V_{iA}$ must be negative. This yields the magnitude stability condition of the feedback oscillator as [7,8]

$$\left. \frac{\partial T(\omega_0)}{\partial V_i} \right|_{V_i = V_{iA}} < 0 \quad (7)$$

Note that, although an oscillator satisfies the magnitude stability condition, its amplitude of the output voltage may fluctuate with the change of its environment. To suppress such amplitude fluctuations, besides minimizing the environment fluctuations and decreasing the sensitivity of devices in the oscillator, one important point is to increase the slope of $T(\omega_0)$ at the balanced point, that is, to increase the absolute value of

$$\left. \frac{\partial T(\omega_0)}{\partial V_i} \right|_{V_i = V_{iA}}$$

Hence, a small drift of V_i will cause a large change of $T(\omega_0)$. Because of the negative slope of $T(\omega_0)$, the drift of V_i is countered and a new balanced condition will be established very close to V_{iA} .

Suppose that the oscillator satisfies the phase-balanced condition when $\omega = \omega_0$, that is, $\varphi_T(\omega_0) = 0$. As the circuit characteristics drift, $\varphi_T(\omega_0)$ may be either larger or smaller than 0. In the former case, the phase of the feedback voltage leads the phase of the original input voltage of the amplifier. In the latter case, the phase of the feedback voltage lags behind the phase of the original input voltage of the amplifier. It is known that the frequency is the derivative of the phase. If $\varphi_T(\omega_0) > 0$, the phase of the feedback voltage leads continuously, so the corresponding frequency will be higher than the original oscillation frequency. However, if $\varphi_T(\omega_0) < 0$, the phase of the feedback voltage lags behind continuously, and the corresponding frequency will be lower than the original oscillation frequency.

In fact, $\varphi_T(\omega)$ varies with the frequency. If $\varphi_T(\omega)$ decreases with an increase of ω [i.e., if $\varphi_T(\omega)$ and ω are inversely proportional], and if the oscillation frequency is higher than the original oscillation frequency, then $\varphi_T(\omega)$ decreases; therefore, the frequency increase will be prevented. However, if the oscillation frequency is lower, $\varphi_T(\omega)$ increases, and thus the frequency decrease will be prevented. Thus, a new balanced condition will be established very close to the original frequency. On the other hand, if $\varphi_T(\omega)$ increases with an increase of ω , the drift of the oscillation frequency is accelerated and cannot satisfy the phase-balanced condition.

Hence, in order to maintain a steady oscillation, nearby ω_0 , $\varphi_T(\omega)$ must decrease with the increase of ω ; thus, the derivative of $\varphi_T(\omega)$ at $\omega = \omega_0$ must be negative. This is the phase stability condition of the feedback oscillator [7,8]:

$$\left. \frac{\partial \varphi_T(\omega)}{\partial \omega} \right|_{\omega = \omega_0} < 0 \quad (8)$$

Note that although an oscillator satisfies the phase stability condition, the frequency of its output voltage may fluctuate with the change in its environment. To suppress such frequency fluctuations, besides to minimizing the environment fluctuations and decreasing the sensitivity of devices in the oscillator, one important point is to increase the slope of $\varphi_T(\omega)$ at the balanced point, that is, to increase the absolute value of

$$\left. \frac{\partial \varphi_T(\omega)}{\partial \omega} \right|_{\omega = \omega_0}$$

Hence, a small drift of ω will cause a large change of $\varphi_T(\omega)$. Because of the negative slope of $\varphi_T(\omega)$, the drift of ω is countered and a new balanced condition will be established very close to ω_0 [1–3,6–8].

In a practical feedback oscillator, the amplifier is an active device such as an operational amplifier, a field-effect transistor (FET), a bipolar junction transistor (BJT), or a logical gate. The feedback system is generally a passive resonant network. Any network can be used as

Figure 2. Schematic of π -type network feedback oscillator: (a) π -type network feedback oscillator; (b) simplified equivalent circuit.

the feedback network as long as the Barkhausen criterion is satisfied.

Practical feedback oscillators can be realized with different active devices and feedback network.

3. LC OSCILLATORS

LC oscillators are widely used in modern communication systems as the local oscillator for the upconverters and downconverters. LC oscillators use passive inductors and capacitors as the feedback network. Usually, the LC oscillators use a transistor or differential pairs as the active device. Many LC oscillator circuits use a π -type impedance network as the feedback network [1–3,5–9]. The circuit schematic is shown in Fig. 2.

The forward gain is

$$A = -\frac{g_m R_0 Z_L}{Z_L + R_0} \quad (9)$$

where

$$Z_L = \frac{Z_2(Z_1 + Z_3)}{Z_1 + Z_2 + Z_3} \quad (10)$$

The feedback factor is

$$\beta = \frac{Z_1}{Z_1 + Z_3} \quad (11)$$

Therefore, the loop gain is

$$T = A\beta = \frac{-g_m R_0 Z_1 Z_2}{Z_1 Z_2 + Z_2 Z_3 + R_0(Z_1 + Z_2 + Z_3)} \quad (12)$$

Suppose that the impedances are purely reactive (either inductive or capacitive), specifically, $Z_i = jX_i$ ($i = 1,2,3$); we then have

$$T = \frac{g_m R_0 X_1 X_2}{-X_2(X_1 + X_3) + jR_0(X_1 + X_2 + X_3)} \quad (13)$$

According to the Barkhausen criterion, the phase of the loop gain should be equal to zero; thus we have

$$X_1 + X_2 + X_3 = 0 \quad (14)$$

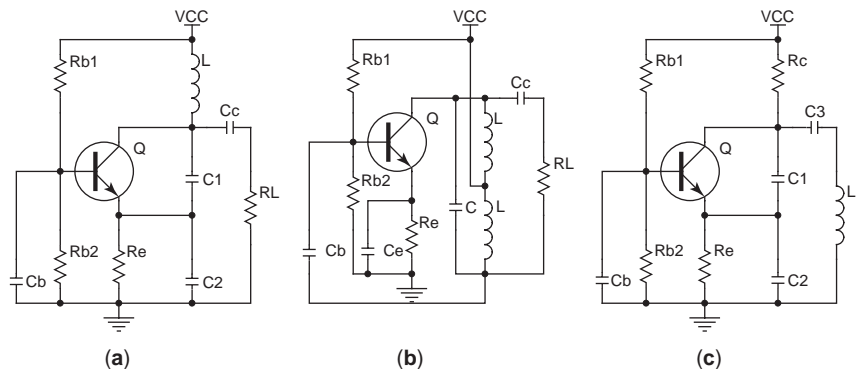

$$T = \frac{g_m R_0 X_1}{X_2} \quad (15)$$

According to the Barkhausen criterion, the magnitude of the loop gain should be equal to 1. Therefore, X_1 and X_2 must have the same sign; specifically, they must have the same kind of reactance, either inductive or capacitive. It follows from (14) that $X_3 = -(X_1 + X_2)$ must possess the other type of reactance. If X_1 and X_2 are capacitors and X_3 is an inductor, the circuit is called a *Colpitts oscillator*; if X_1 and X_2 are inductors and X_3 is a capacitor, the circuit is called a *Hartley oscillator*. Other combinations are also used. For example, if X_1 and X_2 are capacitors and X_3 is a series combination of an inductor and a capacitor, the circuit is called a *Clapp oscillator*. Figure 3 shows the schematic of these typical oscillators.

4. FREQUENCY STABILITY

Frequency stability is one of the most important performance factors for an oscillator. The feedback oscillator involves an active amplifier with a passive resonant

Figure 3. Schematics of typical LC oscillators: (a) Colpitts oscillator; (b) Hartley oscillator; (c) Clapp oscillator.

feedback network. The oscillation frequency ω_0 is determined mainly by the resonant of the feedback network. For an LC oscillator, suppose that the drift of the inductor and capacitor is ΔL and ΔC , respectively. The offset of the resonant frequency is [7]

$$\Delta\omega \approx -\frac{1}{2}\omega_0\left(\frac{\Delta L}{L} + \frac{\Delta C}{C}\right) \quad (16)$$

Hence, one means to improve the frequency stability is to reduce the drift of the inductor and capacitor in the resonant network.

Besides the parameter drift, the effective quality factor Q_e is also very important for frequency stability.

As we discussed before, increasing the absolute value of

$$\left.\frac{\partial\omega_T(\omega)}{\partial\omega}\right|_{\omega=\omega_0}$$

will also enhance the frequency stability. Thus, we may define the frequency stability factor as [7]

$$\text{SF} = \omega_0 \left.\frac{\partial\omega_T(\omega)}{\partial\omega}\right|_{\omega=\omega_0} \quad (17)$$

For a parallel RLC circuit, the impedance is

$$\mathbf{Z}(j\omega) = \frac{j\omega\frac{1}{C}}{\omega_0^2 - \omega^2 + j\frac{\omega_0\omega}{Q_e}} \quad (18)$$

where $\omega_0 = 1/\sqrt{LC}$ and $Q_e = R\sqrt{C/L}$.

The phase angle of the impedance as a function of frequency is

$$\varphi(\omega) = \frac{1}{2}\pi - \arctan\frac{\frac{\omega_0\omega}{Q_e}}{\omega_0^2 - \omega^2} \quad (19)$$

and its derivative with respect to ω is

$$\frac{\partial\varphi}{\partial\omega} = -\frac{Q_e\omega_0(\omega_0^2 + \omega^2)}{(\omega_0\omega)^2 + Q_e^2(\omega_0^2 - \omega^2)} \quad (20)$$

At the resonant frequency, this yields

$$\left.\frac{\partial\varphi}{\partial\omega}\right|_{\omega=\omega_0} = -\frac{2Q_e}{\omega_0} \quad (21)$$

and then the frequency stability factor

$$\text{SF} = -2Q_e \quad (22)$$

This result implies that the higher the Q value of the resonant circuit, the higher the frequency stability of the oscillator. Hence, another way to improve the frequency stability is to increase the effective quality factor of the resonant circuit [6–8].

5. PHASE NOISE

Phase noise is another important performance factor of an oscillator. Phase noise is usually characterized in terms of the signal sideband noise spectral density [4,5,10–16], namely, the decibels below the carrier per hertz (dBc/Hz), and is defined as

$$L_{\text{total}}(\Delta\omega) = 10 \cdot \log\left[\frac{P_{\text{sideband}}(\omega_0 + \Delta\omega, 1\text{ Hz})}{P_{\text{carrier}}}\right] \quad (23)$$

where $P_{\text{sideband}}(\omega_0 + \Delta\omega, 1\text{ Hz})$ represents the signal sideband power within a measurement bandwidth of 1 Hz at the frequency with offset $\Delta\omega$ from the carrier.

The most used approach to calculate the phase noise of an oscillator is the extended Leeson–Cutler phase noise model expressed as [4,5]

$$L(\Delta\omega) = 10 \log\left\{\frac{2FkT}{P_{\text{sig}}} \cdot \left[1 + \left(\frac{\omega_0}{2Q_e\Delta\omega}\right)^2\right] \cdot \left(1 + \frac{\omega_c}{|\Delta\omega|}\right)\right\} \quad (24)$$

where F denotes the noise figure of the active device, k is Boltzmann's constant, T is the absolute temperature, P_{sig} is the average power dissipated in the resistive part of the tank, ω_0 is the oscillation frequency, Q_e is the effective quality factor of the tank with all the loadings, $\Delta\omega$ is the offset from the carrier, and ω_c is the flicker frequency of the active device. A typical plot of the phase noise is shown in Fig. 4.

6. OTHER KINDS OF FEEDBACK OSCILLATORS

6.1. Microwave Oscillators

The LC oscillators described above are usually used in the low-frequency band. As the frequency increases to the microwave band and even millimeter-wave band, the lumped components are no longer suitable for resonance. Distributed components, such as transmission lines and cavities, should be adopted. Another important consideration is the treatment of the active devices in microwave band. The junction capacitance, parasitic capacitances, and inductances of microwave active devices should be taken into account. Generally, the S parameters are often employed to characterize the behavior of a microwave active device;

Figure 4. Typical plot of the phase noise of an oscillator versus offset from the carrier.

Figure 5. Design of microwave oscillators based on *S* parameters.

thus the design of microwave oscillators based on *S* parameters is widely adopted.

The oscillation condition of the circuit shown in Fig. 5 is given by [2,3]

$$\begin{aligned}
 K &< 1 \\
 S'_{11}\Gamma_1 &= 1 \\
 S'_{22}\Gamma_2 &= 1
 \end{aligned}
 \tag{25}$$

where

$$\begin{aligned}
 K &= \frac{1 - |S_{11}|^2 - |S_{22}|^2 + |S_{11}S_{22} - S_{12}S_{21}|^2}{2|S_{12}S_{21}|} \\
 S'_{11} &= S_{11} + \frac{S_{12}S_{21}\Gamma_2}{1 - S_{22}\Gamma_2} \\
 S'_{22} &= S_{22} + \frac{S_{12}S_{21}\Gamma_1}{1 - S_{11}\Gamma_1} \\
 \Gamma_1 &= \frac{Z_S - Z_0}{Z_S + Z_0} \\
 \Gamma_2 &= \frac{Z_L - Z_0}{Z_L + Z_0}
 \end{aligned}$$

In many cases, the *S* parameters of a microwave transistor do not satisfy the oscillation condition; some type of external feedback network is needed. The usual method is to add a segment of transmission line between the grid of the FET or the base of the BJT and the ground as a serial feedback network to aid the oscillation. A typical microwave oscillator with microstrip is shown in Fig. 6, where TL means microstrip transmission line [2]. TL2 acts as the

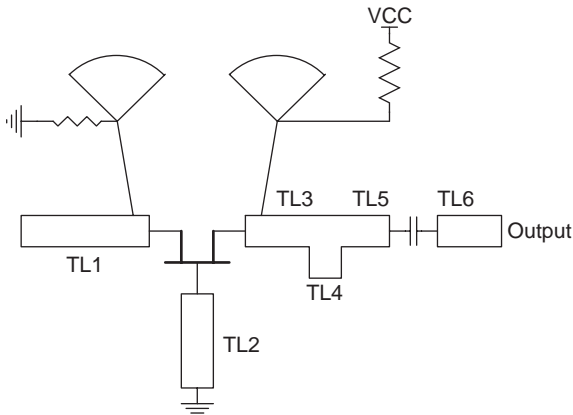

Figure 6. An FET microwave oscillator with microstrip as distributed feedback network.

Figure 7. An SIW feedback oscillator.

serial feedback network. Usually, the length of TL2 dominates the oscillation frequency.

A so-called substrate integrated waveguide (SIW) cavity [43] has been used as the feedback resonant network, followed by development of a feedback microwave oscillator [44]. Figure 7 is a flowchart of the SIW feedback oscillator (for further details, please see Ref. 44).

The oscillator operates at 12.02 GHz. Good phase noise and harmonic level have been obtained.

6.2. Crystal and Dielectric Oscillators

As component characteristics change with age, temperature, signal level, and other parameters, the oscillation frequency will drift. The main cause of frequency drift is the drift of circuit parameters and the *Q* factor. The crystals used in oscillators are usually quartz, and the quartz crystal has extremely high *Q* and mechanical stability. A crystal oscillator is often used in extremely high stability oscillators. Figure 8 shows two typical crystal oscillators [17–19].

Besides the quartz crystals, other kinds of materials, such as SAW devices [20,21], Sapphire [22–25], and dielectric resonators [26–33] are often used for high-performance oscillators. In the microwave band, the dielectric resonator oscillator (DRO) has become one of the most widely used oscillators. A typical microwave DRO is shown in Fig. 9 [33].

6.3. RC Oscillators

RC oscillators using *RC* feedback network are useful oscillators in low-frequency bands [6–8]. The Wien bridge oscillator is the most widely used *RC* oscillator that adopts a balanced bridge as the feedback network, as shown in Fig. 10.

The oscillation frequency is determined by *R* and *C* as

$$f_0 = \frac{1}{2\pi RC}
 \tag{26}$$

The oscillation will be sustained if

$$\frac{R_2}{R_1} = 2
 \tag{27}$$

6.4. Ring Oscillators

Ring oscillators are commonly used in integrated circuits [34–38]. They consist simply of *n* inverters in a ring, where *n* is odd. A simple schematic of the ring oscillator is shown in Fig. 11.

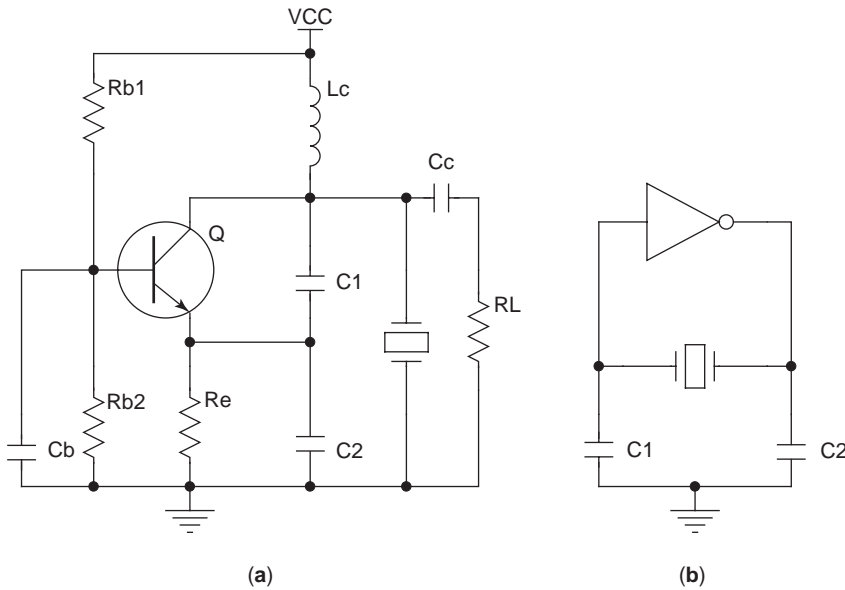

Figure 8. Two typical crystal oscillators: (a) Pierce crystal oscillator; (b) crystal oscillator with a NOT gate.

Figure 9. Microwave dielectric resonator oscillator (DRO).

For a simple analysis of the ring oscillator, it is assumed that each inverter can be characterized by a propagation time delay T_{pd} . The oscillation period is then simply twice the total propagation time delay:

$$f_0 = \frac{1}{2n \cdot T_{pd}} \quad (28)$$

6.5. Comparison of Different Oscillator Types

Table 1 compares the different types of feedback oscillators described above.

7. VOLTAGE-CONTROLLED OSCILLATORS

Many applications require oscillators to be electrically tunable. For example, in the superheterodyne receiver, the local oscillator should be tuned over an appropriate

Figure 10. Wien bridge oscillator.

Figure 11. Ring oscillator.

frequency range so that the mixer will convert the incoming RF signal with different frequency down to the IF signal with the same intermediate frequency. In many applications, such as direct FM or in phase-locked loops, the tuning of the oscillator should be automatic. One way to achieve this purpose is using a voltage-controlled oscillator (VCO) [1–3,6–8,39–42]. A device that can be used in a VCO is the varactor diode. Any diode is a p-n junction, and thus has a junction capacitance. A varactor diode is designed so that the junction capacitance can be controlled by the reverse bias voltage across the junction

$$C(V) = C_0 \left(1 - \frac{V}{V_d}\right)^{(1/2)} \quad (29)$$

Table 1. Comparison of Feedback Oscillators

Type	Operation Frequency	Stability	Phase Noise	Cost	Tuning
LC	Low frequency–UHF	Moderate	Moderate	Low	Easy
Microwave	Microwave band	Moderate	Moderate	Moderate	Hard
Crystal	Low frequency–VHF	Good	Very low	Moderate	Moderate
Dielectric	Microwave band	Good	Low	High	Very hard
RC	Low-frequency band	Poor	Poor	Low	Easy
Ring	Low frequency–UHF	Poor	Poor	Low	Hard

**Figure 12.** Typical schematic of a voltage-controlled oscillator.

where V is the reverse bias, C_0 is a constant, and V_d is the diffusion barrier voltage of the junction [1–3,6–8].

A typical schematic of the voltage-controlled oscillator is shown in Fig. 12.

8. CONCLUSION

The principles and typical practical circuits of feedback oscillators are reviewed. Three important conditions and two kinds of main specifications required in an oscillator are summarized. Typical practical oscillators, such as the LC oscillators, RC oscillators, crystal oscillators, microwave oscillators, and voltage-controlled oscillators, are illustrated. These circuits are widely used in communication systems and other electronic equipment.

FEEDFORWARD AMPLIFIERS

P. GARDNER

1. INTRODUCTION

Highly linear transmitters are required in modern RF and microwave radiocommunication systems, to facilitate the transmission of multiple carriers and/or nonconstant envelope, bandwidth efficient modulated signals, while minimizing the intermodulation and spectral spreading distortion caused by nonlinearity, particularly in the

power amplifier. Approaches to this problem may be divided broadly into

- Amplifier linearization techniques, whereby the RF/microwave transmitter is linearized as a separate component
- Linear transmitter architectures, in which the modulation and amplification processes are merged, with feedback or other control applied to the whole transmitter, usually by demodulating a sample of the output, and comparing with the modulation input

The three main techniques for linearization of the amplifier itself are feedforward linearization, RF predistortion, and feedback linearization.

Feedforward, the subject of this article, uses two analog signal loops. The first extracts the distortion occurring in the amplifier, and the second subtracts distortion from the output signal. One of the main attractions of this technique is that the correcting signal is derived from the nonlinear amplifier itself; the correction circuit does not need to be programmed with a nonlinear model of the amplifier. High levels of distortion cancellation (≥ 30 dB) can be achieved, and broad bandwidths are possible, at the expense of very precise phase and amplitude matching in the two loops.

In RF predistortion, a circuit module at the amplifier input is designed to have a nonlinear characteristic opposite to that of the main amplifier. For example, if the main amplifier has a gain that compresses as the input level increases, the predistorter is designed to have a compensating gain expansion. Similarly, the variation of phase with signal level in the predistorter is designed to compensate the phase change with signal level in the amplifier. An alternative view of the operation of a predistorter is that it generates intermodulation distortion components with an amplitude and phase such that, after amplification in the main amplifier, they cancel out the corresponding components generated within the amplifier itself. Predistortion linearisers provide an excellent method for achieving modest levels of distortion reduction (~ 10 dB), without the additional circuit complexity of feedforward systems.

Amplifier linearization using negative RF feedback relies on the fact that the transfer function of a closed-loop system is dominated by the feedback path, so long as the open-loop gain is high compared to the closed-loop gain. Thus, if the feedback path is linear, the closed-loop gain and phase remain linear. The main difficulty of this technique at RF and microwave frequencies is that the feedback path necessarily has a significant electrical length, compared to a guided wavelength, so the linearization works only over a narrow bandwidth, and instabilities are likely to occur at other frequencies. Negative feedback is therefore not widely used as a linearization technique in the RF–microwave range.

Linear transmitter architectures include a number of configurations, such as polar loop, Cartesian loop, and adaptive digital predistortion. These techniques can provide extremely high levels of linearity, usually measured in terms of low adjacent-channel power levels. However, because much of the associated processing is done digitally at baseband or IF, the achievable percentage bandwidth

is relatively low. Since the modulation scheme is effectively programmed into the transmitter architecture, such linearization techniques could be regarded as less adaptable than a standalone amplifier lineariser. Continual improvements in DSP (digital signal processing) hardware, however, will make linear architectures increasingly attractive options in system design.

2. BASIC PRINCIPLE OF FEEDFORWARD OPERATION

The invention of feedforward linearization can be traced back to a patent by Black [1]. After long neglect, the idea was revived for microwave applications by Seidel [2]. The basic principle of the feedforward amplifier is illustrated in Fig. 1. At the input to the main amplifier, coupler 1 samples the undistorted input signal. A sample of the signal at the output of the main amplifier is also taken using coupler 2. If the main amplifier were perfectly linear, this would be simply an amplified version of the input sample. In reality, nonlinear distortions in the amplifier cause the output sample to be an amplified version of the input signal along with an additional error signal. The error signal includes the intermodulation components generated in the main amplifier. The function of the feedforward system is first to isolate the error signal and then to remove it from the amplifier output, leaving an undistorted, linearly amplified signal.

This is achieved by first linearly adjusting the levels of the two samples and combining them in antiphase (i.e., subtracting them) using coupler 3, to cancel out the wanted signal and leave only the error signal. The coupling ratios in couplers 1, 2, and 3, and the phase shifts, delays, and attenuations in the first loop, are adjusted to achieve this cancellation. The error signal is then adjusted in phase and amplified by the auxiliary amplifier to a suitable amplitude level, so that when recombined, using coupler 4, with the output from the main amplifier, the error signal is canceled completely from the final output. To illustrate this operation, Fig. 1 includes spectrum diagrams showing the operation of a feedforward linearised amplifier with a two-tone input signal.

In principle, therefore, feedforward is a way to achieve perfect linear amplification without distortion. To assess its applicability in a practical transmitter system, several key performance parameters must be assessed, including

- Efficiency
- Bandwidth
- Degree of distortion suppression required
- Size and complexity

These parameters and the factors that influence them are outlined in this section and in more detail in Section 3.

2.1. Efficiency

Three main and interacting factors limit the overall efficiency of a feedforward amplifier:

1. The auxiliary amplifier consumes a significant level of DC power without adding to the level of the

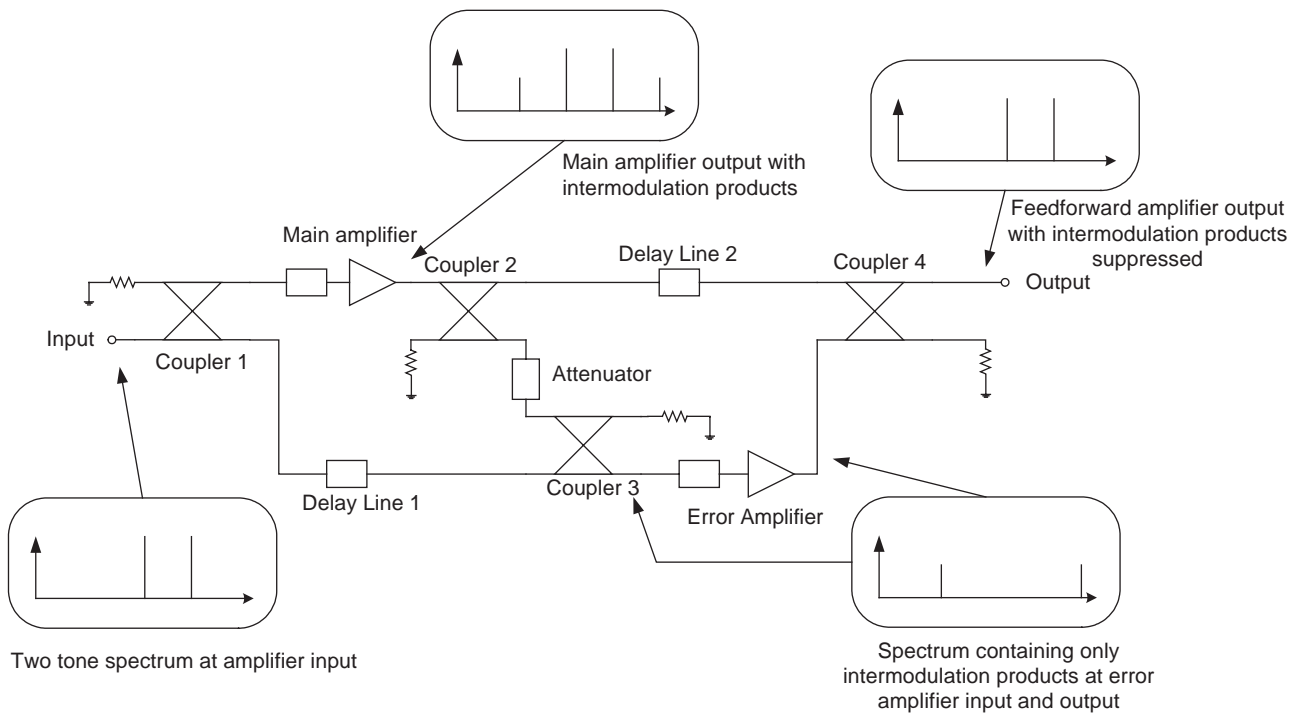

Figure 1. Basic configuration for a feedforward amplifier, including indicative spectra for the case of a two-tone input.

wanted output signal. If the first loop of the feedforward system is correctly balanced, the auxiliary amplifier only has to amplify the distortion. However, it has to amplify it linearly, and to a level somewhat higher than the distortion in the main branch of the system, because of the coupling ratio of coupler 4. For example, if the main amplifier produces intermodulation products 20 dB below the output carriers, and the output coupler has a 13 dB coupling ratio, the error signal at the output of the auxiliary amplifier must be 13 dB above the level of the main amplifier intermodulation products, or in other words, only 7 dB below the level of the wanted signal in the main branch. For perfect operation, the auxiliary amplifier must not introduce any significant level of further distortion. A class A amplifier, backed off well below saturation, is therefore normally used. In the example above, therefore, the auxiliary amplifier would need to have a DC power rating of the same order of magnitude as that of the main amplifier. Thus, to a crude approximation, the cancellation of distortion is achieved at the expense of doubling the DC power consumption or halving the efficiency.

2. The output coupler (coupler 4 in Fig. 1) degrades the overall efficiency because of its inherent ohmic and dielectric losses, and also because it couples a portion of the wanted output power into the matched termination on its fourth port. Clearly there is a tradeoff here between loose coupling in coupler 4 (say, > 20 dB), to limit the wastage of main amplifier power, and tight coupling (say, < 10 dB) to limit the

demands on the auxiliary amplifier. The ideal level of coupling, for maximum overall efficiency, therefore depends on the level of distortion occurring in the main amplifier that needs to be canceled.

3. The efficiency of the main amplifier strongly influences the overall efficiency. To limit the demands on the auxiliary amplifier, it is desirable not to operate the main amplifier too close to saturation; however, this reduces its efficiency.

The net result of these three factors influencing efficiency is that the overall efficiency of a typical feedforward amplifier is at best about 10%. However, to achieve comparable levels of intermodulation suppression without feedforward, by simply using a higher power linear amplifier and backing off its output power, could reduce the efficiency by several further orders of magnitude. Thus feedforward amplifiers can be a good choice where linear amplification is required with reasonable efficiency.

2.2. Bandwidth and the Degree of Distortion Suppression

In feedforward amplifiers, the main and auxiliary signals both propagate in the same forward direction through the system. This is in contrast to the situation in feedback amplifiers, where, self-evidently, the feedback signal propagates in the reverse direction. This leads to two advantages of feedforward systems as compared to feedback systems: (1) because there is no closed loop (assuming ideal coupler directivity), we do not have the danger inherent in feedback systems where the feedback becomes positive

at certain frequencies, leading to oscillation problems; and (2) by ensuring that the propagation delays are equal on both sides of each loop of the feedforward system, we can maintain signal cancellation in the first loop and suppression cancellation in the second, over a broad frequency range.

In practice, the accuracy of the two cancellation processes depends on the bandwidth over which the designer attempts to achieve them. Near-perfect cancellation, leading to extremely low intermodulation levels, is possible in a very narrowband design. In more realistic scenarios, there is a tradeoff between the bandwidth and the degree of suppression achievable. This is made more difficult by the fact that the delays through the active and passive components of the system are not frequency-independent.

The practical tradeoff between bandwidth and suppression level depends on the complexity of the balancing and adaptation circuits used; there is no exact rule to relate the parameters. However, the following examples give an idea of what is achievable. A feedforward amplifier operating over greater than an octave bandwidth was reported by Steel et al. [3], with an implied suppression of 14 dB. A feedforward bandwidth of the order of 8% was reported by Konstantinou et al. [4], with intermodulation product suppression of around 20 dB. A review article by Raab et al. [5] quotes 25–30 dB as the practical upper limit for manufactured equipment.

2.3. Size and Complexity

The addition of an auxiliary amplifier and the associated couplers, attenuators, and phase shift networks clearly adds to the overall size and complexity of the amplifier subsystem. Achieving a sufficiently accurate balance over the full bandwidth requires fine adjustment of phase and amplitude. Fine tuning in production can be achieved by means of mechanically trimmed variable attenuators and phase shifters, or by electronically controlled components such as vector modulators. Where electronic adjustment is incorporated, it is possible to introduce electronic control to compensate for drift with time and temperature. Feed-

forward amplifiers reported to date have been hybrid systems, too complex to allow monolithic integration, given the need for fine adjustment. Mechanical and thermal issues and the establishment of tuning procedures are crucial in the design of a complete feedforward amplifier for a production environment. In many circumstances, it is also necessary to devise control and adaptation algorithms to maintain optimum performance, compensating for parameter drifts that occur with aging, temperature, or variations in signal-level statistics.

3. DETAILED DESIGN CONSIDERATIONS

In this section, design equations for the basic feedforward system are established, using a revised and expanded version of the analysis given by Potheary [6], leading to phase and amplitude margins for accurate cancellation. Further feedforward amplifier parameters, such as the overall input and output match, noise figure, and efficiency are also analyzed.

3.1. Basic Signal Flow Analysis

In the generic form of the feedforward amplifier shown in Fig. 2, the lowercase symbols indicate the following complex voltage transfer coefficients:

- c_1 through c_4 are coupling coefficients of the couplers.
- a_1 through a_4 are coupler losses, that is, the transfer coefficients from the input port to the direct output port of each coupler.
- i_1 through i_4 are the isolation coefficients of the four couplers, that is, the transfer coefficients from the input to the nominally isolated port.
- l_1 and l_3 are the transfer coefficients of the two delay lines.
- l_2 is the attenuation of the attenuator mounted between couplers 2 and 3.
- g_m and g_e are the complex gains of the main and error amplifier, respectively.

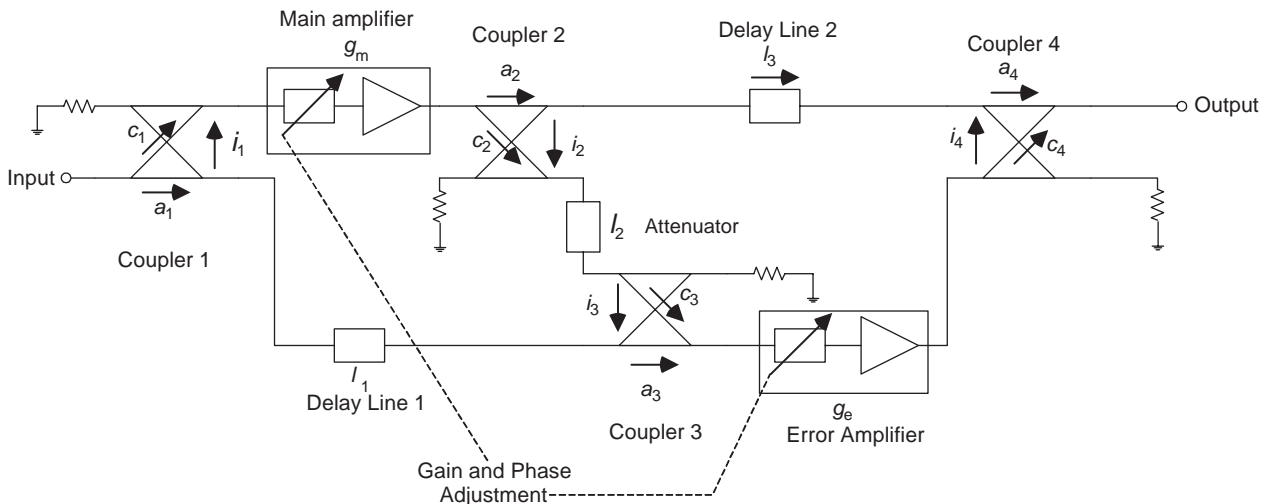

Figure 2. Feedforward amplifier annotated for signal flow analysis.

Note that although the transfer coefficients are indicated using arrows showing the main signal flow direction, the passive components are all reciprocal, and at some points in the analysis it is necessary to use the same transfer coefficients for a signal in the opposite direction. The same symbols in uppercase are used later to indicate the corresponding quantities expressed in decibels.

It is assumed that both amplifiers have adjustable gain and phase to facilitate balancing of the loops. In practice, this adjustability would be built into the early amplifier stages, rather than the output stages and so would be achieved without significantly affecting the output power ratings or DC power consumption.

It is also assumed that the individual passive components are well matched to the system impedance (typically $50\ \Omega$), so that the complications of multiple reflections can be ignored.

The input voltage wave amplitude is V_{in} . The distortion and noise in the main amplifier are represented by the addition of a voltage V_d to the amplified input. Thus the total output of the main amplifier, at the input to coupler 2, is given by

$$V_{out_main} = g_m c_1 V_{in} + V_d$$

The resulting voltage at the input to the error amplifier is given by

$$\begin{aligned} V_{in_error} &= (g_m c_1 V_{in} + V_d) c_2 l_2 c_3 + a_1 l_1 a_3 V_{in} \\ &= (g_m c_1 c_2 l_2 c_3 + a_1 l_1 a_3) V_{in} + c_2 l_2 c_3 V_d \end{aligned} \quad (1)$$

The condition for balancing the first loop is that the input to the error amplifier should depend only on the distortion voltage V_d . The condition is therefore found by setting the coefficient of V_{in} in (1) to zero:

$$g_m c_1 c_2 l_2 c_3 + a_1 l_1 a_3 = 0 \quad (2)$$

The output from coupler 4 (i.e., the output of the whole feedforward amplifier) is given by

$$\begin{aligned} V_{out} &= V_{out_main} a_2 l_3 a_4 + g_e c_4 V_{in_error} \\ &= a_2 l_3 a_4 (g_m c_1 V_{in} + V_d) \\ &\quad + g_e c_4 ((g_m c_1 c_2 l_2 c_3 + a_1 l_1 a_3) V_{in} + c_2 l_2 c_3 V_d) \end{aligned}$$

If the first loop matching condition (2) is met, then this reduces to

$$V_{out} = a_2 l_3 a_4 g_m c_1 V_{in} + (g_e c_4 c_2 l_2 c_3 + a_2 l_3 a_4) V_d \quad (3)$$

Balancing of the second loop is achieved when the coefficient of V_d in this equation is zero, that is, when

$$g_e c_4 c_2 l_2 c_3 + a_2 l_3 a_4 = 0 \quad (4)$$

Then, substituting (4) into (3), we can express the gain of the whole feedforward amplifier as

$$g_{ff} = \frac{V_{out}}{V_{in}} = g_m c_1 a_2 l_3 a_4 \quad (5)$$

If we represent the transfer coefficients in decibels instead of in complex amplitude format, using the corresponding upper case symbols, then

$$G_{ff} = G_m + C_1 + A_2 + L_3 + A_4 \quad (6)$$

As expected, the overall gain is the gain of the main amplifier reduced by the losses of the passive components in the main signal path.

3.2. First-Loop Balance

Balancing the first loop is necessary to minimize the load on the error amplifier. Any distortion resulting from overloading the error amplifier with residual carrier power adds to the overall distortion of the feedforward amplifier—there is no mechanism to cancel it out. The amplified residual carrier signal reaching coupler 4 through the error amplifier would also alter the overall gain of the feedforward amplifier. This could be an increase or a decrease depending on the phase of the residual signal. The balance conditions for the first loop need to be achieved over a frequency range that encompasses the input signal spectrum.

3.3. Second-Loop Balance

Balancing the second loop is necessary to ensure deep cancellation of distortion. The bandwidth over which balance must be achieved is normally greater than that required for the first loop because distortion products (e.g., intermodulation products) are likely to fall outside the range of the wanted signal.

3.4. Phase and Amplitude Matching Limits

Considering further the balance condition for the second loop, we can rewrite (4) as

$$1 - x = 0, \quad \text{where } x = \frac{-c_2 l_2 c_3 g_e c_4}{a_2 l_3 a_4} \quad (7)$$

where x is a complex number, equal to unity for perfect balance and equal to zero if the second-loop correction is not applied. The squared magnitude of the distortion suppression ratio is thus $|s|^2 = |1 - x|^2$.

Analyzing this in terms of the magnitude and phase imbalance, we obtain

$$\begin{aligned} |s|^2 &= |1 - x|^2 = |1 - |x| \cos \theta - j|x| \sin \theta|^2 \\ &= (1 - |x| \cos \theta)^2 + |x|^2 \sin^2 \theta \\ &= 1 - 2|x| \cos \theta + |x|^2 \end{aligned} \quad (8)$$

where θ is the phase imbalance and $20 \log_{10} |x|$ is the amplitude imbalance in decibels.

Figure 3 shows plots of the loop suppression in decibels versus phase imbalance, for varying levels of amplitude imbalance. It shows that there is some limited scope for trading off phase error against amplitude error, but for high levels of suppression, very good phase and amplitude accuracy are both required. For example, 30 dB suppression can be achieved if the phase balance is better than 1.2° and the amplitude balance is better than 0.2 dB. To illustrate the fine adjustment required, in physical layout terms this 1.2° phase balance corresponds to a pathlength balance between the two sides of the loop of better than $1/f\sqrt{\epsilon_{\text{eff}}}$ mm, where f is the frequency in gigahertz and ϵ_{eff} is the effective dielectric constant of the circuit medium.

3.5. Noise Figure

The noise figure of a feedforward amplifier is dominated by the error amplifier path. If the loops are properly balanced, the noise generated in the main amplifier (being uncorrelated with the input signal) is canceled at the output of the fourth coupler, in just the same way as the distortion. Thus, with reference to Fig. 2, the total noise figure f_{total} is given by

$$f_{\text{total}} = \frac{f_e}{|a_1 l_1 a_3|^2}$$

where f_e is the noise figure of the error amplifier. Alternatively, expressing all quantities in decibels, we obtain

$$F_{\text{total}} = F_e - A_1 - L_1 - A_3 \tag{9}$$

Since A_1 , L_1 , and A_3 are all negative, the total noise figure is clearly somewhat higher than that of the error amplifier. L_1 may be regarded as a parasitic loss and should be fairly small (of the order of a few tenths of a decibel). A_3 can also be made small in most cases because other degrees of freedom are available to balance the loops. So the main design choice affecting the noise figure is the input coupler loss A_1 . In a feedforward amplifier design in which the noise figure must be kept to a minimum, it is therefore necessary to direct most of the input power toward the linear branch of the first loop by making a_1 close to unity (i.e., A_1 close to 0 dB). Consequently, as power is conserved

Figure 3. Loop suppression versus phase error.

in the input coupler, c_1 is small, and the gain of the main amplifier must be increased to compensate for this input attenuation. This is rarely a problem because small-signal gain is relatively cheap in terms of components and DC power.

3.6. Return Losses

The input and output return losses of the feedforward amplifier are affected by the multiple signal paths.

3.6.1. Input Return Loss. Considering first the input port, with reference to Fig. 2, the reflected voltage wave is made up of the vector combination of reflections from couplers 1 and 3, the two amplifiers, and the first delay line. There is also a potentially significant contribution from the main amplifier output, fed back to the input via coupler 2 and the isolated path through coupler 3. It is assumed that the reverse isolations (output to input) through the amplifiers and the isolation factors of the couplers are sufficiently high to eliminate any significant contributions to the input return loss from all other possible signal paths.

Assuming further that the individual passive components have negligible reflection coefficients, we can write the input reflection coefficient as follows:

$$\begin{aligned} \Gamma_{\text{in}} &= c_1^2 \Gamma_{\text{in_main}} + a_1^2 l_1^2 a_3^2 \Gamma_{\text{in_error}} \\ &\quad + c_1 g_m c_2 l_2 c_3 \Gamma_{\text{in_error}} a_3 l_1 a_1 \\ &\quad + c_1 g_m c_2 l_2 i_3 l_1 a_1 \\ &= c_1^2 \Gamma_{\text{in_main}} \\ &\quad + a_1 l_1 a_3 (a_1 l_1 a_3 + c_1 g_m c_2 l_2 c_3) \Gamma_{\text{in_error}} \\ &\quad + c_1 g_m c_2 l_2 i_3 l_1 a_1 \end{aligned} \tag{10}$$

If the first-loop balance condition (2) is met, the coefficient of $\Gamma_{\text{in_error}}$ in (10) is zero, and the equation can be simplified to

$$\Gamma_{\text{in}} = c_1^2 \Gamma_{\text{in_main}} - \frac{a_1^2 l_1^2 a_3 i_3}{c_3} \tag{11}$$

The first contribution will be small if the input coupling ratio is made low, as also required for a low-noise figure (see Section 3.5). The second contribution in (11) can be minimized by designing coupler 3 to have a high directivity factor, $d_3 = c_3/i_3$.

3.6.2. Output Return Loss. Considering now a signal injected into the output port of the feedforward amplifier, and making corresponding assumptions again about the reverse isolation factors of the amplifiers and the reflection coefficients of the passive components, we can arrive at the following equation for the output reflection

coefficient:

$$\begin{aligned}
 \Gamma_{\text{out}} &= c_4^2 \Gamma_{\text{out_error}} + a_4^2 l_3^2 a_2^2 \Gamma_{\text{out_main}} \\
 &\quad + a_4 l_3 a_2 \Gamma_{\text{out_main}} c_2 l_2 c_3 g_e c_4 \\
 &\quad + a_4 l_3 i_2 l_2 c_3 g_3 a_4 \\
 &= c_4^2 \Gamma_{\text{out_error}} \\
 &\quad + a_4 l_3 a_2 (a_4 l_3 a_2 + c_2 l_2 c_3 g_e c_4) \Gamma_{\text{out_main}} \\
 &\quad + a_4 l_3 i_2 l_2 c_3 g_3 a_4
 \end{aligned} \tag{12}$$

If the second-loop balancing condition (4) is met, the coefficient of $\Gamma_{\text{out_main}}$ is zero. This is a result of the fact that the second loop fulfills its function of canceling any output signals not originating from the input. The signal reflected by the output of the main amplifier is canceled just as noise and distortion are. Thus Eq. (12) can be rearranged to give

$$\Gamma_{\text{out}} = c_4^2 \Gamma_{\text{out_error}} + \frac{a_4^2 l_3^2 a_2 i_2}{c_2} \tag{13}$$

c_4 is typically small, to avoid wasting main amplifier power (but not so small as to overstretch the error amplifier), so the second term, involving the directivity of coupler 2, namely, $d_2 = c_2/i_2$, could be the dominating contribution to the output return loss.

3.7. Stability

Although feedforward is generally regarded as an inherently stable amplifier configuration, it does contain closed signal loops that need to be analyzed carefully to check for possible instabilities. As in the case of the input and output return losses, a key consideration here is again the directivity of the couplers.

Considering the first loop first, we can express a loop gain factor g_1 as

$$g_1 = i_1 g_m c_2 l_2 i_3 l_1 \tag{14}$$

If the first loop balance condition (2) is met, this can be written as:

$$g_1 = -\frac{a_1 l_1^2 a_3}{d_1 d_3} \tag{15}$$

Since $|d| \gg 1$ for a well-designed directional coupler, and since all the parameters in the numerator have magnitudes less than unity, Eq. (15) suggests that stability is unlikely to be a problem, since $|g_1| < 1$. However, care must be taken if the bandwidth of the main amplifier is significantly broader than the bandwidths of the couplers, since their isolation may degrade out of band, leading to an unstable condition where Eq. (14) gives $|g_1| > 1$, at some frequency outside the intended frequency range of the feedforward amplifier.

Similarly, considering the second loop, we can express a loop gain factor g_2 as follows:

$$g_2 = g_e i_4 l_3 i_2 l_2 c_3 \tag{16}$$

Applying the second-loop balance condition (4) allows this to be rewritten as

$$g_2 = -\frac{a_2 l_3^2 a_4}{d_2 d_4} \tag{17}$$

As in the case of the first loop, good directivity in the couplers ensures stability over the intended operating range, but if the error amplifier has a bandwidth broader than those of the couplers or than the intended operating frequency range of the feedforward amplifier, it is advisable to check that (16) does not lead to $|g_2| > 1$ at any frequency.

3.8. Efficiency

The overall efficiency of a feedforward amplifier (not including power consumption by power conditioning, control circuits and cooling systems) is a function of the efficiencies of both the main and error amplifiers, as well as the losses in the output circuit.

If the output power of the main amplifier is P_M , then the output from the feedforward amplifier is $P_{\text{OUT}} = |a_2|^2 |l_3|^2 |a_4|^2 P_M$. If the efficiencies of the main and error amplifiers are N_M and N_E , then the total DC power consumption is $P_{\text{DC_TOTAL}} = P_M/N_M + P_E/N_E$, where P_E is the power output of the error amplifier.

Thus the overall efficiency can be written as follows:

$$\begin{aligned}
 N_{\text{TOTAL}} &= \frac{P_{\text{OUT}}}{P_{\text{DC_TOTAL}}} \\
 &= \frac{|a_2|^2 |l_3|^2 |a_4|^2 P_M}{P_M/N_M + P_E/N_E} \\
 &= \frac{|a_2|^2 |l_3|^2 |a_4|^2 N_M}{1 + P_E N_M / P_M N_E}
 \end{aligned} \tag{18}$$

This shows that in the limiting case where the power demands on the error amplifier are very small compared to those on the main amplifier, the overall efficiency approaches that of the main amplifier, but reduced by the losses of the output couplers and delay lines. In the more typical situation where the powers are comparable, the overall efficiency is reduced by the presence of the error amplifier. Typically, the error amplifier is likely to have an efficiency lower than that of the main amplifier because it needs to be highly linear to avoid generating additional uncompensated distortion, and it may also have been designed with an emphasis on noise figure rather than efficiency.

Figure 4 shows a set of curves indicating the efficiency reduction factor, $1/(1 + P_E N_M / P_M N_E)$, as a function of P_E/P_M for typical values of N_E and N_M . They show, as expected, that the efficiency is halved if $P_E = P_M$ and $N_E = N_M$.

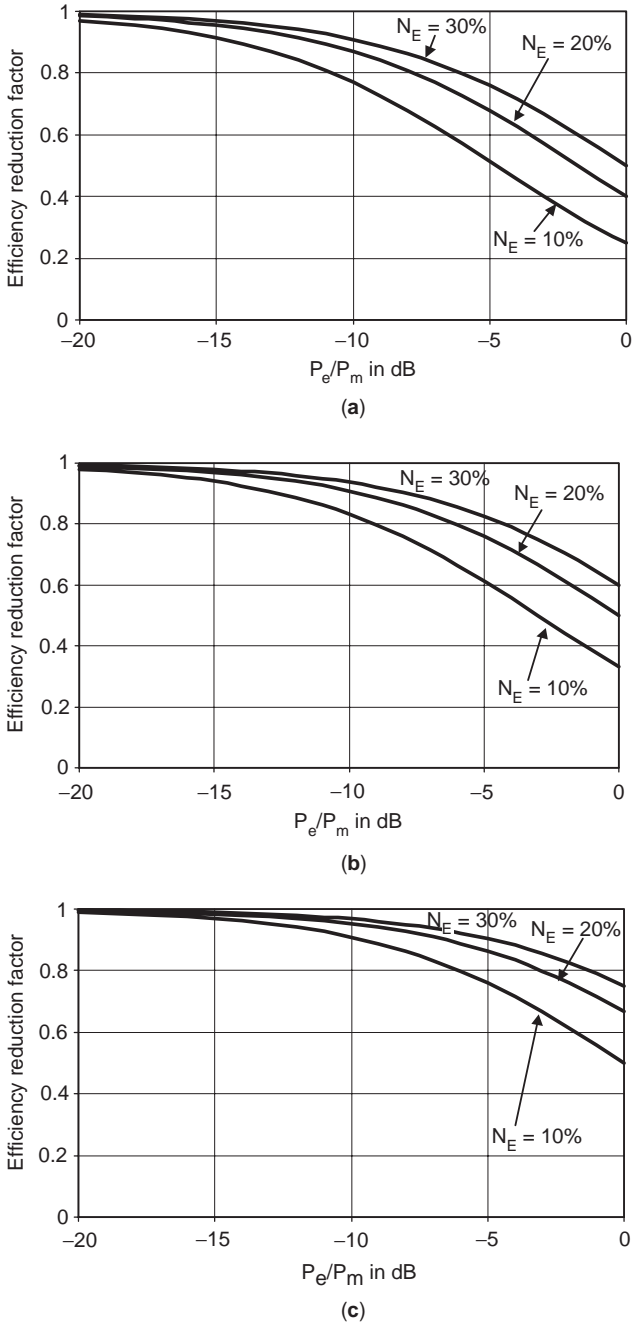

Figure 4. Feedforward efficiency reduction with $N_M = 30\%$ (a), 20% (b), and 10% (c).

3.9. Bandwidth

As discussed earlier, the main limitation on the bandwidth of a feedforward amplifier is usually the frequency range over which the rigorous phase and amplitude matching conditions can be met.

Considering Figs. 2 and 3 again, the problem becomes one of meeting amplitude and phase matching limits required for the desired degree of suppression over the full bandwidth. The two paths from the main amplifier output to the feedforward output have transfer functions t_a and t_b , where $t_a = a_2 l_3 a_4$ and $t_b = c_2 l_2 c_3 g_e c_4$.

Typically, the main path characterized by t_a has a relatively small variation of amplitude with frequency and a phase that varies linearly with frequency, consistent with a constant delay. Some amplitude variation and deviation from constant delay may occur if the couplers are working near the edge of their frequency ranges. The phase of transfer function t_a can thus be expected to vary with frequency as follows:

$$\text{Arg}(t_a) = \phi_a - \tau_d(\omega - \omega_0) \tag{19}$$

where τ_d is the time delay at center frequency ω_0 .

The path through the error amplifier, characterized by transfer function t_b , is likely to have more complex amplitude and phase variations with frequency. The phase variation is typically characterized by a polynomial, of the form

$$\text{Arg}(t_b) = \phi_b - \tau_g(\omega - \omega_0) + p(\omega - \omega_0)^2 + R(\omega) \tag{20}$$

where τ_g is the group delay at center frequency ω_0 , p is a parabolic phase coefficient, arising mainly from the band-pass response of the error amplifier, and $R(\omega)$ is a residual phase ripple function, caused by higher-order transfer function terms and multiple reflections within the error amplifier and associated components.

The second-loop balance equation requires that

$$\text{Arg}(t_a) - \text{Arg}(t_b) = \pm \pi$$

From (19) and (20), it is clear that this can be satisfied by making $\phi_a - \phi_b = \pm \pi$ and $\tau_d = \tau_g$, as long as the amplifier bandwidth is large enough to render the influence of the parabolic and ripple components negligible. Thus, to achieve broadband feedforward cancellation, it is necessary to have at least 2 degrees of freedom in the adjustable parameters of the second loop, so that both the phase offset and the delay can be equalized. It may be necessary to arrange for cancellation of quadratic and higher terms also, necessitating the inclusion of carefully designed all-pass filter networks. However, if only narrowband operation is required, it is sufficient to have just one adjustable phase parameter in each loop. Similar considerations apply to achieving amplitude balance.

In a more realistic design scenario, it is likely that a CAD model rather than an analytical equation would be used to characterize the amplifier and the associated passive components. A procedure such as that reported by Konstantinou et al. [7] can then be used. First, the loop 1 balance is optimized by injecting a small signal into the input of coupler 1 and adjusting the variable elements to achieve minimum power at the input to the error amplifier, over the required range of frequency and input power. The reference path is then broken by removing the delay line and replacing it with two matched and isolated terminations. The carrier signal should then appear at the input to the error amplifier. If the second loop is correctly adjusted, this will cancel the carrier signal at the output of coupler 4. Thus the second loop can be optimized by adjusting the variable elements for minimum output from

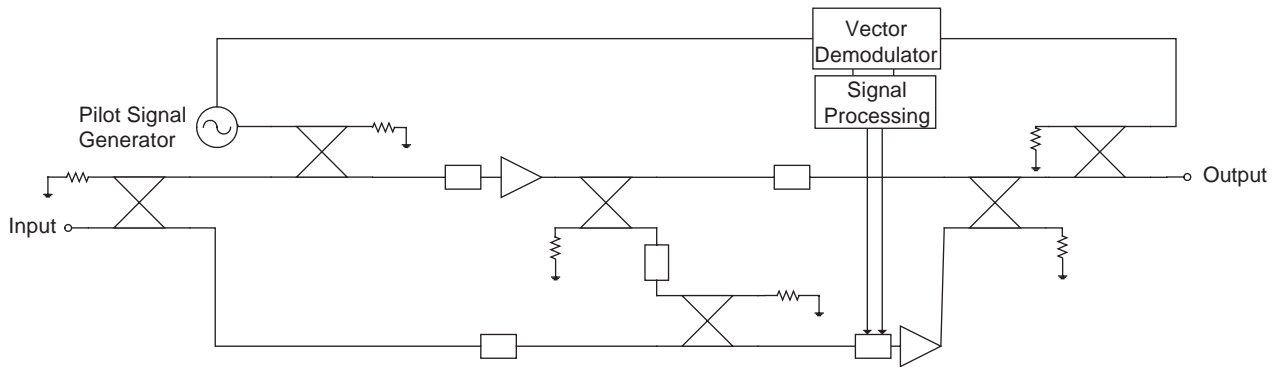

Figure 5. Feedforward amplifier with pilot signal injection for loop 2 control.

coupler 4, while the input signal varies over the full frequency range. Then, after loop 1 is reestablished, a nonlinear measurement or simulation, such as a two-tone test, can be performed to ensure that adequate cancellation occurs.

An alternative to the technique of opening the first loop while optimizing the second would be to inject a pilot signal at the input to the main amplifier, as illustrated in Fig. 5 [6]. The first loop is optimized by ensuring that the ratio of the input signal to the pilot signal at the input to the error amplifier is minimized. The second loop is optimized by ensuring that the level of the pilot signal seen at the feedforward amplifier output is minimized. This concept forms one basis for automatic control of a feedforward loop, to compensate for changes in the amplifier performance with temperature, aging, and varying signal statistics.

4. ADVANCED TECHNIQUES AND CHALLENGES

This section briefly reviews some advanced techniques in recent and current (as of 2004) research on feedforward linearisation.

4.1. Dual-Loop Feedforward

Since a complete feedforward amplifier is itself an amplifier in its own right, it is possible to incorporate the whole thing, recursively, inside an outer feedforward loop, as

shown in Fig. 6. The outer loop can be used to compensate for the residual distortion left by the inner loop and for any distortion introduced by the first error amplifier, leading to even lower distortion levels but increasing the tuning complexity even further.

4.2. Nonlinear Phase Equalizers for Improved Broadband Suppression

Hau et al. [8] demonstrated that by the use of nonlinear phase equalizers formed from allpass networks, the IM3 cancellation of a feedforward amplifier operating over the full 1.7–1.9-GHz band could be improved from 15 to 21 dB.

4.3. Feedforward Adaptation and Control

Cavers [9] established a theoretical basis for the adaptation of a feedforward system, showing that different considerations apply in the two loops. In the first loop (the signal cancellation loop) adaptation can be achieved by monitoring the error signal (at the input to the error amplifier). One possible method is to seek minimum power in this signal, but the favored method seeks zero correlation between the error signal and the input modulation, leading to a gradient-based adaptation algorithm that does not require pilot signals or other deliberate periodic perturbations to ensure that the optimum setting is maintained. Adaptation times of the order of 1–10 ms can be achieved in this way. In the second loop (the error correction loop) the high level of the wanted signal

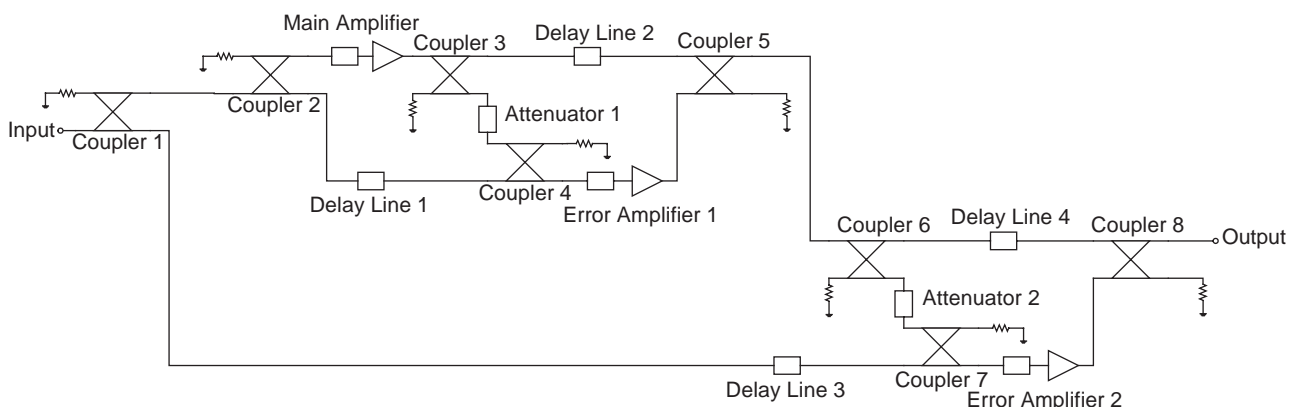

Figure 6. A dual-loop feedforward amplifier.

relative to the error necessitates much longer integration times, leading to much slower adaptation. This problem can be overcome, and the accuracy improved, by using a carrier suppression filter before performing the gradient calculation.

Chen et al. [10] proposed an alternative fast adaptive algorithm to track the linearizer control parameters, separating the rapidly varying but known factors (i.e., the signal statistics) from the slowly varying environmental factors affecting the power amplifier model, resulting in swift and accurate convergence.

Echeverría et al. [11] demonstrated that very high levels of intermodulation suppression, over 60 dB, could be achieved by tuning the control loops manually for individual 10 MHz subbands, over a total bandwidth of 19 MHz (2.01–2.205 GHz).

4.4. Hybrid Feedforward Amplifiers

It is possible to combine feedforward linearization with other linearization methods for improved overall results. For example, Horiguchi et al. [12] demonstrated a high-power 2.12 GHz feedforward power amplifier in which the overall operating efficiency was improved by 1% by the addition of a simple predistortion linearizer to the input of the main amplifier.

Another more radical hybrid feedforward amplifier concept has been proposed by Randall et al. [13], in which part of the first loop is replaced by a DSP implementation. The main and reference signals are both generated by DSP before upconversion to the carrier frequency. The second loop would operate conventionally. The advantage of DSP implementation is that phase and amplitude equalization of both the main and reference signals can be carried out and adapted as required in DSP software, rather than in RF analog components, allowing more accurate cancellation.

4.5. MMIC Integration

Integrating the whole feedforward amplifier onto a single MMIC is an attractive proposition from the point of view of miniaturization and repeatability at higher microwave frequencies or even millimeter-wave frequencies. Achieving such integration is, however, a major research challenge, because of the difficulty of creating the necessary high-isolation couplers, low-loss delay lines, and phase shifters on a MMIC, along with high linearity, high efficiency, and accurately modeled amplifiers. Parkinson and Paul [14] have carried out initial studies of the possibility of using a distributed amplifier structure as an active coupler within a MMIC feedforward amplifier, as a starting point for full MMIC integration.

1. INTRODUCTION

The circulator is one of the elementary building blocks in radiofrequency and microwave circuits. It is used extensively in making basic devices for communications and radar systems. The latter are often used in broadband and high-power rating systems at microwave and millimeter-wave frequencies. It is, however, seldom found in consumer products because some of its functions can be performed

by simpler and cheaper alternatives. However, interest in circulators has been revitalized with the emergence of mobile communications. As an increasing number of users are accustomed to the freedom provided by cellular phones, communication without the constraint of an attached wire is considered as natural as breathing air. In addressing the ever-increasing public demands, numerous wireless systems have been launched and more are coming. The most notable ones are wireless local area network, wireless local subscriber loops, and other high-bit-rate yet low-error-rate systems of data transmission. For these systems, the overlooked circulator enjoys a competitive edge as most active switches could not deliver the needed power rating and bandwidth at a reasonable price, especially those in the ultra-high-frequency band and beyond.

For engineering students, the circulator is perhaps the first multiport device covered in their foundation course on microwave engineering, and it might be the first nonreciprocal passive device encountered [1,2]. The importance of this three-port device in communication systems can be explained by its functionality. Simply put, waves entering one of the identical ports of a circulator, say, port 1, are totally transmitted to one of the output ports, port 2, with none to the remaining one, port 3. Similarly, those inputted to port 2 are passed on to port 3 without loss while port 1 is isolated. The cycle is completed as signals entering port 3 are outputted to port 1 only. Schematically, a circulator is shown in Fig. 1.

The scattering matrix of the clockwise circulator shown in Fig. 1 is

$$[S]_{\text{clockwise}} = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \quad (1)$$

Depending on the physical layout of a circuit and one's point of view, a circulator can also be counter-clockwise

Figure 1. A schematic sketch of a circulator.

and the relevant scattering matrix is

$$[S]_{\text{counterclockwise}} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix} \quad (2)$$

Extension of a three-port circulator to an m -port one is possible, but it is skipped here because it introduces no new concepts, yet the algebra involved is so tedious that the logic flow of this introductory article could be derailed. Note that, the scattering matrices given in (1) and (2) are valid for lossless three-port circulators with perfectly matched inputs and outputs. Modifications of the theories and practices presented in this article to low-loss m -port ones with less than perfect matched input and output ports have been conducted in many pioneering studies [3,4]. Again, they are omitted here, and interested readers are referred to a comprehensive book [5].

The passive traffic control in circulators is facilitated by an anisotropic element. Isotropy or anisotropy is an intrinsic characteristic of all matters that finds its origin in their molecular structures and atomic dipole moments of electric or magnetic nature [6]. In general, these dipole moments are randomly oriented in the absence of an external excitation; therefore the material on the whole has a negligibly small net dipole moment. The scenario could change abruptly with the introduction of an applied static electric field as the electric dipole moments align themselves with the impressed force and a net electric dipole moment results. Similarly, a spontaneous magnetic dipole moment is obtained by a biasing magnetic field. The dipole alignment is dependent on the strength of the excitation until all dipoles are almost perfectly oriented. The alignment, in fact, depends on the molecular structure of the material, the ambient temperature, the initial settings, and other physical conditions. In general, the relationship between the dipole alignment and the applied field is nonlinear, and for some materials, it is anisotropic.

The principles of circulator operation, basic theories of anisotropy, wave propagation in anisotropic materials, and circulator applications will be briefly presented in Sections 2–4, followed by a general description of selected circulators in Section 5. The most popular ones, especially waveguide junction circulators, will be analyzed in depth in Section 6. A few concluding remarks will be presented in Section 7.

2. ANISOTROPY AND ANISOTROPIC MATERIALS

In theory, both electrical and magnetic materials can be used to produce anisotropic effects in a circulator. Magnetic anisotropy is, however, still used in practically all circulators over a half-century since its invention. Hence, the discussion in this section focuses on magnetic anisotropy. Nevertheless, the potential of using electrically anisotropic materials in circulators in the future cannot be dismissed. One of the major candidates for this is the uniaxial chiral material especially made for microwave frequencies. Although significant progress has been observed

in this area in recent years, the technologies at our disposal at this moment are far from satisfactory. Thus it has been decided not to further investigate the use of electrically anisotropic materials in circulators until more mature technologies are available.

As this is only an introductory article on circulators, we will not attempt to cover all circulators available on the market. For similar reasons, only theories of anisotropy directly relevant to the selected circulators discussed here will be presented.

2.1. Spinning Electron in Free Space

The angular momentum of an electron in an atom or an ion arises from two factors: its orbital motion around the atomic nucleus and its spin. Based on quantum mechanics, the total angular momentum of an electron in free space is given by

$$s = \frac{1}{g} \frac{h}{2\pi} \quad (3)$$

where $h = 6.626 \times 10^{-34}$ J/s is Planck's constant and g is Lande's factor. If the angular momentum of an electron is due solely to its orbital motion, then $g = 1$. At the other extreme, a $g = 2$ factor is used to signify a spin-only momentum. For most materials of interest in microwave systems, it can be shown that g ranges from 1.98 to 2.01; therefore $g = 2$ is a good approximation. Based on Bohr's model, the magnetic dipole moment of an electron is

$$m = \frac{e}{m_0} \frac{h}{4\pi} = 9.27 \times 10^{-24} \text{ A/m}^2 \quad (4)$$

where $e = 1.6 \times 10^{-19}$ C is the charge of an electron and $m_0 = 9.1 \times 10^{-31}$ kg is its mass.

Comparing (3) and (4), it is found that the ratio of the magnetic dipole moment of a spinning electron to its angular momentum is a constant, the so-called called gyro-magnetic ratio:

$$\gamma = \frac{m}{s} = \frac{e}{m_0} = 1.759 \times 10^{11} \text{ C/kg} \quad (5)$$

According to Hund's rule, electrons in a shell would spread out over the available states with spins in the same direction until the shell is half-filled, and all subsequent additions would have spins in the opposite direction. Thus, the magnetic dipole moment of an atom with a fully filled outermost shell such as found in the inert gases is zero. At the other extreme, the maximum dipole moment is obtained in a half-filled shell, and in the 10-state d shell it is 5.

Returning to the familiar Newtonian mechanics, the magnetostatic torque acting on the dipole moment due to an impressed static magnetic field \mathbf{H}_{DC} is

$$\mathbf{T} = \mu_0 \mathbf{m} \times \mathbf{H}_{DC} \quad (6)$$

As electrons are negatively charged, its angular momentum is opposite to its dipole moment:

$$\mathbf{m} = -\gamma \mathbf{s} \quad (7)$$

Since torque is equal to the rate of change of angular momentum, one arrives at

$$\frac{d\mathbf{s}}{dt} = \mathbf{T} = -\mu_0 \gamma \mathbf{s} \times \mathbf{H}_{DC} \quad (8)$$

The equation of motion for a spinning electron is obtained by substituting (7) into (8)

$$\frac{d\mathbf{m}}{dt} = -\mu_0 \gamma \mathbf{m} \times \mathbf{H}_{DC} \quad (9)$$

Without loss of generality, the study can be furthered with a \hat{z} -biased \mathbf{H}_{DC} . Thus, the components of the vector equation above are

$$\frac{dm_x}{dt} = -\mu_0 \gamma m_y H_{DC} \quad (10)$$

$$\frac{dm_y}{dt} = \mu_0 \gamma m_x H_{DC} \quad (11)$$

$$\frac{dm_z}{dt} = 0 \quad (12)$$

Differentiating (10) and (11) once more, two harmonic equations are derived

$$\frac{d^2 m_x}{dt^2} + \omega_0^2 m_x = 0 \quad (13)$$

$$\frac{d^2 m_y}{dt^2} + \omega_0^2 m_y = 0 \quad (14)$$

where ω_0 is the Larmor frequency of precession, given by

$$\omega_0 = \mu_0 \gamma H_{DC} \quad (15)$$

A solution to both (13) and (14) is

$$m_x = A \cos \omega_0 t \quad (16)$$

$$m_y = A \sin \omega_0 t \quad (17)$$

It is observed from (4) that the magnitude of \mathbf{m} is fixed; therefore one gets

$$m^2 = \left(\frac{\gamma h}{4\pi} \right)^2 = m_x^2 + m_y^2 + m_z^2 = A^2 + m_z^2 \quad (18)$$

In short, \mathbf{m} would precess around the \hat{z} axis with an angle θ :

$$\sin \theta = \frac{A}{m} \quad (19)$$

Moreover, the projection of \mathbf{m} on the x - y plane would trace a circular path with an angular frequency ω_0 as depicted in Fig. 2. For a standalone atom in free space, \mathbf{m} could precess indefinitely. However, for an atom in a crystal, the electron would experience numerous gravitational and

Figure 2. Angular momentum and magnetic dipole moment of a spinning electron.

electromagnetic forces. Altogether, these interactions would constitute a damping force that causes \mathbf{m} to spiral inward, and in due course, \mathbf{m} would align with the biasing field.

Even after the dipole alignment is completed, the magnetic flux density due to magnetization for most materials is very weak, compared with the biasing magnetic field. Hence, the relative permeability in paramagnetic materials is slightly greater than 1, while that of diamagnetic materials is marginally less than unity.

Here, it is worthwhile to comment on the units used in this article. Traditionally, studies of magnetism are conducted in CGS units with the magnetic field strength expressed in oersteds and the magnetization in gauss. The units are chosen such that the magnetic flux density B and the magnetic field strength H in free space would have equal numeric values. On the other hand, in line most engineering texts, formulas presented in this article will be derived in MKS units. Hence, utmost care must be taken in using some properties of magnetic materials quoted in CGS units. For easy reference, some of the most frequently used unit conversions are tabulated in Table 1.

2.1.1. Ferromagnetic and Ferrimagnetic Materials. In general, magnetization effects are very weak even for atoms with a half-filled outermost shell such as chromium and manganese. A different mechanism is needed to enhance the magnetization. It is found in some substances, called *ferromagnetic materials*. From a microscopic point

of view, ferrous metals are composed of tiny domains of linear dimensions of a few micrometers. It is proved in quantum mechanics that strong coupling forces exist between atoms in each domain such that all atomic dipole moments are kept in parallel even when there is no external field. As the dipole moments of these domains are randomly oriented, a demagnetized ferromagnetic material shows no magnetization effect, from a macroscopic perspective. Analogous to the ionic dipole moments in paramagnetic and diamagnetic materials, the magnetic dipole of every domain in ferrous metals reacts to an impressed field, except that the responses are much stronger. Consequently, the permeability of ferromagnetic materials is notably higher than its paramagnetic and diamagnetic counterparts, a factor of many orders. Again, the magnetization depends on the field strength until saturation. Probably as a result of some form of domain deformation during the magnetization processes, certain domain rotations are not reversible after the external bias is removed, and a residue magnetic effect results. This remanent magnetization plays a key role in subsequent magnetizations and contributes to the infamous hysteresis loop.

Significant magnetization can also be observed in the so-called antiferromagnetic materials. Even though the dipole moments in the latter class of materials align with the applied field equally fervently, their directions are either in line with or opposite to that of the excitation, and the end result is a complete cancellation of magnetization effects.

Another class of substances, termed *ferrimagnetic materials*, exhibits a behavior intermediate between ferromagnetism and antiferromagnetism. The pattern of dipole alignment in these materials is similar to that of antiferromagnetic ones except the number of magnetic dipoles in opposite polarities is different and their magnitudes are not equal. Hence, a partial cancellation of dipole moments is observed. As expected, magnetization of ferrimagnetic materials is considerably lower than that of ferrous metals. The maximum magnetic flux density in ferrimagnetic materials is seldom greater than 0.3 Wb/m^2 , approximately one-tenth that of ferromagnetic ones. However, a magnetization of this magnitude is significantly higher than that of nonmagnetic matters; therefore they are often used in picking up spurious waves in electromagnetic compatibility and electromagnetic interference control.

Ferrimagnetic materials can be found in nature in a variety of forms such as lodestones. They were first mentioned in history more than 4500 years ago when natural magnets played a decisive role in a major battle in China as a component in compasses. A nonnatural ferrimagnetic material was first produced by Hilpert in 1909 [7], and practical ones were developed shortly after

Table 1. Conversion between CGS and MKS Units

	Symbol	MKS Units	CGS Units
Magnetic flux	ψ	1 weber	10^8 maxwell
Magnetic flux density	B	1 tesla = 1 weber/meter ²	10^4 gauss
Magnetic field intensity	H	1 ampere-turn/meter	$4\pi \times 10^{-3}$ oersted
Magnetization	M	1 weber/meter ²	$2500/\pi$ gauss

World War II [8]. Synthetic ferrimagnetic materials are usually polycrystalline. For some applications, large crystals can be made, but they are seldom used as they are very expensive.

Humanmade (synthetic) ferrimagnetic materials are now called *ferrites* for easy reference. Over the years, numerous ferrites have been synthesized for assorted applications at different frequencies. Based on their crystal structures, these ferrites can be grouped into three categories, namely, spinels, garnets, and hexagonal ferrites.

Mineral spinels have a molecular formula of $(\text{MgAl}_2\text{O}_4)_8$. Over the years, many synthetic spinels have been developed and they share a structure similar to that of $(\text{MFe}_2\text{O}_3)_8$, where “M” represents divalent metal, including cobalt, aluminum, cadmium, copper, lithium, iron, magnesium, manganese, nickel, titanium, zinc, and their combinations. As metallic ions are smaller than oxygen ions, the crystal structure of spinels depends solely on the arrangement of oxygen ions, the face-centered cubic lattice [10] as shown in Fig. 3. Also shown in Fig. 3 are the sites where metallic ions can be found. It can be shown that a metallic ion in site A has four oxygen neighbors and thus is called *tetrahedral site*; site B is termed *octahedral* because it has six adjacent oxygen ions. In a unit crystal of 56 ions, there are only 8 tetrahedral and 16 octahedral metallic ions; therefore not all sites in the crystal lattices of 32 oxygen ions are filled. It is also found that the magnetic moments in tetrahedral and octahedral sites cancel one another; the remaining 8 octahedral ones give the ferrite crystal its net magnetic moment [11].

Common garnet or andradite has a molecular structure of $\text{Ca}_3\text{Fe}_2\text{Si}_3\text{O}_{12}$. The frequently used yttrium iron garnet (YIG) is obtained by replacing calcium by yttrium and silicone by iron. The net magnetic moment can be adjusted by substituting some iron ions by aluminum ones (YAG), or yttrium by a rare earth such as gadolinium, holmium, or dysprosium. For synthetic garnets, a unit crystal of 40 ions has a molecular formula of $(\text{Fe}_2\text{O}_3)_5 (\text{M}_2\text{O}_3)_3$; where “M” stands for rare earth. There exist three types of sites in the crystal structure for housing the metallic ions and all sites are filled.

Ferrites can be mass-produced as if they were ceramics, except the demands on purity of raw materials, uniformity in grain sizes, correctness in mix proportion, homogeneity of the suspension, precision in casting, timing and temperature control in firing, and other manufacturing pro-

Figure 3. Tetrahedral (A) and octahedral (B) sites in the crystal structure of oxygen ions.

cesses are very stringent and the error margin is very slim. The raw materials include oxides, carbonates, nitrates, oxalates, and some metallic compounds. As the facilities used in making ferrites are very expensive and the exact procedures are usually company secrets, few laboratories can make them from scratch. It is, however, recommended that research centers be equipped with diamond wheels and other apparatuses for cutting and grinding raw ferrites into the desired shapes because the physical dimensions of ferrites have direct consequences on the performance of circulators, as are the smoothness and the cleanliness of their surfaces.

As ferrites are ceramiclike compounds, they are very hard, brittle, and low in thermal conductivity. Unlike ferromagnetic materials, ferrites have low electrical conductivities; thus, they are frequently used in electrical and electronic devices for a variety of purposes. However, the feature that makes ferrites indispensable in microwave circuit designs is anisotropy, not low conductivity. Of course, an in-depth study of anisotropy is beyond the scope of this article, but a brief outline of its origin is deemed appropriate for a better understanding the nature of wave circulations in magnetized ferrites.

2.1.2. Magnetization of Ferrites. The configuration of interest is a ferrite crystal under an internal magnetic field \mathbf{H}_{int} . The excitation exterior to a ferrite specimen is different from \mathbf{H}_{int} , and it will be treated later. For a sample with N unbalanced electron spins per unit volume, the total magnetization is

$$\mathbf{M}_{\text{DC}} = N\mathbf{m} \quad (20)$$

Similar to (9), the equation of motion is

$$\frac{d\mathbf{M}_{\text{DC}}}{dt} = -\mu_0\gamma\mathbf{M}_{\text{DC}} \times \mathbf{H}_{\text{int}} \quad (21)$$

As the damping force inside a ferrite crystal is much stronger than that acting on a standalone atom in free space, the magnetic dipole moments will align with the magnetic excitation readily. With an increase in \mathbf{H}_{int} , an increasing number of magnetic dipoles line up with the biasing field, and eventually the alignment process is completed and the magnetization is saturated as depicted in Fig. 4. The saturation magnetization \mathbf{M}_s is a physical property of ferrite, and typically it ranges within $4\pi M_s = 300\text{--}5000$ G. Unless mentioned otherwise, ferrites operate in the state of saturation magnetization because they are very lossy at lower levels of magnetization. Hence, the equation of motion in (21) could be rewritten as

$$\frac{d\mathbf{M}_s}{dt} = -\mu_0\gamma\mathbf{M}_s \times \mathbf{H}_{\text{int}} \quad (22)$$

Regardless of whether the magnetization is saturated, ferrite will be permanently magnetized after the magnetization process. The crystal structure of having dipole moments of opposite polarities in an alternating fashion may constitute a cementing force that keeps the alignment intact after the external bias is removed. In some

Figure 4. Magnetization of ferrites versus magnetic field intensity.

circulators, a premagnetized ferrite is adequate and external magnetization is not needed [32].

It is well known that atoms can pick up thermal energy from the surrounding environment and vibrate accordingly. Sometimes, the atomic vibration in ferrites could make the dipole alignment very difficult even at room temperature. As a rule of thumb, an increase in ambient temperature is accompanied by a decrease in saturation magnetization. At a sufficiently high temperature, called the Curie temperature T_c , the vibrational energy could overwhelm the electromagnetic energy, and the process of dipole alignment would break down as illustrated in Fig. 5.

3. WAVE PROPAGATION IN FERRITE

Our attention now turns to wave propagations in magnetized ferrites. Without loss of generality, a ferrite specimen is magnetized in the \hat{z} direction and is illuminated by an incident plane wave of arbitrary orientation and of amplitude H_{RF} . The total magnetic field and magnetization are

$$\mathbf{H} = \mathbf{H}_{int} + \mathbf{H}_{RF} = H_x \hat{x} + H_y \hat{y} + (H_{int} + H_z) \hat{z} \quad (23)$$

$$\mathbf{M} = \mathbf{M}_s + \mathbf{M}_{RF} = M_x \hat{x} + M_y \hat{y} + (M_s + M_z) \hat{z} \quad (24)$$

Figure 5. Magnetization of ferrites versus ambient temperature.

The corresponding equation of motion is

$$\begin{aligned} \frac{d\mathbf{M}}{dt} &= \frac{d\mathbf{M}_s}{dt} + \frac{d\mathbf{M}_{RF}}{dt} \\ &= \frac{d\mathbf{M}_{RF}}{dt} = -\mu_0 \gamma \mathbf{M} \times \mathbf{H}. \end{aligned} \quad (25)$$

In its components, the equation of motion is

$$\begin{aligned} \frac{dM_x}{dt} &= +\mu_0 \gamma M_y (H_{int} + H_z) \\ &\quad - \mu_0 \gamma H_y (M_s + M_z) \end{aligned} \quad (26)$$

$$\begin{aligned} \frac{dM_y}{dt} &= \mu_0 \gamma M_x (H_{int} + H_z) \\ &\quad - \mu_0 \gamma H_x (M_s + M_z) \end{aligned} \quad (27)$$

$$\frac{dM_z}{dt} = -\mu_0 \gamma M_x H_y + \mu_0 \gamma M_y H_x \quad (28)$$

Since $H_{RF} \ll H_{int}$, $M_x H_y$ and similar products can be ignored in accordance with the small signal approximations. As a result, the preceding equations can be simplified to

$$\begin{aligned} \frac{dM_x}{dt} &= -\mu_0 \gamma M_y H_{int} + \mu_0 \gamma M_s H_y \\ &= -\omega_0 M_y + \omega_m H_y \end{aligned} \quad (29)$$

$$\begin{aligned} \frac{dM_y}{dt} &= \mu_0 \gamma M_x H_{int} - \mu_0 \gamma M_s H_x \\ &= \omega_0 M_x - \omega_m H_x \end{aligned} \quad (30)$$

$$\frac{dM_z}{dt} = 0 \quad (31)$$

where ω_0 is the Larmor frequency of precession, and

$$\omega_m = \mu_0 \gamma M_s \quad (32)$$

Comparing (15) and (32), ω_m can be expressed as

$$\omega_m = \omega_0 \frac{M_s}{H_{int}} \quad (33)$$

Differentiating (29) and (30) once more, one gets

$$\frac{d^2 M_x}{dt^2} = -\omega_0^2 M_x + \omega_0 \omega_m H_x + \omega_m \frac{dH_y}{dt} \quad (34)$$

$$\frac{d^2 M_y}{dt^2} = -\omega_0^2 M_y + \omega_0 \omega_m H_y - \omega_m \frac{dH_x}{dt} \quad (35)$$

In a time-harmonic analysis, these equations can be simplified to

$$(\omega_0^2 - \omega^2) M_x = \omega_0 \omega_m H_x + j \omega \omega_m H_y \quad (36)$$

$$(\omega_0^2 - \omega^2) M_y = -j \omega \omega_m H_x + \omega_0 \omega_m H_y \quad (37)$$

Note that both M_x and M_y are dependent on H_x as well as H_y . In other words, a tensor is needed to characterize the relationship between magnetization \mathbf{M} and its driving force, the magnetic field intensity \mathbf{H} ; that is

$$\mathbf{M} = \bar{\bar{\chi}} \mathbf{H} = \begin{bmatrix} \chi_{xx} & \chi_{xy} & 0 \\ \chi_{yx} & \chi_{yy} & 0 \\ 0 & 0 & 0 \end{bmatrix} \mathbf{H} \quad (38)$$

The nonzero components of the susceptibility tensor $\bar{\bar{\chi}}$ are

$$\chi_{xx} = \chi_{yy} = \frac{\omega_0 \omega_m}{\omega_0^2 - \omega^2} \quad (39)$$

$$\chi_{xy} = -\chi_{yx} = \frac{j\omega \omega_m}{\omega_0^2 - \omega^2} \quad (40)$$

Consequently, the magnetic flux density \mathbf{B} must be modified to

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) = \bar{\bar{\mu}} \mathbf{H}. \quad (41)$$

The z -bias Polder permeability tensor $\bar{\bar{\mu}}$ is given by [13]

$$\bar{\bar{\mu}} = \mu_0(\bar{\bar{I}} + \bar{\bar{\chi}}) = \begin{bmatrix} \mu & j\kappa & 0 \\ -j\kappa & \mu & 0 \\ 0 & 0 & \mu_0 \end{bmatrix} \quad (42)$$

where $\bar{\bar{I}}$ is an identity tensor.

The components of the permeability tensor are

$$\mu = \mu_0(1 + \chi_{xx}) = \mu_0 \left(1 + \frac{\omega \omega_m}{\omega_0^2 - \omega_m^2} \right) \quad (43)$$

$$\kappa = -j\mu_0 \chi_{xy} = \mu_0 \frac{\omega_0 \omega_m}{\omega_0^2 - \omega_m^2} \quad (44)$$

It is observed that an \hat{x} -directed or \hat{y} -directed \mathbf{H} would give rise to both \hat{x} and \hat{y} components of \mathbf{B} with a quadratic phase shift between them. A material having this type of properties is called *gyrotropic*.

If the biasing magnetic field is \hat{x} -directed, the corresponding gyrotropic permeability tensor is

$$\bar{\bar{\mu}} = \begin{bmatrix} \mu_0 & 0 & 0 \\ 0 & \mu & j\kappa \\ 0 & -j\kappa & \mu \end{bmatrix} \quad (45)$$

3.1. Forced Precession

If the incoming wave in the preceding section is a right-handed circularly polarized plane wave propagating in the z direction, $H_x = -jH_y = H_0^+$, the relevant magnetization can be determined by (36) and (37):

$$M_x = \frac{\omega_m H_0^+}{\omega_0^2 - \omega^2} (\omega_0 + \omega) = \frac{\omega_m H_0^+}{\omega_0 - \omega} \quad (46)$$

$$M_y = \frac{-j\omega_m H_0^+}{\omega_0^2 - \omega^2} (\omega + \omega_0) = \frac{-j\omega_m H_0^+}{\omega_0 - \omega} = -jM_x \quad (47)$$

Hence, the magnetization vector is also circularly polarized and rotates in the same direction with an angular velocity ω . It then follows that the magnetic flux density is circulating synchronously with the driving force and the effective permeability is given by

$$\mu_0^+ = \mu_0 \left(1 + \frac{\omega_m}{\omega_0 - \omega} \right) \quad (48)$$

It is interesting to compare the angle of precession of the magnetic field intensity θ_H and that of the magnetization vector θ_M^+ :

$$\tan \theta_H = \frac{H_0^+}{H_{\text{int}} + H_z} \cong \frac{H_0^+}{H_{\text{int}}} \quad (49)$$

$$\begin{aligned} \tan \theta_M^+ &= \frac{M_x}{M_s + M_z} \cong \frac{\omega_m}{\omega_0 - \omega} \frac{H_0^+}{M_s} \\ &= \frac{\omega_0}{\omega_0 - \omega} \frac{H_0^+}{H_{\text{int}}} \end{aligned} \quad (50)$$

By invoking (32), we can rewrite (50) as

$$\tan \theta_M^+ = \frac{\omega_0}{\omega_0 - \omega} \frac{H_0^+}{H_{\text{int}}} \quad (51)$$

Hence, as long as $\omega < 2\omega_0$, then $\theta_M^+ > \theta_H$ as shown in Fig. 6. Since $H_0^+ \ll H_{\text{int}}$, the angle of precession is usually very small except when $\omega = \omega_0$, the Larmor frequency. As indicated in (29) and (30), the magnetization could be infinitely large at $\omega = \omega_0$; therefore ω_0 is also known as *ferrimagnetic resonance*. We will revisit ferrimagnetic resonance later because circulators usually operate in its vicinity.

If the driving force is a \hat{z} -directed left-handed circularly polarized wave, the magnetization and the magnetic flux

Figure 6. Force precession with $\theta_M^+ > \theta_H$.

density are also similarly polarized, and the corresponding effective permeability and angles of precession are

$$\mu_0^- = \mu_0 \left(1 + \frac{\omega_m}{\omega_0 + \omega} \right) \quad (52)$$

$$\tan \theta_M^- = \frac{\omega_0}{\omega_0 + \omega} \frac{H_0^-}{H_{\text{int}}^-} \quad (53)$$

Here, $\theta_M^- < \theta_H$ and the magnetic dipole moment rotates in a direction opposite to its free precession as indicated in Fig. 7. In short, the external excitation sets up a preferential pattern of precession and leads to nonreciprocal characteristics in wave propagation.

3.2. Damping

As mentioned previously, circulators are usually magnetized such that they operate in the vicinity of ferrimagnetic resonance. Based on (47), both M_x and M_y could be infinitely large with $\theta_M = 90^\circ$. To stabilize the magnetization vector at resonance, a damping term must be added into the equation of motion in (25). Landau and Lifshitz (as cited by Helszajn [12]) have shown that the damping force pulling the magnetization vector toward the driving force \mathbf{H}_{int} is

$$\mathbf{F}_{\text{damping}} \propto \mathbf{M} \times \frac{d\mathbf{M}}{dt} \quad (54)$$

The damping force acting on the precession is illustrated in Fig. 8. The equation of motion with the damping force

Figure 7. Forced precession with $\theta_M^- < \theta_H$.

Figure 8. Effect of damping force on the precession.

included is

$$\frac{d\mathbf{M}}{dt} = -\mu_0 \gamma \mathbf{M} \times \mathbf{H} - \frac{\alpha \mu_0}{|\mathbf{M}|} \mathbf{M} \times \frac{d\mathbf{M}}{dt} \quad (55)$$

where α is a dimensionless constant.

Using small argument approximations and following procedures presented in deriving (39) and (40), the components in the susceptibility tensor can be derived as

$$\chi_{xx} = \chi_{yy} = \frac{\omega_m(\omega_0 + j\alpha\omega)}{(\omega_0 + j\alpha\omega)^2 - \omega^2} \quad (56)$$

$$\chi_{xy} = -\chi_{yx} = \frac{j\omega\omega_m}{(\omega_0 + j\alpha\omega)^2 - \omega^2} \quad (57)$$

It appears that the susceptibility with damping factors can be obtained by replacing ω_0 in the loss-free formulas with $\omega_0 + j\alpha\omega$. Watch out, the conventional way in deriving damping effects is to replace ω by $\omega + j\alpha\omega$! Usually, the susceptibility tensor is expressed in its real and imaginary parts; that is

$$\chi_{xx} = \chi'_{xx} + j\chi''_{xx} \quad (58)$$

$$\chi_{xy} = \chi'_{xy} + j\chi''_{xy} \quad (59)$$

where

$$\chi'_{xx} = \frac{\omega_0\omega_m(\omega_0^2 - \omega^2) + \alpha^2\omega_0\omega_m\omega^2}{[\omega_0^2 - \omega^2(1 + \alpha^2)]^2 + 4\alpha^2\omega_0^2\omega^2} \quad (60)$$

$$\chi''_{xx} = \frac{\alpha\omega_m\omega[\omega_0^2 + \omega^2(1 + \alpha^2)]^2}{[\omega_0^2 - \omega^2(1 + \alpha^2)]^2 + 4\alpha^2\omega_0^2\omega^2} \quad (61)$$

$$\chi'_{xy} = \frac{-\omega_m\omega[\omega_0^2 - \omega^2(1 + \alpha^2)]^2}{[\omega_0^2 - \omega^2(1 + \alpha^2)]^2 + 4\alpha^2\omega_0^2\omega^2} \quad (62)$$

$$\chi''_{xy} = \frac{2\alpha\omega_0\omega_m\omega^2}{[\omega_0^2 - \omega^2(1 + \alpha^2)]^2 + 4\alpha^2\omega_0^2\omega^2} \quad (63)$$

Note that all components reach a common peak at

$$\omega_{0,\max} = \omega\sqrt{1 + \alpha^2} \approx \omega\left(1 + \frac{\alpha^2}{2}\right) \quad (64)$$

Since ω_0 is given in terms of the impressed driving force H_{int} , the magnetic field needed to attain a ferrimagnetic resonance at a given frequency is

$$H_{\text{fr}} = \frac{\omega_{0,\max}}{\mu_0\gamma} \approx \frac{\omega}{\mu_0\gamma}\left(1 + \frac{\alpha^2}{2}\right) \quad (65)$$

The susceptibility component of particular interest is χ''_{xx} , whose maximum is

$$\chi''_{xx,\max} = \frac{\omega_m}{2\alpha\omega} \quad (66)$$

Variation of χ''_{xx} with the impressed magnetic field is sketched in Fig. 9, which shows the so-called linewidth of ferrites. Linewidth is the parameter provided by ferrite manufacturers to describe magnetic losses at resonance. It is defined as the difference between the magnetic fields where χ''_{xx} is one-half of $\chi''_{xx,\max}$ for a given frequency.

Assuming that χ''_{xx} is changing quadratically near resonance, the linewidth can be derived as

$$\Delta H \approx \frac{2\alpha\omega}{\mu_0\gamma} \quad (67)$$

In general, circulators are operated in the region either above resonance $H_{\text{int}} > H_{\text{fr}}$ or below resonance $H_{\text{int}} < H_{\text{fr}}$ as indicated in Fig. 9.

3.3. Demagnetization

As mentioned previously, the biasing field exterior to a ferrite sample is different from the interior one. This relationship is dependent on the shape of the specimen as well as the orientation of the external excitation. For example, if the impressed field \mathbf{B}_{ext} is normal to the surface of a ferrite slab or infinite extent, the continuity of the

Figure 9. Variation of χ''_{xx} with H_{int} .

normal component of magnetic flux density dictates that

$$B_{\text{ext}} = \mu_0 H_{\text{ext}} = \mu_0 (H_{\text{int}} + M_s) \quad (68)$$

Hence

$$H_{\text{int}} = H_{\text{ext}} - M_s \quad (69)$$

However, if the applied field is parallel to the slab's surface, the continuity of the tangential magnetic field intensity demands that

$$H_{\text{ext}} = H_{\text{int}} \quad (70)$$

In general, the magnetic field intensity in ferrite can be determined in terms of a demagnetization factor ζ :

$$H_{\text{int}} = H_{\text{ext}} - \zeta M_s \quad (71)$$

The argument is valid for all directions; therefore there are three ζ values, one for each coordinate. Moreover, the demagnetization factors are dependent on the shape of the ferrite sample as well as the direction of the external field, relative to the specimen. It can be proved that the sum of three demagnetization factors in Cartesian coordinates is equal to 1:

$$\zeta_x + \zeta_y + \zeta_z = 1 \quad (72)$$

For a circular ferrite disk of negligible thickness, the demagnetization factors can be determined as if it were a slab such as that just mentioned, that is, $\zeta_z = 1$ and $\zeta_x = \zeta_y = 0$. On the other hand, if a ferrite post of infinite length is magnetized axially, the demagnetization factor in the z direction is zero, and the ζ values on the x - y plane can be determined by twofold symmetry; therefore $\zeta_x = \zeta_y = \frac{1}{2}$. Similarly, on the basis of threefold symmetry, the demagnetization factors for a sphere excited in any coordinate are $\zeta_x = \zeta_y = \zeta_z = \frac{1}{3}$.

3.4. Propagation Transverse to Magnetization

In the study of forced precessions, a plane wave propagates in the direction of the static magnetic excitation. Preferential treatment of some waves and ferrimagnetic resonance are established. However, wave propagations in most circulators are transverse to the biasing magnetic field. To illustrate the latter phenomenon, the simplest configuration is used. It is a rectangular ferrite slab of infinite width and depth but of negligible thickness. For consistency with the notations used in waveguides and microstrip lines, the external magnetic field is \hat{x} -directed and the permeability tensor given in (45) is applicable.

The ferrite slab is illuminated by an incident plane wave propagating in the \hat{z} direction:

$$\mathbf{E} = (\hat{x}E_x + \hat{y}E_y)e^{-j\beta_0 z} \quad (73)$$

$$\mathbf{H} = (\hat{x}H_x + \hat{y}H_y)e^{-j\beta_0 z} \quad (74)$$

In a gyrotropic medium, the Maxwell equations are

$$\nabla \times \mathbf{E} = -j\omega\bar{\mu}\mathbf{H} \quad (75)$$

$$\nabla \times \mathbf{H} = j\omega\epsilon\mathbf{E} \quad (76)$$

$$\nabla \cdot \mathbf{D} = 0 \quad (77)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (78)$$

It is found that (75) can be satisfied with a nonzero E_z or a nonzero H_z , but not both. Hence, a more general form for waves in ferrite is selected:

$$\mathbf{E} = (\hat{x}E_x + \hat{y}E_y + \hat{z}E_z)e^{-j\beta z} \quad (79)$$

$$\mathbf{H} = (\hat{x}H_x + \hat{y}H_y + \hat{z}H_z)e^{-j\beta z} \quad (80)$$

According to this postulation, $\partial/\partial z = -j\beta$; by symmetry, $\partial/\partial y = 0$; and by the negligible thin approximation, $\partial/\partial x = 0$. Thus, the constituents of the curl equations in (58) can be reduced to

$$j\beta E_y = -j\omega\mu_0 H_x \quad (81)$$

$$-j\beta E_x = -j\omega(\mu H_y + j\kappa H_z) \quad (82)$$

$$0 = -j\omega(-j\kappa H_y + \mu H_z) \quad (83)$$

Similarly, the curl equation in (76) can be simplified to

$$j\beta H_y = j\omega\epsilon E_x \quad (84)$$

$$-j\beta H_x = j\omega\epsilon E_y \quad (85)$$

$$0 = j\omega\epsilon E_z \quad (86)$$

Based on (86), E_z is zero; therefore H_z must be nonzero. Moreover, from both (84) and (85), the intrinsic impedance of the medium is found:

$$\eta = \frac{E_x}{H_y} = -\frac{E_y}{H_x} = \frac{\beta}{\omega\epsilon} \quad (87)$$

Substituting (87) into (81), the propagation constant is derived:

$$\beta^2 = \omega^2\mu_0\epsilon \quad (88)$$

It is also observed in (83) that H_z can be evaluated in terms of H_y :

$$H_z = \frac{j\kappa}{\mu} H_y \quad (89)$$

This formula can be used to eliminate H_z from (82):

$$\begin{aligned} \beta E_x &= \omega \left(\mu + j\kappa \frac{j\kappa}{\mu} \right) H_y \\ &= \frac{\omega}{\mu} (\mu^2 - \kappa^2) H_y \end{aligned} \quad (90)$$

Combining (87) and (90), another solution for the propagation constant is obtained

$$\beta_e^2 = \frac{\omega^2\epsilon}{\mu} (\mu^2 - \kappa^2) = \omega^2\mu_e\epsilon \quad (91)$$

where β is denoted by β_e to distinguish it from the other solution given in, and μ_e is an effective permeability of the medium, given by

$$\mu_e = \frac{\mu^2 - \kappa^2}{\mu} \quad (92)$$

If the electric field of the incident wave is \hat{y} -directed, the continuity of the tangential electric field intensity at the air-ferrite interface implies that $E_x = 0$; so that H_y is also zero, and by (89) H_z also vanishes. Hence, the only solution for β is (88) and the wave is called ‘‘ordinary,’’ which means that wave propagation in ferrite is not affected by the magnetization. However, if the electric vector is \hat{x} -directed, the only viable β is that given in (91). With a nonzero H_y , H_z is also nonzero, and the resultant wave is called ‘‘extraordinary.’’ Thus, wave propagation in ferrite is polarization-dependent. On the other hand, if the incident field has both \hat{x} and \hat{y} components, it is treated as a combination of two linearly independent entities, and each propagates independently with a different phase velocity. As a result, two images are created, the so-called birefringence effect. It is also noticed that κ is frequency-dependent; therefore the effective permeability for a given H_{int} and M_s could become negative if the frequency is high enough, and an incident wave will be totally reflected from ferrite. This scenario can be viewed from a different angle in which the frequency is fixed and evanescent effects can be obtained by changing the external magnetic field intensity.

3.5. Wave Circulation around a Ferrite Cylinder of Infinite Length

The configuration of interest in this subsection is a ferrite cylinder of radius a and of infinite length. It is placed on the \hat{z} axis and magnetized axially; therefore the permeability tensor given in (42) is appropriate. Wave propagation in ferrite can be determined by treating the cylinder as a dielectric resonator. It is assumed that the cylindrical surface would behave as if it were a magnetic wall; that is, $E_\phi = 0$ at $\rho = a$. So are the surfaces on top of and at the bottom of the cylinder; therefore $E_\rho = 0$ for $z = \pm \infty$. Since the cylinder is infinitely long, $\partial/\partial z = 0$; consequently $E_z = 0$ everywhere. Using standard coordinate transformations, the nonzero components of the magnetic flux density can

be determined by (41):

$$\begin{aligned} B_\rho &= B_x \cos \varphi + B_y \sin \varphi \\ &= (\mu H_x + j\kappa H_y) \cos \varphi \\ &\quad + (-j\kappa H_x + \mu H_y) \sin \varphi \\ &= \mu H_\rho + j\kappa H_\varphi \end{aligned} \tag{93}$$

$$\begin{aligned} B_\varphi &= -B_x \sin \varphi + B_y \cos \varphi \\ &= -(\mu H_x + j\kappa H_y) \sin \varphi \\ &\quad + (-j\kappa H_x + \mu H_y) \cos \varphi \\ &= -j\kappa H_\rho + \mu H_\varphi \end{aligned} \tag{94}$$

The components of the curl equation in (75) in cylindrical coordinates can be expressed as

$$\frac{1}{\rho} \frac{\partial E_z}{\partial \varphi} = -j\omega(\mu H_\rho + j\kappa H_\varphi) \tag{95}$$

$$= -j\omega\mu H_\rho + \omega\kappa H_\varphi$$

$$-\frac{\partial E_z}{\partial \rho} = -j\omega(-j\kappa H_\rho + \mu H_\varphi) \tag{96}$$

$$= -\omega\kappa H_\rho - j\omega\mu H_\varphi$$

Hence, the magnetic field components can be written in terms of E_z :

$$H_\rho = \frac{1}{\omega\mu_e} \left(-\frac{\kappa}{\mu} \frac{\partial E_z}{\partial \rho} + \frac{j}{\rho} \frac{\partial E_z}{\partial \varphi} \right) \tag{97}$$

$$H_\varphi = \frac{j}{\omega\mu_e} \left(-\frac{\partial E_z}{\partial \rho} + \frac{j}{\rho} \frac{\kappa}{\mu} \frac{\partial E_z}{\partial \varphi} \right) \tag{98}$$

Similarly, the curl equation in (59) can be reduced to a scalar one:

$$\frac{1}{\rho} \left(\frac{\partial(\rho H_\varphi)}{\partial \rho} - \frac{\partial H_\rho}{\partial \varphi} \right) = j\omega\epsilon E_z \tag{99}$$

Substituting (97) and (98) into (99), a wave equation of E_z is obtained:

$$\frac{\partial^2 E_z}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial E_z}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2 E_z}{\partial \varphi^2} + \beta_e^2 E_z = 0 \tag{100}$$

This wave equation is the characteristic equation for finding the admissible a . It is identical to that of a cylindrical dielectric waveguide whose solutions are

$$E_{z,n} = (A_n^+ e^{jn\varphi} + A_n^- e^{-jn\varphi}) J_n(\beta_e \rho), \quad n = 1, 2, \dots \tag{101}$$

where J_n is a Bessel function of the first kind of the n th order. The magnetic field of interest is H_φ , which can be

found by substituting (101) into (98):

$$\begin{aligned} H_\varphi &= \frac{-j}{\eta_e} \left\{ A_n^+ e^{jn\varphi} \left[J'_n(\beta_e \rho) + \frac{n}{\beta_e \rho} \frac{\kappa}{\mu} J_n(\beta_e \rho) \right] \right. \\ &\quad \left. + A_n^- e^{-jn\varphi} \left[J'_n(\beta_e \rho) - \frac{n}{\beta_e \rho} \frac{\kappa}{\mu} J_n(\beta_e \rho) \right] \right\} \end{aligned} \tag{102}$$

The resonance can be obtained by enforcing that $H_\varphi = 0$ at $\rho = a$:

$$J'_n(\beta_e a) \pm \frac{n}{\beta_e a} \frac{\kappa}{\mu} J_n(\beta_e a) = 0; \quad n = 1, 2, \dots \tag{103}$$

Note that there are two possible roots for each n , associated with waves circulating in the clockwise direction $e^{jn\varphi}$ and the other in the counterclockwise direction, $e^{-jn\varphi}$. In most cases, the $n = 1$ mode is the dominant one, and the corresponding solution of (103) is 1.84. Hence, β_e is derived as

$$\beta_e a = 1.84 \tag{104}$$

The waves circulating in opposite directions could be made in phase at one of the output ports and out of phase at the remaining port. Assume that port 1 at $\varphi = 0$ is the input, the electric field at $\rho = a$ can be obtained by (101) for $n = 1$:

$$E_{z,1} = E_0 = (A_1^+ + A_1^-) J_1(\beta_e a) \tag{105}$$

At the isolated port at $\varphi = -120^\circ$, the electric field intensity is

$$E_{z,1} = (A_1^+ e^{-j120^\circ} + A_1^- e^{j120^\circ}) J_1(\beta_e a) \tag{106}$$

If the output at the isolated port is made zero, the unknown constants can be determined by solving the simultaneous equations in (105) and (106):

$$A_1^+ = \frac{1+j/\sqrt{3}}{2J_1(\beta_n a)} E_0 \tag{107}$$

$$A_1^- = \frac{1-j/\sqrt{3}}{2J_1(\beta_n a)} E_0 \tag{108}$$

It is interesting to find that the electric field at the output port at $\varphi = 120^\circ$ is

$$E_{z,1} = (A_1^+ e^{j120^\circ} + A_1^- e^{-j120^\circ}) J_1(\beta_e a) = -E_0 \tag{109}$$

By substituting (107) and (108) into (102), the tangential magnetic field at every port of the circulator can be determined in terms of E_0 . After a lengthy yet straightforward algebraic manipulation, the results are

$$H_\varphi(\rho = a) = \begin{cases} E_0/\eta_e, & \varphi = 0^\circ \\ E_0/\eta_e, & \varphi = 120^\circ \\ 0, & \varphi = 240^\circ \end{cases} \tag{110}$$

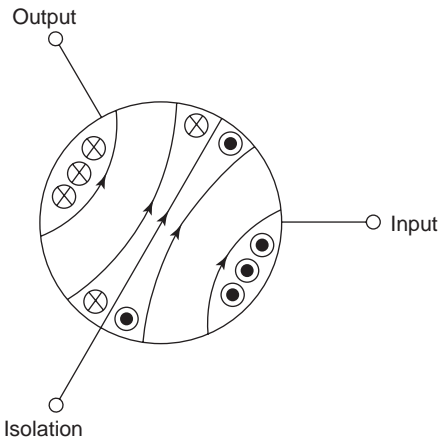

Figure 10. Standing-wave pattern in a magnetized ferrite cylinder.

where η_e is the effective impedance of ferrite, given by

$$\eta_e = \sqrt{\frac{\mu_e}{\epsilon}} \tag{111}$$

Sketched in Fig. 10 is the standing-wave pattern in a magnetized ferrite cylinder. It is clearly shown that energy inputted to port 1 is outputted to port 2 with none to port 3.

For comparison, the field pattern in a cylindrical dielectric resonator is shown in Fig. 11, where the signals at ports 2 and 3 are equal in both amplitude and phase.

3.6. Typical Ferrites Used in Circulators

In circulator designs, the selection of an appropriate ferrite element is of paramount importance. On one hand, it must satisfy the electromechanical requirements on size, weight, power handling, and temperature range. On the other hand, it must meet the stipulated performance electronically, including center frequency, bandwidth, insertion loss, and linearity.

Figure 11. Standing-wave pattern in a demagnetized ferrite cylinder.

Table 2. Major Characteristics of Spinel

Composition	$4\pi M_s$ (G)	T_c ($^{\circ}$ C)	ΔH (Oe)
MgAl	650	100	115
	1700	225	120
	2420	310	180

	1300	140	135
	1750	225	225
MgMnZn	2500	275	520
	3000	240	190
	NiAl	1000	400
NiZn	2500	570	490
	4000	500	270
LiTi	5000	375	160
	1000	330	300
	2000	490	400
	2900	600	550

Besides the physical dimensions and shape of a ferrite specimen, the characteristics of the material could make a major difference in the performance of a circulator. The most important ferrite parameters are saturation magnetization ($4\pi M_s$), Curie temperature (T_c), and linewidth (ΔH). For reference, the characteristics of some spinels and garnets are listed in Tables 2 and 3.

For example, the magnetic field needed to establish ferrimagnetic resonance at $f = 4$ GHz is

$$H_{fr} \approx \frac{\omega}{\mu_0 \gamma} = 1.137 \times 10^5 \text{ A/m} = 1429 \text{ Oe}$$

For a specimen of zinc–nickel spinel with $4\pi M_s = 5000$ G, the Cuire temperature is 375° C, and the damping factor is

$$\alpha \approx \frac{\mu_0 \gamma}{2c\omega} \Delta H = \frac{1}{2H_{RF}} \Delta H = 0.17 \text{ Np/m}$$

Table 3. Major Characteristics of Garnets

Composition	$4\pi M_s$ (G)	T_c ($^{\circ}$ C)	ΔH (Oe)
Y	1800	280	45
Yal	250	100	40
	550	160	40
	1000	210	40
	1600	265	40
	210	110	65

	700	240	90
	800	240	110
CaVIn	600	200	25
	1200	220	10
	1850	240	15

If the circulator is designed to operate in the abovementioned resonance region, the external magnetic field required must be greater than

$$H_{\text{ext}} = H_{\text{int}} + M_s > H_{\text{RF}} + M_s = 1827 \text{ Oe}$$

4. APPLICATIONS

4.1. Isolator

The principal application of circulators is load isolation, a low transmission loss in one direction, and a relatively high attenuation in the reverse path. At microwave frequencies, generators are vulnerable to frequency shifting due to load variations; therefore isolation is needed to protect them from waves reflected from the less than perfectly matched loads. Reasonable isolation can be implemented by inserting a circulator between the source and its load as depicted in Fig. 12.

For better protection, the isolation can be obtained by a series of circulators. However, if amplifiers are used, additional isolations as shown in Fig. 13 are recommended because amplifiers are seldom unconditionally stable for all loads.

Shown in Fig. 14 is a circulator inserted between a receiving antenna and a low-noise amplifier. In satellite receiving antennas, isolation is needed to prevent waves leaking from the low-noise amplifier from interfering with the weak signals picked up by the antenna.

Good isolation between the source and the load can be obtained by using a one-port negative-resistance amplifier as illustrated in Fig. 15. It is noted that many IMPATT (impact ionization avalanche transit time) and BARITT (barrier-injected transit time) diodes exhibit a negative input impedance of Z_d . The output signal is that reflected from the diode as a result of impedance mismatch, and the gain of the amplifier is equal to

$$\rho^2 = \left(\frac{Z_d - Z_0}{Z_d + Z_0} \right)^2 = \left(\frac{Z_0 + |Z_d|}{Z_0 - |Z_d|} \right)^2 \tag{112}$$

where Z_0 is the characteristic impedance of the transmission line.

In fact, greater isolation can be obtained by inserting an additional circulator in the isolator in Fig. 15 as shown in Fig. 16.

4.2. Duplexer

A duplexer is a device that allows an antenna to serve as a transmitter as well as a receiver. Many duplexers made of hybrids junctions, solid-state switches, and others are available on the market, but simple ferrite duplexers are preferred because they allow a single antenna to carry out both functions simultaneously. The outgoing waves are coupled to the transmitting antenna through a circulator, and signals picked up by the antenna are fed to the receiving amplifier via a circulator such as that shown in Fig. 17.

Figure 12. Isolation between the source and its load.

Figure 13. Isolation between the source, the amplifiers, and the load.

Figure 14. Isolation between a receiving antenna and a low noise amplifier.

Figure 15. A negative-resistance isolator.

Figure 16. An enhanced negative-resistance isolator.

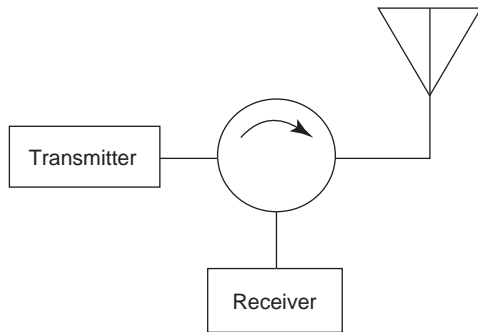

Figure 17. A ferrite duplexer.

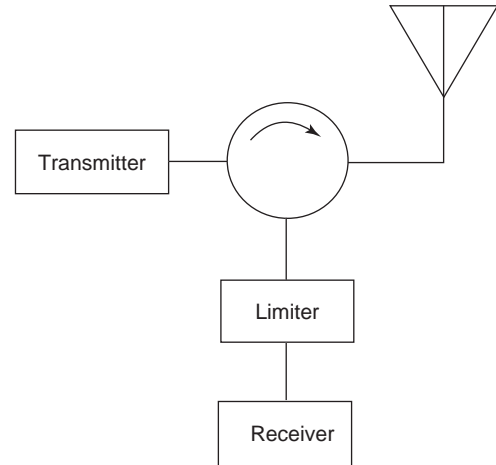

Figure 18. A ferrite duplexer with a limiter.

For a poorly matched antenna, part of the outgoing signal is reflected by the antenna and is directed by the circulator to the amplifier with the incoming signal. In order to enhance the transmitter-receiver isolation and to prevent damage to the amplifier, a limiter is usually added at the output port of the circulator as shown in Fig. 18.

4.3. Reciprocal Ferrite Switch

As wave circulation in a circulator is dependent on the polarity of its excitation, the direction of circulation can be reversed by reversing the biasing magnetic field. It is also noted that ferrite retains its magnetization even after the external driving force is removed and waves can circulate in the same course until the permanent magnetization effect wears off. If the magnetic field is generated electromagnetically by a current coil, magnetization can be reversed by a large current pulse in an appropriate direction. On the basis of this idea, a reciprocal ferrite switch has been designed and is sketched in Fig. 19.

Figure 19. A reciprocal ferrite switch.

4.4. Multiplexing

A multiplexer is a device that carries many channels of signals in a given bandwidth. The simplest one is the diplexer in Fig. 20. Signals output from the lowpass filter are directed by the circulator to the highpass filter, where they are rejected. The reflected waves are then forwarded to the common channel with the output of the highpass filter via the same circulator.

In general, multiplexers can be built by simply interconnecting the filters together, but utmost care must be taken to reduce interactions among various filters. Multiplexers with circulators, on the other hand, can accommodate almost any filter because the circulator serves as an isolator as well as an integrator. Naturally, this concept can be extended to design a three-channel multiplexer as sketched in Fig. 21. As circulators have insertion losses, this configuration is not recommended for building a multiplexer of many channels.

5. TYPES OF CIRCULATORS

Of all the available circulators, the junction circulator is by far the dominant one. Over the years, many types of junction circulators of different power ratings have been developed for use at a wide range of frequencies, from VHF

Figure 20. A diplexer.

Figure 21. A three-channel multiplexer.

Figure 22. A Y-junction waveguide circulator.

to millimeter waves. Depending on the transmission medium, circulators can be sorted into categories of waveguides, microstrip lines, striplines, and coaxial lines. Common to all junction circulators, the magnetization is transverse to the direction of wave propagation.

For comparison, waves propagate in the direction of magnetization in differential phase shift circulators and Faraday rotation circulators. Hence, the principle of operation is drastically different from that of junction circulators. These four-port circulators are skipped in this article simply because they are seldom used in modern systems.

5.1. Waveguide Y-Junction Circulators

At microwave and millimeter-wave frequencies, the only feasible circulator is a waveguide junction circulator, constituting a Y junction of three *H*-plane rectangular waveguides as shown in Fig. 22 [13,14]. A ferrite cylinder spanning the height of the waveguide is mounted normal to the floor of the waveguide junction. It is placed at the center of the Y junction for symmetry. Moreover, a metal plate with three symmetric spikes pointing toward the ports of entry is added between the ferrite specimen and the waveguide floor for better impedance matching as shown in Fig. 23. Also shown in the same figure is the glue that serves as an insulating layer separating the ferrite post and the impedance-matching plate. The ferrite post is magnetized axially by a permanent magnet or an electromagnet outside the waveguide.

Figure 23. Side view of a ferrite post in a waveguide Y junction.

Figure 24. Side view of a partial ferrite post in a waveguide Y junction.

Even though the connecting waveguides are operating in TE_{10} modes, higher-order modes, including the evanescent ones, exist in the junction. Note that the ferrite cylinder itself is a dielectric resonator whose resonant frequency is dependent on its length ℓ and its radius a_f . To bring about wave circulations in the waveguide junction, a_f is obtained by solving the characteristic equation given in (103). However, the result obtained from (104) is adequate for most cases:

$$a_f = \frac{1.84}{\beta_e} = \frac{1.84\lambda}{2\pi\sqrt{\mu_e\epsilon}} \tag{113}$$

The leverage in adjusting ℓ does provide us a mechanism to generate higher-order modes [33] such as HE_{11} for improving the performance of the circulator, including impedance matching, bandwidth, quality factor, and insertion loss [15]. To this end, a partial-height ferrite cylinder on an elevated floor as shown in Fig. 24 is developed. For stronger mechanical support, the space above and below the shortened post is filled by two dielectric cylinders of similar shape. Moreover, it is observed that the electric field tangential to the central plane of the waveguide is either maximum or zero due to symmetry. If the post is cut into two halves, a zero tangential field is obtained. Hence, an additional option is gained by cutting the ferrite post into two with one remaining on the floor and the other attached to the ceiling as shown in Fig. 25.

Ferrite posts of circular and triangular cross sections are the popular choices, but hexagonal and other shapes can also be used. Since disks can be made by slicing a cylinder and their principles of operation are identical, it is

Figure 25. Side view of a divided partial ferrite post in a waveguide Y junction.

considered as a cylinder. It has been shown that circulator with a triangular ferrite cylinder might have a marginally lower insertion loss [16], but its overall performance is comparable to that of a circular one. However, in cases where the tolerance on physical dimensions is very slim, the circular post prevails because grinding and polishing the superhard and brittle ferrite cylinder to a cross section of a perfect circle is much easier than making one with a faultless equilateral triangle. The situation is especially critical for millimeter-wave circulators because the diameter of the relevant ferrite posts is less than a millimeter. Along this line of thought, a new design is proposed in which the cylinder is replaced by a sphere as shown in Fig. 26. Spheres are chosen because they can be mass-produced with the highest precision as if they were ball bearings produced by the time-honored technologies [17]. In fact, the major gain in this maneuver is ease in implementation. As the base of a ferrite cylinder is very small, mounting it normally on a flat surface is easier said than done; therefore erecting one properly on the floor of an equally minuscule Y-junction circulator is very tricky. This agony is totally resolved in the present design because a sphere is always normal to the floor. The performance of this circulator is at least on par with the traditional one. Rigorous analysis and experimental studies of waveguide circulators with ferrite spheres will be examined in later sections.

5.2. Stripline Y-Junction Circulators

At ultrahigh frequencies, stripline circulators are more popular because waveguides are seldom used in this frequency range [18]. The junction where three striplines meet is a conducting disk of radius a_c . Anisotropic effects are provided by two ferrite disks of radius a_f above and below the center conductor. For better performance, $a_f \geq a_c$, and both of them are much larger than the width of the stripline w . Preferably, the ferrite disks are thin enough such that the sandwich can be squeezed between the upper and lower conducting plates of the original striplines as shown in Fig. 27. The junction circulator is magnetized externally such that the magnetic vector is normal to the surface of the ferrite disks. The ferrite disks and the center conductor may be in any shape as long as the threefold symmetry is retained.

The striplines carry TEM modes only; therefore wave propagations are transverse to the magnetization vector. As $w \ll a_c$, the tangential magnetic field is constant over the widths of the striplines and is zero on the circumfer-

Figure 26. Side view of a ferrite sphere in a waveguide Y junction.

Figure 27. A stripline junction circulator.

ence of the center conductor. Since $a_f \approx a_c$, the magnetic field strength on the peripheral of the ferrite disk is obtained by enforcing the continuity of tangential magnetic fields, a constant at the input ports and zero elsewhere. The normal electric field in ferrite E_z satisfies the Helmholtz equation given in (100), and the magnetic fields are expressed in terms of E_z as given in (97) and (98).

The required wave equation is derived by expressing E_z as

$$E_z(\varphi) = \int_{-\pi}^{\pi} G(\varphi; \varphi') H_\varphi(\varphi') d\varphi' \quad (114)$$

where $G(\varphi; \varphi')$ is the Green function [18], given by

$$G(\varphi; \varphi') = -j \frac{\eta_e}{2\pi} \frac{J_0(\beta_e a_f)}{J_0(\beta_e a_f)} + \frac{\eta_e}{\pi} \sum_{n=1}^{\infty} \frac{\frac{\kappa n J_n(\beta_e a_f)}{\mu \beta_e a_f} \sin n(\varphi - \varphi') - j J_n'(\beta_e a_f) \cos n(\varphi - \varphi')}{[J_n'(\beta_e a_f)]^2 - \left[\frac{\kappa n J_n(\beta_e a_f)}{\mu \beta_e a_f} \right]^2} J_n(\beta_e a_f) \quad (115)$$

Except for simple configurations, the wave equation in a Y-junction stripline circulator stated in (103), (114), and (115) cannot be solved analytically in a closed form. However, the electric and magnetic fields can be accurately and efficiently determined by numerical means. In terms of the field quantities, other characteristics of the junction circulator such as input impedance, reflection coefficient, transfer function, isolation, bandwidth, quality factor, and insertion loss can be derived.

However, for most applications, the radius of the ferrite disks required for resonance can be obtained by (113) and the field pattern in ferrite is similar to that sketched in Fig. 10. Moreover, stripline junction circulators are usually biased far above resonance in the UHF region: $H_{\text{int}} \gg H_{\text{fr}}$. It then follows that μ and κ can be approximated by

$$\mu_e \approx \mu = 1 + \frac{4\pi M_s}{H_{\text{int}}} \quad (116)$$

$$\kappa = \frac{4\pi M_s H_{\text{fr}}}{H_{\text{int}}^2} \quad (117)$$

Figure 28. A junction circulator with microstrip lines on a substrate of ferrite disk.

It is also recommended that the minimum radius required be

$$a_f > \frac{4w}{3} \tag{118}$$

5.3. Microstrip-Line Y-Junction Circulators

One reason why circulators are seldom used today is the lack of effective circulators for microstrip lines, the most popular media of wave transmission at UHF and microwave bands. Traditionally, a microstrip-line junction circulator is made by laying three metallic strips on a ferrite disk as shown in Fig. 28. For better impedance matching, the center conductor may assume any three-way symmetric shape such as the equilateral triangle shown in Fig. 28. Unlike its stripline counterpart, a microstrip-line junction circulator has only one ferrite disk on a large ground plane. For the microstrip line on a substrate of ferrite, its characteristic impedance is quite different from that on a dielectric substrate. Hence, an additional impedance matching is needed at every port of entry.

In order to improve impedance matching and to reduce cost, a simpler version is developed. Instead of putting the microstrip lines and the center conductor on a ferrite disk, they are printed on a dielectric substrate as illustrated in Fig. 29. Wave circulation is made possible by covering the junction with a ferrite disk of radius a_f . Similar to a waveguide Y-junction circulator, the disk can be replaced by a hemispherical one. The major advantage gained in this maneuver is flexibility because the frequency of a given circulator can easily be altered by replacing its ferrite by a different material or by changing its physical shape or dimension. Unfortunately, the performances of the aforementioned circulators are not very satisfactory and further improvements are needed.

Figure 29. A microstrip-line junction circulator with a ferrite disk on top.

Figure 30. A microstrip-line junction circulator with a ferrite sphere.

One improvement proposed is a microstrip-line circulator with a ferrite sphere as shown in Fig. 30 [19]. Even though a better performance is observed, it remains inferior to those waveguide and stripline circulators. With the increasing popularity of microstrip lines and other coplanar waveguides, development in this direction is desperately needed.

5.4. Lumped-Element Circulators

Common to all junction circulators, as mentioned previously, the size of the ferrite specimen is proportional to wavelength. This means that the circulator could become prohibitively large in HF and VHF regions. To this end, a simple circulator is designed by winding three coils around a ferrite disk as shown in Fig. 31 [20]. The coils in these lumped-element circulars are oriented 120° from one another, so are the magnetic fields created by these coils. Two ferrite disks of 10–15 mm in diameter and 1–2 mm thick are packed inside a grounded metal box. The so-called coil in each port in fact consists of two one-turn coils in parallel; one returns through the bottom of the shielding box and the other via its top, as illustrated in Fig. 32. In order to distribute the magnetic field more evenly in ferrite, the current is divided into multiple filaments as shown in Fig. 33. The magnetic field is parallel to the surface of the ferrite disk. The magnetization vector is normal to the magnetic fields due to the coils and the ferrite disk is usually biased above resonance.

Figure 31. A lumped constant circulator.

Figure 32. Side view of a lumped constant circulator.

Applying the concept of a balanced three-phase power circuit, the neutral or return line can be obliterated, provided the three branches are 120° out of phase from one another. The combined length of each coil is much shorter than a wavelength, so it is essentially an inductor. To restore resonance at the junction, each branch is shunted to ground via a capacitor, and the resultant star circuit is depicted in Fig. 34a. Alternatively, a series capacitor C_s can be added in series with the coil as shown in Fig. 34b. It can be shown that the waves rotating in opposite directions in ferrite can be characterized by two inductances, namely

$$L_+ = L_0(\mu + \kappa) \tag{119}$$

$$L_- = L_0(\mu - \kappa) \tag{120}$$

where L_0 is the inductance of each phase with the ferrite disk removed. For an ideal circulation, these inductances are given by

$$L_+ + L_- = \frac{2}{\omega^2 C_s} \tag{121}$$

$$L_+ - L_- = 1.156 \frac{Z_0}{\omega} \tag{122}$$

The gyrotropic parameters can be determined on the basis of (119)–(122):

$$\mu = \frac{1}{\omega^2 L_0 C_s} \tag{123}$$

$$\kappa = \frac{Z_0}{1.73 \omega L_0} \tag{124}$$

Figure 34. Equivalent circuit of the lumped constant circulator: (a) shunt; (b) series.

Figure 33. Magnetic field lines in ferrite and around the current coil.

6. IN-DEPTH ANALYSIS OF SOME SELECTED CIRCULATORS

The formulas presented in Section 4 are derived for circulators with clear-cut geometries, and they are based on many approximations, including the over simplified ones. It is obvious that these simple formulas are not accurate enough for computer-aided designs of miniature circulators at microwave and millimeter-wave frequencies. In-depth analyses of circulators, on the other hand, do exist, but the number is limited because the topic itself is commonly considered as old-fashioned, compared with mobile communications, networking, nanotechnology, and other trendy ones. Even if one exists, it is customarily developed for waveguide circulators. Nonetheless, it is worthwhile to present some of the techniques in detail in this section because they can be modified to treat other types of circulators. Most important of all, the rationale behind the development of these techniques and the insights gained during the process are invaluable in the design of innovative circulators in the future.

All in all, four techniques for analyzing typical circulators will be covered. Note that the emphasis is not placed on the techniques themselves, but on how the technique is applied to solve the problem and the characteristics of the circulators. Through the examples, readers may pick up the skill for identifying an appropriate method for analyzing their circulators.

6.1. Finite-Difference Method

The configuration of interest is an H -plane waveguide Y-junction circulator with a full-length ferrite post as sketched in Fig. 22. Consistent with the assumption that the only mode propagating in the waveguide in the dominant TE_{10} mode, all field quantities in the circulator are independent of z , a direction normal to its floor. Hence, the problem is reduced to a two-dimensional one. It can be shown that the transverse components of the electromagnetic wave in ferrite can be determined in terms of E_z and H_z . In the cylindrical coordinate system, the characteristic equations in ferrite are

$$\frac{\partial^2 E_z}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial E_z}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2 E_z}{\partial \phi^2} + \beta_e^2 E_z = 0 \tag{125}$$

$$\frac{\partial^2 H_z}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial H_z}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2 H_z}{\partial \phi^2} + \beta^2 H_z = 0 \tag{126}$$

where β and β_e are as given in (88) and (91), respectively. Equations similar to (125) and (126) can be used to determine both E_z and H_z exterior to the ferrite post in the junction, provided β_e in (125) is replaced by β .

The major difficulty in solving the characteristic equations is to resolve the conflict due to the rectangular waveguides and the cylindrical junction. The simplest yet sufficiently in-depth method for solving this boundary problem is the finite-difference method proposed by Yung and his researchers [21]. In order to keep the boundary of a waveguide Y junction cylindrical in shape, a truncation boundary as illustrated in Fig. 35 is introduced. With evanescent modes ignored, the field values at the truncation boundary can be expressed in terms of the TE_{10} modes at the input and output ports; therefore all boundary values are defined. It is readily recognized that discretization of (125) requires the field values at five nodes. A unique solution is obtained by enforcing that the tangential electric and magnetic fields are continuous on the surface of the ferrite post.

The finite-difference method is applied to analyze a waveguide Y circulator with a G1002 ferrite post ($\epsilon_r = 15.4$, $4\pi M_s = 1000$ G, $\Delta H = 20$ Oe, and $a_f = 3$ mm). The width of the waveguide is 22.86 mm and the internal

Figure 35. The truncation boundary and the nodal pattern in the waveguide junction.

magnetic field is $H = 200$ Oe. The reflection coefficient, the insertion loss, and the isolation are plotted in Figs. 36 and 37, and 38, respectively. Also shown in these figures are the experimental data published in Ref. 22. Excellent agreement between the analytical results and measurements is seen. It is also observed from the plots that the finite loss of ferrite has negligible effects on the general performance of a circulator except when the frequency is close to ferrimagnetic resonance.

6.2. Finite-Difference Time-Domain Method

Other than full-height ferrite posts, the field quantities in the waveguide junction are usually dependent on z , even though the dominance of TE_{10} remains valid in the input and output waveguides. For a three-dimensional case, the finite difference method just mentioned is no longer adequate, but the finite-difference time-domain (FDTD) method is. Yee's discretization scheme [23] is chosen because it does not require the time-consuming matrix inversion and convergence is assured. In terms of Yee's mesh, the FDTD

 \end{aligned}$$

where Δx , Δy and Δz are the widths of the Yee cell, and $\mu_{11} = \mu_{22} = \mu_{xx}$ and $\mu_{12} = \mu_{21} = \mu_{xy}$ are as given in (56) and (57), respectively.

As the FDTD approximations above are expressed in Cartesian coordinates, the algebra involved in solving a waveguide Y-junction circulator will be very tedious and the resultant time of computation prohibitively long. To better depict the nature of the FDTD scheme, it is applied to solve a waveguide T-junction waveguide as shown in Fig. 39. Although a partial-height ferrite post is shown, the FDTD scheme is, in fact, applicable for any body of arbitrary shape, including a sphere. Moreover, it is noted that some values in (127)–(132) are not available directly from Yee’s scheme, but fortunately, they can be generated by a linear interpolation of the neighboring fields. Details are not given here; interested readers are referred to the paper by Schneider and Hudson [24].

The waveguide T-junction circulator under investigation consists of three X-band waveguides of dimensions 22.86×10.16 mm, and the radius of its full-height ferrite post is $a_f = 3.5$ mm. Variations of the reflection coefficient at the input, the insertion loss at the output, and the isolation at the isolated port are respectively plotted in Figs. 40 and 41, and 42 as a function of frequency. It is readily seen that excellent agreement with the results published in Ref. 25 is observed.

Figure 40. Variation of the reflection coefficient at the input port with frequency.

Figure 41. Variation of insertion loss at the output port with frequency.

To better depict the characteristics of wave circulation, the power density in the ferrite post is plotted in Fig. 43 as a function of φ at $f = 10.3$ GHz for three different ρ values. The input and output power densities in a closed path at a given ρ are always conserved as ferrite is assumed to be lossless and no power is dissipated in the waveguide junction area. It is also observed that the power entering the input port at $\varphi = 90^\circ$ is transmitted to the output port at $\varphi = 270^\circ$.

For comparison, the variations of power densities outside the ferrite post are plotted in Fig. 44, where R_0 is the radius of the largest circle inside the T junction. The nature of power transfer to the output port is clearly demonstrated.

Although we have absolute faith in the accuracy of our results computed in the numerical analysis, it is always nice to know that they compare well with those obtained in experimental studies. In fact, readings in measurement are vulnerable to numerous errors and constraints, including purity of the materials, uniformity of the mixture, tolerance of the physical cuttings, stability of the frequency generation, imperfect matching of the interconnects, loss due to spurious radiations, and precision of the measuring instrument. There is no reason to believe that

Figure 42. Variation of the isolation at the other output port with frequency.

Figure 43. Variation of the power density inside the ferrite post with φ .

measurements are more reliable than computational data. However, most engineers and researchers will feel more comfortable whenever they see a reasonably good agreement between the analytical and the experimental results. In this connection, the FDTD study is repeated for a waveguide circulator with a NiZn ferrite sphere ($a_f = 1.0$ mm, $\epsilon_r = 2.25$, $4\pi M_s = 5000$ G, $H_{ext} = 1700$ Oe, and $\Delta H = 120$ Oe). The numerically obtained reflection coefficients, insertion losses, and isolations are plotted against the experimental data in Fig. 45. Given the complexity of the configuration and the gyrotropic nature of the problem, the agreements between the analytical results and the measurement are more than acceptable.

6.3. Finite-Element Method

The finite-element method (FEM) is known for its capability to model complex structures. Since it requires only information about the geometry of the device to be analyzed, the method can be developed into a general-purpose software package, for example, Ansoft HFSS. With the use of edge-based vector elements, the FEM can handle discontinuity interfaces between different materials without invoking spurious solutions. When combined with the

Figure 44. Variation of the power density outside the ferrite post with φ .

Figure 45. Comparison of reflection coefficients, insertion losses, and isolations for a waveguide T-junction circulator with a ferrite sphere with measurements.

asymptotic waveform evaluation (AWE) and complex frequency-hopping (CFH) techniques, the FEM can generate frequency responses over a wide band very efficiently. Although the low-order FEM suffers from the problem of numerical dispersion, which tends to accumulate as the wave propagates, this problem has been largely overcome with the development of higher-order finite elements [28]. The major remaining difficulty is the relatively long computing time and the associated memory requirements for the resulting finite-element system. More recently, the preconditioned iterative solutions [29] and numerical de-embedding techniques [30] have been developed to accelerate solutions and reduce memory.

Consider a microwave ferrite device with multiple ports, inside the ferrite device, where the field satisfies the vector partial differential equation

$$\nabla \times \{[\mu_r]^{-1} \cdot (\nabla \times \mathbf{E})\} - k_0^2 \epsilon_r \cdot \mathbf{E} = 0 \quad (133)$$

The boundary condition on the surface of port i can be derived as

$$\hat{\mathbf{n}}_i \times \nabla \times \mathbf{E} + P_i(\mathbf{E}) = U_i^{\text{inc}} \quad (134)$$

where $\hat{\mathbf{n}}_i$ denotes the outward unit vector normal to the surface S_i , the cross section of port i , and

$$P_i(\mathbf{E}) = \sum_m \frac{k_0^2}{jk_m} e_{e,m}^{\text{TM}} \iint_{S_i} e_{e,m}^{\text{TM}} \cdot \mathbf{E} ds - \sum_n jk_n e_n^{\text{TE}} \iint_{S_i} e_{e,n}^{\text{TE}} \cdot \mathbf{E} ds \quad (135)$$

$$U_i^{\text{inc}} = \hat{\mathbf{n}}_i \times \nabla \times \mathbf{E}_i^{\text{inc}} + \sum_m \frac{k_0^2}{jk_m} e_{e,m}^{\text{TM}} \iint_{S_i} e_{e,m}^{\text{TM}} \cdot \mathbf{E}_i^{\text{inc}} ds - \sum_n jk_n e_n^{\text{TE}} \iint_{S_i} e_{e,n}^{\text{TE}} \cdot \mathbf{E}_i^{\text{inc}} ds \quad (136)$$

In the above, $e_{t,m}^{\text{TM}}$ denotes the transverse part of the electric field of the m th transverse magnetic (TM) mode, and $e_{t,n}^{\text{TE}}$ denotes the transverse part of the electric field of the n th transverse magnetic (TE) mode. E_i^{inc} denotes the incident fields at port i . In accordance with the general variational theory, the functional for the boundary value problem defined above given by

$$F(\mathbf{E}, \mathbf{E}_a) = \frac{1}{2} \iiint_V \{(\nabla \times \mathbf{E}_a) \cdot (\nabla \times \mathbf{E}) - \epsilon_r k_0^2 \mathbf{E}_a \cdot \mathbf{E}\} dV - \frac{1}{2} \sum_{i=1}^N \iint_{S_i} [\mathbf{E}_a \cdot P_i(\mathbf{E}) - \mathbf{E}_a \cdot U_i^{\text{inc}}] ds \quad (137)$$

where N denotes the total number of ports and \mathbf{E}_a denotes the solution to a properly defined adjoint problem. The FEM discretization of (137) using vector basis functions yields the resulting matrix equation:

$$[A][E] = \{b\} \quad (138)$$

The solution of (138) can be done using an iterative solver such as conjugate-gradient method (CGM) and generalized minimum residuals method (GMRES), and preconditioned techniques can be used to improve the condition number of the FEM system and accelerate the convergence rate of iterative solvers. As a result, this will yield the electric fields everywhere, including those over the ports from which the S parameters can be determined. A three-port circulator loaded with a full-height ferrite post is simulated with the FEM algorithm given above. The circulation characteristics are shown in Fig. 46 and are compared with the experimental data of Ref. 31. Another example considers an 8-mm waveband H -plane Y-junction waveguide circulator with a partial-height ferrite post [30]. The computed and experimental results are given in Fig. 47 and show good agreement.

Figure 46. Performance of the H -plane Y-junction circulator with a full-height TT1-109 circular ferrite post (— values computed from this theory; + + + values given by Ref. 31).

Figure 47. Performance of the H -plane Y-junction circulator with a partial-height circular ferrite post (—values computed from this theory; + + + experimental results given by Ref. 30).

6.4. Mode-Matching Method

Discrete-domain techniques such as the finite-difference and finite-element methods are slowly convergent, even for those with simple configurations. Straight application of the aforementioned FDTD scheme to analyze a waveguide Y-junction circulator with a ferrite specimen of arbitrary shape is possible but is used only as a last resort. The culprit is its complex boundary condition, which involves rectangular walls in the feeding waveguides, cylindrical truncation border of the waveguide junction, and the spherical surface of the ferrite sphere. It is further complicated by the anisotropic nature of ferrite. As illustrated earlier in this section, the computation time can be significantly reduced if a three-dimensional problem can be approximated by a two-dimensional one. Of course, this is not a realistic assumption for most circulators, but sometimes this scenario can be created in a piecewise sense by partitioning the configuration of interest appropriately. For example, the partial-height ferrite post shown in Figs. 23 and 24 can be divided horizontally into three parts such that each part contains a cylindrical resonator of uniform content. In contrast to the previous example, the field quantities in a resonator of finite height is not independent of z , yet the subsequent computation can be significantly cut by assuming that its dependence takes up the $e^{j\beta_z z}$ form. As a result, the relevant characteristic equation is similar to that of a two-dimensional case given in (100) with β_e replaced by β_n , given by

$$\beta_n = \sqrt{\beta_e^2 - \beta_z^2} \quad (139)$$

The electric and magnetic fields in these resonators are obtained by summing up all possible solutions or modes of the characteristics equation. Finally, the overall solution is deduced by stipulating that the tangential electric and magnetic fields be continuous at both ends of the cylindrical resonators in the adjacent parts.

Figure 48. Segmentation of a half circle into a cascade of waveguide tubes with annulus bases.

The mode-matching scheme can be extended to cover a ferrite body of revolution such as a sphere. For illustration, if the circle shown in Fig. 48 is segmented vertically into parallel parts, a cascade of tubes is formed by revolving the partitioned circle around the z axis. Note that each tube consists of three components of heights h_1 , h_2 , and h_3 . Success of the present scheme relies on our ability to find the field quantities in a waveguide tube of uniform content analytically. Again, details are skipped and readers are referred to another source [27] for an in-depth analysis of a waveguide tube of an annular base. The final solution is obtained by requiring that the tangential electric and magnetic fields be continuous on the cylindrical surfaces as well as the annular bases of the waveguide tubes.

Although the mathematical derivation is very time-consuming and the equations obtained are very lengthy, the required computation time is very short. Characteristics of a waveguide Y-junction circulator with a ferrite sphere can easily be determined. Results similar to those given in Figs. 49–51 can be computed in a personal computer in milliseconds, and excellent agreement between the analytical with experimental results is observed. Due to the computational efficiency, we can afford to find the general field pattern inside a waveguide junction circulator. Shown in Fig. 49 are the strength and direction of the electric field vector in a magnetized ferrite sphere. The field pattern in the waveguide junction exterior to the magnetized ferrite sphere is shown in Fig. 50. In both figures, the nature of wave circulation is clearly demonstrated. For comparison, the symmetric field pattern in the waveguide with a demagnetized ferrite sphere is sketched in Fig. 51.

Figure 49. Strength and direction of the electric vector inside a magnetized ferrite sphere. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

7. CONCLUDING REMARKS

Study of circulators is a multidisciplinary one that covers material science, ferrimagnetism, wave propagation, and circuit design; therefore, it finds a special position in many engineering curricula. Design of circulators marks a sharp deviation from the current trend in problem solving as engineers are inclined to solve their assignments by brute force, such as using a faster computer, a better database, a larger memory, and a wider bandwidth at a higher frequency. Here, an engineer's ingenuity can be fully shown as significant improvement can be obtained by using different material, changing the size and shape of ferrite, fine-tuning its location, and other insignificant altera-

tions. Circulators may be replaced in the future, but the underlying principles will prevail forever as it is an excellent manifestation of our ability in harnessing the nature for our benefit.

1. ISOLATORS AND THEIR APPLICATIONS

The transmission of a radiofrequency or microwave signal (above 1 GHz) along a line differs with that of a low-frequency signal essentially in the fact that one of the dimensions of the line is greater than the wavelength. This means that at a given time the instant value of the signal varies along this dimension. Furthermore, the signal may propagate along the line according to the opposite directions (forward and backward propagations).

The behavior of the wave is characterized by the mapping of the electric and magnetic fields. This mapping depends on the geometry of the line as well as the conductivity, the dielectric, and the magnetic constant of the materials used in the structure. The *characteristic impedance* is calculated from the mapping of the electric field and the magnetic field; its value is often set at 50 Ω for practical use.

If several kinds of lines are used to transmit a signal from a source to a load, the electromagnetic field map will be different along each line. As a result, the signal will be perturbed at each connection. The impedance mismatch between two lines causes a *return loss*, that is, a reflection of a part of the signal toward the source and a weaker wave transmitted to the load. Since this reflection is undesirable and may be disruptive or even destructive, it has to be eliminated by the use of an *isolator*.

Isolators are two-port circuits that allow the microwave energy to propagate along a direction and stop it along the opposite one (Fig. 1a). The flow is restricted to one direction; hence any reflected energy at the load is trapped or dissipated. Because the behavior of the isolator differs for direct and reverse propagations, it is referred to as a *non-reciprocal device*.

Operating frequencies above 10 GHz are currently the higher limit for a correct functioning of active isolators or circulators, not only because of the limited bandwidth of semiconductors but also because of noise generation and power dissipation. On the other hand, microwave ferrite material can be regarded as a mature technology, and their interesting anisotropic properties have been widely exploited for passive nonreciprocal applications [1,2].

1.1. Applications

Isolators are intensively used in microwave communication systems. Their applications include the decoupling between a generator and its load, the decoupling of several amplifiers, and the combining of two or more transmitters.

1.1.1. Decoupling between Generator and Load. Generators are usually affected by any power coming back to

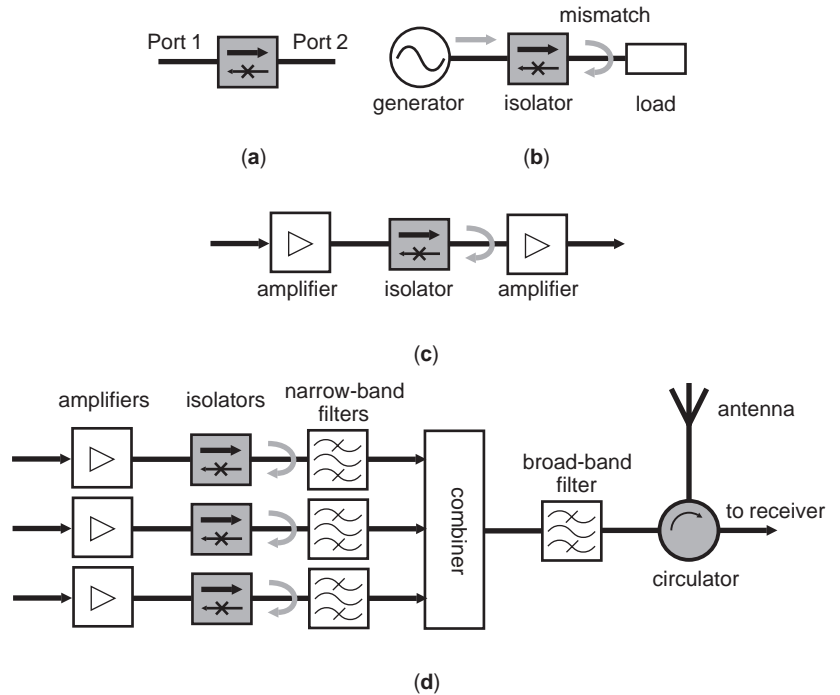

Figure 1. Some applications of isolators: (a) circuit symbol; (b) decoupling of generator and load; (c) decoupling of amplifiers; (d) combination of transmitters.

them, which may result in nonlinear effects such as frequency shift and instability. To overcome these problems, an isolator is used to eliminate the coupling between the generator and the load as shown in Fig. 1b, where the isolator attenuates only the backward wave and protects the generator.

1.1.2. Decoupling of Amplifier Stages. In applications where amplifiers are connected in series, they can affect each other in relation to their input impedance. The influence increases if their working frequency band is narrow because their input impedance varies sharply. If different amplifier stages are decoupled by isolators as shown in Fig. 1c, they can be tuned and adjusted without affecting the others, and if one stage is unbalanced, the others will not be overloaded.

1.1.3. Combination of Several Transmitters. A typical emitter stage of a mobile phone base station includes several transmitters working at different frequencies (Fig. 1d). The signal of each transmitter passes through an isolator, which has a low insertion loss, and a filter centered on the transmitter’s frequency. It travels then to the combiner. This lets the signal of each transmitter travel to the antenna without disturbing the others.

1.2. Characteristics

A perfect isolator should transmit all the energy from port 1 to port 2, cut all the backward energy from port 2 to port 1, and provide no reflection at port 1 and at port 2 (Fig. 2a).

The corresponding *S* parameters can be expressed in the following matrix:

$$\begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \tag{1}$$

Actual isolators response is not so ideal (Fig. 2b), and their specification must take into account several fundamental parameters such as insertion loss, isolation, and standing-wave ratio, as well as frequency bandwidth, intermodulation, and thermal and power considerations.

1.2.1. Insertion Loss. It corresponds to the neutrality of the component in the forward direction and its magnitude must be close to the unity. When a signal is applied to port 1, the insertion loss (IL) will be the ratio of the input power (port 1) to the output power (port 2). Typical values, expressed in decibels (dB), are between 0.1 and 1 dB and are calculated by the following expression:

$$IL \text{ (dB)} = 20 \log_{10} \left| \frac{a_1}{b_2} \right| = -20 \log_{10} |S_{21}| \geq 0 \tag{2}$$

1.2.2. Isolation. This corresponds to the ability of cutting the backward wave. Its magnitude must reach high values. When a signal is applied to port 2, the isolation (IS) will be the ratio of the input power (port 2) to the output power (port 1). Typical values, expressed in dB, are between 20 and 30 dB and are calculated by the following

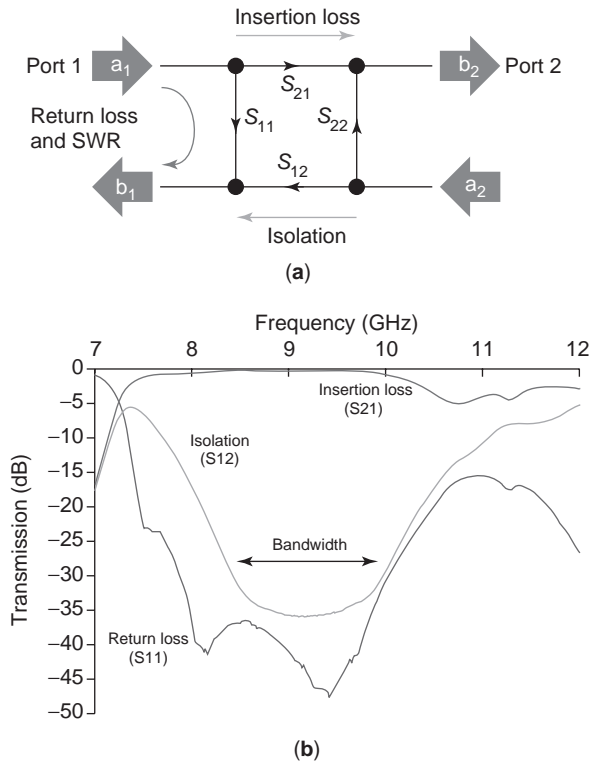

Figure 2. Characteristics of an isolator: (a) S parameters; (b) actual frequency response.

expression:

$$IS \text{ (dB)} = 20 \log_{10} \left| \frac{a_2}{b_1} \right| = -20 \log_{10} |S_{12}| \gg 0 \quad (3)$$

1.2.3. SWR. The standing-wave ratio (SWR) specifies how the input signal will be reflected back toward the source. It depends directly on the magnitude of return loss (R) at port 1, that is, the ratio of the incident power to the reflected power. The SWR is always greater than one and typical values are between 1.05 and 1.2, to maintain a good impedance matching:

$$|R| = \left| \frac{b_1}{a_1} \right| = |S_{11}| \simeq 0 \quad (4)$$

$$SWR = \frac{1 + |R|}{1 - |R|} \gtrsim 1 \quad (5)$$

1.2.4. Bandwidth. The operating bandwidth can be expressed as the difference between the high and low working frequencies divided by the center frequency multiplied by 100 (percentage bandwidth). Various bandwidth values are available according to the technology of the isolator, but 10% is often presented.

1.2.5. Intermodulation. When nonlinear elements such as ferrite materials are used, harmonics ($2f_1$, $3f_1$, etc.) appear but can be easily eliminated thanks to their high frequency value. However, in the case of several but close frequencies (f_1 and f_2), intermodulation rays appear

($2f_1 - f_2$ and $2f_2 - f_1$) and their influence is qualified by a third-order intermodulation product defined as the ratio of the intermodulation magnitude to the fundamental magnitude.

1.2.6. Temperature Range. The operating temperature range of an isolator is limited by the materials used in the device, especially by ferrites. Magnetic materials indeed exhibit nonlinear behaviors and frequency shift due to temperature variation and become nonmagnetic above their Curie temperature. Operating temperatures from -20 to $+70^\circ\text{C}$ are common.

1.2.7. Power Dissipation. For low-power isolators, exceeding the power limit causes nonlinearity effects in the ferrite material and provides a frequency shift and an increase in the insertion loss. For high-power isolators, average power induces an increase of temperature and cooling of the device is sometimes needed. The peak power should cause breakdown or arcing, which generally results in permanent degradation of performance. Power depends on the technology and can be limited from a few watts (planar drop-in isolators) to several hundred watts (waveguide isolators). Acceptable average power decreases with the working frequency. Peak power can reach several kilowatts.

2. DEVICES

The first experimental microwave ferrite device was demonstrated in 1949. The development of this type of device was strongly linked to ferrite materials preparation and to the knowledge of spin interaction in ferrimagnetic materials [3–5].

The behavior of microwave ferrite devices is based on the gyromagnetic property of ferrimagnetic materials. Several effects can be exploited to provide nonreciprocal propagation of the signal, such as *Faraday rotation*, *ferrimagnetic resonance*, and *field displacement*.

Many microwave components such as circulators, isolators, phase shifters, or gyromagnetic filters are using ferrite materials and are always essential because there is no alternative semiconductor-based device that satisfies similar requirements.

Furthermore, microwave technologies are moving to higher frequencies, up to 100 GHz, where high-resistivity materials are needed so that ferrites remain the first choice and semiconductor materials are currently not competitive.

2.1. Waveguide Isolators

The microwave applications of ferrites had their foundations in the Faraday effects, and the first devices were circular waveguide Faraday rotators. Then, rectangular waveguide components were developed using resonance absorption or field displacement [6].

2.1.1. Faraday Rotation Isolator. The linear polarization of a wave rotates if it propagates in a longitudinally magnetized ferrite. This phenomenon, called *Faraday*

Figure 3. Waveguide Faraday rotation isolator.

rotation, is nonreciprocal so that the polarization always rotates in the same direction whatever the propagation direction. The Faraday rotation can be used in an isolator if waves are absorbed or not, according to the rotation of their polarization. The device is made from a circular waveguide containing a 45° rotator between two 45° shifted rectangular waveguides. Absorbing sheets are placed in rectangular-to-round waveguide transitions (Fig. 3).

The polarization of the electric field of a wave entering port 1 is parallel to the smallest side of the rectangular waveguide so that it is normal to the first resistive sheet and is not affected by it. The polarization is rotated 45° clockwise by the rotator and becomes normal to the second resistive sheet. The wave can therefore emerge without attenuation.

In the reverse direction, a wave entering port 2 is rotated 45° in the same direction (clockwise) so that the electric polarization is parallel to the port 1 resistive sheet. The wave is then absorbed and cannot propagate.

The average power that can be absorbed is limited by resistive sheets. On the other hand, insertion loss and isolation are improved if the magnitude of circular polarizations is not affected by the rotator so that no perpendicular polarization appears before resistive sheets.

2.1.2. Resonance Isolator. A circularly polarized wave that penetrates into a magnetized ferrite may be absorbed or not, according to its rotation direction. The effect is maximum at the gyromagnetic resonance frequency of the ferrite. This phenomenon can be used in a rectangular waveguide where the polarization is circular at two different positions (Fig. 4). If a ferrite is placed at one of these

Figure 4. Waveguide resonance isolator.

positions, the nonreciprocal absorption of the microwave energy is used to make an isolator [7]. A transverse DC field is required to magnetize the ferrite.

The optimum position of the ferrite is chosen for a circular polarization of the internal microwave magnetic field. This position may however differ from that of the empty guide because of the ferrite presence. Several ferrite shapes can be used (*E*-plane or *H*-plane resonance isolator), but *H*-plane ferrite geometry, consisting of two thin flat ferrite rods, shows better performance. It has the particular advantage of setting the ferrite rods against the waveguide with a maximum contact area so that the material can be cooled through the metal waveguide.

2.1.3. Field Displacement Isolator. In a partially ferrite-filled waveguide, the microwave energy may be rejected from the material according to its direction of propagation. As a result, the microwave electric field vanishes near the ferrite for direct propagation direction and is maximum for the reverse direction (Fig. 5).

If a resistive sheet is placed against the ferrite slab where the difference of energy is maximum, it will have little effect on the direct propagation, but there will be strong absorption in the backward propagation.

As for resonance isolator, a transverse DC magnetic field is applied to the ferrite, but a lower intensity is required. This kind of isolator gives low insertion loss about 0.1 dB. It is well suited for low-power operations because the resistive sheet cannot be cooled as it is not in contact with the waveguide.

2.2. Planar Isolators

The development of planar circuits, fabricated by conventional printed-circuit techniques, has liberated the microwave designer from high costs and many constraints encountered with waveguides and coaxial lines [8,9]. Ferrite devices were rapidly developed for stripline and microstrip circuits such as *edge-guided-mode* isolators or *Y-junction* circulators.

2.2.1. Coplanar Resonance Isolator. The coplanar waveguide is a surface strip transmission line and consists of a central conductor strip separated from ground planes by two slots on a dielectric substrate [10]. At high frequencies, the propagation in this structure is no longer TEM (transverse electromagnetic) because a longitudinal

Figure 5. Waveguide field displacement isolator.

Figure 6. Coplanar resonance isolator.

component of the microwave magnetic field appears. Thus the resulting elliptically polarized magnetic field in the slot can be used for nonreciprocal operations if it interacts with a ferrite material. A resonant isolator can be fabricated by attaching ferrite rods at the air–dielectric interface between the conductors (Fig. 6). A horizontal magnetic polarization is applied to the ferrite, perpendicular to the microwave elliptic polarization plane.

This device will show better performances if the microwave polarization is circular. High insertion loss and moderate isolation values are the consequences of an ellipticity different from unity. However, since the dominant propagation mode is TEM, the microwave polarization will never be circular but the ellipticity could be improved under one of these conditions: a higher permittivity substrate, wider strip and slots dimensions, or a higher working frequency [11].

2.2.2. Stripline Resonance Isolator. TEM transmission lines are not suitable for nonreciprocal devices because there is no longitudinal component of the microwave magnetic field. However, the line may be antisymmetrically loaded with a dielectric material so that a longitudinal field appears according to Maxwell’s equations and boundary conditions [6]. Ferrite rods are placed near the air–dielectric interface, where the longitudinal field is higher. A longitudinal magnetic field is required to obtain an elliptic polarization such as that in the device described above as it will interact with the magnetic rods to provide nonreciprocal attenuation of the signal. Figure 7 shows ferrite isolators based on a coaxial line and a stripline. They are both half-filled with a dielectric material and contain vertically magnetized ferrite rods. The nonreciprocal effect is maximum at the ferrite resonance as in the case of the coplanar isolator.

2.2.3. Coupled Microstrip Line Isolator. The coupling between two microstrip lines on a ferrite substrate is nonreciprocal if the gyrotropic material is magnetized [12]. The nonreciprocal effect is a differential phase shift between S_{12} and S_{21} that can be used to create an isolator.

Figure 7. Coaxial and stripline resonance isolator. (From [10]; © 1969 IEEE, reproduced with permission.)

Figure 8. Coupled microstrip-line isolator.

The coupling length is adjusted so that the direct signal at one port is coupled to the other line and the reverse one is not delivered to the first line. External matching loads are placed at the end of each line to absorb reflected power (Fig. 8).

2.2.4. Microstrip Edge-Guided-Mode Isolator. A microstrip or a stripline using a ferrite substrate, with a magnetization normal to the ground plane, with a wide strip conductor, shows an exponential field variation of the dominant mode along the device width (Fig. 9). This field displacement effect is nonreciprocal as it is reversed for each direction of wave propagation and for opposite magnetic polarizations [13]. The energy is concentrated near opposite edges of the component and may be dissipated in the reverse propagation direction by placing an absorbing film on one edge of the strip.

The field displacement is caused by the gyromagnetic properties of the ferrite, which is magnetized below the resonance in the low-loss region. The device therefore shows better performance with a low field bias. On the other hand, the use of a strip much wider than the substrate thickness produces a low characteristic impedance so that suitable impedance transformers are required for approximate matching to 50-Ω-impedance lines.

Because the presence of the absorber should provide insertion loss, several improvements were proposed. The absorbing film can be replaced by a short circuit of one edge of the strip with the ground plane. The addition of an iron plate near the short circuit provides a strong interaction with the magnetic field that improves the nonreciprocal effect [14].

2.2.5. Sawtooth Edge-Mode Isolator. Other authors suggested printing the wide strip with a slots on its edge without absorber [15]. The direct wave is not affected by the slot discontinuity, while the reverse one is reflected by this effective open circuit and dissipates in the ferrite substrate. This device is strictly planar and requires no absorber.

Figure 9. Microstrip edge-guided-mode isolator. (From [13]; © 1971 IEEE, reproduced with permission.)

Figure 10. Sawtooth edge-mode isolator. (From [16]; © 2001 IEEE, reproduced with permission.)

To improve the bandwidth, a multislot (sawtooth) configuration is used and a lossy material covers only the sawtooth to reduce insertion loss (Fig. 10). The behavior of the device can be tuned by varying the size of those slots; isolation is increased with a large sawtooth design, while low insertion loss is obtained with a small sawtooth design [16].

2.2.6. Slotline Field Displacement Isolator. It is also possible to obtain a nonreciprocal field displacement in a ferrite-loaded slotline (Fig. 11). If a horizontal static magnetic field is applied, the energy travels along each side of the ferrite according to the propagation direction [17]. Thus the presence of an absorbing material at the bottom of the ferrite provides the isolation. An alumina substrate may be placed between the ferrite and the lines to reduce the insertion losses of the device. The main drawback of such a structure is the transition between the slotline and a coaxial line (or other lines) at each port of the device that provides mismatch losses. The same kind of device can be built using a finline structure [18].

2.2.7. Circulator-Based Isolator. One of the most popular planar isolators proposed by manufacturers for low-power applications is based on a three-port circulator by adding a matching termination to one port. A usual form consists of a stripline symmetric Y junction with a circular center conductor surrounded with two ferrite disks (Fig. 12). The circular junction behaves like a resonant cavity with two contrarotating modes resulting in a standing wave. If a static magnetic field is applied perpendicularly to the disks, the resonant frequencies of the two modes are different. The pattern of the standing wave

Figure 11. Slotline field displacement isolator. (From [17]; © 1975 IEEE, reproduced with permission.)

Figure 12. Circulator-based isolator. (From [24]; © 1965 IEEE, reproduced with permission.)

is therefore rotated so that the third port is isolated while the others are coupled [19].

The easy fabrication and the good performance of the Y-junction circulator make this miniature nonreciprocal device one of the most widely used, as a circulator as well as an isolator.

3. NONRECIPROCAL EFFECTS

The functioning of passive microwave isolators is based on ferromagnetic resonance properties of ferrite materials. Magnetized ferrites are indeed anisotropic and characterized by an antisymmetric permeability tensor, which is necessary to obtain nonreciprocal effects such as isolation. Most passive magnetic devices need a saturated state of the ferrite or at least a magnetic polarization that is performed by permanent magnets or magnetic coils.

3.1. Ferromagnetic Resonance

To understand the origin of the anisotropy, the interaction between magnetic moments of the ferrite and a magnetic field needs to be studied.

3.1.1. Magnetic Units. The current ferrite literature still uses cgs units (centimeter, gram, second) for historical reasons. Therefore, conversions between this system and SI units (meter, kilogram, second, ampere) frequently have to be performed.

In the SI system, the following relations correspond to the response of a material (M and B) immersed in an applied field (H)

$$\chi \mathbf{H} = \mathbf{M} = \frac{d\mathbf{m}}{dV} \tag{6}$$

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) = \mu_0\mathbf{H}(1 + \chi) = \mu_0\mu_r\mathbf{H} \tag{7}$$

The ratio of the magnetization to the applied field is the susceptibility (6), and the ratio of the induction to the field is the permeability (7). The susceptibility vanishes and the relative permeability equals one for nonmagnetic materials. In the case of anisotropic materials, induction, magnetization, and applied field are not parallel and the susceptibility as well as the permeability become tensorial.

In the cgs system, vacuum permeability is set at the unity and (7) must be written as follows

$$\mathbf{B} = \mathbf{H} + 4\pi\mathbf{M} \quad (8)$$

and the conversion between cgs and SI units are [20]

$$1 \text{ A/m} = 4\pi 10^{-3} \text{ Oe magnetic field } (H) \quad (9)$$

$$1 \text{ A/m} = 10^{-3} \text{ emu/cm}^3 \text{ magnetization } (M) \quad (10)$$

$$1 \text{ T} = 10^4 \text{ G induction } (B) \quad (11)$$

3.1.2. Static Magnetic Field. When a static magnetic field (\mathbf{H}_0) is applied to a magnetic material, its magnetic moments (\mathbf{m}) and the corresponding magnetization (\mathbf{M}) for a given volume precess around the field axis with an angular velocity proportional to the magnitude of the field (Fig. 13a). This phenomenon, called *Larmor's precession*, is governed by the following relations, which give the gyromagnetic equation of motion, the angular velocity, and the gyromagnetic ratio, respectively:

$$\frac{d\mathbf{m}}{dt} = -\gamma\mu_0(\mathbf{m} \times \mathbf{H}_0) \quad (12)$$

$$\omega_0 = \gamma\mu_0 H_0 \quad (13)$$

$$\gamma = 176 \cdot 10^9 \text{ rad s}^{-1} \text{ T}^{-1} (\Leftrightarrow 28 \text{ GHz/T}) \quad (14)$$

3.1.3. Microwave Field. If, in addition, the material is submitted to a microwave field (\mathbf{h}) perpendicular to the static one, the magnetic moments tend to precess around a total field that oscillates (Fig. 13b). When the angular velocity of the moments reaches the frequency of microwave oscillations, the microwave energy is transmitted to the material and absorbed.

3.1.4. Polder's Model. After taking into account the microwave field, the spectral expression of the equation of motion leads to a relative permeability tensor:

$$\bar{\mu}_r = \begin{pmatrix} \mu_r & 0 & +jk \\ 0 & 1 & 0 \\ -jk & 0 & \mu_r \end{pmatrix} \quad (15)$$

Figure 13. Precession of ferrite moments under an applied field: (a) static applied field; (b) static and microwave applied fields; (c) with losses.

This tensor is used for a y -axis applied field (xy , yx , yz , and zy elements vanish) and for a saturated material (yy element is equal to 1). The presence of the imaginary number j corresponds to the rotation of the moments; that is, there is a 90° phase difference between m_x and m_z .

The elements of the permeability tensor depend on the frequency

$$\mu_r = 1 + \frac{\omega_0 \omega_M}{\omega_0^2 - \omega^2} \quad (16)$$

$$\kappa = \frac{\omega \omega_M}{\omega_0^2 - \omega^2} \quad (17)$$

$$\omega_M = \gamma\mu_0 M_S \quad (18)$$

and they both depend on the magnitude of the applied field (13) and on the saturation magnetization of the material (18).

3.1.5. Damping Factor. If losses are taken into account, the angle between \mathbf{m} and \mathbf{H}_0 will decrease until these elements are aligned (Fig. 13c). Tensor elements become complex quantities, and a damping parameter is introduced in (16) and (17):

$$\mu_r = \mu_r' - j\mu_r'' = 1 + \frac{(\omega_0 + j\alpha\omega)\omega_M}{(\omega_0 + j\alpha\omega)^2 - \omega^2} \quad (19)$$

$$\kappa = \kappa' - j\kappa'' = \frac{\omega \omega_M}{(\omega_0 + j\alpha\omega)^2 - \omega^2} \quad (20)$$

The real and imaginary parts of the elements of the permeability tensor are shown in Fig. 14 for a 180 mT saturation magnetization and 0.1 damping factor. Figure 14a shows a frequency sweep with a fixed applied field, which is currently the most common representation, thanks to vector analyzer measurements facilities. For historical reasons, Fig. 14b is the most widely known representation because it was previously easier to work with a single-frequency microwave source and to vary the applied field by adjusting a continuous current.

According to Fig. 14b, the resonance losses are characterized by the width of the imaginary part, which increases for lossy materials. The width at midheight of the curve is called *linewidth* and is frequently used by manufacturers (often expressed in oersteds). It depends on the damping factor and on the working frequency:

$$\gamma\mu_0 \Delta H = 2\alpha\omega \quad (21)$$

Figure 14b also shows three different zones according to the magnitude of the applied field. The expressions *below*, *above*, or *at resonance* refer to a field sweep and not to a frequency sweep. The confusion could be reinforced if the static field were expressed as a frequency as in (13).

Polder's model is defined for saturated material so that the magnetization of the ferrite reaches the saturation magnetization. Under particular operation conditions such as low bias fields, several magnetic domains with different magnetization magnitudes and orientations are

Figure 14. Ferromagnetic resonance; real and imaginary parts of the elements of the permeability tensor: (a) frequency sweep and 150 kA/m applied field; (b) field magnitude sweep and 5 GHz frequency.

present. Therefore new models must be used to take into account the resulting effects on the gyromagnetic phenomenon [21].

3.1.6. Demagnetizing Factors. All the previous definitions concern materials influenced by an internal magnetic field, that is, the actual field experienced by the spin dipoles. In an infinite medium, the internal field equals the applied field, but in the case of a finite medium, there is a discontinuity of the magnetic field at the boundary between materials with different permeability values. Determining the field inside an arbitrarily shaped sample is not always possible, but the problem is tractable for an approximate ellipsoidal shape. Thus, the internal field can be expressed from the applied field as follows

$$\mathbf{H}_i = \mathbf{H}_0 - \bar{\mathbf{N}}\mathbf{M} \tag{22}$$

$$\bar{\mathbf{N}} = \begin{pmatrix} N_x & 0 & 0 \\ 0 & N_y & 0 \\ 0 & 0 & N_z \end{pmatrix} \tag{23}$$

where the demagnetizing factors, N_x , N_y , and N_z , depend on the shape of the sample. The sum of these terms are equal to one. Each term equals $\frac{1}{3}$ in the case of a sphere;

the term tends to zero if the corresponding size increases and to one if it becomes thinner. Several approximations have been calculated and are helpful in estimating internal fields for arbitrary shapes [22].

Since the demagnetizing factors concern static and microwave fields, the tensor elements are dramatically changed and the resonant frequency is given by Kittel's equation for a z -direction applied field:

$$\omega_r = \gamma\mu_0 \sqrt{[H_0 + (N_x - N_z)M][H_0 + (N_y - N_z)M]} \tag{24}$$

3.2. Nonreciprocal Wave Propagation

Because waveguide or planar configurations are difficult to solve, nonreciprocal effects in ferrites can be more elementarily understood by considering the microwave propagation in infinite media. Maxwell's equations can be combined to include the permeability tensor and, considering a propagation along the z axis, it gives

$$\nabla \times \nabla \times \mathbf{H} - \omega^2 \epsilon_0 \mu_0 \epsilon_r \bar{\mu}_r \mathbf{H} = 0 \tag{25}$$

$$\mathbf{H} = \mathbf{h} \exp(j\omega t) \exp(-\gamma z) \tag{26}$$

where

$$\gamma = \alpha + j\beta = j \frac{\omega}{c} \sqrt{\epsilon_e \mu_e} \tag{27}$$

is the propagation coefficient that represents both the attenuation and the phase delay of the signal. In an infinite medium, they depend on the effective permittivity and permeability of the material.

According to the direction of the static magnetic field, which fills the permeability tensor (15) in different ways, several phenomena on the effective permeability and on the propagation occur.

3.2.1. Longitudinal Field. If a static magnetic field is applied parallel to the propagation direction (z axis), then (25) leads to an eigenproblem where the eigenvalues are

$$\mu_+ = \mu_r + \kappa \tag{28}$$

$$\mu_- = \mu_r - \kappa \tag{29}$$

These associated eigenvectors are respectively a right-hand circular polarized magnetic field for (28) and a left-hand polarization for (29). This means that the microwave must be decomposed according to these two polarizations and each part propagates with the corresponding effective permeability.

The effective permeability values, obtained from Fig. 14b, are plotted versus the applied field in Fig. 15a. In an infinite medium, the propagation coefficients of the corresponding plane wave are given by

$$\gamma_{\pm} = j \frac{\omega}{c} \sqrt{\epsilon_r \mu_{\pm}} = j \frac{\omega}{c} \sqrt{\epsilon_r (\mu_r \pm \kappa)} \tag{30}$$

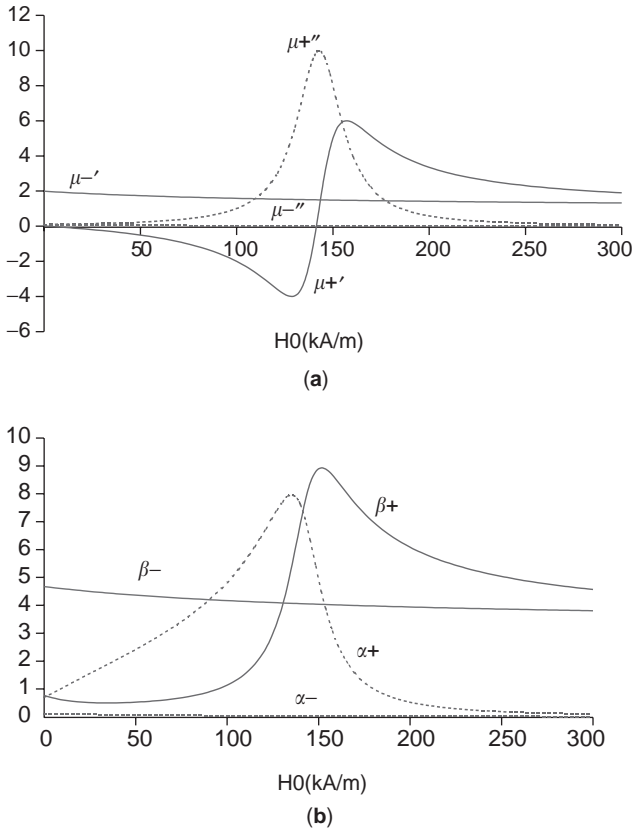

Figure 15. Microwave propagation parallel to the applied field: (a) effective permeability values; (b) nonreciprocal propagation coefficients.

and are plotted in Fig. 15b. Since real parts and imaginary parts are all different, nonreciprocal effects can be obtained not only for absorption but also for phase.

3.2.2. Transverse Field. If the permeability tensor is filled according to a perpendicular field (x or y axis), propagation will occur with two effective permeability values

$$\mu_{+} = \frac{\mu_r^2 - \kappa^2}{\mu_r} \quad (31)$$

$$\mu_{-} = 1 \quad (32)$$

The eigen vectors are now linear polarizations. Permeability values and propagation coefficients are plotted in Fig. 16. Nonreciprocal effects are also possible.

Although the explanations above are defined for plane waves (without longitudinal field components), they can be generalized for cases of propagation in waveguides or planar lines where longitudinal fields (non-TEM modes) appear.

3.2.3. Faraday Rotation. Figure 15b shows different values of the phase delay. If a linearly polarized incident microwave field is decomposed in both right-hand and left-hand circular polarizations, each part will be differently phase-shifted for a given distance (Fig. 17). Then the combination of the two emerging circular polarizations (with

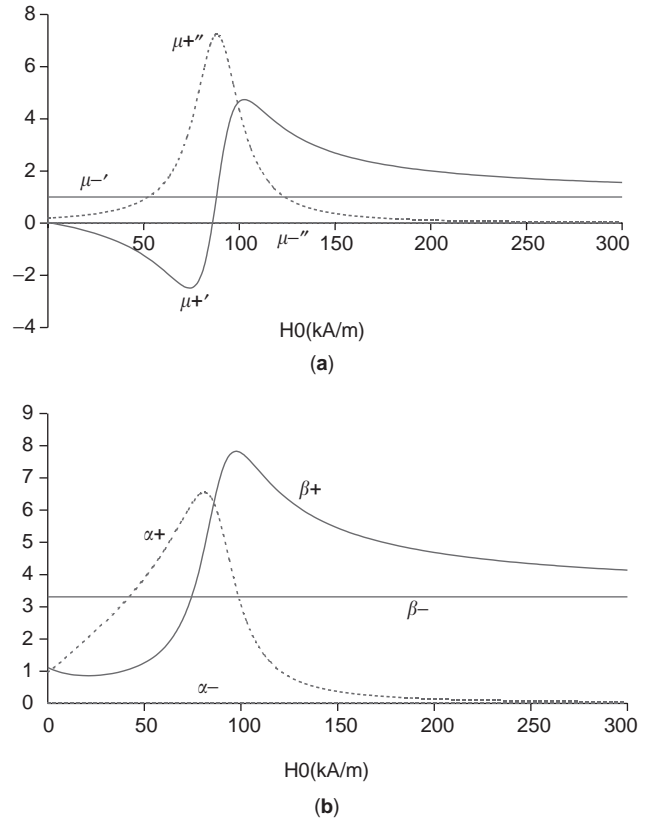

Figure 16. Microwave propagation perpendicular to the applied field: (a) effective permeability values; (b) nonreciprocal propagation coefficients.

the same magnitude) gives a linear polarization with a rotation equal to the half phase difference:

$$\theta = \frac{\Delta\phi}{2} = \frac{\beta_{-} - \beta_{+}}{2} L \quad (33)$$

The rotation is nonreciprocal. The polarizations of backward and forward waves rotate in opposite directions (respectively to the left or to the right) according to their own coordinate system because the applied field is inverted. As a result, rotations are in the same direction according to the ferrite axes.

Faraday rotation should be performed for low field values where losses are weak to ensure that the circular magnitudes are not attenuated and the emerging

Figure 17. Faraday rotation of a linearly polarized wave.

polarization remains linear. The nonreciprocal rotation effect, similar to the behavior of Faraday rotation in optical media, was the first phenomenon exploited in microwave ferrite devices and is widely used to build circulators or isolators as shown in Fig. 3.

3.2.4. Resonance Absorption. Figures 15b and 16b both show nonreciprocal absorption according to the polarization of the wave. Losses are added in (28) and vanish in (29), where the imaginary part of the effective permeability is nearly zero regardless of the applied field. The maximum nonreciprocal attenuation occurs at the resonance where phases are equal.

In the first configuration, a left-hand circular polarization is absorbed while a right-hand polarization can propagate. If the polarization of the incident wave is elliptic, the attenuation depends on whether the magnitude of the right-hand circular polarization is maximum or not (Fig. 18).

In the second configuration, a linearly polarized microwave magnetic field parallel to the static field does not interact with the ferrite and the wave propagates in the same way as in a dielectric material. On the other hand, a polarization perpendicular to the applied field is strongly absorbed.

The resonance absorption is widely used in devices where a longitudinal magnetic field exists. If longitudinal and transverse fields are 90° phase-shifted, then they form an elliptic polarization that can interact with the rotation of the moments in a ferrite. The material must be magnetized perpendicular to the plane where the microwave polarization and the magnetic moments rotate. If longitudinal and transverse magnitudes are equal, the polarization becomes circular and effects are maximum. This configuration is used in rectangular waveguide resonance isolators (Fig. 4) and in coplanar and stripline isolators (Figs. 6 and 7).

3.2.5. Transverse Field Displacement. The negative value of the effective permeability, in Figs. 15b and 16b, implies that the microwave field is rejected from the material, while the other permeability allows the wave to penetrate. If a waveguide is partially filled with a ferrite material and if the case of a negative permeability occurs, the energy therefore propagates in the empty region. This phenomenon is a form of field displacement and is used in the rectangular waveguide isolator described in Fig. 5.

Another configuration where field displacement can be observed is the case of two wide strips separated by a ferrite substrate. In this type of structure, only TE modes are considered because TM modes cannot exist between parallel strips when the spacing is less than a half-wavelength [13].

The field components can be expressed as follows

$$E_x, H_y, H_z = A_{x,y,z} \exp(-\alpha_y y) \exp(-j\beta_z z) \tag{34}$$

where the propagation coefficients depend on the elements of the permeability tensor:

$$\beta_z = \omega \sqrt{\mu_0 \epsilon_0 \epsilon_r \mu_r} \tag{35}$$

$$\alpha_y = \omega \frac{\kappa}{\mu_r} \sqrt{\mu_0 \epsilon_0 \epsilon_r \mu_r} \tag{36}$$

The corresponding wave can therefore propagate along the z axis (purely imaginary coefficient in the propagation direction) while it is attenuated along the y axis (purely real coefficient along the width), so that the field magnitudes decrease exponentially along the width. This is the edge-guided mode (Fig. 19). The phenomenon is more efficient if the material is magnetized below the resonance with a weak internal field to avoid losses, just enough for the saturation.

If the applied field is inverted, the sign of the attenuation is changed and the exponential decay is inverted.

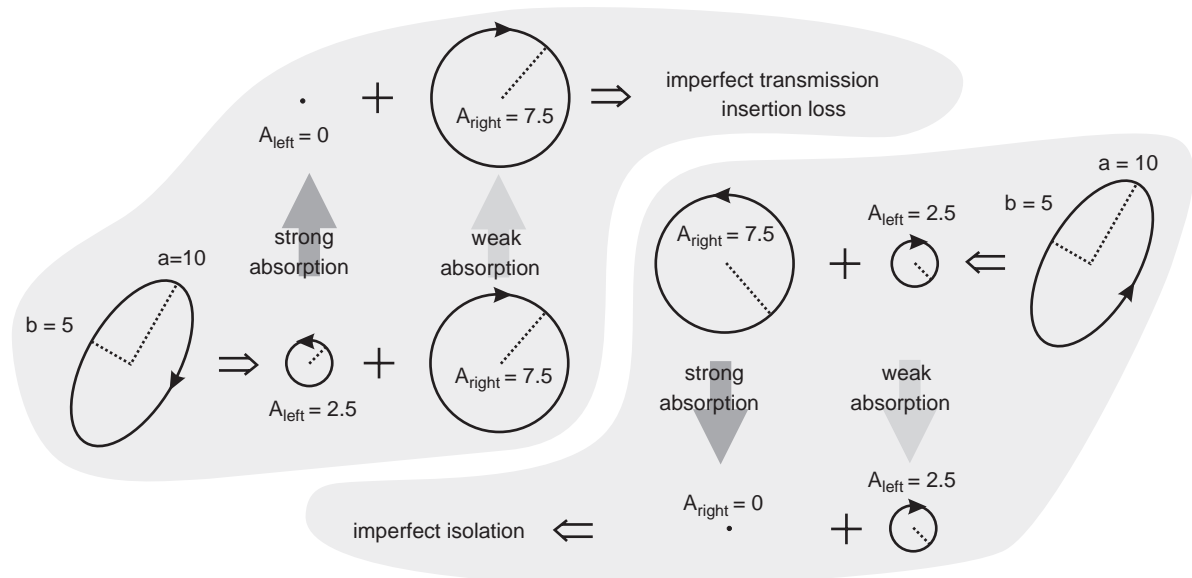

Figure 18. Resonance absorption of left-hand and right-hand polarizations.

Figure 19. Field displacement and edge-guided mode. (From [13]; © 1971 IEEE, reproduced with permission.)

The same changes occur for a reverse propagation. The field displacement is therefore nonreciprocal and can be used to build a stripline or a microstrip isolator by adding an absorber on one edge as shown in Fig. 9. For high frequencies, other modes of propagation with a sinusoidal pattern can exist. As a result, the field displacement, corresponding to the edge-guided mode, is frequency-limited.

3.2.6. Ferrite Junction Circulation. A ferrite disk placed between two conducting planes is a geometry of planar junction circulator. Electric fields are supposedly mainly perpendicular to the conductors and the boundary conditions lead to two different configurations of electromagnetic waves: right-handed and left-handed rotating waves. A standing-wave pattern is established where fields intensities are equal and oppositely directed on either side of the conductor (Fig. 20).

For an isotropic substrate (or unmagnetized ferrite), the corresponding effective indices where the rotating waves propagate are equal. The standing wave intensity is maximum at the input port (port 1), and vanishes at 90° from the input port. As a consequence, a small amount of energy is coupled to ports 2 and 3.

For a gyrotropic substrate (magnetized ferrite), the two rotating modes are oppositely phase-shifted so that a rotation of the electromagnetic pattern occurs. If the rotation reaches 30°, port 2 is then coupled (transmission) and port 3 is isolated [23].

In this case, the effective permeability is given by

$$\mu_e = \frac{\mu_r^2 - \kappa^2}{\mu_r} \tag{37}$$

Figure 20. Ferrite junction circulation. (From [24]; © 1965 IEEE, reproduced with permission.)

and the solutions of the electromagnetic equations give magnetic microwave fields [24] proportional to

$$A_+ = J_{n-1}(kr) - \frac{J_n(kr)}{kr} \left(1 + \frac{\kappa}{\mu}\right) \tag{38}$$

$$A_- = J_{n-1}(kr) - \frac{J_n(kr)}{kr} \left(1 - \frac{\kappa}{\mu}\right) \tag{39}$$

where J_n are n th-order Bessel functions, and where

$$k^2 = \omega^2 \epsilon_0 \mu_0 \epsilon_r \mu_e \tag{40}$$

is the wavenumber associated with the effective permeability and r is the distance to the center of the ferrite disk. The first modes ($n = 1$) show two opposite areas of maximum energy as in Fig. 20. The positive and negative rotating modes are strongly linked to the ratio of the terms of the ferrite permeability tensor and differ in sign.

Magnetic fields vanish at the boundaries (magnetic wall if r equals the radius). Magnitudes (38) and (39) are then equal to zero, and their solutions lead to the radius of the ferrite disk for given working frequency and permeability tensor.

The input impedance of each port can be adjusted with the thickness of the disk, and the width of the access strip and can be improved by an impedance transformer.

The best performance is obtained above the resonance (according to the applied field, that is, at low frequencies), but the circulator can also operate below resonance [25]. The rotation is then inverted because the sign of the ratio is changed.

One of the most popular structure is the stripline Y-junction circulator with two ferrite disks (Fig. 12).

3.3. Ferrite Materials

Microwave ferrites are high-resistivity ferrimagnetic materials used at frequencies above 0.1 GHz. They are ferrimagnetic oxides made of oxygen anions around metal (such as iron) divalent or trivalent cations [26]. The possibility of mixing the composition to adjust their behavior is one very attractive property of ferrites. If a divalent iron cation is replaced by any divalent composition, it gives a mixed ferrite with sometimes completely different properties. In addition, the substitution of a trivalent iron cation

gives a substituted ferrite whose behavior can be thinly adjusted.

3.3.1. Properties. Although ferrites usually show weaker performance than do magnetic metals, they are highly resistive, so that an electromagnetic wave can penetrate and interact with the material. Their resistivity can indeed vary between 10 and $10^8 \Omega \cdot \text{cm}$, a value that must be compared to the $10^{-4} \Omega \cdot \text{cm}$ resistivity of ferromagnetic metals. The relative dielectric permittivity of ferrites is almost constant at microwave frequencies and close to 15. Dielectric losses result mainly from the existence of both trivalent and divalent iron cations. There is an excess of electrons that may jump from one iron cation to another and therefore cause some conduction and losses.

A fundamental property such as permeability has to be considered because it governs the interaction between the wave and the material. Low coercivity is a condition for low losses. High Curie temperature and low magnetostriction constant are the main factors in improving the stability of ferrites. High saturation magnetization implies high gyromagnetic anisotropy but also intense magnetic field to saturate the material.

3.3.2. Spinel. Historically, spinel ferrites were the first type of ferrite used in microwave devices, in the 3–30 GHz range. The typical composition of a spinel ferrite is as follows:

Nickel mixed ferrite has a Curie temperature of about 570°C and is therefore rather stable. Its saturation magnetization is about 320 mT. Because it contains Ni ion, which is a relaxing ion, the spinel ferrite is a lossy material reserved for power applications. Lower magnetizations (down to 140 mT) are obtained by aluminium substitution for iron, while partial substitution of zinc for nickel increases the saturation magnetization (480 mT) at a lower temperature (400°C).

Lithium ferrite has a magnetization of about 360 mT with a high Curie temperature near 645°C . The lack of divalent iron ions results in a narrow linewidth that renders this ferrite suitable for low power levels with low losses. Magnetization can be decreased (down to 230 mT) by Ti substitution and increased by Zn substitution (500 mT).

3.3.3. Garnets. Yttrium iron Garnet (YIG) is a very-narrow-linewidth material (near 3 kA/m, compared to 15–35 kA/m of spinels) that remains the best microwave material in the 1–10-GHz band. It can easily be saturated thanks to its weak saturation magnetization (175 mT). As the Curie temperature of YIG is 286°C , the stability with temperature is low. The chemical formula is

Aluminum substitution of iron ions decreases the magnetization as well as the Curie temperature, while Gd substitution of Y ions reduces the magnetization without

changing this temperature, which results in a better stability. Narrow linewidth as low as 0.8 kA/m can be obtained with In or Zn substitutions (associated with Ca ions).

3.3.4. Hexaferrites. These materials have a hexagonal structure with a c axis of symmetry. Their crystalline structure is essentially uniaxial of the M-type with the following formula

for barium (BaM) or strontium (SrM) hexaferrites. They have a high saturation magnetization (480 mT) and a Curie temperature as high as 700°C .

They also have a high magnetocrystalline anisotropy, which results in an anisotropy field H_a (mainly near 1500 kA/m and up to 2700 kA/m) that can be added to the internal field to reach resonance frequencies higher than (24)

$$\omega_r = \gamma\mu_0 \sqrt{[H_0 + H_a + (N_x - N_z)M][H_0 + H_a + (N_y - N_z)M]} \quad (44)$$

They are also characterized by a squared hysteresis loop with high remanence that allows a self-polarization of the material.

4. CURRENT DEVELOPMENTS

The manufacturing of ferrite materials is difficult, especially for small dimensions. These constraints do not make this kind of components easy to integrate or to miniaturize. Several ways of improving the performance and compactness of ferrite devices are proposed [27,28].

In order to reduce the size of the devices, some authors propose using hard magnetic materials with high remanence so that no external field is needed. Hexagonal ferrites such as SrM (315 mT saturation magnetization and 1500 kA/m anisotropy field) were successfully used in a 33-GHz rectangular waveguide circulator [29]. A 30-GHz self-biased microstrip circulator using a 130- μm -thick SrM substrate were realized [30]. Another interesting property of this material is its high crystalline anisotropy, which can be added to the internal field so that the resonance occurs at higher frequencies, above 10 GHz and up to 90 GHz.

In the case of thin ferrite plates, ohmic losses caused by metal resistivity may become the main contribution to total loss. To overcome this effect, the integration of superconductive materials in ferrite microwave devices has been investigated and its feasibility has been demonstrated in the case of a 10-GHz ring network circulator made of niobium or YBaCuO superconductors cooled to 77 and 4 K [31]. The same criteria are considered for the choice of ferrite material at either cryogenic temperature or at room temperature with, however, higher saturation magnetization values.

The main issue of current research is the integration of ferrite devices with semiconductor technologies. Several attempts at depositing ferrite films on silicon substrates were performed using pulsed laser deposition, evaporation, or sputtering [32]. Since the deposited film is amorphous and nonmagnetic, a thermal process is needed to recover ferrimagnetic properties. High temperature values above 600°C are required, either during the deposition process or during a postdeposition annealing, in order to crystallize the material.

It may be possible to use a semiconductor to make a millimeter-wave isolator or circulator instead of a ferrite because its permittivity becomes tensorial if a static magnetic field is applied. This phenomenon is the dual of permeability tensor of ferrites. A 60-GHz circulator was demonstrated experimentally using an n-type indium antimonide (InSb) disk at an operating temperature of 77 K [33].

Isolator structures can also be used as a microwave measurement technique for determination of the complex permeability tensor components of magnetized materials. A microstrip measurement cell based on Fig. 19 was realized and provided measurements up to 6 GHz [34]. The central zone between the strip and lower ground plane is filled with the ferrite, and two different dielectric materials are placed on each side to provide a nonreciprocal effect necessary to extract all the tensor components.

FERRITE-LOADED WAVEGUIDES

RICARDO MARQUÉS
University of Seville
Seville, Spain

Ferrites and their technological applications have been known for a long time. *Magnetite*, the first known magnetic material, is actually a ferrous ferrite. In 1269 Peter Peregrinus gave a detailed description of a compass made with a floating *magnetite* needle, probably a Chinese invention. The Spanish word for the compass, *brújula*, which literally means “small witch,” clearly shows former navigators’ amazement with the mysterious magnetic properties of the lodestone. The first experimental ferrite device in microwave technology was demonstrated in 1949 [1]. Since then, applications of artificial ferrite materials in microwave technology have grown rapidly and have become a mature technology, which has been discussed in many classical textbooks [2–10]. A good historical survey of the beginnings of the microwave ferrite technology can be found in Button [1]. A complete bibliography containing the most relevant contributions in this field during the years that followed can be found in Refs. 11 and 12. Finally, an authorized survey of the most recent advances in microwave ferrite technology in Europe, the United States, and Japan is found in Refs. 13, 14, and 15, respectively.

This article describes the main physical effects due to the propagation and guidance of electromagnetic waves in ferrite-loaded waveguides useful in microwave technology. The linear approach, in which the high-frequency magnetic susceptibility of the ferrite is a function of the internal static magnetic field, will be considered valid. This approach includes the analysis of exchange free electromagnetic waves, as well as magnetostatic waves and other approximations, but not the analysis of spin waves and nonlinear effects, magnetoelastic waves, and other complex interactions.

The choice of units in the analysis of microwave applications of ferrites presents some particularities. SI (International System) units are preferred for most of the electronic and electrical engineers. Nevertheless, cgs (centimeter–gram–second) units are used mainly by researchers in the area of the constitutive electromagnetic properties of ferrites. The usage in this text is a compromise between both alternatives. Since in the linear theory the equations for the static biasing magnetic field are decoupled from the radiofrequency field equations, we will use cgs units in the derivation of the internal magneto-static field, as well as in the expression of the magnetic

permeability in terms of the static bias field \mathbf{H}_0 , measured in oersteds, and the saturation magnetization $4\pi\mathbf{M}_0$, with \mathbf{M}_0 measured in gauss (1 Oe = 4πG). For the electromagnetic RF equations we will use SI units.

1. FUNDAMENTALS OF ELECTRODYNAMICS OF FERRITE MATERIALS

As long as the linear approach remains valid, the problem of finding the radiofrequency electromagnetic field inside a magnetized ferrite can be divided into three steps. First we must find the internal static field \mathbf{H}_0 as a function of the external applied static field \mathbf{H}_{ext} . Then we must obtain the RF magnetic permeability tensor that will be a function of the internal static field. Finally, we must solve the Maxwell equations for the RF field with the appropriate boundary conditions. Note that, in the linear approach, the equations for the static field \mathbf{H}_0 remains independent from the equations for the RF field. The coupling between these two fields occurs only by means of the dependence of the RF magnetic permeability tensor on the static magnetic field.

1.1. The Static Field

As a general statement, the internal static field \mathbf{H}_0 is the solution of the static equations inside the ferrite with the appropriate constitutive relations and boundary conditions. In the simplest case of a saturated isotropic ferrite, the static constitutive relations reduces to $\mathbf{B}_0 = \mathbf{H}_0 + 4\pi\mathbf{M}_s$ (remember that we will use cgs units in this part of the analysis), where \mathbf{M}_s is the magnetization of the ferrite at saturation, which, in isotropic ferrites, will be parallel to both \mathbf{B}_0 and \mathbf{H}_0 . In many cases, the ferrite is placed in a known external static and uniform field \mathbf{H}_{ext} provided by a magnet. In this case the internal static field is the sum of the external field and a demagnetization field H_d created by the ferrite internal magnetization. For ellipsoidal ferrite samples, rods and plates this problem is a classical one and is solved analytically, expressing the demagnetization field as the dot product of the saturation magnetization by a known demagnetization tensor, which depends on the shape and the orientation of the ferrite sample. In particular, for ferrite plates and rods placed in an external magnetic field parallel to the rod axis or the plane of the plate, it is easy to show that $\mathbf{H}_0 = \mathbf{H}_{\text{ext}}$. For ferrite plates placed in an external magnetic field perpendicular to the plate, it is $H_0 = H_{\text{ext}} - 4\pi M_s$.

1.2. The RF Magnetic Permeability Tensor

In this section we will state the more usual RF constitutive relationships for magnetized ferrites. First we will consider the simplest case of an intrinsically isotropic ferrite. In this context *intrinsic isotropy* means that the internal static magnetic field is the only source of anisotropy (induced anisotropy). Thus, after magnetization, the ferrite becomes an uniaxial medium with an RF permeability tensor given by (the z axis is chosen as the direction of

internal magnetization)

$$[\mu] = \mu_0 \begin{pmatrix} [\mu]_t & 0 \\ 0 & \mu_z \end{pmatrix} = \mu_0 \begin{pmatrix} \mu & j\kappa & 0 \\ -j\kappa & \mu & 0 \\ 0 & 0 & \mu_z \end{pmatrix} \quad (1)$$

where μ and κ are in general complex quantities that depend on the internal magnetic field and ferrite magnetization. This particular form of both $[\mu]$ and $[\mu]_t$ ensures the invariance of the permeability tensor after rotations around the z axis, which is the unique symmetry requirement. Notice that, if $\kappa \neq 0$, the tensor is not symmetric. Thus, a magnetized ferrite is a nonreciprocal medium. For lossless ferrites the permeability tensor must be Hermitian, and therefore μ , κ , and μ_z are real numbers.

The theory leading to appropriate expressions for μ , κ , and μ_z , valid for intrinsically isotropic saturated ferrites was first developed by Polder in 1949 from an analysis of the precession of molecular magnetic dipoles in the static internal field. The derivation of such expressions may be found in many textbooks [2–7]. The final expressions are given here for completeness

$$\mu = 1 + \frac{\omega_M \omega_H}{\omega_H^2 - \omega^2} \quad (2)$$

$$\kappa = \frac{\omega \omega_M}{\omega_H^2 - \omega^2} \quad (3)$$

and $\mu_z = 1$, where ω_H is the resonance frequency given by

$$\omega_H = \gamma H_0 \quad (4)$$

and

$$\omega_M = 4\pi\gamma M_s \quad (5)$$

(γ is the gyromagnetic ratio $\gamma = ge/2m_e c$, where g is the Lande factor; $-e$ and m_e , are the electron charge and mass, respectively; and c the speed of light. In most ferrites the magnetization is due to the electron spin alone; therefore $g = 2$ and $\gamma = 1.76 \times 10^7$ rad/s.Oe).

There is also a wide class of useful microwave devices that use ferrites at the remanent magnetization. These are termed *latch* ferrite devices and use ferrite materials with a square hysteresis loop, so that the remanence magnetization M_r is very close to the saturation magnetization. At remanence $H_0 = 0$ and (2) and (3) simplify to $\mu = 1$ and $\kappa = -4\pi M_r / \omega$. Nevertheless, the use of these expressions is subject to some restrictions related to the magnetic losses that may appear at low values of \mathbf{H}_0 [6].

The lossless ferrite is an approximation. Actually, there are many mechanism of losses in ferrites. Some of them, such as the ohmic conductivity, can be introduced in the RF constitutive relationships adding an imaginary part to the dielectric permittivity. Moreover, they are magnetic losses as a consequence of the damping of the magnetic oscillations described by the Polder tensor. The presence of the resonance frequency ω_0 in that tensor clearly suggest the presence of losses in real ferrites, with a maximum at

this frequency. Magnetic losses may be included in the Polder tensor after the transformation [10]

$$\omega_H \rightarrow \omega_H + j\alpha\omega \quad (6)$$

where α is a new parameter that accounts for the losses. The α parameter is often substituted by the *resonance linewidth* ΔH , which is the width of the resonance curves for the real part of κ and $\mu - 1$ plotted against H_0 . The resonance linewidth is related to α by $\Delta H = 2\alpha\omega_H/\gamma$. The magnitude of magnetic losses varies widely in ferrites used for microwave applications. The resonance linewidth ranges from about 0.1 Oe for single YIG crystals to several hundreds for polycrystalline ferrite materials. In the first case we can obtain meaningful results neglecting magnetic losses, but this approximation may lead to significant misleadings in other cases.

Until now we have considered only ferrites with intrinsic isotropy. This assumption is not realistic in all cases because ferrites are crystalline materials with complex internal structure. Magnetocrystalline intrinsic anisotropy usually induces in the crystal easy and hard directions of magnetization (i.e., directions on which the ferrite can—or cannot—be magnetized to saturation by a small applied magnetic field). The modifications of the Polder tensor induced by the magnetocrystalline anisotropy are complex and will not be analyzed here. The reader interested in this topic is referred to any of the textbooks that develop such expressions [e.g., 8].

The most important magnetocrystalline effect occurs in uniaxial hexagonal ferrites. In these crystals, the resonance is pushed to a extremely high frequency, even when the applied static field is small. Thus, hexagonal ferrites found most of its practical applications at millimeter wave frequencies.

1.3. The Radiofrequency Field

The RF field in a ferrite, characterized by the tensor permeability (1), is obtained by solving the Maxwell equations with the appropriate boundary conditions. Assuming a time-harmonic dependence of the kind $\exp j\omega t$, as well as the vanishing of current sources, these equations will read

$$\nabla \times \mathbf{E} = -j\omega[\mu] \cdot \mathbf{H} \quad (7)$$

$$\nabla \times \mathbf{H} = j\omega\epsilon\mathbf{E} \quad (8)$$

where the dielectric permittivity ϵ will be in general a complex quantity, in order to incorporate dielectric and ohmic losses.

1.3.1. Uniform Plane Waves with Longitudinal Magnetization. Although the aim of this article is to analyze the propagation along waveguides, the analysis of the propagation in an unbounded ferrite medium will provide a useful introduction to some relevant aspects of the propagation in waveguides. We will first suppose a uniform plane wave with a spacetime dependence of the kind $\exp j(-kz + \omega t)$ (this factor will be suppressed in the following

text) and an internal static magnetic field directed along the z axis: $\mathbf{H}_0 = H_0 \mathbf{a}_z$.

The analysis of (7) and (8) with these restrictions leads to two TEM-wave solutions with right-handed circular polarization (RCP) and left-handed circular polarization (LCP) referred to the static field \mathbf{H}_0 orientation. These two waves have different phase constants given by

$$k^\pm = \omega \sqrt{\epsilon \mu_{\text{eff}}^\pm} \tag{9}$$

where the plus sign stands for the RCP polarization and the minus sign, for the LCP polarization and μ_{eff} is an effective magnetic permeability given by the two eigenvalues of $[\mu]$:

$$\mu_{\text{eff}}^\pm = \mu_0 (\mu \pm \kappa) \tag{10}$$

Note that the hand of polarization has been referred to the internal static magnetic field orientation, regardless of the direction of propagation. Therefore, if one of these waves is fully reflected (e.g., by a perfect conducting plate perpendicular to propagation), the hand of the circular polarization, as well as the effective magnetic permeability, will remain unchanged, giving rise to a stationary wave.

The values of k^\pm for an isotropic lossless ferrite with RCP and LCP polarizations are shown in Fig. 1 for a ferrite magnetized under the usual technological condition of $H_0 < 4\pi M_0$. A forbidden frequency range for RCP waves, in which k^+ becomes imaginary, is given by

$$\omega_H < \omega < \omega_H + \omega_M \tag{11}$$

If magnetic losses are considered, the transformation (6) must be introduced in the expressions for μ_{eff}^\pm . This leads to two complex propagation constants, that of the RCP wave having a typical resonant behavior with high resonance losses (see Fig. 1).

The most important effect related to plane-wave propagation in a longitudinally magnetized ferrite is the non-

Figure 1. Normalized complex propagation constant for the RCP wave (10) in a lossy ferrite with $\omega_M = 1.5 \omega_H$ and $\gamma \Delta H = 0.1 \omega_H$ (solid lines). The normalized phase constants for the two RCP and LCP waves in a lossless ferrite with $\omega_M = 1.5 \omega_H$ and $\gamma \Delta H = 0$ are also shown (dashed lines).

reciprocal Faraday rotation of the plane of polarization of a linearly polarized wave. A linearly polarized wave is not a solution of (7) and (8), but it can be obtained by adding two contrarotating RCP and LCP waves of equal amplitude. Since the phase constants of these two waves are not equal, the result is a rotation of the plane of polarization of the linearly polarized wave. The rotation angle after the wave has advanced a length Δz is given by

$$\theta = \frac{1}{2} (k^- - k^+) \Delta z \tag{12}$$

When a linearly polarized wave is reflected backward, the hand of rotation of the polarization plane remains unchanged. Thus, the planes of polarization of the incident and the reflected waves will be different at a given distance from the plane of reflection. Therefore, the Faraday rotation in ferrites is nonreciprocal. If losses are considered, both the RCP and the LCP waves in which the linearly polarized wave splits have different attenuation constants. This leads to an unequal change in the amplitudes of the RCP and LCP waves, which causes Faraday ellipticity of the original linearly polarized wave. Detailed treatments of Faraday rotation and ellipticity may be found in the literature cited in the introduction [1–15].

1.3.2. Transverse Magnetization. We will now suppose an uniform plane wave with a spacetime dependence of the kind $\exp j(-kx + \omega t)$ (this factor will be suppressed in the following text) and an internal static magnetic field directed along the z axis: $\mathbf{H}_0 = H_0 \mathbf{a}_z$. The solution to (7) and (8) with these restrictions leads two independent uniform plane waves with the \mathbf{E} field linearly polarized. One of them is a TEM wave with the magnetic field parallel to \mathbf{H}_0 . Thus, there is no interaction between the RF field and the electronic spins, and the effective magnetic permeability is $\mu_{\text{eff}} = \mu_0 \mu_z$. This solution is called the ordinary wave, with phase constant $k^2 = \omega \sqrt{\epsilon \mu_0 \mu_z}$. There is also an extraordinary wave, whose propagation constant is still given by (9), but with μ_{eff} given by

$$\mu_{\text{eff}} = \mu_0 \frac{\mu^2 - \kappa^2}{\mu} \tag{13}$$

The extraordinary wave is a TE wave with the electric field polarized parallel to \mathbf{H}_0 and the magnetic field elliptically polarized in the plane perpendicular to \mathbf{H}_0 . The values of the propagation constants of the extraordinary waves for the lossless and the lossy ferrites of Fig. 1 are shown in Fig. 2. For the lossless extraordinary wave there is a frequency-forbidden range, in which k becomes imaginary, defined by

$$\sqrt{\omega_H(\omega_H + \omega_M)} < \omega < \omega_H + \omega_M \tag{14}$$

The presence of an ordinary wave and an extraordinary wave with orthogonal polarization, recalls the birefringence of uniaxial crystals. This birefringence can be used

Figure 2. Normalized phase and complex propagation constants for the extraordinary waves in the infinite lossless (dashed lines) and lossy (solid lines) ferrites of Fig. 1 with transverse magnetization.

in the design of microwave devices such as half- and quarter-wave plates and polarizers.

1.3.3. Magnetization at Any Angle. In this case, the phase constant can still be written as in (9), with an effective magnetic permeability that depends on the angle θ_k between the static magnetization and the wave phase velocity. The final expression for this effective permeability is [10]

$$\mu_{\text{eff}}(\theta_k) = \mu_0 \frac{2 + \left(\frac{\mu_t}{\mu_z} - 1\right) \sin^2 \theta_k \pm \sqrt{\left(\frac{\mu_t}{\mu_z} - 1\right)^2 \sin^4 \theta_k + 4 \frac{\kappa^2}{\mu^2} \cos^2 \theta_k}}{2 \left(\frac{\sin^2 \theta_k}{\mu_z} + \frac{\cos^2 \theta_k}{\mu} \right)} \quad (15)$$

with $\mu_t = (\mu^2 - \kappa^2)/\mu$. For a fixed frequency, a plot of k , θ_k in polar coordinates, with $k = \omega \sqrt{\epsilon \mu_{\text{eff}}}$, gives the phase constants corresponding to the two solutions of (15). These curves can also be interpreted as isofrequency curves of the dispersion equation $\omega = \omega(k, \theta_k)$ in the k , θ_k plane. Thus, the group velocity $\mathbf{v}_g = \nabla_k \omega$ will be perpendicular to these curves at each angle θ_k . For an arbitrary θ_k , the direction of the optical ray will not be parallel to the direction of propagation of the wavefronts.

1.3.4. Nonreciprocity. One of the basic theorems of electromagnetism is the Lorentz reciprocity theorem. It applies to any linear and causal medium whose constitutive relationships can be described by symmetric frequency-dependent dielectric permittivity and/or magnetic susceptibility tensors. As was already mentioned, since the tensor magnetic susceptibility (1) is not symmetric, this is not the case for ferrites. In fact, many of the practical applications of ferrites in microwave technology, such as circulators or isolators, arise from this nonreciprocal

behavior. However, it is still possible to reformulate the reciprocity theorem in a form that is applicable to ferrite media. Following Harrington [16] and McIsaac [17], we will start from the Onsager relation, which states that any tensor macroscopic susceptibility of a causal and linear medium must be equal to the medium's transpose after reversal in time of all the physical relevant quantities. For an externally magnetized ferrite, taking into account that the static bias field changes of sign after reversal in time, we conclude that the tensor magnetic susceptibility of a ferrite (1) must equal its transpose after the change of sign of the static biasing field. From this conclusion, we can directly state the reciprocity theorem for ferrite media

$$\iint (\mathbf{E} \times \mathbf{H}' - \mathbf{E}' \times \mathbf{H}) \cdot d\mathbf{S} = \iiint (\mathbf{E}' \cdot \mathbf{J} - \mathbf{E} \times \mathbf{J}') dV \quad (16)$$

where the physical quantities must be reinterpreted as follows: \mathbf{E} , \mathbf{H} and \mathbf{E}' , \mathbf{H}' are two independent electromagnetic field configurations produced by source current densities \mathbf{J} and \mathbf{J}' respectively, at frequency ω in the same ferrite medium, except that the medium in which the prime quantities are defined has a reverse static magnetization: $\mathbf{H}'_0 = -\mathbf{H}_0$. The surface integrals on the left side of (16) are over any surface containing the source current densities included in the volume integral on the right side. This generalized reciprocity theorem is useful in the analysis of mode orthogonality in ferrite-loaded waveguides, as well as in the analysis of ferrite-loaded waveguide junctions.

2. MICROWAVE PROPAGATION IN FERRITE-LOADED WAVEGUIDES

In the preceding section microwave propagation in unbounded ferrite media was analyzed. Many of the studied effects, such as Faraday rotation and nonreciprocity, also appear when the RF field propagates along waveguides. Moreover, the microwave propagation along ferrite-loaded waveguides presents new useful effects, such as unidirectionality and field displacement, complex and backward modes, slow magnetostatic waves, and circulation.

In the following paragraphs we will choose the z axis as the waveguide axis, and a spacetime dependence of the kind $\exp j(\omega t - kz)$ will be supposed. The mode phase constant k will be in general a complex number $k = \beta - j\alpha$. Both β and α will be chosen real without loss of generality, and the factor $\exp j(\omega t - kz)$ will be suppressed.

2.1. Unidirectional and Bidirectional Modes

A mode with phase constant k that does not have a symmetric pair with the opposite phase constant $-k$ is called *unidirectional*. All lossless and reciprocal waveguides are bidirectional. This is not the case for ferrite loaded waveguides, because ferrites are nonreciprocal media that are not invariant after time reversal. The presence of unidirectional modes of propagation in ferrite-loaded waveguides is useful in many microwave devices, such as isolators and nonreciprocal phase shifters. However, many ferrite-loaded waveguides, which remain invariant

after some symmetry transformations, are bidirectional; specifically, unidirectional modes cannot propagate along these waveguides. McIsaac [18] and, more recently, Dmitriyev [19] have investigated these symmetries. McIsaac [18] concludes that bidirectionality is ensured if the waveguide remains the same after one or more of the following transformations:

- Reflection in a plane perpendicular to z axis
- Rotation by 180° about an axis perpendicular to the z axis
- Inversion at any point

In performing these transformations, the pseudovectorial nature of the static bias field \mathbf{H}_0 has to be taken into account (i.e., \mathbf{H}_0 remains the same after spatial inversion and after reflection in a perpendicular plane, but changes sign after a reflection in a parallel plane). In particular, any ferrite-loaded waveguide with longitudinal magnetization must be bidirectional, because this waveguide remains unchanged after reflection in a plane perpendicular to the z axis.

Bidirectionality does not imply that all the characteristics of the modes remain unchanged when the direction of propagation is reversed. For instance, the energy distribution and/or the polarization of a pair of bidirectional modes having the same but opposite phase constants may be different. Moreover, although all modes in bidirectional ferrite-loaded waveguides must be bidirectional, not all the modes in nonbidirectional ferrite-loaded waveguides are unidirectional; some of them, having the appropriate polarization, may be bidirectional.

2.2. Complex and Backward Modes

Complex modes in inhomogeneously filled lossless waveguides were first reported by Tai in 1960 and Carri coats in 1965 [20]. Complex modes in lossless isotropic waveguides are characterized by a complex propagation constant $k = \pm\beta \pm j\alpha$ and appear in groups of four solutions, in which all the possible combination of signs are allowed. Carri coats also shown that, for a single complex mode, power flows in opposite directions along the different media filling the waveguide, giving a zero net power flux. Therefore, complex modes in lossless waveguides are reactive modes. Complex modes have proved to be a very important part of the spectra of ferrite-loaded waveguides [20] (in fact, they were first reported for ferrite-loaded waveguides by Tai). In particular, all the unidirectional and reactive modes in ferrite-loaded waveguides must be complex [21,22].

Complex modes are closely related to *backward modes* (i.e., modes with negative group velocity). In fact, a pair of complex modes in lossless waveguides usually changes to a pair of propagating *forward* and *backward* modes when frequency varies [20]. Backward modes in the spectra of ferrite loaded waveguides, mainly in the *magnetostatic wave* region, has been widely analyzed (see, e.g., Ref. 8).

2.3. Mode Orthogonality

Mode orthogonality in ferrite-loaded waveguides was analyzed in Ref. 23. Applying the generalized reciprocity

theorem (16) to two modes $bfe_m, \mathbf{h}_m(x, y) \exp j(\omega t - k_m z)$ and $bfe'_n, \mathbf{h}'_n(x, y) \exp j(\omega t - k'_n z)$ of the actual waveguide and the *complementary* waveguide (the *complementary waveguide* is defined as the original one with the static magnetic field reversed), the following relation is obtained

$$(k'_n + k_m) \iint (\mathbf{e}'_n \times \mathbf{h}_m - \mathbf{e}_m \times \mathbf{h}'_n) \cdot \mathbf{u}_z dx dy = 0 \quad (17)$$

where the integral is over the cross section of the waveguide. This equation may be considered as a general orthogonality relation since the integral must be zero unless $k_m = k'_n$. This relation simplifies for most practical situations in which the static magnetic field is either parallel or perpendicular to the waveguide axis. The explicit orthogonality relationships for these particular but important magnetizations can be found in Ref. 23.

2.4. Field Displacement Effects

It was pointed out earlier that electromagnetic wave propagation in ferrites at an arbitrary angle with respect to the magnetizing field usually implies that the optical rays (and the power flux) are not parallel to the phase velocity. However, in a nonradiating waveguide, both power flux and wave propagation are forced to be parallel to the waveguide axis. Thus, this effect cannot be present in nonradiating waveguides. Instead, this tendency of power to flow in a direction different from the wave propagation may cause strongly unsymmetric accumulations of electromagnetic energy across the waveguide section. This nonreciprocal field displacement effect is used in the design of microwave isolators and phase shifters.

2.5. The Magnetostatic Approximation

Near the resonances $\mu_{\text{eff}} \rightarrow \infty$ and the effect of the Maxwell displacement current may be neglected with regard to the Faraday induction effects. This leads to the magnetostatic approximation. Taking into account that $\nabla \cdot \mathbf{B} = 0$, a magnetostatic potential $\mathbf{H} = -\nabla\psi$ is defined, which must satisfy

$$\nabla \cdot ([\mu] \cdot \nabla\psi) = 0 \quad (18)$$

(in ferrite-loaded waveguides, the nabla operator is replaced by $\nabla \rightarrow \nabla_t - jk\mathbf{u}_z$). The solutions to (18), with the appropriate boundary conditions, are the magnetostatic modes of the waveguide. Magnetostatic waves in ferrite-loaded waveguides, have been analyzed extensively [8]. The main applications of magnetostatic waves in microwave technology arise from its small wavelength. This result in broad applications in miniature controllable devices, such as delay lines, filters, power limiters, and signal-to-noise enhancers [24].

2.6. Basic Properties of Ferrite-Loaded Waveguide Junctions

A waveguide junction is characterized by its scattering matrix S_{ij} . It is a well-known fact that if the materials filling the junction are reciprocal, the scattering matrix must be symmetric. If the junction is nonreciprocal, this

statement must be modified as a consequence of the reformulation of the reciprocity theorem (16). This modification leads to the following relations between the scattering matrix elements of a ferrite-loaded junction and its complementary (i.e., the junction with the biasing static magnetic field reversed):

$$S_{ij}(\omega, \mathbf{H}_0) = S_{ji}(\omega, -\mathbf{H}_0) \quad (19)$$

If the junction is also lossless, the scattering matrix must be unitary ($S_{ij}S_{kj}^* = \delta_{ik}$, where the rule of summation over all the repeated subindex has been used). Other symmetries of the scattering matrix may be deduced from the spatial symmetries of the junction (including the bias field) [19].

The use of the scattering matrix symmetry properties is useful in the design of many microwave devices, such as isolators, phase shifters, and circulators. The *Y circulator* is perhaps the most useful and best known nonreciprocal junction. An *Y circulator* is a symmetric three-port junction with some specific properties. A symmetric three-port junction must have $S_{1,1} = S_{2,2} = S_{3,3}$, $S_{1,2} = S_{2,3} = S_{3,1}$, and $S_{2,1} = S_{1,3} = S_{3,2}$. These relations are fulfilled by any junction having a rotation symmetry axis of third order and magnetized along this axis. The circuit theory of three- and *N*-port circulators may be found in Ref. 6 and other textbooks. It can be shown that if a lossless, nonreciprocal, and symmetric three-port waveguide junction is matched (i.e., $S_{1,1} = 0$), it is also an ideal *Y circulator* [i.e., $S_{1,2} = 1$ or 0 and $S_{1,3} = 0$ or 1]. If the magnetization of a nonreciprocal three-port *Y circulator* is reversed, the direction of circulation is also reversed, as a consequence of (19).

3. FERRITE-LOADED WAVEGUIDES FOR PRACTICAL APPLICATIONS

In this section we will describe the most widely used ferrite-loaded waveguides. There are many classical textbooks and papers [2,3,5–7], and more recent ones [9,25] that describe these waveguides, as well as the most useful microwave devices that may be designed using them. The reader may use these and other texts to broaden the information contained in this section.

3.1. Circular Waveguides with Longitudinal Magnetization

It is well known from the theory of hollow waveguides that the fundamental mode of the empty circular waveguide is the $TE_{1,1}$ mode, which is a double degenerate mode with two perpendicular polarizations in the waveguide cross section. This mode has a field distribution that is almost TEM in the vicinity of the waveguide axis. Thus, if a ferrite rod with longitudinal magnetization is placed at the center of the waveguide (see Fig. 3), the two orthogonal and degenerate $TE_{1,1}$ fundamental modes will interact as a consequence of the Faraday rotation effect, giving rise to two nondegenerate circularly polarized RCP and LCP modes (with the hand of polarization defined with respect to the static bias field orientation). These modes can be approximated by the same RCP and LCP modes of a cir-

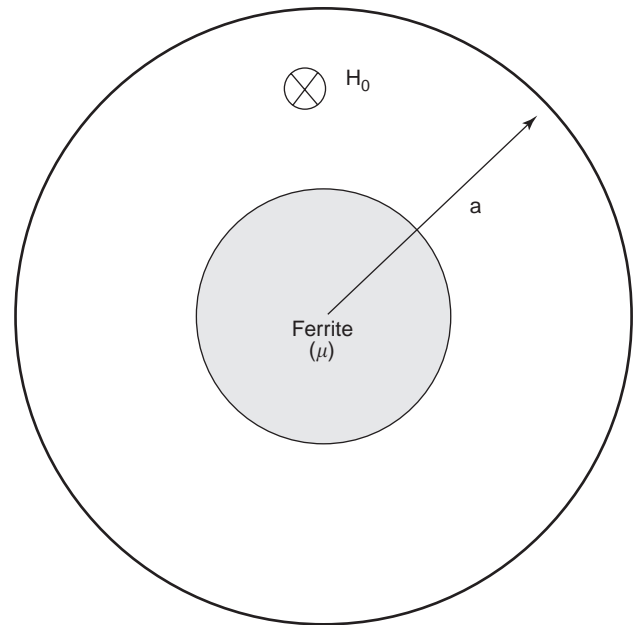

Figure 3. Cylindrical waveguide with an inner centered ferrite rod of longitudinal magnetization.

cular waveguide with an inner isotropic rod with a scalar magnetic susceptibility given by (10). In the same way, if a linearly polarized wave with linear polarization enters the ferrite-loaded waveguide, this wave will experience a Faraday rotation by an angle given approximately by (12), where k^+ and k^- are now the phase constants of the RCP and LCP ferrite-loaded waveguide modes.

The phase constants, as well as the mode fields of the two nondegenerate RCP and LCP ferrite-loaded waveguide modes, were obtained analytically by Waldron in 1958. Analytical solutions, not only for the cylindrical waveguide with a ferrite rod but also for many other related structures, such as cylindrical waveguides loaded with ferrite and dielectric tubes, may also be found in the literature [4]. Modes in this kind of ferrite-loaded waveguide are not TE nor TM, but become TE and TM at cutoff [4], these modes are termed *HE* and *EH* depending on whether the magnetic H_z or the electric E_z field dominates. At cutoff, *HE* modes become TE and *EH* modes become TM.

Ferrite-loaded circular waveguides with longitudinal magnetization are extensively used in Faraday rotation devices, based on the aforementioned rotation of the polarization plane of a linearly polarized wave. The most known Faraday rotation device is the four-port circulator, described in many textbooks. Faraday rotation may be also used in the design of magnetically tuned variable attenuators, isolators and phase shifters (see, e.g., Ref. 9 and references cited therein). In the early years of microwave ferrite technology, much effort was devoted to develop Faraday rotation circulators and other microwave devices with cylindrical geometry. In the following years, however, the *Y*-junction circulators, as well as phase shifters and attenuators in rectangular and/or planar technology, were found to be smaller, simpler, and more appropriate for

Figure 4. (a) Plot of the intensities of the magnetic field components $|H_x|$ and $|H_z|$ of the fundamental $TE_{1,0}$ mode in a rectangular hollow waveguide (frequency 9 GHz, $a = 23$ mm; dashed lines—planes of circular polarization); (b) rectangular waveguide loaded with a transversely magnetized ferrite slab at a plane of circular polarization of the RF magnetic field.

most applications; the research effort then began to focus on these devices.

3.2. E-Plane Transversely Magnetized Ferrite-Loaded Rectangular Waveguides

Figure 4a shows the variation of the magnetic field components H_x and H_z of the fundamental $TE_{1,0}$ mode in a hollow rectangular waveguide. The magnetic field is circularly polarized around the y axis where $|H_z| = |H_x|$. This condition occurs at two symmetric positions, at a distance d of the rectangular sidewalls, given by

$$d = \frac{a}{\pi} \cot^{-1} \left(\sqrt{\frac{4a^2}{\lambda_0^2} - 1} \right) \quad (20)$$

If an E -plane ferrite slab biased with a static magnetic field directed along the y axis is placed at a distance d of one of the lateral sidewalls (see Fig. 4b), the wave propagating in the positive (negative) direction along the z axis is right (left)-handed-polarized with respect to the static bias field. Thus we can expect that the forward (backward) wave will see the effective magnetic permeability of the slab $\mu_{\text{eff}}^+(\mu_{\text{eff}}^-)$, given by (10). Therefore, wave propagation will be unidirectional, with different phase constants for opposite directions of propagation. Moreover, since the dependence of μ_{eff}^+ with \mathbf{H}_0 is much stronger than those of μ_{eff}^- , the forward wave will be much more affected by variations in the intensity of \mathbf{H}_0 than the backward one. If the bias field is chosen in a region in which μ_{eff}^+ is positive and presents a strong dependence on the bias field intensity, the waveguide may be used as a nonreciprocal phase shifter. If the bias field is chosen at the resonance condition ($\omega_H = \omega$), the forward wave will see a resonant magnetic permeability and will experience strong attenuation due to the resonance losses. Then, the waveguide may be used as a resonance isolator. If the bias field is chosen at the antiresonance condition $\omega_H = \omega - \omega_M$, the forward wave will see a perfect diamagnet with $\mu_{\text{eff}}^+ = 0$, which imposes perfect diamagnetic boundary conditions at both slab sides and, therefore, zero tangential electric RF field at these boundaries. If an absorber is located at the inner boundary of the slab, it is expected that the forward wave will not be attenuated whereas the backward wave will be strongly attenuated. This waveguide may thus be used as a field displacement isolator.

The wave propagation characteristics along this waveguide may also be found analytically. The first published

results on this subject are due to of Kales (1953). Gardiol [26] gave a general method for computing the propagation characteristics of rectangular waveguides filled with an arbitrary number of anisotropic slabs, including ferrite slabs, making use of the transverse transmission matrix method. Referred to the geometry of Fig. 4b, the transverse transmission matrix of the i region $[\mathbf{T}_i]$ is defined as the matrix relating the tangential fields, E_y and H_z , at both sides of the i th region of the waveguide. In a notation that becomes apparent, we can write

$$\begin{aligned} \begin{pmatrix} E_y \\ H_z \end{pmatrix}_{x=a} &= [\mathbf{T}_3] \cdot [\mathbf{T}_2] \cdot [\mathbf{T}_1] \cdot \begin{pmatrix} E_y \\ H_z \end{pmatrix}_{x=0} \\ &= \begin{pmatrix} t_{1,1} & t_{1,2} \\ t_{2,1} & t_{2,2} \end{pmatrix} \cdot \begin{pmatrix} E_y \\ H_z \end{pmatrix}_{x=0} \end{aligned} \quad (21)$$

Since the lateral sidewalls are assumed to be perfect conducting walls, the tangential electric field must vanish at these boundaries. This implies that $t_{1,2} = 0$, which may be considered an implicit equation for the phase constant. This method may be applied to rectangular waveguides with any number of E -plane transversely magnetized ferrite slabs and/or lossy dielectric slabs, thus providing a general method for the analysis of isolators and phase shifters.

The nonreciprocal isolation and phase variation effects of the E -plane ferrite-loaded waveguide of Fig. 4b may be increased by placing a symmetric ferrite slab with reverse magnetization at the remaining plane of circular polarization of the $TE_{1,0}$ mode. Since at this plane the circular polarization of the $TE_{1,0}$ wave has opposite handedness, the effect of the new ferrite slab adds to the effect of the former one. A variation of this two-slab ferrite-loaded waveguide is the latch ferrite toroid in rectangular waveguide (Fig. 5a) proposed by Treuhaft (1958) [9] for phase-shifting applications. The main advantage of this configuration is that the permanent magnet is substituted by a ferrite toroid magnetized at remanence by an electric current pulse, driven by a single wire at the center of the waveguide (this wire is perpendicular to the RF electric field and has a negligible effect on microwave propagation). This structure is also suitable for rapid switching between the two opposite nonreciprocal states of the waveguide. In the analysis of this structure, the upper and lower branches of the ferrite toroid, which do not have substantial effect on phase change, may be neglected

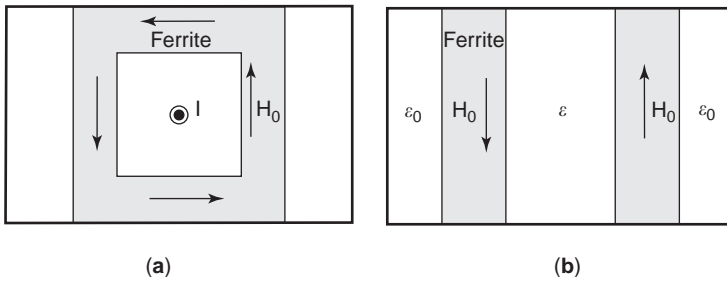

Figure 5. (a) Rectangular waveguide loaded with a latch ferrite toroid; (b) rectangular waveguide loaded with two oppositely magnetized ferrite slabs at the planes of circular polarization of the RF magnetic field.

leading thus to the simpler structure of Fig. 5b. Gardiol [27] gives expressions that transform the geometry of Fig. 5a into the geometry of Fig. 5b with a gain in accuracy. An alternative for reducing the unwanted effects of the upper and lower branches of the ferrite toroid is to replace this into a rectangular grooved waveguide, as proposed in Ref. 28. If nonreciprocity is not desired, a reciprocal phase shifter may still be obtained magnetizing both slabs of Fig. 5b with parallel and equal static magnetic fields. This structure is symmetric after inversion at a point in the waveguide axis and, therefore, is bidirectional.

3.3. Other Useful Cylindrical and Rectangular Ferrite-Loaded Waveguides

Although the circular and rectangular geometries seem to be the natural geometries for longitudinal and transverse magnetization, respectively, there are also some useful devices that use transversely magnetized circular waveguides and longitudinally magnetized rectangular waveguides. Field displacement effects similar to those reported earlier for rectangular waveguides may be achieved in cylindrical waveguides loaded with latch ferrite tubes magnetized in the azimuthal direction. The dual-mode ferrite phase shifters include latch and transversely magnetized circular waveguide sections [29]. A widely used ferrite-loaded rectangular waveguide with longitudinal magnetization is the Reggia–Spencer phase shifter [30], which consists of a ferrite rod with longitudinal magnetization placed at the center of a rectangular waveguide. If the dimensions of the hollow waveguide allows for the propagation of only the first $TE_{1,0}$ mode, Faraday rotation cannot take place. Instead, a strong variation of the wave phase constant with the applied static magnetic field occurs. Like all waveguides having longitudinal magnetization, the Reggia–Spencer phase shifter is bidirectional; thus the phase change is reciprocal.

4. FERRITE-LOADED MICROSTRIPS, SLOTLINES, AND FINLINES

After the mid-1960s, when planar microwave integrated circuits became a viable technology, ferrite-loaded microstrips and slotlines began to be investigated as an alternative to traditional ferrite-loaded waveguides for the design of reciprocal and nonreciprocal phase shifters [31], isolators [32], and other useful devices, which have been summarized in some classical review papers [25] and textbooks [9]. Later, when finlines emerged as a useful

alternative for planar technology in millimeter-wave circuits, ferrite-loaded finlines [33,34] also began to be investigated.

4.1. The Ferrite-Loaded Parallel-Plate Waveguide

Before considering more complicated structures, it will be useful to analyze the simpler parallel-plate waveguide loaded with ferrite slabs (Fig. 6). It has been shown [25] that for magnetization parallel to propagation, these waveguides supports a quasi-TEM mode and that the ferrite layers may be characterized by an effective permeability given by (13). For magnetization perpendicular to both the direction of propagation and the plane of the waveguide, the ferrite layers may be again characterized by the scalar effective permeability (13), but the field is no longer TEM because of the birefringence effects. Finally, for magnetization perpendicular to propagation and parallel to the waveguide plane, there is almost no interaction between the static magnetic field and the RF field and the ferrite layers are characterized by the scalar permeability μ_z . Near the forbidden frequency range, the analysis becomes more involved, due to the apparition of magnetostatic modes. Magnetostatic modes in parallel-plate ferrite-loaded waveguides have been extensively analyzed (see, e.g., Ref. 8 and references cited therein).

4.2. Ferrite-Loaded Microstrip Lines

Microstrip line (see Fig. 7a) is the most widely used waveguide in planar technology. Although exact methods of analysis are now available, considerable insight into the physical behavior of ferrite-loaded microstrip lines may be obtained from the well-known parallel-plate microstrip

Figure 6. Parallel-plate waveguide filled by a multilayer medium including one or more ferrite slabs [$\epsilon(y)$ and $[\mu](y)$ are piecewise constant functions of y].

Figure 7. (a) Microstrip line on a multilayer ferrite-loaded substrate [as in Fig. 6, $\varepsilon(y)$ and $[\mu](y)$ are piecewise constant functions of y]; (b) parallel-plate waveguide model for the microstrip line of (a).

model (see Fig. 7b). In this model, the microstrip line is substituted by a section of parallel-plate waveguide between two magnetic walls. This section is slightly wider than the microstrip, in order to incorporate the effects of the fringing fields. Nevertheless, if, at the operating frequency, magnetostatic modes could be excited in the housing surface waveguide at both sides of the microstrip (see Fig. 7a), they could actually be excited by the microstrip, which would then become a magnetostatic wave transducer [8,24].

4.2.1. Microstrip with Longitudinal Magnetization. Using the model of Fig. 7b and the results reported earlier, the qualitative behavior of these kinds of microstrips may be investigated by means of the analysis of a section of parallel-plate waveguide loaded with one or more slabs of effective magnetic permeability given by (13), bounded by two perfect magnetic walls. This model provides a quasi-TEM and bidirectional fundamental mode with a phase constant that is a function of the biasing magnetic field. The same qualitative results are provided by more accurate quasi-TEM analyses of the actual microstrip line, using either the effective permeability (13) [25], the tensor magnetic permeability (1) [35,36], or by a full-wave analysis, discussed later in this article. The main application of microstrip lines with longitudinal magnetization is in phase shifting by meanderlines, a design that minimize the size of the device [31]. The phase variation with the applied magnetic field may be increased if strongly coupled quarter-wave meanderline sections are used. These structures provides strong nonreciprocal phase shifting [31] were nonreciprocity is due to the coupling effects.

4.2.2. Transversely Magnetized Microstrip Lines. We will consider the two orthogonal magnetizations, perpendicular and parallel to the ground plane. For the second one there is no expected interaction between the static bias field and the RF field in the parallel plate waveguide model of Fig. 7b because of the RF magnetic field parallel to the static bias field. In fact, only a slightly nonreciprocal phase shift may be observed, due to the fringing field near the microstrip edges.

Of much more interest is the microstrip line with magnetization perpendicular to the ground plane. Considering anew the parallel plate model of Fig. 7b, the ferrite slab can be characterized by a layer of effective magnetic permeability (13). However it must be realized that, for this magnetization, the RF field is not quasi-TEM, due to the

birefringence effects in the ferrite layer. Hines [32] showed that in a semiinfinite ferrite-filled parallel-plate waveguide, with a perpendicular magnetic wall at its end, and magnetized along the direction perpendicular to the ground planes, there is a TEM mode propagating along the waveguide and attenuating in the direction perpendicular to the magnetic wall. The phase constant of this mode is given by $\mathbf{k} = k_0(j\sqrt{\varepsilon_r}\mu\mathbf{a}_z - (\kappa/\mu)\sqrt{\varepsilon_r}\mu\mathbf{a}_x)$ [note that $\mathbf{k} \cdot \mathbf{k} = k_0^2\varepsilon_r(\mu_{\text{eff}}/\mu_0)$; that is, \mathbf{k} is the same as for a nonuniform plane wave in a slab of effective permeability μ_{eff}]. Hines also showed that this mode is unidirectional. The TEM mode described by Hines fulfills all the requirements imposed by the lateral magnetic walls of Fig. 7b for sufficiently wide strips. Moreover, since the mode in the semiinfinite parallel-plate waveguide was unidirectional, the microstrip mode will present a strong field displacement from one to another strip edge when the direction of propagation is reversed.

Although the analysis above has focused on ferrite-filled parallel-plate waveguides, the same qualitative results also apply to multilayered ferrite-loaded parallel-plate waveguides and microstrips. Hines modes are usually termed *edge modes* in microstrips because the RF field is concentrated mainly in the vicinity of a microstrip edge. Edge modes in microstrip are useful in the design of wideband edge-mode isolators and nonreciprocal edge-mode phase shifters [32,38,39], which use the same principle as do field displacement isolators and phase shifters. Analysis of such structures is usually performed using approximate models. More recently, spectral-domain analysis has been successfully applied to analyze edge-mode isolators without approximations [40].

4.3. Ferrite-Loaded Slotlines and Finlines

Slotlines (Fig. 8a) and coplanar waveguides are an useful alternative to microstrip in the design of microwave integrated circuits. In millimeter-wave technology, finlines in rectangular waveguides (Fig. 8b) also represent a good alternative for integration without radiation losses. By adding ferrite layers to these waveguides, many of the effects described for ferrite-loaded microstrips may be achieved. Since the RF magnetic field in slotlines and finlines is concentrated mainly in the slot and directed perpendicular to the air interface, it is expected that the strongest effects for transversely magnetized slotlines and finlines will occur for magnetization parallel to the fins. These structures have been extensively analyzed for the design of field displacement isolators and phase shifters [25]. A

Figure 8. (a) Slotline on a multilayer ferrite-loaded substrate; (b) finline with a multilayer ferrite-loaded substrate. As in Figs. 6 and 7, $\epsilon(y)$ and $\mu(y)$ are piecewise constant functions of y .

millimeter-wave field displacement finline isolator has been proposed [33]. Transversely magnetized slotlines and finlines for nonreciprocal phase-shifting applications have also been analyzed [37,42–44]. Applications of finlines with longitudinal magnetization have been also investigated [34].

4.4. Methods of Analysis of Ferrite-Loaded Quasiplanar Layered Structures

With a few exceptions, quasi-TEM analysis usually provide sufficiently accurate results for the analysis of conventional microstrip and coplanar or slotlines. However, this analysis is seldom suitable for these structures when they are ferrite-loaded. In fact, quasi-TEM modes are by definition bidirectional, and therefore the quasi-TEM analysis cannot account for many of the most relevant physical effects in ferrite-loaded transmission lines. Quasi-TEM analysis in its standard form is restricted to longitudinally magnetized lines [35,36]. More recently, however, some attempts have been made in order to generalize this analysis to transversely magnetized structures [41]. Nevertheless, in general, planar and quasiplanar ferrite-loaded transmission lines require full-wave analysis.

With respect to numerical techniques, spectral-domain analysis (SDA) is by far the most widely used technique for the analysis of ferrite-loaded strip and/or slot structures [35–37,40,43–45]. The basic fundamentals of SDA may be found in many textbooks, such as that of Mirshekar-Syahkal [46]. SDA is specially well suited for the analysis of microstrips and/or slot- and finlines on planar single- or multilayer substrates, because of the translational symmetry of these substrates. Since the SDA applied to microstrip or microslot structures is adequately described in Ref. 46 and other textbooks, we only briefly describe here the main specific characteristics of the SDA when it is applied to ferrite-loaded microstrip and/or microslot waveguides. The main difficulty in the application of the SDA to ferrite-loaded microstrip or microslot on infinite planar substrates is in the determination of the spectral-domain Greens function dyad $\bar{\mathbf{G}}(k_x, k_z)$, which relates a surface current source $\mathbf{J}_s = \mathbf{J}_{s,0} \exp -jk_x x \exp -jk_z z$ in the plane of the structure, with the RF tangential electric field $\mathbf{E}_t = \mathbf{E}_{t,0} \exp -jk_x x \exp -jk_z z$ ($\mathbf{E}_t = (E_x, E_z)^t$) over the same or other parallel plane:

$$\mathbf{J}_0 = \bar{\mathbf{G}}(k_x, k_z) \cdot \mathbf{E}_{t,0} \quad (22)$$

General methods for the computation of the spectral Green dyad in multilayered ferrite-loaded substrates (in fact, in general layered bianisotropic substrates) have

been reported [47,48]. The *Fourier-transformed matrix method* reported in Ref. 47 is, in fact, an application of the transverse transmission matrix procedure described earlier to the determination of the spectral Green dyad (22) in general bianisotropic media with arbitrary surface current sheets. The equivalent boundary method, described in Ref. 48, proposes a procedure for computing the spectral Green dyad of an n -layered medium starting from $4n$ (in the worst case) single-layer Green dyads defined for each layer of the structure with appropriate boundary conditions. This results in a recurrence algorithm that is found to have a high numerical stability [45,48].

The SDA may also be applied to boxed stripline and finline structures. In this case the integral Fourier transform of the field and currents must be substituted by a Fourier series transform in an equivalent periodic structure. For magnetized ferrite-layered media in rectangular metallic boxes, this imposes an important restriction—strictly speaking, the SDA can be applied only to substrates with static magnetization perpendicular to the lateral sidewalls. In any other case, due to the properties of the magnetic field after spatial reflection, it is not possible to find an equivalent periodic structure with translational symmetry suitable for the application of the series Fourier transform. Therefore, the application of the SDA to boxed structures magnetized in any direction different from the aforementioned one, must be considered only as an approximation.

The SDA, as described previously, applies only to structures with strips or fins of negligible thickness. Structures with nonnegligible fin or strip thickness may be analyzed using a mode-matching technique in the transverse direction, which also implies an SDA [49]. A similar method may be applied to boxed structures with asymmetric rectangular piecewise boxes [50]. Finally, the SDA also applies to structures having fully or partly lossy strips or fins, provided these lossy strips or fins can be described by a suitable surface impedance, defined over the strip or the fin region [40].

FERRITE PHASE SHIFTERS

WILLIAM E. HORD
 Microwave Applications Group
 Santa Maria, CA

Phase shifters are used extensively in the microwave and millimeter-wave region primarily as array elements in phased-array antennas. The first application of ferrite phase shifters in antenna arrays was during the decade of the 1960s. Since then growth has been dramatic with military applications being the motivating force. The air defense systems of the former Soviet Union are designed and built around ferrite phase shifting devices as are several of the ground-based, naval, and airborne systems of the United States. The article describes the evolution of ferrite phase shifters that have made the transition from the research laboratory to the production floor. Wherever possible, the author has identified the systems that use a specific type device.

Ferrite phase shifters are two-port devices operating in the microwave and millimeter-frequency range between 1.4 and 100 GHz. A variable insertion phase between input port and output port is accomplished by varying the bias magnetic field of the ferrite material. The insertion phase of a phase shifter is the phase delay experienced by a radiofrequency (RF) signal propagating between port 1 and port 2 and is the angle of S_{21} , the transmission coefficient from port 1 to port 2. If the angle of S_{21} equals the angle of S_{12} , the transmission coefficient from port 2 to port 1, the phase shifter is *reciprocal*, while if these two angles are not equal the device is *nonreciprocal*. The phase shifter consists of (1) a microwave circuit containing magnetized ferrite whose purpose is to provide a variable insertion phase to the RF signal and (2) an electrical circuit containing electronic components whose purpose is to vary the magnetic bias of the ferrite and control the amount of variable insertion phase. Because the state-of-the-art of electronic control circuits changes rapidly depending on device availability, the focus of the following discussion will be on the microwave portion of the ferrite

phase shifter and the electronic control techniques will be limited to basic principles.

The use of magnetized ferrite to provide the variable phase shift was recognized as early as 1953 [1]. Phase shifter applications were stimulated by the discovery of the reciprocal, ferrite phase shifter in 1957 [2] and the latching ferrite phase shifter in 1958 [3]. During the 1960s, major efforts were undertaken on phase shifter development, and the toroid phase shifter [4] and dual-mode phase shifter [5] evolved into their present configurations during this decade. The rotary-field phase shifter was reported in the early 1970s [6].

Although they find application in many areas, the major use of ferrite phase shifters are as phase shifting elements in electronic scanning antennas where the data rate is high enough to preclude the use of a mechanical scanning antenna or where the aperture must be shared by several functions requiring the antenna have an agile beam shape. Antennas used for systems tracking large numbers of targets such as the AWACS (airborne warning and control system) require data rates not attainable with mechanical scanning antennas. A ground-based air defense system such as the Patriot must track a particular target while continuing to search for other threats necessitating an electronic scanning system. Ferrite phase shifters are also used as feed elements for reflector antennas where the pattern of the reflector may be changed by changing the feed pattern providing different coverages. Electronic control is desirable since the system may be located in space and the reliability of mechanical switches is not adequate. Other antenna feeds use four phase shifters to provide a variable phase to each quadrant of the antenna resulting in a conical scanning beam for the antenna. A third use is as the variable element in microwave circuits used for high-power switches and variable-power dividers and combiners. Because of the low insertion loss and excellent phase accuracy attainable with ferrite phase shifters, high-power electronic switches with insertion loss as low as 0.5 dB and with isolations approaching –40 dB may be realized. A circuit providing variable phase shift in each leg of a bridge circuit has been used to combine the azimuth and elevation difference signals from a monopulse antenna and by properly phasing the signals compensate electronically for aircraft roll. Finally, ferrite phase shifters have been used as Doppler simulators, frequency translators, and so on.

1. FERRITE MATERIALS AND PROPERTIES

A material is called *magnetic* if it exhibits a magnetic moment in the absence of an applied magnetic field. The magnetic moment is due to the presence in the material of at least two different electronic spin systems. If these spin systems are equal and parallel, the material is ferromagnetic; if the spin systems are equal and antiparallel, the material is antiferromagnetic; and if the spin systems are unequal and antiparallel, the material is ferrimagnetic and is generically referred to as *ferrite*. Ferrite materials are ionic crystals with no free electrons, resulting in high resistivity and making them potentially useful for

application in the microwave and millimeter frequency ranges. Two types of ferrites both with cubic crystalline structure but one (spinel) having structure similar to spinel and the other (garnets) having the garnet structure have been used for phase shifter fabrication. A sample of ferrite material of a size required for microwave components usually does not exhibit a net magnetic moment in the absence of an external bias field. The material is composed of magnetic domains; each of these exhibits a net magnetic moment but is randomly aligned, resulting in zero net magnetic moment when summed over the sample. Application of an external magnetic bias field rotates the domains that align with the bias field and produce a net magnetization. When all domains in a sample are aligned, the material is saturated and the magnetization is called the *saturation magnetization* $4\pi M_s$. A virgin sample of material exhibits a magnetization curve similar to that of iron.

When the magnetizing current is removed, some magnetic flux may remain in the sample, and a current in the opposite direction must be applied to reduce this flux to zero. This phenomenon is called *hysteresis*. A ferrite material formed in a closed loop exhibits a hysteresis loop similar to that shown in Fig. 1, where the squareness of the loop is a function of the chemical composition of the material. The magnetic field intensity required to reduce the magnetic flux density to zero is called the *coercive force* H_c , while that magnetic flux density remaining after the magnetic field intensity has been reduced to zero is called the *remanent flux density* B_r . Magnetic material properties are sensitive to temperature; and above a certain temperature, called the *Curie temperature*, the magnetic properties vanish.

Ferrite phase shifters require values of saturation magnetization ranging from approximately 200 to 5500 G (gauss) (the maximum attainable value with commercially available materials). By substituting aluminum ions for

Figure 1. Ferrite hysteresis loop for a square-loop material defining the remanent magnetization B_r and the coercive force H_c .

ferric ions in YIG, the saturation magnetization may be reduced from 1780 gauss (the value for pure YIG) to about 175 G. For the lithium spinel family the substitution of titanium ions for ferric ions is used, and both aluminum and zinc separately or in combination have been used to vary the saturation magnetization for the magnesium–manganese ferrite family and the nickel ferrite family. In general, when substitution is made the Curie temperature is lowered from that of the unadulterated material. Doping with rare-earth ions may be used to increase peak power capacity, although the insertion loss may increase slightly.

Phase shifters providing variable values of insertion phase operate with the ferrite partially magnetized. The ferrite exhibits a tensor permeability whose on-diagonal elements μ vary slightly as a function of the applied magnetization. The off-diagonal elements of the tensor $\pm j\kappa$ are equal but of opposite sign, leading to the nonreciprocal behavior of ferrite devices. These off-diagonal elements are in phase quadrature with the on-diagonal elements and are proportional to the ratio of applied magnetization to saturation magnetization. If the RF energy is circularly polarized, the effective permeability of the ferrite medium is equal to $(\mu + \kappa)$ for one sense of circular polarization and $(\mu - \kappa)$ for the other sense of circular polarization, both of which are dependent on the applied magnetization through the off-diagonal element of the permeability tensor. The permittivity of the ferrite is scalar with a dielectric constant in the range 10–18. The dielectric loss tangent of ferrite is about 0.0002 for garnets, 0.0003 for magnesium spinels, 0.0005 for lithium spinels, and 0.001 for nickel spinels.

Phase shifter characteristics determined by the microwave circuit are the mode of operation, either reciprocal or nonreciprocal; operating frequency; instantaneous and tunable bandwidth; polarization of the input and the output signals; peak and average RF power; insertion loss and modulation of the insertion loss; and return loss. Parameters determined by the microwave circuit and the electrical control circuit are phase quantization, phase accuracy, switching time, switching rate, and control power. Physical parameters of the phase shifter include size; weight; cooling requirements; input interfaces for RF signal, data, and control power; and output interfaces for RF signal and built-in test. The phase shifter must conform with environmental requirements such as operating and storage temperature range, operating and transportation shock, operating and transportation vibration, and operating and storage humidity. Finally, requirements generally exist for the reliability, interchangeability, and maintainability of the phase shifter.

2. TYPES OF FERRITE PHASE SHIFTERS

Many ferrite phase shifters are described in the literature, but only three types have been produced in quantity and deployed in the field in various antenna systems. The one characteristic shared by these three different devices is an insertion loss less than 1 dB. System and antenna designers are unwilling to use devices with higher loss because of

reduction in antenna gain and cooling problems associated with dissipation of the transmitter power in the antenna.

The J-STARS airborne surveillance system, the Patriot mobile, ground-based air defense system, and the Aegis naval air defense system use variations of the nonreciprocal toroidal phase shifter. This device operates in a nonreciprocal mode, requiring that the phase shifter be switched immediately after the transmitter pulse to provide the proper phase shift for propagation in the receive direction. The phase shifter is switched again just prior to the next transmitter pulse, resulting in a switching rate twice the pulse repetition rate of the radar. Switching time is a few microseconds depending on operating frequency. This type of phase shifter may be designed to have extremely wide operating bandwidth approaching 2 octaves in some cases.

The second type of phase shifter, also nonreciprocal, consists of a longitudinally magnetized ferrite rod located on the axis of either square or circular waveguide. Several of the ground-based, mobile air defense systems of the Confederation of Independent States use these phase shifters in antennas, radiating one sense of circular polarization and receiving the orthogonal sense of circular polarization—the “single bounce” return. An adaptation of the phase shifter that provides reciprocal phase shift is referred to as the “dual mode” device and has been successfully employed in several antenna designs most notably the multimode offensive radar systems of the B-1B. Switching times for these phase shifters are in the tens of microseconds depending on the frequency of operation. Operating bandwidth is more modest than the toroid phase shifter, typically being 10–15%, although 40% bandwidth has been achieved for experimental devices.

The phase shifters described above provide a variable insertion phase by varying the magnitude of the bias magnetic field, resulting in a variation in the equivalent inductance of the waveguide and yielding a variable propagation delay through the device. The final phase shifter described in this section does not use this phenomenon but rather makes use of the variation in the direction of the bias magnetic field to effect change in insertion phase with no change in the propagation delay. Because of the similarity of the phase shifter to the rotary-vane [7] mechanical phase shifter, it has been called the *rotary-field phase shifter*. The rotary-vane device uses a dielectric vane to realize a half-wave plate that can be rotated about the axis of a circular waveguide housing. A circularly polarized RF signal receives phase shift when passing through the half-wave plate equal to twice the mechanical angle of rotation of the half-wave plate. Substitution of a transversely magnetized ferrite rod for the dielectric half-wave plate results in an electrically variable version of this phase shifter. This phase shifter has been employed in a single-axis scanning configuration for the antenna for the AWACS surveillance aircraft and for several single-axis scanning, ground-based, mobile air defense systems. The switching time for the device is of the order of hundreds of microseconds, and the operating bandwidth is about the same as that of the dual-mode phase shifter.

2.1. Toroidal Phase Shifters

The toroidal phase shifter consists of one or more ferrite toroids inserted into a rectangular waveguide as shown in Fig. 2. The cross section shown in Fig. 3a is the original version of the toroidal phase shifter reported by Truehaft and Silber (3) in 1958. The toroid is fabricated from a material with a square hysteresis loop. Current flowing in the switching wire induces a magnetic flux in the toroid that remains after the current is removed. The phase shifter is said to be “latched”; operation in this mode is desirable since control energy is required only when the phase shifter is set to a new state. The magnetic field intensity of the TE_{10} mode in a rectangular waveguide is circularly polarized in a longitudinal plane parallel to the narrow wall of the waveguide and located a distance from the waveguide centerline, which makes the longitudinal magnetic field intensity equal in magnitude to the transverse magnetic field intensity. The opposite sense of circular polarization exists in the longitudinal plane located the same distance on the other side of the waveguide centerline. If a sample of magnetized ferrite is placed in the region of circular polarization, a strong interaction between the RF and the ferrite will occur, provided the direction of the bias field is interchanged on either side of the waveguide centerline.

The geometry shown in Fig. 3b makes more efficient use of the ferrite toroid and provides more total phase shift than the geometry of Fig. 3a at a minimal increase in insertion loss by loading the “window” in the toroid with a dielectric. The dielectric loading effect of the ferrite toroid and dielectric used to load the toroid window distorts the behavior of the fields of the waveguide mode so that the region of circular polarization no longer lies in the same plane as that of the air-filled waveguide. Computer-aided analysis programs have been evolved [8,9] to predict the performance of the phase shifter as a function of toroid placement and dielectric loading. A disadvantage of the geometries shown in Figs. 3a and 3b is the excitation of the TEM mode, which is easily established by the switching wire coupling to the rectangular waveguide. Two toroids separated by a dielectric slab spacer as shown in

Figure 2. Prototypical toroidal phase shifter. First described in the 1950s, this device was the first latching, ferrite phase shifter. By pulsing the switching wire the flux may be latched to either $+B_r$ or $-B_r$. Sustaining drive current is not required.

Figure 3. Evolution of the toroidal phase shifter into the twin-toroid device. The window inside the toroid is loaded with high dielectric material in order to improve the phase shifter RF performance in (b) while in (c) another toroid is added that greatly decouples the switching wires from the RF field.

Fig. 3c reduce this coupling by concentrating the RF energy in the region adjacent to the dielectric slab and locating the switching wires in regions of very low RF energy. This geometry is referred to as the *dual-toroid* and has come to be the preferred realization for this class device.

The ferrite–dielectric composite is housed in a rectangular waveguide that typically has a cross section smaller than that of the connecting waveguide because of the dielectric loading. Quarter-wave transformers are used to match into and out of the ferrite–dielectric composite. These transformers increase the length of the device but do not contribute significantly to the insertion loss. When the connecting transmission line is a TEM-type line such as microstrip, a high dielectric constant (≈ 100) material may be used as the dielectric spacer to reduce the cross-sectional dimensions of the phase shifter and lower the characteristic impedance level to around $50\ \Omega$. This has the added benefit of reducing the length of the device because of the increase in electrical length caused by the dielectric loading. The ferrite toroids are bonded to the high-dielectric-constant rib, and the composite is coated with a conducting material to form the waveguide. Connection to the TEM line may be made with a short length of wire

with a chip capacitor located at the point of connection of the wire to the phase shifter in order to resonate the inductance of the wire loop.

In order to establish a reference condition for the phase shifter the toroid is *reset*; that is, a voltage pulse of magnitude and duration sufficient to saturate the toroidal core is applied to the control wire. The current in the control wire remains roughly constant until the core saturates, at which time the current increases sharply. Sensing the current and removing the drive voltage when a predetermined current has been attained allows the core to relax to the remanent flux and establishes a stable reference point. The magnitude of the voltage pulse is not critical for the reset operation. The *set* operation establishes a flux level in the core corresponding to a given value of phase shift. Faraday’s law states that the change of flux is equal to the time integral of the applied voltage; a variable flux level may be set by using a variable amplitude voltage pulse for a fixed time duration or a fixed amplitude voltage pulse for a variable time duration. If either the voltage or the pulse-width varies substantially from that used to calibrate the phase shifter, the error in setting the flux may be excessive and resorting to more complicated methods such as integration of the voltage pulse may be necessary. Typical switching waveforms are shown in Fig. 4.

During switching, the toroidal core presents a resistive load to the source. Application of a voltage pulse to the control wire results in a current pulse whose amplitude is determined by Ampere’s law, $NI = \int H dl$. The magnetic field intensity is constant and equal to the coercive force, the number of turns is unity, and the integral of dl is equal to the mean length around the ferrite toroid. Thus $I = H_c l$. The flux change from one remanent state to the other remanent state is $2B_r A$, where B_r is the remanent flux density and A is the cross-sectional area of the toroid normal to the direction of flux. For a constant voltage V applied to the core for a time T , $VT = 2B_r A$, yielding a switching time $T = 2B_r A/V$. This is the maximum value of the time to establish the reset condition; the total switching time would

Figure 4. Switching waveforms of the latching phase shifter when driven from a constant voltage source. The voltage remains approximately constant during switching until the ferrite saturates. Saturation of the core to obtain a stable reset state is exhibited by the abrupt rise in the current in the reset waveform. The area under the voltage waveform for the set pulse determines the amount of flux switched into the ferrite core and hence the amount of phase shift.

be at least twice this value. Increasing the applied voltage reduces the switching time and increases the dynamic core resistance, which is given by $R = 2B_r A / (TH_c l)$.

2.2. Dual-Mode Phase Shifters

Latching operation of the ferrite rod phase shifter is realized by filling the waveguide completely with ferrite and providing a magnetic return path for the bias flux through the use of external ferrite yokes as shown in Fig. 5. The control power is furnished by a coil that is wound around the waveguide. Again the insertion phase of the device is dependent on the value of magnetic flux existing in the ferrite rod, and variable phase is realized by changing this value. The RF energy propagating through the ferrite rod must be circularly polarized, which may require the input polarization be converted from linear polarization to circular polarization. Each sense of circular polarization receives a different value of insertion phase when propagated through the device, and these values are interchanged when either the direction of propagation or the direction of magnetization is reversed. However, if an antenna uses these phase shifters and receives the “single bounce” return, transmitting right-hand circular and receiving left-hand circular or vice versa, switching between transmit and receive is not required.

Adaptation of the ferrite rod phase shifter to the reciprocal dual-mode phase shifter is illustrated schematically in Fig. 6, and the physical realization of the phase shifter is shown in Fig. 7. Nonreciprocal circular polarizers (NCPs) located on either end of the ferrite rod function as the circulators shown in the schematic diagram converting linearly polarized RF energy into circularly polarized RF energy and vice versa. The NCP physically consists of a section of the ferrite rod that is transversely magnetized with a four-pole bias field by a permanent magnet located exterior to the microwave circuit. This four-pole bias field provides a differential phase shift of 90° to cross-polarized signals. If the input to the NCP is

Figure 5. The Faraday rotation phase shifter. The ferrite-filled circular waveguide provides the signal path for the RF energy. Longitudinal magnetization is obtained using a drive coil wrapped around the ferrite rod. Latching operation is realized using latching yokes for a return path for the bias magnetic flux.

Figure 6. A reciprocal phase shifter realized using four nonreciprocal components. The two circulators and two nonreciprocal phase shifters provide port-to-port reciprocal behavior.

linearly polarized at an angle of 45° with respect to the axis of the NCP, the output will be circularly polarized with the sense of circular polarization depending on the orientation of the input linear polarization. For a circularly polarized input signal, the output of the NCP will be linearly polarized with orientation depending on the sense of the circularly polarized input signal. The NCP on the left side of the device in Fig. 7 converts input linear polarization into right-hand circular polarization in the ferrite rod section when RF energy is propagated from left to right. This circularly polarized energy receives a variable value of insertion phase dependent on the magnitude of the remanent bias flux density in the ferrite rod. The circular polarization is then restored to linear polarization by the NCP on the right side of the figure. For propagation from right to left, the RF energy in the ferrite rod is converted to left-hand circular polarization by the NCP on the right side of the figure, resulting in the signal receiving the same value of variable insertion phase irrespective of the direction of propagation through the device. The signal is restored to linear polarization by the NCP located on the left side of the device.

The electronic control of the dual-mode device is similar to that used for the toroid, but two major exceptions exist.

Figure 7. Physical realization of the dual-mode reciprocal phase shifter. This compact realization of the schematic shown in Fig. 6 has proved to be compatible with the packaging requirements for electronic scanned phased array antennas with wide-scan-angle requirements.

The drive coil is almost always a multiturn coil, which results in the apparent resistance and inductance of the ferrite core being increased by the square of the number of turns of the drive coil. Second, the waveguide walls do not enclose the magnetic circuit in its entirety. The magnetic flux cuts through the waveguide walls as it passes from the ferrite rod and is returned through the external yokes, resulting in an induced voltage in the waveguide walls whenever the flux is changed. Since the waveguide walls are made of low-resistivity material, a low-resistance path allows eddy currents to flow in the waveguide walls and produces the phenomenon called *shorted-turn damping*. This effect may be modeled by including a parallel resistance due to this damping in the equivalent-circuit of the phase shifter.

2.3. Rotary-Field Phase Shifters

The geometry of the rotary-field phase shifter is shown in Fig. 8. A composite ferrite–dielectric rod is metallized with a thin metallic coating to form the microwave portion of the circuit. This is inserted into a laminated steel yoke that provides the variable magnetic bias field. The rod–yoke assembly is housed in a two-piece metallic housing that interfaces to standard rectangular waveguide. Two interlaced windings wound on the multislot yoke generate the four-pole bias field. Dielectric quarter-wave plates on either end of the ferrite rod convert linearly polarized RF energy to circularly polarized energy, and vice versa, for propagation through the ferrite half-wave section. The linearly polarized RF input signal is converted to circularly polarized energy by means of the dielectric quarter-wave plate. This circularly polarized energy passes through the ferrite half-wave plate and receives a variable phase shift dependent on the orientation of the ferrite half-wave plate. At the output of the ferrite half-wave plate the sense of circular polarization is reversed, allowing the output dielectric quarter-wave plate to

Figure 8. The rotary-field phase shifter. This device provides excellent phase accuracy and is capable of relatively high values of RF power.

reconstitute the same sense of linear polarization as the input polarization. The phase shift through the device is the same for either direction of propagation so that it is referred to as a *reciprocal device*. In the strictest sense it is nonreciprocal since a fixed 180° phase shift exists between signals propagating through it in opposite directions.

Latching operation of the rotary-field device was reported in 1995 [10] and units presently deployed operate with continuous holding current, resulting in a substantial DC power supply for array applications. This has limited the device to single-axis electronic scanning antenna applications such as the surveillance antenna for the AWACS aircraft. Typically the electronic control for these devices are two parallel drivers to control the two independent windings on the yoke, with the control current on one winding set proportional to the cosine of the desired phase angle and the control current on the remaining winding set proportional to the sine of the desired phase angle.

3. PHASE SHIFTER CHARACTERISTICS

Most phase shifter designs are custom designs having been developed for specific purposes and programs. Specific operating parameters will not be provided, but rather general electrical and physical characteristics will be discussed. Finally, typical numbers are provided for the reliability of the devices.

3.1. Electrical Characteristics

Electrical characteristics of importance are the operating mode (reciprocal/nonreciprocal), the operating frequency, the instantaneous bandwidth, the tunable bandwidth, the input polarization, the output polarization, the peak and average RF power, the insertion loss and the insertion loss modulation, the return loss, the quantization of the phase shift, the phase accuracy, the switching time, the switching rate, and the control power. Although it would seem that reciprocal operation would be preferred over nonreciprocal operation, there are many more nonreciprocal phase shifters deployed than reciprocal ones. The interaction of ferrite with RF energy is nonreciprocal and historically the earlier successful phase shifters were the nonreciprocal toroidal types. The choice of operating mode is generally dictated by system requirements; and in several cases such as communication satellites, nonreciprocal operation is not a handicap.

The operating frequency is another choice of the system designer with phase shifters having been developed from 1.4 to 94 GHz. The *instantaneous bandwidth* refers to the frequency band over which the phase shift remains within specified tolerances, while the *tunable bandwidth* refers to the frequency band over which the phase shifter may be adjusted to bring the phase shift within the specified tolerance. The nonreciprocal toroidal phase shifter has been designed to yield two octaves of instantaneous bandwidth, while the dual-mode phase shifter and the rotary-field phase shifter yield instantaneous bandwidths in the 2–4% range with tunable bandwidth of the order of 15%.

The input and output polarization depends on the application for which the phase shifter is intended and may be either linear or circular or switchable between the various linear and circular polarizations. The nonreciprocal toroidal phase shifter operates in a linearly polarized waveguide mode so that the input and output polarizations are linearly polarized. The dual-mode phase shifter may use circularly polarized input–output polarization operating in the non-reciprocal mode or linearly polarized input–output polarizations when operating in the reciprocal mode. This phase shifter lends itself well to incorporating polarization switching so that various output polarizations are available even when the phase shifter is excited with a linearly polarized input. The rotary-field phase shifter usually uses linearly polarized input and output signals, although this is not required.

The peak RF power capacity of a ferrite phase shifter is determined by the choice of ferrite used to realize the phase shifter. If the RF magnetic field intensity exceeds a threshold value, excitation of spin waves results and the RF insertion loss increases substantially. Doping of garnet material with rare-earth ions may be used to increase the threshold value, but at the expense of increased low power insertion loss. The average RF power capacity of a phase shifter is determined by the mechanical design and may be increased only by improving the heat flow path away from the ferrite.

The insertion loss of the phase shifter, as mentioned previously, should be below 1 dB in order to merit consideration from antenna designers. Of the phase shifters discussed, the rotary-field device has the lowest loss with values as low as 0.3 dB obtained in production quantities for a device operating in the 5 GHz frequency range. The toroidal phase shifter and the dual-mode phase shifters have insertion loss in the range from 0.6 to 1.0 dB. The variation of the insertion loss as a function of the insertion phase of the device is greatest for the reciprocal devices, generally of the order 0.2–0.4 dB, while the toroidal device has loss modulation less than 0.1 dB.

The return loss of the ferrite phase shifters depends on the RF input and output connections, and values cited will be for linearly polarized input–output configurations. The toroidal phase shifter generally has a maximum value of return loss of -20 dB, while the reciprocal phase shifters have maximum values of return loss of the order of -14 to -17 dB.

Ferrite phase shifters are generally designed to provide 360° of electrical phase shift. Early ferrite phase shifters were realized using discrete lengths of ferrite to provide quantization of the phase shift in steps of 180° , 90° , 45° , and 22.5° . This method results in a simple electronic driver design but a complicated microwave structure. Modern ferrite phase shifters are realized using a continuous piece of ferrite in order to minimize the cost of the microwave structure, resulting in a continuous range of phase shift. Quantization is provided by the electronic driver. Since the driver commands are distributed over the total range of phase shift, which is often greater than 360° , the final quantization is 1 bit less than that provided by the electronic driver; that is, an 8-bit driver command results in 7-bit phase shift quantization. Quantization levels greater

than this are found in the control electronics of variable power dividers/combiners but rarely are used in other phase shifter applications.

The *phase accuracy* of the phase shifter refers to the precision with which the insertion phase of the device may be set. For the toroid phase shifter, this parameter is a function of the stability of the reset state, the operating frequency, and the operating temperature, and accuracies of the order of 2–3° RMS error can be achieved. Improvements in accuracy can be achieved at the expense of added calibration. For the dual-mode phase shifter the alignment of the nonreciprocal polarizer magnets is another source of phase error, and accuracies of the order of 3–4° RMS error are common with this device. The rotary-field phase shifter may be set very accurately since the insertion phase is proportional to the ratio of the two currents that control the rotation angle of the magnetic bias field. Typical phase accuracies for this device are in the range 1–1.5° RMS and are not particularly sensitive to frequency and/or temperature.

The switching time of the phase shifter is the time required to establish a new insertion phase state and includes the times for resetting and setting the toroid and dual-mode phase shifter. The switching time is a function of the operating frequency since the size of the phase shifter is dependent on the frequency. Typical switching times for a toroid phase shifter range from about 20 μ s at 2 GHz operating frequency to about 5 μ s at 20 GHz. Typical switching times for a dual-mode phase shifter range from about 200 μ s at 5 GHz to about 50 μ s at 20 GHz. The nonlatching rotary-field phase shifter requires switching times ranging from 200 μ s at 3 GHz to about 100 μ s at 10 GHz but requires a high-voltage boost circuit in order to attain these speeds. The switching rate of the phase shifter is generally determined by system requirements, where the control power is directly proportional to the switching rate.

3.2. Physical Characteristics

Important physical characteristics of the phase shifter are the size, the weight, the cooling requirements, and the physical location of the input and output interfaces. The size is dictated by the operating frequency, average power requirements, and type of phase shifter. In general the toroid phase shifter has the smallest cross section, and the rotary-field phase shifter has the largest cross section with the dual-mode somewhere between the two. The weight of the phase shifter is proportional to size; the toroid phase shifter is generally the lightest weight unit, the rotary field the heaviest, and the dual-mode in between the two. The RF interfaces are the input and output RF ports, which may be coaxial cable, microstrip transmission line, rectangular waveguide, radiating elements into free space, or any combination of these. Electrical interfaces consist of the input data and any output data, such as built-in-test, control, power, and ground.

The electrical and mechanical design must be such that the phase shifter meets the specified values over operating temperatures ranging from -40 to $+95^\circ\text{C}$. In many cases a reduced temperature range for full performance with

degraded performance over the temperature extremes is allowed. Nonoperating temperatures normally range from -55 to $+125^{\circ}\text{C}$. Operating shock and vibration requirements are determined by the mechanical design of the system and the phase shifter mounting.

The reliability of the phase shifter as measured by the mean time before failure (MTBF) is an important consideration. The microwave portion of the phase shifter has high reliability since it is composed of a ferrite core and associated windings. The overall reliability is generally determined by the electronic driver with values of roughly 200,000 h for the latching phase shifters and values of 50,000 h for the nonlatching phase shifters because of the requirement for continuous drive current.

4. FUTURE DEVELOPMENTS

Two developments in waveguide devices offer promise. The first is an attempt to provide a reciprocal phase shifter using the toroid phase shifter in a geometry similar to that of the dual-mode device but using microstrip circulators. The difficulty with this approach is that the microstrip circulator is realized naturally as a three-port device and the schematic diagram of Fig. 6 requires a four-port circulator to adequately isolate the input and output ports. Work continues in this development. The second development in the waveguide area is the latching rotary-field phase shifter, which has been reported in the literature [6] but has not been deployed in the field. Data taken on experimental units are very encouraging.

There is a continuing effort to develop a ferrite phase shifter in a planar geometry suitable for integration with microstrip transmission line. The literature contains many references to these devices, but the insertion loss continues to be a drawback to deployment. The textbook cited in the Further Reading section contains several examples of planar phase shifters as well as many references.

FERROELECTRIC MATERIALS

R. K. PANDEY
The University of Alabama
Tuscaloosa, Alabama

1. INTRODUCTION

Before discussing the fundamentals of ferroelectric materials and their applications, it is important to acquire some background on how any material, especially insulators such as ferroelectrics, behave under the equilibrium conditions given by forces such as electrical, mechanical, and thermal. Each of these forces gives rise to certain properties depending on the basic physical nature of the material. For example, an electric field (E) causes displacement (D) [or polarization (P)], stress (T_{ij}) causes strain (S_{ij}), and entropy (S) is caused by temperature (T). These effects are not isolated from each other. In fact, when the system is in equilibrium, they interact with each other and give rise to additional properties. It is helpful to understand the relationship between these effects in order to appreciate the nature and properties of electronic and other materials.

In 1925 Heckmann [1] proposed an equilibrium diagram between electrical field, temperature, and stress, which was later modified by Nye [2] in 1957. A simplified version of this diagram is given in Fig. 1. It is assumed that the system is in equilibrium and the properties can be described with reference to changes that are thermodynamically reversible. Interaction between stress (T_{ij}) and displacement (D) causes direct piezoelectric effect whereas the converse piezoelectric effect is caused by the strain (S_{ij}) and electric field (E). The relationship between displacement and temperature is called the *pyroelectric effect*. The piezoelectric and pyroelectric effects are inherently important for discussing ferroelectricity.

The interactions between the three principal agents (E , T_{ij} , and T) within themselves and between the secondary agents such as displacement (D), strain (S_{ij}), and entropy (S) are responsible for materials to acquire certain properties. Many of them are identified in Fig. 1. However, for our purpose we need to consider only two more effects:

Figure 1. Modified equilibrium diagram between electric field (E), temperature (T), and stress (T_{ij}) and their associated effects.

(1) the thermal expansion effect, which is caused by the interaction between strain (S_{ij}) and temperature (T); and (2) the heat of deformation, which originates from the interaction between the strain (S_{ij}) and entropy (S). Both these, especially the thermal expansion coefficient, is a very important parameter for the selection of a suitable substrate for the growth of piezoelectric or ferroelectric films to produce integrated structured devices for many novel applications.

The three parameters—entropy, displacement, and strain—undergo small changes corresponding to the small changes experienced by the agent's temperature, electric field, and stress, respectively. Mathematically they can be represented by the following three simple relationships

$$ds = \frac{C_v}{T} dT \quad (1)$$

where c_v is the specific heat per unit volume and it is assumed that the system is in equilibrium and fully reversible; and

$$dD_i = \kappa_{ij} dE_j \quad (2)$$

where κ_{ij} is the permittivity tensor and

$$dS_{ij} = s_{ijkl} dT_{kl} \quad (3)$$

where s_{ijkl} is the elastic compliance.

In discussing ferroelectric materials and associated topics, we will make use of these concepts in gaining a good insight into the field of ferroelectricity.

The phenomenon now universally known as *ferroelectricity* got its name more because of its phenomenological similarity with ferromagnetism than because of the underlying physics describing these two phenomena found in materials. The name is deceptive in some sense. Ferro-

electricity, as the word implies, leads us to assume that it has something to do with iron (*ferum* in Latin). In reality it has hardly anything to do with this magnetic metal. In fact only a handful of materials having iron (or other prominent members of the ferromagnetic family such as nickel and cobalt) have been reported to exhibit ferroelectricity. However, they are certainly not members of the mainstream ferroelectrics and are rarely researched actively. Some examples are cadmium iron niobate, $\text{Cd}_2\text{FeNbO}_6$, some members of the barium fluoride group [e.g., barium iron fluoride (BaFeF_4), barium cobalt fluoride (BaCoF_4), and barium nickel fluoride (BaNiF_4)], and antimony sulfide-iodide-type compounds such as iron sulfide (FeS) [3,4]. Apart from the naturally found mineral FeS , another mineral termed *ilmenite* (FeTiO_3), containing copper has also been reported to be ferroelectric with a Curie point of approximately 580 K [5]. No other group has made such a claim. This author's research group [6] has searched extensively for ferroelectricity in laboratory-processed doped ilmenite without any success.

Almost all well-known ferroelectric materials are man-made (synthetic), in contrast to leading ferromagnetic materials, which are found abundantly in nature. Classic examples are iron, cobalt, and nickel and their alloys. So far as ferroelectricity is concerned only FeS and FeTiO_3 are naturally found in which the possibility of ferroelectricity might exist. Further research is warranted to establish the fact.

Ferromagnetism was already a well-established field of science and technology long before the birth of so-called ferroelectricity. In 1921 Valasek [7] discovered the hysteresis effect between polarization and electric field in potassium sodium tartarate tetrahydrate ($\text{KNaC}_4\text{H}_4\text{O}_6 \cdot 6\text{H}_2\text{O}$), which is commonly known as *Rochelle salt* after its discoverer who lived in France in the seventeenth century. Since its discovery over 80 years ago, the field of ferroelectricity has established itself as an important branch of

Figure 2. Idealized hysteresis loops of typical (a) ferromagnet, (b) ferroelectric, and (c) ferroelastic materials [4].

physics and engineering. During this span of time, hundreds of new ferroelectric materials have been discovered leading to the emergence of novel technologies that exploit various properties commonly found in ferroelectrics. The range of applications of this class of materials is vast, encompassing the spectrum from classical to ultramodern applications. On one hand, because of their high dielectric constant, ruggedness, and the reliability with which the materials can be processed reproducibly in very large volumes, ferroelectrics are the materials of choice for the fabrication of capacitors varying in size from miniature, used in microelectronics, to large, used in power circuits. On the other extreme, they find applications in such modern technologies as electrooptics, nonvolatile memory, uncooled focal plane arrays, microelectromechanical system (MEMS), and wireless communication.

The physical mechanisms involved in these two fields are entirely different and have practically nothing to do with each other. While ferromagnetism is anchored in the quantum-mechanical properties of an electron, especially its spin, ferroelectricity is macroscopic in nature, originating from the long-range interactions of the electric dipoles and the noncentrosymmetry of the unit cell of the crystal.

The phenomenological similarity between these two mechanisms goes beyond the existence of a hysteresis loop. Like ferromagnetism, ferroelectricity also shows the existence of the Curie point, at which it ceases to be ferroelectric and enters the nonpolar phase called the *paraelectric state*, analogous to paramagnetism. Furthermore, as there are antiferromagnetic materials, there are also antiferroelectric materials. Both ferromagnetic and ferroelectric materials have domains, and their structures help in describing terms such as *paramagnetism* and *paraelectric* as well as *antiferromagnetism* and *antiferroelectricity*. Piezoelectricity and pyroelectricity are inherently present in all ferroelectric materials and are strongly coupled with each other. In other words, all ferroelectrics are piezoelectric as well as pyroelectric, whereas not all piezoelectrics are ferroelectrics; nor are all pyroelectrics also ferroelectrics. The simultaneous presence of piezoelectricity and pyroelectricity in a ferroelectric material makes it truly a multifunctional material and therefore very attractive for the emerging fields of applications where multifunctionality is the most desired property of a material. Ferromagnetic and ferroelectric materials are not the only ones that display hysteresis loops. There is another class of material in which a hys-

teresis loop exists between the stress and the strain; these are called ferroelastic materials. Grouped together, ferromagnetic, ferroelectric, and ferroelastic are called “ferroic” materials.

According to the IEEE standard definitions [8], ferroelectrics, ferroelastics, and ferromagnetics define the class of *primary ferroics*. It is entirely possible to switch the direction of spontaneous magnetization, spontaneous polarization, or spontaneous strain by applying magnetic or electric fields or stresses, respectively. Figure 2 shows the idealized examples of the three types of hysteresis loops for typical (a) ferromagnet, (b) ferroelectric, and (c) ferroelastic materials [8].

2. FERROELECTRICITY AND ASSOCIATED PHENOMENA

2.1. Background Information

Ferroelectric materials are important members of the ferroic group. Compared to magnetism, they represent a relatively new field and yet have significantly impacted the development of electronic technology. As described in the preceding section, ferroelectric materials are truly multifunctional in nature because at least two other important phenomena, namely, piezoelectricity and pyroelectricity, coexist with them. Even a casual inspection of Fig. 1 makes it obvious that cause and effect between the electric field (E), temperature (T), and mechanical stress (T_{ij}) respectively play a dominant role in inducing dielectric, electric, and thermal properties in any material. Ferroelectricity is a typical example of such a manifestation. Because of the interplay between these forces, special effects take place, giving rise to distortion of the unit cell of a crystal structure and rendering it noncentrosymmetric. Table 1 and Fig. 3 will help in understanding the background of crystal symmetry, structure, and other classifications.

As shown in Table 1, the seven crystal systems are divided into three groups based on their optical classification. “Isotropic” means that the refractive index of the cubic crystal remains unchanged irrespective of whether it is measured in the a , b , or c direction of the crystal; thus, cubic crystal has no birefringence. The terms *tetragonal*, *hexagonal*, and *trigonal* are lumped together as *uniaxial*, meaning that they have one value of birefringence because they can have two different values of refractive index when measured along the different crystallographic

Table 1. Crystal System and Symmetry

Crystal System	Optical Classification	Characteristic Symmetry	Order of Symmetry
Cubic	Isotropic (also called <i>anaxial</i>)	Four 3-fold axes	Highest ↑ Lowest
Tetragonal	Uniaxial	One 4-fold axis	
Hexagonal	Uniaxial	One 6-fold axis	
Trigonal (also called <i>rhomboidal</i>)	Uniaxial	One 3-fold axis	
Orthorhombic	Biaxial	Three mutually perpendicular 2-fold axes; no axes of higher order	
Monoclinic	Biaxial	One 2-fold axis	
Triclinic	Biaxial	A center of symmetry or no symmetry at all	

directions *a*, *b*, or *c*. Similarly, because of three possible values of refractive index, the biaxial crystals can have maximum of two values of birefringence. Such a classification is very important for determining the electrooptic properties of ferroelectrics and other electrooptic crystals. The third column in Table 1 gives the number of characteristic symmetry for each crystal system. As we can imagine, the order of symmetry is the highest in the cubic system and the lowest in triclinic. Progressively from the lowest to the highest order, it goes from triclinic to cubic system as indicated by the arrow in the last (rightmost) column.

It is a well-established fact of crystal physics that out of the seven fundamental crystal systems one can generate 14 fundamental three-dimensional (3D) configurations called the *unit cells*. It was the French physicist Auguste Bravais in 1850 who first demonstrated that, according to the periodic arrangements of atoms found in a crystal, there could be only 14 possible arrangements of atoms in space. These are the famous 14 Bravais lattices, which are also known as *fundamental unit cells*. They can be in four types: primitive (P), body-centered (I), face-centered (F) and base-centered (C). For example, a cubic crystal can exist as simple cubic, or body-centered, or face-centered. Only in the orthorhombic structure are all four classes of unit cells found. Out of

the possible 14 Bravais lattices, 32 point groups originate. These are possible combinations of macroscopic symmetry elements, and once again, on the basis of the atomic periodicity of crystal, there can be only 32 point groups.

In Fig. 3 we show how these 32 point groups can be subdivided into groups of centrosymmetric and noncentrosymmetric unit cells. Out of these 32 classes, 11 are centrosymmetric and 21 noncentrosymmetric. These 21 are theoretically capable of exhibiting either ferroelectricity, piezoelectricity, or pyroelectricity, or a combination thereof. In reality only 20 of these 21 noncentrosymmetric crystals do show these properties. One of them has other symmetry elements, making this a special class of point groups.

Noncentrosymmetry of the unit cell of a crystal is a necessary condition for the existence of ferroelectricity, piezoelectricity and pyroelectricity. Figures 4a and 4b show a simple representation of a centrosymmetric crystal before and after being subjected to a mechanical force [9]. Obviously, in the presence of an external force, the interplanar distance becomes smaller in the direction of the applied force. But the crystal still retains its center of symmetry. From Figs. 5a and 5b we also see that the crystal retains its noncentrosymmetry before and after application of an external force while experiencing, as in the

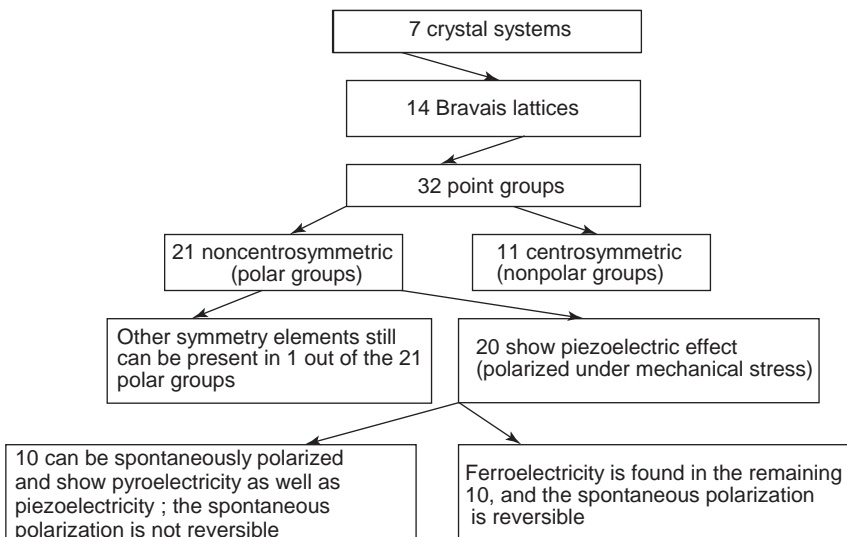

Figure 3. Point groups and their subgroups.

previous case, contraction in the interplanar distance along the direction of the force [9].

2.2. Parameters, Symbols, and Units

As are many other fields of science, ferroelectricity is also described by inconsistent symbols spread over decades of literature. This causes confusion, which might lead to misinterpretation of phenomena and the applications originating from their properties. To avoid such confusion, we follow here the definitions and symbols recommended by the Committee of the Institute of Electrical and Electronics Engineers, Inc. (IEEE). This group was charged with developing standard definitions of terms used in ferroelectricity and associated polar phenomena of piezoelectricity as well as pyroelectricity [8]. Important parameters, their symbols and units are reproduced in Table 2.

2.3. Ferroelectricity

We have already discussed some of the general features of ferroelectricity in order to grasp an understanding of its differences with ferromagnetism. A *ferroelectric* material is defined as a class of material in which the spontaneous polarization exists even when no electric field is applied to it. It is capable of existing in two equivalent states that are totally reversible, making ferroelectrics suited for many applications.

There is another class of materials known as *electrets*, which are often confused with *ferroelectricity*. These are also dielectric materials in which quasipermanent real charges can reside on the surface. They can also be found in the bulk of the material, or as frozen-in aligned dipoles in the bulk. Electrets behave in the same way as a battery

Table 2. Physical Properties and Their Symbols and Units

Terms	Symbol	Units (SI Units)
Curie constant	C	K (Kelvin)
Capacitance	C_x, C_p, C_i	F (Farad)
Elastic stiffness constant	c_{ijkl}, c_{pq}	N/m ² (newtons/meter ²)
Electric displacement (vector)	D_i	C/m ² (coulombs/meter ²)
Piezoelectric charge (or strain) coefficient	d_{ijk}, d_{ij}	C/N (or m/V)
Electric field (vector)	E_i	V/m (volts/meter)
Coercive field (or coercivity)	E_c	V/m
Piezoelectric stress coefficient	e_{ijk}, e_{ij}	C/m ²
Pyroelectric current	i_p	A (ampere)
Dielectric polarization (vector)	P_i	C/m ²
Remanent polarization	P_r	C/m ²
Spontaneous polarization	P_s	C/m ²
Maximum polarization	P_{max}	C/m ²
Pyroelectric coefficient	p_i	C/m ² · K
Strain (second-rank tensor)	S_{ij}	Dimensionless
Elastic compliance constant	s_{ijkl}, s_{pq}	Dimensionless
Curie point	T_c	K or °C
Stress (second-rank tensor)	T_{ij}	N/m ²
Permittivity of free space	ϵ_0	F/m
Permittivity (second-rank tensor)	ϵ_{ij}	F/m
Relative dielectric constant	K_{ij}	Dimensionless

or an electrical counterpart of a permanent magnet. However, they are not ferroelectrics. Ferroelectric materials are distinctly different from electrets in two respects: (1) its polarization is spontaneous, which is retained even at zero electric field; and (2) this polarization is controlled by the crystal's symmetry.

From Fig. 3 we find that the ferroelectric effect can be present in the 10 noncentrosymmetric polar groups in which the spontaneous polarization is reversible. Absence of the center of symmetry is the essential condition for the existence of not only ferroelectricity but also of piezoelectricity and pyroelectricity. As we will see later, a piezoelectric material assumes its polarization when subjected to a mechanical stress. Here the polarization is not spontaneous. It disappears when the mechanical force is removed. However, pyroelectrics are also spontaneously polarized in the same way as ferroelectrics but are not switchable. This is an important distinction between these two closely related phenomena. Ferroelectrics are also distinguished from pyroelectrics in one additional important way—only in ferroelectrics does the spontaneous polarization disappear at a well-defined temperature, called the *Curie point*. There is no concept of the Curie point in either piezoelectric materials, pyroelectric materials, or electrets. This characteristic temperature enables ferroelectrics to exist in two distinct phases: the polar (i.e., ferroelectric) phase and the nonpolar (the paraelectric) phase. Furthermore, ferroelectrics are well known to be materials showing very high dielectric constant, sometimes in excess of 50,000. The uniqueness of ferroelectric materials reflects itself in many ways, which make them

extremely attractive for diverse applications. We will discuss some of these later in this article. To sum up, the characteristic features of a ferroelectric material are (1) switchable spontaneous polarization, (2) high dielectric constant, (3) the Curie point that clearly defines the transition between the polar and nonpolar states, (4) hysteresis loop between polarization and electric field, and (5) crystal structures that lack center of symmetry.

The relationship between barium titanate (BaTiO_3) and ferroelectricity is similar to that between silicon and a semiconductor. It is the most prominent member of the family of ferroelectricity and well established in technology. It is isostructural with the mineral calcium titanate (CaTiO_3) and synthesizes in *perovskite* structure, commonly represented by the formula ABO_3 . The typical structure of BaTiO_3 in its ferroelectric phase (below the Curie point of 120°C) is shown in Fig. 6.

Here the Ba^{2+} ions occupy the eight corners of the unit cell, which is based on close-packed face-centered cubic crystal, the Ti^{4+} ions are located in the body-centered position, and the O^{2-} ions are at the face-centered positions. The barium ions are coordinated with 12 oxygen ions and the Ti ions in the octahedral interstices. At and above the Curie point, the unit cell of BaTiO_3 undergoes a phase transition from nonpolar to polar state. That is, it is no more ferroelectric above the transition point. The presence of the Curie point is an important characteristic of all ferroelectrics. Obviously, this is a material constant and can vary for different materials.

The majority of the well-known ferroelectric materials synthesize in perovskite structure. Some examples of technologically important ferroelectric materials with this structure are K niobate, K tantalate niobate (KTN), Pb titanate, and Pb zirconate-titanate (PZT). It is interesting to note that besides ferroelectrics, many other electronic materials of great scientific and technological importance can also crystallize in this structure. This was realized in the late 1980s, when high-temperature superconductivity was discovered. Leading examples were prominent members of the high-temperature superconductor family, namely, 123 YBCO (YBaCu oxide) and the colossal magnetoresistive materials of the type LaCaCu oxide and LaSrCu oxide. These discoveries have made the perovskite group of materials a subject of intensive research in attempts to discover some novel phenomenon.

Figure 6. Perovskite structure of BaTiO_3 below T_c .

Another prominent ferroelectric group is found in the tungsten bronze structure shown in Fig. 7. They are represented by the generic formula of AB_2O_6 . Leading members of the family are Pb (meta)niobate (PbNb_2O_6), Pb (meta)tantalate (PbTa_2O_6), PbK niobate (PKN) having the formula ($\text{Pb}_2\text{KNb}_5\text{O}_{15}$), and BaSr niobate (SBN) with the formula of $\text{Ba}_2\text{Sr}_3\text{Nb}_{10}\text{O}_{30}$ [4]. PKN has been identified to have the largest piezoelectric coupling coefficient and was researched heavily in the mid-1980s. However, it was almost impossible to grow good crystals without producing multiple cracks. With the advancement of film technology and integration with silicon, PKN may once again receive renewed attention. Among all the electrooptic materials, SBN crystals show the most interesting properties and was the choice material for the fabrication of delay lines.

Ferroelectric crystals, like their magnetic counterparts, consist of a large number of *domains* in which the polarization is oriented in one unique direction. The neighboring domains are separated from each other by *domain walls*. All the polarization vectors point in one single direction and are parallel to each other, resulting in the maximum value of the spontaneous polarization for the bulk of the material. This picture is attainable under two conditions: (1) close to the absolute zero temperature and (2) when subjected to a strong external electric field. Between absolute zero and the Curie point the domain structure goes from fully ordered state (maximum polarization) to fully disordered state (zero polarization). Figure 8 shows schematically the parallel and antiparallel configurations of ferroelectric domains. Even at room

Figure 7. The framework of the tungsten bronze structure looking down the tetragonal c axis. The interstitial sites labeled A1, A2, and C can accommodate A-type cations. The B-type cations occupy the octahedron centers labeled B1 and B2 [10].

temperature the energy associated with lattice vibration is sufficient to destroy the ordered structure and cause the domains to orient randomly, resulting in zero polarization in the absence of an external field.

The hysteresis loop of ferroelectrics is obtained by using the simple circuit originally given by Sawyer and Tower [11] in 1930 and later modified by Sinha [12]. The switching time between the two states of remanent polarization is determined by the method proposed in 1966 by Fatuzo and Fatuzo [13]. A typical hysteresis loop of a ferroelectric material is shown in Fig. 9.

The material at room temperature has randomly oriented domains, as discussed earlier, and therefore zero value of the polarization. Initially when the field is applied and its magnitude is small, the P -versus- E curve is linear because the field induces the polarization here. This corresponds to the linear portion of the curve OA in Fig. 9 when the applied field is very small. Once its magnitude increases, an increasing number of domains orient in its direction. Eventually the polarization enters the nonlinear region and continues to increase with the field until it reaches its maximum value $+P_m$ in the first quadrant labeled I. This path is followed as shown by the dashed

curve OA and called the “virgin curve.” After this the effect of increasing field is negligible. At point $+P_m$ all the domains are fully oriented in one unique direction as shown by the upward-pointing arrows. The interpolation of the uppermost curve in quadrant I cuts the polarization axis at zero field at point P_s ; P_s is termed the *spontaneous polarization*. Strictly speaking, this definition is not exactly correct because theoretically the value of the spontaneous polarization is defined as the polarization at absolute zero. However, the value derived from the hysteresis curve is the value of the spontaneous polarization for all practical purposes. In quadrant I, when the field is reduced from its maximum value at P_m , it does not retrace its original path. Instead, it shows hysteric effect and meets the polarization axis at $+P_r$. This is the value of the polarization remaining from its original value of P_m at zero field; it is called the *remanent polarization*. Usually the ratio of P_r to P_m is less than 1. Ferroelectric materials with this ratio close to 1 are of great importance to memory applications. On further reduction of the field, in quadrant II, we see that the polarization disappears at point $-E_c$; E_c is called the *coercivity* or *coercive field*. In the second quadrant this is the field that is needed to bring the remanent polarization to zero. Here the hysteresis curve has completed its half-cycle. Further reduction of the field, in the third quadrant (III) brings us to $-P_m$. Thus, here the spontaneous polarization has switched by 180° as indicated by the downward arrows representing the orientation of the domains at this point. Once this point is reached, there is no sense in increasing the field in the negative direction any further. The field direction now is reversed and the P -versus- E curve cuts the polarization axis at $-P_r$. From the symmetry of the curve we observe that once again it is the remanent polarization.

Figure 9. Polarization (P) versus electric field (E) hysteresis loop of a ferroelectric material.

The presence of two equivalent states of P_r lends ferroelectrics bistable state similar to that found in ferromagnetism. This particular property is of great technical significance and is the basis of nonvolatile ferroelectric memory. This property is also exploited for many other applications where memory effects are important. In the fourth quadrant (IV) the increasing field brings us back to the coercive field, $+E_c$. Further increase of the electric field allows the polarization to traverse the first quadrant nonlinearly. It eventually reaches the $+P_m$ point. This completes the full cycle of the loop.

No matter how many times the loops are generated, they retrace their original paths. This reproducibility is needed for designing devices based on the nonlinear property of ferroelectrics. The shape of the loop is dependent on the frequency of the AC electric field applied. It is also strongly dependent on temperature. At and very close to the Curie temperature of the ferroelectric material, the nonlinearity ceases to exist because of the disappearance of the spontaneous polarization. For all practical purposes it reduces to a straight line. The temperature at which the hysteresis loop collapses is also a measure of the Curie point. However, it gives only the approximate value. The exact value is to be determined by careful measurement of the spontaneous polarization as a function of temperature. The temperature dependence of the spontaneous polarization is shown in Figs. 10 and 11 [8].

From Figs. 10 and 11 it becomes clear that at the Curie point the material goes through a phase transition from a polar to a nonpolar state. Phase transition can be of two kinds: first-order, in which the change is discontinuous; and the second-order, in which the change is continuous. For many ferroelectrics the first-order transition occurs when it goes through a change in crystal structure such as from tetragonal to cubic. Such is the case for BaTiO₃, PZT, and KTN. Also, we observe that the Curie point is the dividing line between the polar and nonpolar states. Below this temperature ferroelectricity and therefore the nonlinear behavior dominates whereas above it the material is linear, as is any other dielectric. The polar and nonpolar

Figure 10. Spontaneous polarization versus temperature for first-order phase transition [8].

Figure 11. Spontaneous polarization versus temperature for second-order phase transition [8].

phases in a ferroelectric are totally reversible, and this can be explained on the basis of domain theory; specifically, above the Curie point the domain orientations are random, and as the temperature is lowered below the Curie point, the spontaneous polarization in these domains begins to renucleate and the number of these domains continues to increase as the temperature is lowered. At absolute zero they attain the highest order, allowing the spontaneous polarization to reach its maximum possible value.

The nature of the phase transition is also reflected in the temperature dependence of the relative dielectric constant (K) as shown in Fig. 12. In each case, the value of K goes to infinity at the Curie point. Ideally above the Curie point K^{-1} increases linearly with increase in temperature. This is predicted by the Curie-Weiss law

$$K = \frac{C}{T - T_c} \tag{4}$$

In Fig. 12(a), θ is the asymptotic Curie point at which K reaches its maximum value and in almost all cases it is close to the value of the Curie point determined by other

Figure 12. Temperature dependence of inverse of relative dielectric constant of a ferroelectric material undergoing phase transformations at the Curie point of the (a) first order and (b) second order [8].

Figure 13. Capacitance versus bias voltage plot of PNZT solgel film [14].

experiments. It should also be emphasized that not all ferroelectrics follow the Curie–Weiss law strictly.

The capacitance–voltage plot, shown in Fig. 13, is also a good indication of the materials quality of a ferroelectric. Here too we observe that the nature of the curve is hysteric with respect to the decreasing and increasing bias voltage. The width of the peak of the curves, as shown by dashed lines, is a measure of the coercive force. Selected

examples of ferroelectric materials and their properties are presented in Table 3.

2.4. Piezoelectricity

Like many other terms of science, this, too, is derived from a Greek word meaning “to press.” As we have seen in Fig. 1, the relationship between the mechanical stress (T_{ij}) and the electric field (E) gives rise to piezoelectricity. Also, we find from this figure that there are two types of piezoelectric effects: direct and converse. Direct piezoelectric effect occurs because of the interaction between the mechanical stress (T_{ij}) and the displacement (D). Similarly the interaction between the electric field (E) and the strain (S_{ij}) gives rise to the converse effect. Both these piezoelectric effects have significant importance in technology.

If a stress is applied to a piezoelectric crystal, it develops an electric moment per unit volume (or charge per unit area). The magnitude of polarization is proportional to the stress applied. This is called *direct piezoelectric effect*.

Mathematically this is represented by the following equation

$$P = dT \quad (5)$$

where d is the piezoelectric coefficient, P the polarization, and T the stress; or, more precisely as

$$\Delta P_i = d_{ijk} \Delta T_{jk} \quad (6)$$

Table 3. Selected Ferroelectric Materials and Their Properties

Name (Abbreviation)	Chemical Formula	Curie Temperature (°C)	Spontaneous Polarization P ($\mu\text{C}/\text{m}^{-2}$) at (°C)	Crystal Structure	
				$>T_C$	$<T_C$

Source: Ref. 15.

The converse piezoelectric effect takes place on the application of an electric field to a piezoelectric material that induces the shape to deform (or, change) slightly. This is also a linear effect and can be represented by the following simple relationship

$$\Delta S_{jk} = d_{ijk} \Delta E_i \quad (7)$$

where S is the strain and E the electric field.

We have seen earlier that the elastic coefficient, the piezoelectric coefficient, and the dielectric constant are tensors and there can be as many as 45 independent coefficients. For example, the elastic constant can have 21 values; the dielectric constant, 6; and the piezoelectric coefficient, 18. But in practice one need not worry about all these different coefficients. One would usually apply the electric field, for example, in only one direction and measure the mechanical response in some other direction. For all practical purposes, the following two simple equations will suffice to describe piezoelectricity [9]

$$T = cS - dE \quad (8)$$

$$D = \varepsilon E + dS \quad (9)$$

where ε is the dielectric constant. The validity of these equations is given by the following arguments.

If $d = 0$, that is there is no piezoelectric effects present in the material, then we have $T = cS$, which is simply the famous Hooke's law; and $D = \varepsilon E$, which is the most familiar equation of electromagnetism. Alternatively, by setting $E = 0$ in Eqs. (8) and (9) $T = cS$, we once again get the famous Hooke's law and $D = dS$. The latter relation indicates that even in the absence of an electric field in a piezoelectric crystal a finite amount of polarization can develop on the application of strain. Similarly, an electric field can induce strain in a piezoelectric crystal even when there is no mechanical stress applied.

In short, because of the piezoelectric properties, a crystal develops strain when subjected to an electric field. Alternatively, polarization develops under mechanical stress. What follows from these arguments is that piezoelectric materials are ideally suited for applications related to electromechanical transducers. They are the materials of choice for many MEMS devices. Some examples of leading piezoelectric materials are shown in Table 4.

Table 4. Representative Piezoelectric Materials

Material	Type	Piezoelectric Constant $C/N \times 10^{-9}$	Relative Permittivity
Quartz, SiO ₂	Crystal	$d_{33} = 2.33$	4.0–4.5
Polyvinylidene fluoride (PVDF)	Polymer	$d_{31} = 23, d_{33} = 1.59$	12
Barium titanate (BaTiO ₃)	Ceramic crystal	$d_{31} = 78$ $d_{33} = 190$	1700 4100
Lead zirconate (PZ)	Ceramic	$d_{31} = 110, d_{33} = 370$	1200–3000
Zinc oxide (ZnO)	Ceramic	$d_{33} = 246$	1400
Nb-doped PZT ^a (PNZT)	Textured film	$d_{31} = 54$	2200

2.5. Pyroelectricity Effect

We have already encountered the term *pyroelectricity* in Figs. 1 and 3. The origin of this effect lies in the following two facts: (1) interaction between the displacement and temperature and (2) noncentrosymmetry of the unit cell. Thus, pyroelectricity is caused when a crystal having a noncentrosymmetric unit cell and spontaneous polarization undergoes a temperature change. The change in temperature can induce a change in surface charge, which in turn can cause a change in electrical polarization of the material. The end result is the emergence of a thermal current, which can be detected, in an external circuit.

From electromagnetic theory we know that when an electric field is applied to a polar material, the resultant displacement is given by the following simple equation

$$\begin{aligned} D &= \varepsilon_0 E + P_{\text{net}} \\ &= \varepsilon_0 E + (P_s + P_{\text{ind}}) \end{aligned} \quad (10)$$

where D is the displacement, E the electric field, ε_0 the permittivity of vacuum, and P_{net} the net polarization.

Since the total polarization consists of both spontaneous component (P_s) and induced part (P_{ind}), we rewrite Eq. (10) considering that $P_s \gg P_{\text{ind}}$ as follows

$$D \approx \varepsilon E + P_s \quad (11)$$

where ε is the dielectric constant of the material. Differentiating this equation with respect to dT , we get

$$\frac{dD}{dT} \approx \frac{dP_s}{dT} + E \frac{d\varepsilon}{dT} \quad (12)$$

assuming that the E remains constant. We obtain

$$p_{\text{eqv}} \approx p_i + E \frac{d\varepsilon}{dT} \quad (13)$$

where p_{eqv} represents the equivalent pyroelectric coefficient and p_i , the true pyroelectric coefficient.

It is obvious from Eq. (13) that the true pyroelectric coefficient p_i can be evaluated by differentiating the P_s -temperature curves as shown in Figs. 10 and 11. It is also obvious from Eq. (12) that the change in temperature will induce change in the polarization vector. Therefore,

the pyroelectric coefficient can now be defined as

$$\Delta P_i = p_i \Delta T \quad (14)$$

where $i = 1, 2, 3, \dots$

The basic definition of the true pyroelectric coefficient is given by Eq. (14), whereas Eq. (13) gives the actual pyroelectric coefficient measured. The contribution from the second term representing the temperature coefficient of the dielectric constant ($d\epsilon/dT$) cannot be neglected if the pyroelectric measurements are done on a ferroelectric material for which, as we know, the temperature coefficient of the dielectric constant can assume large values.

We have already seen that the large values of the dielectric constant are also one of the most important features of a ferroelectric material and reaches its maximum value at the Curie point. This would mean that the equivalent pyroelectric coefficient (p_{eqv}) would be large for a ferroelectric with the Curie point near room temperature. This is an important consideration while designing a pyroelectric detector. Another important consideration in the device design is the contribution made by the piezoelectric coupling on the performance of the detector. Most of the practical pyroelectrics are also piezoelectrics. Therefore they will experience strain because of the thermal expansion leading to the development of surface charges.

The thermal current (I_p) that can be generated by heating uniformly a pyroelectric material is given by

$$i_p = \frac{dQ}{dt} = A \frac{dP_s}{dT} \cdot \frac{dT}{dt} \quad (15)$$

or

$$i_p = A p_i \frac{dT}{dt} \quad (16)$$

where A is the area of the electrode and p_i the pyroelectric coefficient. Here it is important to note that the heating of the sample must take place at a uniform rate. The current is generally determined when the experiment is conducted in a dynamic mode. Alternatively, the pyroelectric coefficient can be evaluated directly by measuring the charge (using an electrometer) that is generated at different temperatures. The following equation can be used for this

purpose:

$$p_i = \frac{Q_2 - Q_1}{A(T_2 - T_1)} \quad (17)$$

Some examples of technologically important pyroelectric materials are given in Table 5. These materials are used mostly for infrared imaging.

2.6. Pyrooptic Effect

A lesser known property called the *pyrooptic effect* of dielectric materials can also be potentially exploited for detection of infrared. The temperature dependence of the refractive index gives rise to this parameter. It is defined as

$$\theta_p = \left(\frac{d\eta}{dT} \right) \quad (18)$$

where θ_p is the pyrooptic coefficient and η the refractive index.

Performance of a pyrooptic detector will be significantly superior to pyroelectric or photon detector because no metallic contacts to pixel elements are needed to operate this device. Because it is an optical system, it allows for non-contact readout. This leads to an ideal thermal detecting structure as it eliminates a major source of signal-to-noise ratio in the system. In addition, for a pyrooptic detector, the sample thickness need not be greater than the optimum thickness required for supporting the optical waves on reflection. Thus, the pixel volume (or, mass) can be very small.

The concept of a pyrooptic detector was proposed in the early 1990s [24,25]. The device can be built on a single-crystal base or on films of a pyrooptic material. The film can be freestanding or supported on a transparent substrate having poor thermal conductivity.

Leading pyrooptic materials with their pyrooptic coefficients are presented in Table 6. As we can see from this table, once again ferroelectrics appear to be the material for the pyrooptic technology.

It is to be noted that in spite of many attractive features and simplicity, no practical device has become commercially available that is based on this effect. However, with the phenomenal progress made since the mid-1990s in processing of materials, especially films, and in producing

integrated structures with silicon [26], it is reasonable to assume that the pyrooptic effect might attain its rightful importance in the infra-red technology.

2.7. Antiferroelectricity

Once again we have copied this term from the vocabulary of magnetism. In antiferromagnets electronic spins are in antiparallel configuration. Similarly, the dipoles are antiparallel to each other in an antiferroelectric material. In these crystals the polarization is distributed throughout in the bulk of the material in an antiparallel arrangement such that the net polarization is zero. Figure 8b may be considered to schematically represent such a system. Note that this is a highly ordered configuration and must not be confused with the randomness of the dipoles caused by lattice vibrations. According to the classic work by Jona and Shirane [21], an antiferroelectric material is to be defined as an antipolar crystal whose free energy is comparable to that of a polar crystal. In an antipolar crystal the dipole interactions are such that they cause the antiparallel domains to dominate. Obviously these materials do not exhibit hysteresis loops between the polarization and the electric field. But a large anomaly is experimentally detectable when the structure changes from a completely unpolarized state to the antiferroelectric state at the transition point. Antiferroelectricity is a fundamental part of ferroelectricity and plays an important role in understanding the physics behind dielectric materials. Lead zirconate (PbZrO₃) is one of the most famous examples of antiferroelectricity. It shows a large anomaly in the temperature dependence of the dielectric constant at about 250°C and no dielectric loop at all [21]. This is a very important constituent of PLZT, PNZT, PZT, and other compounds that have enormous technical importance.

2.8. Multiferroic Magnetolectrics

No discussion of ferroelectricity can be complete without considering multiferroic materials. These are the materials in which ferroelectricity and ferromagnetism can co-exist in the same phase. They are also known by different terms, such as *magnetolectrics* and *ferromagnetolectrics*.

Ferromagnetism and ferroelectricity have been extensively researched and used in developing many applications and technologies. They both remain to a great extent independent fields of science with little or no overlap. However, the scientific and technological importance has long been realized for materials showing both ferromagnetism and ferroelectricity in the same phase and prefer-

ably above room temperature. Unfortunately such materials are not found in nature and have until relatively recently frustrated the efforts to produce them with a high degree of reproducibility in laboratories. This scarcity might be anchored in the fact that the transition metal *d* electrons, which are essential for the origin of ferromagnetism, tend to reduce the lattice distortion that causes ferroelectricity [27]. This results in a weak coupling between the spontaneous magnetization and spontaneous polarization. Because of the advancement in film technology and successful fabrication of integrated structures and superlattices, the search for new multiferroic materials has become very active. This covers a broad spectrum of materials ranging from composites to epitaxial films. It has been reported that magnetoelectric effects can be introduced in the thin film consisting of nanometric level of CoFe₂O₄ [cobalt ferrite (CFO)], which is a ferromagnetic material, and ferroelectric lead titanate (PbTiO₃) [28]. Bismuth manganate (BiMnO₃) is another material in which magnetoelectricity has been predicted [29]. The experimental search for this effect in BiMnO₃ was presented at a workshop conducted under the sponsorship of the US Office of Naval Research [30].

Of special importance are the two new discoveries. The presence of ferroelectricity in magnetic bismuth ferrite (BiFeO₃) has been conclusively shown by Palkar et al. [31]. They grew pure phase of bismuth ferrite on platinized silicon substrates by the pulsed-laser ablation method (PLD) under multiple partial pressures of oxygen. They report the existence of saturated ferroelectric loop for their samples, and the typical anomalous behavior of the temperature dependence of dielectric constant, which is the signature of a ferroelectric material. This anomaly occurs at the antiferromagnetic transition temperature (T_N) of $\sim 380^\circ\text{C}$. The ferroelectric transition occurs at $\sim 810^\circ\text{C}$. This is a remarkable result and is certain to contribute to the field of multiferroic materials and their applications.

Another equally important discovery has been reported by Hur et al. [32]. Electric polarization reversal and memory effects were induced by external magnetic field ranging from 0 to 2 T (tesla) in terbium manganate (TbMn₂O₃) multiferroic material. This is the first time anyone has been able to demonstrate strong coupling between magnetic and ferroelectric states. Besides polarization reversal induced by a magnetic field, the investigators were also successful in attaining memory effects under the combined influence of magnetic and electric fields. Like the previous work, this outstanding discovery is certain to impact the science and information technology.

3. MATERIALS PROCESSING

The ferroelectric materials are processed in three principal ways: ceramic processing, film deposition, and single-crystal growth. Each of these methods has its merits and demerits. Their selection depends primarily on the factors such as cost, volume of materials needed, and intended use. In the next few paragraphs we will briefly survey the three processing techniques applicable to ferroelectric materials.

3.1. Ceramic Processing

For large-scale production and applications this is the most widely preferred processing technique applied to produce dielectric materials including ferroelectrics. It is a relatively simple technique, is moderately expensive, and gives high returns on investment. Additionally, it lends itself easily to implementation of modifications and parameter adjustments for producing materials with predictable properties in large volumes. On a smaller scale, it provides an excellent research tool for designing and discovering new dielectric materials.

This consists of seven major steps as shown in Fig. 14. The first and foremost step is to begin with highest possible purity grades of raw materials in proper weight or mole

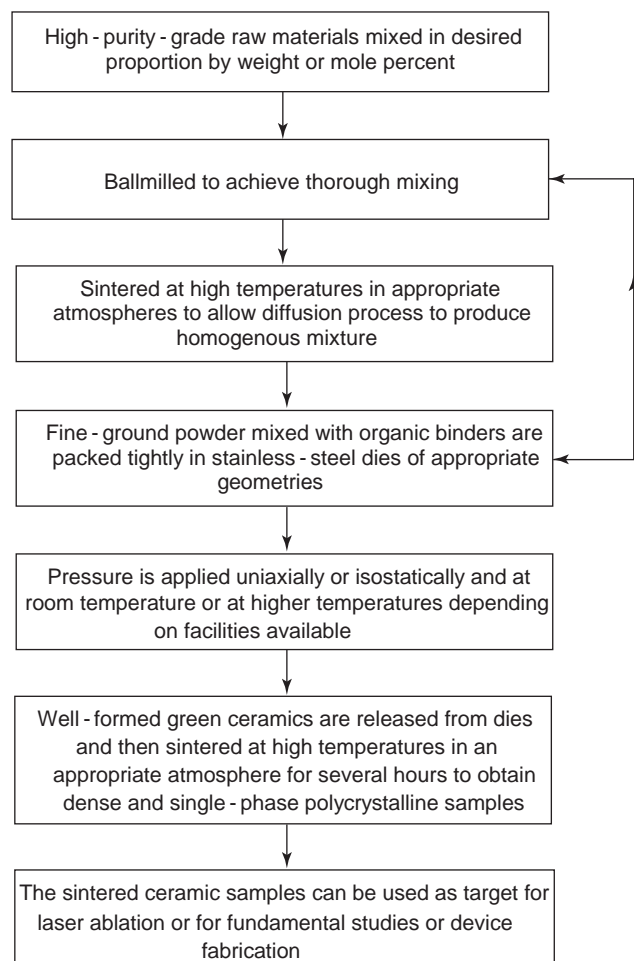

Figure 14. Flow diagram for ceramic pressing.

ratio. Then they should be mixed thoroughly such as by ballmilling to break down the particle size and obtain a homogeneous mixture. The subsequent steps of heat treatment and forming desired shapes and sizes follow this step. Then the most critical step is undertaken. The compaction takes place by applying uniformly high pressures to the dies containing the desired shapes and forms. Hydrostatic pressing at elevated temperatures is the most desirable approach to obtain a high-density and high-quality material. However, if such a system is not available, cold hydrostatic pressing, or simply cold or hot isostatic pressing are available alternatives. Once the pressing is done, the green ceramic needs to be sintered at high temperatures, which are mostly 90% of the melting temperature of the materials, for hours in a specialized atmosphere. Air annealing is usually sufficient. However, depending on the chemistry of the material, it is necessary to do annealing in reducing, oxidizing, or neutral atmospheres. The logic behind sintering at high temperatures for extended time periods is to allow the diffusion process to produce single-phase, homogenous materials with large grains (crystallites) and with practically no voids. Each heat treatment aids in attaining this goal. It is important that the steps shown in boxes (second, third, and fourth seen from the top) in Fig. 14 should be repeated at least 3 times before high-pressure operation takes place. This laborious and time-consuming processing method ensures the quality of the material to be produced. Once the ceramic samples become available, they are ready for use either for scientific experiments or for product development.

3.2. Film Deposition

Because of their multifunctional nature, ferroelectrics lend themselves to a large number of applications and development of novel devices for which high-quality epitaxial or textured films are required. They are grown by a variety of techniques; the most common ones are sputtering, electron-beam evaporation, solgel, metallorganic deposition (MOD), physical vapor transport (PVT), and pulsed-laser deposition (PLD). As in the case of ceramic processing, the choice of the method for film growth depends on many factors; again, the foremost are the cost and quality of films needed. As can be expected, each of these methods has its merits and limitations. The literature is full of excellent books and publications dealing with each of these techniques. Unfortunately, we are not in a position to cover any of these methods in depth in this article. However, we are giving here some basic information related to the methods mostly used by the ferroelectric community for the benefit of the reader.

For large-scale production, sputtering and solgel are the leading methods used on industrial scale. Having similarity with solgel MOD is also widely used but it is not as effective a method as solgel. The PVT method is used only when other methods are not applicable such as if the material has high vapor pressure. These are mostly iodides, fluorides, sulfides, and similar compounds. The PVT method is capable of producing high-quality textured or even single crystalline films on a variety of substrates. However, it has its own limitations and is not easily modifiable

for large-scale applications. Figure 15 shows a simple experimental arrangement developed by us [22] for the growth of antimony sulphoiodide (SbSI) films for pyroelectric and pyrooptic research [26]. High-quality textured or even single-crystal films could be grown of this high vapor pressure material by the PVT method.

The PLD method is versatile and has been used for the growth of a large number of oxides including ferroelectrics, high-temperature superconductors, and colossal magneto-resistant (CMR) materials. Since its discovery in late 1980s when it was first introduced very successfully for the growth of high-temperature superconductor, especially 123 YBCO, PLD has become the choice method for research on oxide growth. It is a versatile method and can be easily adopted to implement necessary changes in growth parameters. Its greatest strength lies in the fact that it retains the chemical homogeneity of the film with respect to its source (called “targets” in the language of PLD) and can produce polycrystalline, textured, or single-crystalline films; integrated structures; and superlattices. It is also used for the growth of complex device configurations. An excellent treatment is given of PLD technology in Ref. 33.

3.3. Single-Crystal Growth

Single-crystal growth has been the most fascinating and challenging area of materials processing. Ceramics, films, integrated structures, and superlattices can meet many scientific and technical needs, yet there are still some very specialized needs for high-quality bulk single crystals. Substrates for epitaxial growth of films are exclusively bulk single crystals. This has been a very well-established field for more than a century. Its biggest impact in technology came with the invention of transistors in the late 1950s when it was realized that device-quality single crystals of silicon were needed for superior performance and reproducibility of the transistors. The crystal growth method, which is today widely known as the “Czochralski technique,” lived up to this enormous technical challenge. It is the most widely used method for crystal growth. Other growth methods are high-temperature solution growth (HTSG), aqueous solution growth (ASG), Bridg-

man growth, top-seeded solution growth (TSSG), and temperature-gradient transport growth (TGTG), to name only a few. The literature is full of crystal growth methods applicable to a variety of materials. Obviously it is not within the scope of this article to survey the literature for the crystal growth of even ferroelectric materials. Interested readers are referred to some excellent work such as given in Refs. 34–36.

Here we plan to limit ourselves to a very introductory presentation of this subject. The selection of an appropriate growth method depends on all the factors outlined in the previous two sections. But the most important criterion is to determine whether a material melts congruently or incongruently. When, for example, the melt and the solid of a material have the same chemical composition, then the material’s melting point is congruent. Otherwise, it is incongruent. Very few ferroelectrics melt congruently. As a result, the famous Czochralski technique cannot be employed for the growth of these materials. This is unfortunate in the sense that other methods are not as versatile as the Czochralski technique in producing large single crystals in a reasonable amount of time. The most successful methods for the growth of ferroelectric crystals have been HTSG, TGTG, TSSG, and ASG. The Czochralski technique has been widely used for the congruently melting members of the family of barium strontium titanate (BST), strontium barium niobate, and lithium niobate (LiNbO_3). All these are highly attractive materials for electrooptic applications and fabrication of optical waveguides. Lithium niobate, an excellent ferroelectric and piezoelectric material, is also widely used as substrates for building integrated structures.

The famous pyroelectric material, TGS, is grown by AGS method. This is an excellent material for IR imaging. But its hygroscopic nature is a drawback. A large number of ferroelectric crystals have been grown by the HTSG method, which is also known as the “flux growth method.” Here a suitable solvent is used for dissolving the raw materials (called “charge” in the vocabulary of crystal growth) at high temperatures and then cooled very slowly (usually $1\text{--}2^\circ/\text{h}$) over many weeks. Relatively large (a few millimeters to a few centimeters) crystals grow that are harvested by dissolving the frozen flux in a suitable solvent. Barium titanate (BaTiO_3) has been grown in device quality by the TSSG method.

A variation of this method is TGTG. This is a very innovative technique and has been applied for the growth of some otherwise difficult-to-grow ferroelectrics with a minimum of compositional gradient within the bulk of the sample. Potassium tantalate niobate (KTN), (Fig. 16), which has excellent electrooptic, ferroelectric, and pyrooptic properties, has been grown as a large single crystal by this method [20].

4. APPLICATIONS

In the preceding sections we have established the multifunctional nature of ferroelectrics. Ferroelectrics, as we have already seen, are high dielectric constant materials, which also possess reversible spontaneous polarization

Figure 15. SbSI films grown by physical vapor transport method.

Figure 16. Potassium tantalate niobate (KTN) single crystals [20]; the length scale shown here corresponds to 1 cm.

and piezoelectric coupling as well as pyroelectricity simultaneously. These properties are the driving forces behind the importance of ferroelectrics in a wide range of technologies. In fact, they play a very vital role in the advancement of technologies ranging from classical to ultramodern. Classically, ferroelectrics are ceramics. Owing to their unique electrical properties they are also important members of the family of *electroceramics*.

It is not within the scope of this article to discuss in depth even the most important applications based on the multifunctional nature of ferroelectric materials. Interested readers will find the two publications [15,37] useful in understanding of applications based on ferroelectrics and associated phenomena and their impact on technology, especially electronic, electrooptic, communication, and information technology.

By carefully evaluating the multiple properties and phenomena associated with these classes of polar materials, we can get an idea of the enormity of its importance to technology and its potential for the development of novel devices. We can summarize them as follows:

- Because ferroelectrics are piezoelectric as well as pyroelectric, they are also multifunctional.

- Piezoelectricity can exist alone in some polar materials, or it can be accompanied by pyroelectricity, or in some other materials all three effects—ferroelectricity, piezoelectricity, and pyroelectricity—can coexist.
- All pyroelectrics are piezoelectrics but not necessarily ferroelectrics as well.
- The discovery of existence of both ferroelectricity and ferromagnetism in the same phase (previously referred to as *multiferroic* or *magnetoelectric*) opens avenues for world-class research in materials science, physics, and microelectronics.
- Because piezoelectricity is an excellent class of electro-optic materials, its impact on the optical industry is conspicuous.

In the beginning of this article we briefly examined the equilibrium diagram (Fig. 1) between three forces, electric field (E), temperature (T), and mechanical stress (T_{ij}), and their respective consequences; namely, displacement (D), entropy (S), and stress (S_{ij}). These six agents couple together in noncentrosymmetric crystals to produce the multifunctional phenomenon of ferroelectricity. Figure 17 presents some of these interactions and their consequences.

We have already seen that the domains in ferroelectrics even at room temperature can be randomly oriented. Therefore, the materials need to be *poled* before they can be utilized for device fabrication and integration. Poling is a relatively simple operation. First, metallic electrodes are deposited by thermal evaporation or sputtering or by other means on the surfaces of the samples so that an electric field can be applied to them. Then they are subjected to a DC electric field, which is much greater than the sample's coercivity, while slowly raising the temperature to a point above the Curie point of the material, where it is held for some time to ensure that the entire material is in equilibrium in its paraelectric state. Subsequently, the temperature is slowly lowered to room temperature in the presence of the field. The process involves the nucleation of domains as soon as the temperature is lowered slightly below the Curie point. Once the domains form they orient themselves in the

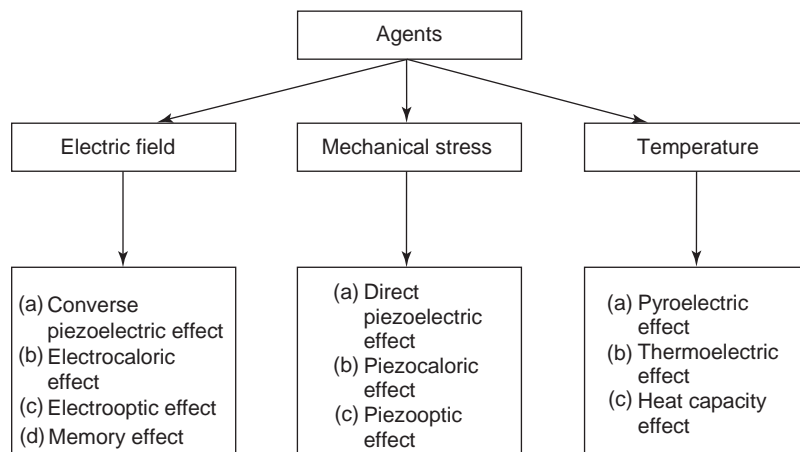

Figure 17. Agents and effects responsible for ferroelectric applications [15].

direction of the field that is present in the sample. Their number keeps on increasing, as the sample is finally reaches room temperature. Now all the domains in the material are should be fully aligned and will remain so even after the field is removed. At this stage, the *poling* has been completed and the field is removed. The sample will retain its poled status as long as it is not reheated above the Curie point. In that event, one will have to re-pole the specimen.

On one end of the application spectrum, ferroelectrics are the dominant material for design and fabrication of ceramics. They are produced in large volumes and have the largest share of capacitor market throughout the world. Because of their unusually high dielectric constant, a large quantity of electrical energy can be stored in a relatively small volume and capacitor size. Therefore, ferroelectric-based capacitors can be made in large to miniaturized shapes and fulfill vital functions in electronics and integrated circuits.

On the other end of the spectrum, ferroelectrics are conspicuously present in an array of modern applications covering as varied fields as MEMS technology, radiofrequency and microwave communication, information technology, electrooptics, optical communications, infrared imaging, uncooled focal plane arrays, and nonvolatile memory, to name just a few applications and technologies to which ferroelectric materials have contributed.

Ferroelectrics dominate the scene of actuators and transducers because of their piezoelectric properties. Among all commercially available piezoelectric materials, Pb zirconate titanate (PZT) plays a very prominent role. Table 4 lists other piezoelectric materials. PZT is the most widely used piezoelectric material and has established itself as a leading transducer material in microelectromechanical (MEMS) technology.

When it comes to infrared imaging applications, ferroelectric materials once again lead the pack of materials suitable for fabrication of detectors that can operate above room temperature. These are the so-called uncooled focal plane arrays. Around 1990 Texas Instruments in Dallas, Texas championed ferroelectric-based *uncooled* focal plane arrays. The original material used was highly dense ceramic of barium strontium titanate (BST) having a transition temperature of around room temperature. In this type of device, the unique pyroelectric properties of ferroelectrics are exploited. In Table 5 we list the leading pyroelectric materials.

Memory devices based on ferroelectric materials are nonvolatile, meaning that the data stored are retained in the memory even when the power fails or is switched off. This is comparable to the well-established magnetic memories. Another class of widely used memory is DRAM (or dynamic random access memory), which consists of volatile memories. These memories are based on silicon integrated circuit technology, in which the stored data are lost once the electrical power of the device is switched off. In spite of this serious drawback and inconvenience, DRAMs are widely used because of their high integration capability. Nonvolatility of a ferroelectric memory is the result of the stable bipolar states of its hysteresis loop

discussed previously in this article. Constant improvements are being made in the design and integration of FeRAMs.

Ferroelectrics are also an established group of materials for microwave communications. Barium strontium titanate (BST) appears to be the leading material for such applications. The literature is full of reports on how BST can be used in developing integrated structured devices to meet various requirements of the microwave communication. Ferroelectrics are attractive materials for microwave devices because (1) they have low microwave losses in the paraelectric phase, (2) dielectric permittivity is DC-field-dependent, (3) tunability is high, and (4) extremely high values of permittivity make it possible to miniaturize the devices. The ferroelectric integrated structures (with silicon and superconductors) are attractive for many microwave applications:

- Varactors and varactor-based devices such as mixers and harmonic generators
- Tunable resonators, filters, and antennas
- Miniature tunable delay lines and phase shifters
- High-density capacitors and small-size low-impedance transmission lines
- Thin-film “bulk acoustic wave” resonators and filters
- Surface acoustic wave (SAW devices) filters, convolvers, converters, and similar devices
- MEMS switches for actuation and transduction.

A good survey of applications of ferroelectric materials in microwave communications is covered by Patel et al. [38]. Interested readers will benefit greatly from consulting this resource. Integrated structured devices using ferroelectric materials as one of the components are becoming increasingly important for development of new microwave [39] and other applications [40–46].

The following books and other publications are recommended for serious readers who would like to gain an insight in the field of ferroelectricity and related phenomena.

FILTER SYNTHESIS

ERNST LUEDER
University of Stuttgart

1. AN OVERVIEW OF CLASSICAL FILTERS

Electrical filters are, as a rule, lossless two-ports embedded in resistances R_1 and R_2 , as shown in Fig. 1. A lossless two-port may contain only inductors, capacitors, and ideal transformers. The filters allow a band of the input frequencies to pass with only a small attenuation while all remaining frequencies are to a large extent suppressed. The transfer function

$$\frac{V_2(p)}{V_0(p)} = F^*(p) \tag{1}$$

also called the *transfer voltage ratio* or the *insertion voltage gain*, is a function of the complex frequency p , where $p=j\omega$ stands for the natural and measurable angular frequencies ω . For brevity ω will from now on be called simply the *frequency*. From $F^*(j\omega) = A(\omega)e^{j\varphi(\omega)}$ are derived the magnitude $A(\omega) = |F^*(j\omega)|$ and the phase $\varphi(\omega) = \arg F^*(j\omega)$ with the group delay $\tau(\omega) = -d\varphi(\omega)/d\omega$. The attenuation function is $a(\omega) = -20 \log |F^*(j\omega)|$ in dB (decibels) or, more seldom, $\ln |F^*(j\omega)|$ in Np (nepers). The relation is $1 \text{ Np} = 8.686 \text{ dB}$.

The synthesis of filters follows a well-established pattern. First the properties of a transfer function $F^*(p)$ of a two-port with given types of components have to be established. This guarantees the existence of a solution with realizable positive values of the components as long as the desired transfer function exhibits the above mentioned properties. The most common types of components for classical filters are lossless inductors and capacitors, as well as ideal transformers for the two-port and resistances R_1 and R_2 as internal resistance of the source and as the terminating load. This case is treated in this article. Other types of components are switches such as FETs, capacitors, and operational amplifiers in so-called switched capacitor filters or delays, adders and multipliers in digital filters or resistors, capacitors and operational amplifiers in RC-active filters, or electromechanical transducers and a set of electrodes in surface acoustic wave (SAW) filters, which are treated in the last section.

The next step in filter synthesis is the approximation of given specifications for a particular filter by functions meeting the requirements of $F^*(p)$. The last step is the

Figure 1. Lossless two-port embedded in resistances R_1 and R_2 .

calculation of the values of the components by mathematical means from the functions approximating the specifications. This step also provides the topology of the two-port. For approximations it is mathematically easier to handle the square of the magnitude $|F^*(j\omega)|^2$. For a lossless two-port in Fig. 1 $F^*(p)$ has the following properties [1,2]:

1. $F^*(p)$ is a rational function in p , real-valued for real-valued p ; as a consequence, the coefficients in $F^*(p)$ are real-valued if the numerator and the denominator of $F^*(p)$ do not contain a common complex factor.
2. Stability requires the poles of $F^*(p)$ to lie in $\text{Re } p < 0$ and the degree of the numerator not to exceed the degree of the denominator. The denominator is hence a Hurwitz polynomial.
3. The numerator is either an even or an odd polynomial in p if common factors in the numerator and the denominator are not canceled.
4. The maximum power available at the output reveals the upper bound (Feldtkeller condition):

$$|F^*(j\omega)| \leq \frac{1}{2} \sqrt{\frac{R_2}{R_1}} = \frac{1}{q} \tag{2}$$

A given $F^*(p)$ meeting these requirements is always realizable by a lossless two-port embedded in R_1 and R_2 . $|F^*(j\omega)|^2$ can also be expressed by the reflection coefficient introduced by S. Darlington [3]

$$S_{11}(j\omega) = \frac{R_1 - Z_1(j\omega)}{R_1 + Z_1(j\omega)} \tag{3}$$

as

$$|F^*(j\omega)|^2 = \frac{R_2}{4R_1} (1 - |S_{11}(j\omega)|^2) \tag{4}$$

where $Z_1(j\omega)$ represents the input impedance of the two-port loaded by R_2 . S_{11} is an element of the scattering matrix. Instead of transfer functions the inverse of the transfer function V_0/V_2 or $V_0/2V_2$ is also applied. These functions are also called the *insertion voltage loss*. In this article

$$\frac{V_0(p)}{V_2(p)} = K^*(p) \tag{5}$$

will be used.

Figure 2. Lowpass filter with cutoff frequency ω_c , 3 dB cutoff frequency ω_c^* , and the equiripple between q^{-2} and $q^{-2} - a^2$.

Figure 3. Highpass filter.

Figure 5. Bandstop filter.

The insertion loss [4]

$$20 \log \frac{R_2}{R_1 + R_2} \left| \frac{V_0(j\omega)}{V_2(j\omega)} \right| = 10 \log \frac{P_0}{P_2} \quad (6)$$

is based on the ratio between the power $P_0 = |V_0(j\omega)|^2 R_2 / (R_1 + R_2)^2$ dissipated in R_2 without the two-port inserted in between the source V_0 with R_1 and the load R_2 and the power $P_2 = |V_2(j\omega)|^2 / R_2$ dissipated in R_2 in the presence of the two-port.

Figures 2–5 depict examples for $|F^*(j\omega)|^2$ of characteristic filters, such as a lowpass, a highpass, a bandpass, and a bandstop. The beginning and the end of the passband are defined by a cutoff frequency ω_c or ω_c^* . For the lowpass in Fig. 2, ω_c^* is chosen as the frequency, where $|F^*(j\omega)|^2$ has decreased to half of the value at $\omega = 0$ (3 dB frequency).

Another choice is a specific frequency ω_c . For example, in Fig. 2 $|F^*(j\omega)|^2$ leaves the band of equiripple behavior, later also called *Chebyshev behavior*.

A typical example for a lowpass circuit is shown in Fig. 6. The zeros of $F^*(p)$ that generate a zero output voltage are visible in the circuit diagram. The series-parallel resonator exhibits an infinite impedance at the resonant frequency ω_1 , preventing signals from reaching the output. The same is true for the shunt-series resonator exhibiting a zero impedance at the resonant frequency ω_2 . Finally, a zero output is observed at $\omega = \infty$ because the shunt capacitors have a zero impedance and the series inductor exhibits an infinite impedance. Nonideal resonators represent a resistor R at the resonant frequency. The larger the quality factor Q of a resonator is, the better the

transmission zero is realized. For series resonators $Q = Z/R$, whereas for parallel resonators $Q = R/Z$ with $Z = \sqrt{L/C}$. L stands for the value of the inductor and C for the value of the capacitor. $|F^*(j\omega)| = \text{const}$ means a lack of amplitude distortion; together with an arbitrary phase $\varphi(\omega)$ it defines an allpass, the transfer function of which is

$$F^*(p) = k \frac{r(-p)}{r(p)}$$

where $r(p)$ is a Hurwitz polynomial in p and k a constant. $F^*(p)$ with a linear phase $\varphi(\omega) = -\omega t_0$ reflecting in a constant group delay t_0 and with an arbitrary magnitude belongs to a two-port without phase distortion. $F^*(p)$ with a constant nonzero magnitude in $|\omega| \in [0, \omega_c]$, zero magnitude otherwise, and a linear phase $-\omega t_0$ is called an “ideal” lowpass, which works as a delay line with delay t_0 for frequencies in the passband.

A filter cascaded by an amplitude equalizer exhibits an overall transfer function with an approximately constant magnitude, whereas a phase equalizer in cascade provides a linear phase of the overall two-port [4]. The phase equalizer is an allpass.

If all reactances in a two-port are discharged at time $t = 0$, then $F^*(p)$ is the Laplace transform of the impulse response $h(t)$ with

$$h(t) = \frac{1}{2\pi j} \int_{\sigma-j\infty}^{\sigma+j\infty} F^*(p) e^{pt} dp$$

Figure 4. Bandpass filter.

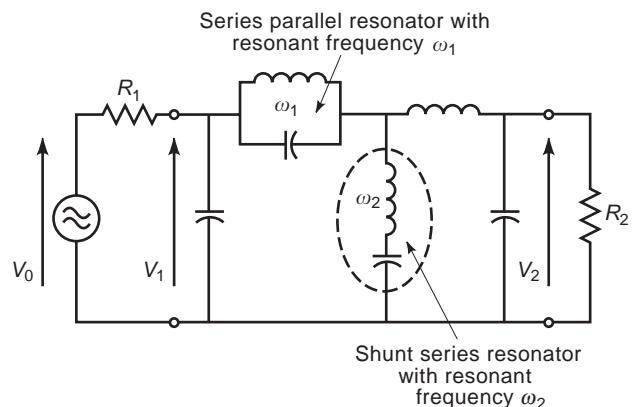

Figure 6. Example of a lowpass circuit.

where $F^*(p)$ is an analytical function in $\text{Re } p \geq \sigma_0 \leq \sigma$. The step response is

$$a(t) = \int_{0-}^t h(\tau) d\tau$$

Some lowpasses with specific characteristics are discussed together with amplitude and phase equalizers in the following subsections.

Guidelines will be presented on how to determine from filter tables the component values of a filter meeting given specifications. This should enable a system engineer to achieve a quick filter design by selecting the appropriate type of filter and by then finding the component values in a table.

1.1. Butterworth Lowpasses

The Butterworth lowpass [9] in Fig. 7 exhibits a maximum flat magnitude $|F^*(j\omega)|$ at $\omega = 0$ —that is, $d^v |F^*(j\omega)| / d\omega^v = 0$ for $v = 1, 2, \dots, n$, where n is the degree of $F^*(p)$. The decay of the magnitude is moderately steep in the transition region and approaches $n \times 20$ dB per frequency decade for large values of ω . $K^*(p) = 1/F^*(p)$ is a polynomial.

We investigate the step response $a(t)$ for various lowpasses, including the Butterworth lowpass. To compare $a(t)$ for those lowpasses, we normalize all of them with the frequency ω_c , where $|F^*(j\omega_c)| = 0.9 \times F^*(0)$ holds. For lowpasses with equiripple behavior, ω_c also stands for the end of the equiripple band. The normalized time is $\tau = \omega_c t$. Figure 8 shows $a(\tau)/a(\infty)$ for a Butterworth lowpass with $F^*(p)$ of seventh degree [10]. There is an overshoot of 15.4% over the value $a(\infty)$, the largest of the lowpasses compared, but followed by rapidly decreasing oscillations around the value $a(\infty)$. Values for the overshoot in % and for the risetime in τ from 10% to 90% of $a(\infty)$ are listed in Table 1 for Butterworth lowpasses with $F^*(p)$ of degree 1–7. For a Butterworth lowpass with $F^*(p)$ of 7th degree the risetime is $t = 2.51\omega_c^{-1}$, the 2nd smallest rise time of all lowpasses in Table 5.

1.2. Thomson Lowpasses

Thomson lowpasses [11] are given by $K^*(p) = 1/F^*(p)$ representing a modified Bessel polynomial. They are therefore often also called *Bessel lowpasses*. $F^*(p)$ exhibits a maximum flat group delay t_0 at $\omega = 0$. The decay of the

Figure 7. A Butterworth lowpass, maximally flat at $\omega = 0$.

Figure 8. Step responses $a(\tau)/a(\infty)$ of various filters with transfer functions $F^*(p)$ of seventh degree. The common characteristics of the filters are provided in the caption and footnote of Table 1.

magnitude is moderately steep in the transition region and for a large ω is again $n \times 20$ dB/decade, where n is the degree of $F^*(p)$. The step response $a(\tau)/a(\infty)$ for the Thomson lowpass with $n = 7$ is plotted in Fig. 8 [10]. It is a remarkably good approximation of an undistorted delayed step. The overshoot is only 0.49% over $a(\infty)$. Oscillations around $a(\infty)$ are only marginal. Table 2 contains values for overshoot and risetime of $a(\tau)$ for $n = 1-7$ [10]. According to Table 5, the risetime for $n = 7$ is $t = 1.22\omega_c^{-1}$, the smallest value of all lowpasses listed in that table.

1.3. Chebyshev Lowpasses

Chebyshev lowpasses (Fig. 2) possess a magnitude oscillating between two constant boundaries in the passband, where each extremum touches the boundaries. This is called an *equiripple*, or a *Chebyshev behavior* in the passband. $K^*(p) = 1/F^*(p)$ is a polynomial. The larger the ripple a^2 (Fig. 2), the steeper is the decay of $|F^*(j\omega)|^2$ in the transition region from the passband into the stopband. From all polynomials this decay is steepest. However, independent of a^2 the decay at large ω s is again $n \times 20$ dB/decade. The step response $a(\tau)/a(\infty)$ for $n = 7$ in Fig. 8 [10]

Table 1. Overshoot and Risetime of Butterworth Lowpasses with $F^*(p)$ of Degree $n = 1-7^a$

exhibits the third largest overshoot over $a(\infty)$; however, the oscillations around $a(\infty)$ decay rather rapidly. According to Table 5 the value for the overshoot is 12.7%, whereas the rise time is $t = 3.4\omega_c^{-1}$, the second largest value in Table 5. Overshoot and risetime of $a(\tau)$ for $n = 1-7$ are listed in Table 3 [10].

1.4. Cauer Filters as Lowpasses

Elliptic filters or Cauer filters [12] (Fig. 9) are lowpasses exhibiting an equiripple behavior in both the passband and the stopband. They are based on elliptic integrals, which is why they are also called “elliptic filters.” $K^*(p) = 1/F^*(p)$ is a rational function in p . The step response of the Cauer lowpasses for $n = 7$ in Fig. 8 exhibits the second largest overshoot and only slowly decaying oscillations around $a(\infty)$ [10]. Overshoot and risetime for $n = 1-7$ are listed in Table 4 [10]. In addition to the properties of the normalization mentioned previously for Butterworth lowpasses, the minimum stopband attenuation of the Cauer filters is chosen to be 60 dB.

Table 5 shows a comparison of overshoot and risetime of the step response for four filter types with $F^*(p)$ of degree 7.

Further filters such as bandpasses, highpasses, bandstops, or filters with several passbands are obtained by a frequency transformation applied to the lowpass, where the frequency characteristics are preserved.

1.5. Design of Filters Using Filter Tables

Three characteristic lowpasses are tabulated to be chosen from for a given task: the Butterworth, the Chebyshev, and the Cauer lowpass, the features of which have been

Table 3. Overshoot and Risetime of Chebyshev Lowpasses with $F^*(p)$ of Degree $n = 1-7^a$

n	Overshoot (%)	Risetime, 10–90% (τ)

Figure 9. A Cauer lowpass (elliptic filter) with equiripple in passband and stopband; ω_s is end of transition region.

discussed above. The Bessel lowpass is, as a rule, not contained in tables as it deals mainly with properties in the time domain.

After the selection of the appropriate type of lowpass the designer turns to the pertinent filter tables. As a rule only solutions for the special case $R_1 = R_2$ are tabulated. If this is not acceptable because an additional amplifier may be required, one has to go through the general design procedure as described in the next paragraph. The general procedure is also mandatory if different types of specifications are given, such as steps in the attenuation in the stopband or the suppression of specific pilot frequencies.

As shown in Fig. 12, the filter requirements are given by four values for the attenuation $a(\Omega) = -20 \log |F^*(j\Omega)|$ in dB, where

$$\Omega = \frac{\omega}{\omega_c} \tag{7a}$$

is the normalized frequency. Those four values in dB are A_0 the minimum attenuation in the passband, A_{\max} the maximum attenuation in the passband, A_{\min} the minimum attenuation in the stopband, and the frequency Ω_s defining the end of the transition region with $a(\Omega_s) = A_{\min}$. For $R_1 = R_2$ we obtain $A_0 = 0$ as a special case. This reduces the number of specifications to three.

First the reflection coefficient $\rho = \sqrt{1 - 10^{-0.1A_{\max}}}$ has to be calculated. A table with $A_{\min} + 10 \log(\rho^{-2} - 1)$ as ordinate and Ω_s as abscissa reveals the required degree n for a given $\Omega_s(\rho)$, A_{\min} , and filter type. Then one turns to tables for the chosen type of lowpass, the degree n , and the value ρ , which provide the normalized values of the components.

Table 4. Overshoot and Risetime of Cauer Lowpasses with $F^*(p)$ of Degree $n = 1-7^a$

Lowpass Type	Overshoot (%)	Risetime, 10–90% (τ)
Thomson	0.49	1.22
Butterworth	15.4	2.51
Chebyshev	12.7	3.40
Cauer	13.7	3.81

^aNormalization as in Table 1.

The normalized values ℓ and c of the reactances provided by the tables are with a normalizing resistor R_1

$$\frac{\omega L}{R_1} = \frac{\omega}{\omega_c} \frac{\omega_c L}{R_1} = \Omega \times \ell \quad (7b)$$

and

$$\omega C R_1 = \frac{\omega}{\omega_c} \omega_c C R_1 = \Omega \times c \quad (7c)$$

where

$$\ell = \frac{\omega_c L}{R_1} \quad (8a)$$

and

$$c = \omega_c C R_1 \quad (8b)$$

ℓ and c are values without dimension.

For the inductors, the denormalized values are

$$L = \frac{R_1}{\omega_c} \cdot \ell$$

and for the capacitors

$$C = \frac{1}{\omega_c R_1} \cdot c$$

This concludes the design with the help of a table.

1.6. Equalization of Amplitude and Phase

In systems the need can arise to change the amplitude, that is, the attenuation $a(\omega)$, most often to render it constant in a given range of frequencies. A simple solution is to replace the resistance R_2 at the output by a two-port with input resistance $R = R_2$, but a frequency-dependent inverse transfer function $K_B^*(p)$ and the associated attenuation $a(\omega) = 10 \log |K_B^*(j\omega)|^2$. $K_B^*(p)$ is multiplied with the inverse transfer function of the given two-port, whereas $a(\omega)$ is added to its attenuation. Such an amplitude equalizer is shown in Fig. 38 with the design equation in the figure caption. If several of those equalizers have to be cascaded it is easily done by replacing the loading resistance $R = R_2$ of the first equalizer by the next equalizer and so on. Table 9 shows $a(\omega)$ for various equalizer two-ports. The shapes of $a(\omega)$ are chosen such that they add to the attenuation to be equalized at the frequencies where this is needed. The equalizers, however, also change the phase of the entire two-port, which is tolerable for all filters where phase is not important, such as in audio systems.

The correction of the phase or the group delay of a given two-port is done by cascading phase equalizers at the output of the given two-port. They are allpasses as depicted in Fig. 40. The phase equalizers exhibit an input resistance $R = R_2$ if terminated by R_2 , thus replacing the load R_2 of the given two-port. The design equations are given in the caption of Fig. 40. The equalizers further offer a unit magnitude that is an attenuation $a(\omega) = 0$ and a group delay as shown in Figs. 39a and 39b. By cascading two-ports, the transfer functions are multiplied and hence the phases in the exponent of the exponential functions are added. This also applies to the group delay. The attenuation of the given two-port remains unchanged due to $a(\omega) = 0$ of the allpasses. Figures 39a and 39b reveal how the allpasses must be chosen to add to the group delay at those frequencies where an increase is needed. Most often the group delay has to become constant by a phase equalization.

So far we have dealt with two-ports. There are also m - n -ports with n input ports and m output ports. They can realize filterbanks.

2. THE SYNTHESIS OF FILTERS

To obtain general results for lowpasses independent of the values of the cutoff frequencies ω_c , we introduce a normalized frequency $\Omega = \omega/\omega_c$ pertaining to the s plane with the imaginary axis $s = j\Omega$. This translates $K^*(p)$ in Eq. (5) in which $p = j\omega$ as follows:

$$\frac{V_0}{V_2} = K^*(j\omega) = K^*\left(j \frac{\omega}{\omega_c} \omega_c\right) = K^*(j\Omega\omega_c) = K(j\Omega)$$

and hence

$$\frac{V_0}{V_2} = K^*(p) = K(s)$$

The synthesis follows the steps as listed and explained here:

1. The given tolerance scheme for $|K(j\Omega)|^2 = P(\Omega)$ is approximated by a realizable

$$|K(j\Omega)|^2 \geq q^2 = 4 \frac{R_1}{R_2} \quad (9)$$

with q in Eq. (2).

2. From $|K(j\Omega)|^2$ the function $K(s)$, the characteristic function $f(s)$; and the elements of the chain matrix $A(s)$ are determined.
3. $A(s)$ is realized by a lossless two-port by a pole removal process.

2.1. Calculations for the Individual Steps

The approximation and calculation may be performed by a general approach based on a least square procedure. However, as a rule, special functions with suitable properties are chosen to solve the approximation problem. These

functions will be discussed. Finally, a general approximation procedure based on a conformal mapping will be outlined.

2.1.1. The Chebyshev Approximation and the Calculation of $K(s)$. The square $|K(j\Omega)|^2$ of the magnitude of the function $K(j\Omega)$ according to the Chebyshev approximation is plotted in Fig. 11. In the passband $|K(j\Omega)|^2$ completely exhausts the tolerance stripe; that is, each extremum of $|K(j\Omega)|^2$ touches the limit of the tolerance band from the inside. In the stopband $|K(j\Omega)|^2$ tends to infinity. As these filter characteristics are most widely used, more detailed information on the Chebyshev approximation must be given. The differential equation for a Chebyshev polynomial $y(x)$ is

$$m^2(1 - y^2) = \left(\frac{dy}{dx}\right)^2 (1 - x^2) \tag{10a}$$

or

$$m^2(y^2 - 1) = \left(\frac{dy}{dx}\right)^2 (x^2 - 1) \tag{10b}$$

Figure 10. (a) A Chebyshev polynomial $y(x)$. (b) The Chebyshev polynomial of fourth and fifth degree m .

where m is a constant. The differential equation equates the zeros in Fig. 10a of $y + 1$ \circ and $y - 1$ \square with the zeros of y^2 and $x - 1$ \bullet as well as $x + 1$ \bullet . The statement

$$x = \cos \vartheta \quad \text{and} \quad y = \cos \eta$$

provides the solution

$$y = \cos(m\vartheta + c) \quad \text{with} \quad \vartheta = \arccos x \text{ for } |x| \leq 1$$

whereas the statement

$$x = \cosh \vartheta \quad \text{and} \quad y = \cosh \eta$$

yields the solution

$$y = \cosh(m\vartheta + c) \quad \text{with} \quad \vartheta = \operatorname{arcosh} x \text{ for } |x| \geq 1$$

where c is the integration constant. For $c = 0$ we obtain

$$T_m(x) = y = \cos m\vartheta \tag{11a}$$

and

$$\vartheta = \arccos x \quad \text{for } |x| \leq 1 \tag{11b}$$

and

$$T_m(x) = y = \cosh m\vartheta \tag{12a}$$

and

$$\vartheta = \operatorname{arcosh} x \quad \text{for } |x| \geq 1 \tag{12b}$$

The known trigonometric equality

$$\begin{aligned} \cos(m + 1)\vartheta &= \cos m\vartheta \cos \vartheta - \sin m\vartheta \sin \vartheta \\ &= \cos m\vartheta \cos \vartheta - \frac{1}{2}(\cos(m - 1)\vartheta \\ &\quad - \cos(m + 1)\vartheta) \end{aligned}$$

yields

$$\cos(m + 1)\vartheta = 2 \cos m\vartheta \cos \vartheta - \cos(m - 1)\vartheta$$

or the recursion for $T_{m+1}(x)$:

$$T_{m+1}(x) = 2T_m(x) \times x - T_{m-1}(x) \tag{13}$$

The starting solutions for $m = 0$ and $m = 1$ are provided by Eqs. (11a) and (11b) as $T_0(x) = 1$ and $T_1(x) = x$. Some polynomials $T_m(x)$ for $m = 2, 3, \dots, 11$ obtained from Eq. (13) are listed in Table 6 and plotted for $m = 4$ and $m = 5$ in Fig. 10b. Even m provide even and odd m odd polynomials $T_m(x)$. The coefficient at the leading term x^m is 2^{m-1} .

We first construct the function $V_0/V_2 = K(s)$ from a given $|K(j\Omega)|^2$. $|K(j\Omega)|^2 = P(\Omega)$ in Fig. 11 is expressed by

$$|K(j\Omega)|^2 = \varepsilon^2 T_m^2(\Omega) + q^2 = p(\Omega) \tag{14}$$

Table 6. Chebyshev Polynomials of Degree $n = 2-11$

$T_2(x) = 2x^2 - 1$
$T_3(x) = 4x^3 - 3x$
$T_4(x) = 8x^4 - 8x^2 + 1$
$T_5(x) = 16x^5 - 20x^3 + 5x$
$T_6(x) = 32x^6 - 48x^4 + 18x^2 - 1$
$T_7(x) = 64x^7 - 112x^5 + 56x^3 - 7x$
$T_8(x) = 128x^8 - 256x^6 + 160x^4 - 32x^2 + 1$
$T_9(x) = 256x^9 - 576x^7 + 432x^5 - 120x^3 + 9x$
$T_{10}(x) = 512x^{10} - 1280x^8 + 1120x^6 - 400x^4 + 50x^2 - 1$
$T_{11}(x) = 1024x^{11} - 2816x^9 + 2816x^7 - 1232x^5 + 220x^3 - 11x$

For $\Omega \gg 1$ we obtain with the coefficient 2^{m-1} of the leading term

$$|K(j\Omega)|^2 \approx \varepsilon^2 2^{2(m-1)} \Omega^{2m} \quad (15)$$

and

$$\begin{aligned} a(\omega) &= 10 \log |K(j\Omega)|^2 \\ &\approx 20[m \log \Omega + (m-1) \log 2 + \log \varepsilon] \end{aligned} \quad (16)$$

This reveals that for a small ripple $\varepsilon < 1$, $\log \varepsilon < 0$ decreases the rise of the attenuation for large Ω and for a large ripple $\varepsilon > 1$, $\log \varepsilon > 0$ increases the rise of the attenuation for large Ω . The increase of $a(\Omega)$ for a decade 10Ω is $\Delta a(\Omega) = 20 m$; that is, 20 dB per decade and per degree m of $T_m(\Omega)$. The attenuation $a(\omega)$ belonging to Fig. 11 is depicted in Fig. 12 with minimum (respectively maximum) attenuation A_0 (respectively, A_{\max}) in the passband and the minimum attenuation A_{\min} in the stopband. The upper limit of the transition region is Ω_s . Chebyshev filters represent the rare case in which all characteristic values q , ε , and m in Eq. (14) can be determined from the given values A_0 , A_{\max} ,

Figure 11. The square of the magnitude $|K(j\Omega)|^2$ of a Chebyshev lowpass with $|K(j\Omega)|^2 = \varepsilon^2 T_m^2(\Omega) + q^2$.

Figure 12. The tolerance scheme in decibels for a Chebyshev lowpass.

and A_{\min} at Ω_s by the equations

$$10 \log q^2 = A_0 \quad (17)$$

and hence

$$q^2 = 10^{A_0/10}$$

$$10 \log(q^2 + \varepsilon^2) = A_{\max} \quad (18)$$

and hence

$$\varepsilon^2 = 10^{A_{\max}/10} - 10^{A_0/10}$$

and

$$a(\Omega_s) = 10 \log(q^2 + \varepsilon^2 \cosh^2 m \times \operatorname{arcosh} \Omega_s) = A_{\min}$$

and hence

$$m = \frac{1}{\operatorname{arcosh} \Omega_s} \operatorname{arcosh} \frac{\sqrt{10^{A_{\min}/10} - 10^{A_0/10}}}{\sqrt{10^{A_{\max}/10} - 10^{A_0/10}}} \quad (19)$$

In Eq. (19) the expression for $T_m(\Omega)$ for $|\Omega| \geq 1$ was used.

The general synthesis procedure outlined next was established by W. Bader [1;16a,b]. It is explained with Chebyshev lowpasses as an example.

From the known $|K(j\Omega)|^2$ we have to calculate the rational function $K(s)$. We consider

$$|K(j\Omega)|^2 = P(\Omega) = P\left(\frac{s}{j}\right) = Q(s) \quad (20)$$

for $s = j\Omega$ and extend s into the entire complex plane. On the other hand, as $K(s)$ is real for real s , we obtain

$$|K(j\Omega)|^2 = K(j\Omega)\overline{K(j\Omega)} = K(j\Omega)K(-j\Omega) = K(s)K(-s) \quad (21)$$

for $s = j\Omega$, which is also extended into the s plane. Equations (20) and (21) hence provide

$$K(s)K(-s) = Q(s) \quad (22a)$$

Obviously, $Q(s)$ is even in s , and real for real s . Hence the zeros occur at $s = s_i$ and $s = -s_i$ as well as at $s = \bar{s}_i$ and $s = -\bar{s}_i$, as plotted in Fig. 13. For $q = 0$, zeros on $s = j\Omega$ are feasible and have an even multiplicity. The zeros in $\text{Re } s < 0$ and half the multiplicity of the zeros on $s = j\Omega$ are assigned to $K(s)$, thus forming a stable or at least quasi-stable $K(s)$ if the zeros on $s = j\Omega$ are single. We perform these operations on $|K(j\Omega)|^2$ in Eq. (14) starting from $P(\Omega)$ and $Q(s)$ in Eqs. (20) and (22b), which yields

$$Q(s) = q^2 + \varepsilon^2 T_m^2\left(\frac{s}{j}\right) = 0 \tag{22b}$$

or

$$T_m^2\left(\frac{s}{j}\right) = -\left(\frac{q}{\varepsilon}\right)^2 \tag{23}$$

As the zeros are complex, we form

$$\begin{aligned} T_m\left(\frac{s}{j}\right) &= \cos m\vartheta \\ &= \cos m(\vartheta_1 + j\vartheta_2) \text{ and } \frac{s}{j} = \cos \vartheta \end{aligned} \tag{24}$$

from which follows

$$\begin{aligned} T_m\left(\frac{s}{j}\right) &= \cos m\vartheta_1 \cosh m\vartheta_2 \\ &\quad - j \sin m\vartheta_1 \sinh m\vartheta_2 = \pm j\left(\frac{q}{\varepsilon}\right) \end{aligned} \tag{25}$$

The solutions are

$$\begin{aligned} \cos m\vartheta_1 \cosh m\vartheta_2 &= 0 \\ \sin m\vartheta_1 \sinh m\vartheta_2 &= \mp \frac{q}{\varepsilon} \end{aligned}$$

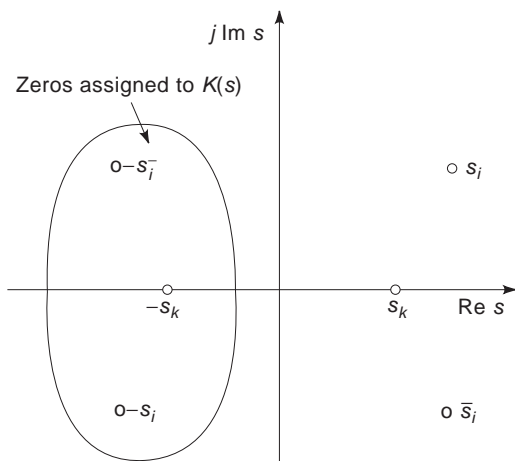

Figure 13. Zeros of $Q(s) = K(s)K(-s)$ in Eq. (22a).

or

$$\vartheta_1 = \frac{2v + 1}{m} \frac{\pi}{2} \quad v = 0, 1, 2, \dots, 2m - 1 \tag{26a}$$

and

$$\vartheta_2 = \frac{1}{m} \text{arsinh} \frac{q}{\varepsilon} \tag{26b}$$

The location of the zeros is, with Eq. (24), $s = j \cos \vartheta = j \cos(\vartheta_1 + j\vartheta_2)$ or

$$s = \sin \vartheta_1 \sinh \vartheta_2 + j \cos \vartheta_1 \cosh \vartheta_2 = \beta + j\gamma \tag{26c}$$

This finally provides

$$\frac{\beta^2}{\sinh^2 \vartheta_2} + \frac{\gamma^2}{\cosh^2 \vartheta_2} = \sin^2 \vartheta_1 + \cos^2 \vartheta_1 = 1 \tag{27}$$

The zeros obviously lie on an ellipse, as shown for $m = 3$ in Fig. 14. Finally

$$K(s) = \pm \varepsilon 2^{m-1} \prod_{i=1}^m (s - s_i) \tag{28a}$$

or

$$F(s) = \frac{\pm 1}{\varepsilon 2^{m-1} \prod_{i=1}^m (s - s_i)} \tag{28b}$$

represents the solution for the desired $K(s)$ and $F(s)$ with the m zeros of Eq. (22b) and the coefficient of the leading

Figure 14. Zeros of $K(s)K(-s)$ and $f(s)f(-s)$ for Chebyshev filters with $m = 3$.

term stemming from the Chebyshev polynomial in Eqs. (14) and (15).

2.1.2. Determination of the Chain Matrix A and of $f(s)$. The chain matrix of the lossless two-port in Fig. 1 is

$$A = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} \quad (29)$$

with

$$\begin{pmatrix} V_1 \\ I_1 \end{pmatrix} = A \begin{pmatrix} V_2 \\ I_2 \end{pmatrix} \quad (30)$$

Necessary and sufficient conditions for a realizable LC chain matrix are as follows [17]:

1. The four elements of A are rational in s and real for real s . A_{11} and A_{22} are even, and A_{12} , A_{21} are odd functions of s .
2. $\det A = 1$.
3. At least three ratios of horizontally or vertically adjoining elements are LC driving point impedances. For $A_{12} \equiv 0$ or $A_{21} \equiv 0$ or $A_{12}, A_{21} \equiv 0$, the elements A_{11} and A_{22} are constants reciprocal to each other.

$K(s)$ can be expressed as

$$K(s) = \frac{V_0}{V_2} = \left(A_{11} + \frac{A_{12}}{R_2} + \left(\frac{q}{2}\right)^2 (R_2 A_{21} + A_{22}) \right) \quad (31)$$

$$\text{with } q = 2\sqrt{\frac{R_1}{R_2}}$$

The term q is explained in Eq. (2). With an unknown ‘‘characteristic’’ function $f(s)$, we obtain

$$A_{11} + \frac{A_{12}}{R_2} = \frac{1}{2}(K(s) + f(s)) \quad (32a)$$

and

$$\left(\frac{q}{2}\right)^2 (A_{22} + R_2 A_{21}) = \frac{1}{2}(K(s) - f(s)) \quad (32b)$$

According to condition 1, A_{11} —respectively, $(q/2)^2 A_{22}$ —are the even parts of $\frac{1}{2}(K(s) + f(s))$ —respectively, $\frac{1}{2}(K(s) - f(s))$. A_{12}/R_2 —respectively, $(q/2)^2 R_2 A_{21}$ —are the odd parts

of $\frac{1}{2}(K(s) + f(s))$ —respectively, $\frac{1}{2}(K(s) - f(s))$. This provides

$$A_{11} = \frac{1}{4}(K(s) + f(s) + K(-s) + f(-s)) \quad (33a)$$

$$\frac{A_{12}}{R_2} = \frac{1}{4}(K(s) + f(s) - K(-s) - f(-s)) \quad (33b)$$

$$\left(\frac{q}{2}\right)^2 A_{22} = \frac{1}{4}(K(s) - f(s) + K(-s) - f(-s)) \quad (33c)$$

$$\left(\frac{q}{2}\right)^2 R_2 A_{21} = \frac{1}{4}(K(s) - f(-s) - K(-s) + f(-s)) \quad (33d)$$

From $\det A = 1$, we drive

$$A_{11} \left(\frac{q}{2}\right)^2 A_{22} - \frac{A_{12}}{R_2} \left(\frac{q}{2}\right)^2 R_2 A_{21} = \left(\frac{q}{2}\right)^2$$

or, with Eqs. (33a)–(33d)

$$K(s)K(-s) - q^2 = f(s)f(-s), \quad \text{with } q = 2\sqrt{R_1/R_2} \quad (34)$$

As $K(s)$ and q^2 are known, $f(s)$ can be determined by the same consideration as applied for finding $K(s)$. The product $f(s)f(-s)$ is even; its zeros are assigned in complex conjugate pairs, if complex, to $f(s)$ and the location with the opposite sign to $f(-s)$. The constraint of stability, mandatory for $K(s)$, does not apply for $f(s)$ as $f(s)$ is no insertion voltage loss.

For Chebyshev filters, from Eqs. (22a), (22b) and (34), we obtain

$$f(s)f(-s) = \varepsilon^2 T_m^2\left(\frac{s}{j}\right) = 0 \quad (35)$$

The zeros can be derived from Eqs. (23), (26a), and (26b) for $q/\varepsilon = 0$, yielding

$$\vartheta_1 = \frac{2\nu + 1}{m} \frac{\pi}{2} \quad (36a)$$

and

$$\vartheta_2 = 0 \quad (36b)$$

with the zeros in Eq. (26c) as

$$s_k = j \cos \vartheta_1 = j \cos \frac{2\nu + 1}{m} \frac{\pi}{2} \quad (37a)$$

$$\nu = 0, 1, \dots, 2m - 1 \text{ and hence } k = 1, 2, \dots, 2m$$

These zeros on the imaginary axis are double as demonstrated in Fig. 14 for $m = 3$.

Finally, from Eq. (35) we obtain

$$f(s) = \pm \varepsilon 2^{m-1} \prod_{k=1}^m (s - s_k)$$

Figure 15. Pole-zero plot of D with admittances Y and impedances Z during partial \surd and full \times removal of poles.

where s_k are half the zeros in Eq. (35) and where a single zero is taken from each location.

Now the elements A_{ik} of the chain matrix can be calculated using Eqs. (33a)–(33d). There are four possibilities to calculate A depending on the selection of the signs for $K(s)$ and $f(s)$.

2.1.3. Development of an LC Two-Port. Starting with a chain matrix A with known elements A_{ik} , the steps leading to an LC two-port embedded in the resistances R_1 and R_2 in Fig. 1 will be given and explained. The basic concept is the development of an LC reactance function into an LC circuit in such a way that the poles of $K(s)$ are realized. The poles of $K(s)$ in Eq. (31) are the zeros of the denominator and the $n - m$ poles at $s = \infty$ that occur if the degree n of the numerator exceeds the degree m of the denominator, manifested by $n - m > 0$. For an all-pole filter, $K(s)$ is a polynomial where all poles lie at $s = \infty$. The Chebyshev filter is an example of an all-pole filter as well as the Butterworth filter or the Thomson filter, which are treated later.

The development of A into an LC two-port starts with the selection of an element A_{ikL} with the largest degree in s . If there is more than one such element, any one may be chosen, yielding different solutions with the same inverse transfer function $K(s)$. Then we form the ratio $D = A_{ikL} / A_{ikN}$ or the inverse $D = A_{ikN} / A_{ikL}$, where A_{ikN} is the element horizontally or vertically next to A_{ikL} . The ratios are LC two-terminal functions. There are four possibilities to form them depending on the selection of the neighbor to A_{ikL} . Together with the four possible chain matrices, we are at this point already faced with at least 16 possible LC one-ports, with every one ensuring an equivalent solution.

The ratios may represent either an input or an output driving point impedance function with a short circuit or an open circuit at the receiving end. The short circuit or the open circuit is later replaced either by the load R_2 or the input voltage V_0 with the resistance R_1 depending on the physical meaning of the two-terminal function.

The development of the LC driving point impedance function is based on a modified continued fraction expansion [16a,b] with partial pole removals [18–20] al-

lowed only at poles of $K(s)$ and preferably at those poles of $K(s)$ at $s = \infty$ or $s = 0$. The process is explained by the pole-zero plot in Fig. 15. The headline shows the poles of $K(s)$ to be realized. A full circle \circ or cross mark \times stands for the two zeros or the two poles at $s = \pm j\Omega$ and for the associated degree 2 in s , whereas a half-circle \cap or a half-cross mark \surd stands for the degree 1 in s . We assume that Y in the second line is the admittance D we have chosen from the chain matrix. The partial fraction to the pole at $s = 0$ is a_0/s . We remove part of this pole by subtracting a_1/s with $a_1 < a_0$. It can be shown (16a,b) that by doing this, all zeros beside the one at $s = \infty$ move toward the pole partially removed. a_1 is chosen such that the zero at $s = j\Omega_1$ moves to $s = j\Omega_0$. a_1/s is realized by the first inductor in Fig. 16. A proof that there is always a $0 < a_1 < a_0$ able to generate the desired zero is missing. Now the admittance Y is inverted, and the pole of the impedance Z at $s = j\Omega_0$ is fully removed (\times) and realized by the series-parallel resonator in Fig. 16. The two-port will exhibit a transmission zero at $s = j\Omega_0$ because the infinite impedance of the series-parallel resonator prevents energy from being delivered into the resistor R_2 , which hence exhibits a zero voltage at frequency Ω_0 . The same is true for a shunt zero impedance. It is even true for a series infinite impedance or a shunt zero impedance, which are generated by a partial pole removal, because these impedances block the energy transfer to

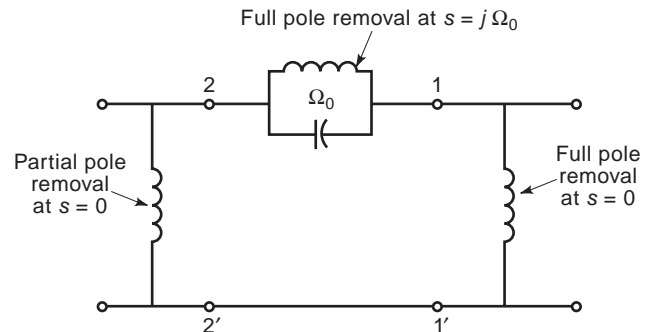

Figure 16. LC two-port generated by the development in Fig. 15.

Figure 17. Always in full pole removal \surd if $K(s)$ is a polynomial in s ; Y =admittances, Z =impedances.

the output resistance R_2 . This imposes the constraint that a partial pole removal is allowed only at poles of $K(s)$.

The partial removal of a pole does not lower the degree of the driving point function. As a consequence, the two-port generated does not exhibit the minimum number of components. To minimize the number of components, partial pole removal preferably should take place at $s = 0$ or $s = \infty$, where it is associated with only one reactance.

So far, the procedure for rational functions D has been described. The function $K(s)$ of Chebyshev filters in Eq. (28a) is a polynomial where all poles lie at $s = \infty$. The development of the LC two-port is a special case plotted in Figs. 17 and 18 [16c]. We start with an impedance, the pole of which at $s = \infty$ is fully removed, realizing a pole of $K(s)$ at $s = \infty$ by the inductor L_1 in Fig. 18. The full pole removal in the admittance of the next step provides the shunt capacitor C_1 realizing another pole at $s = \infty$. The process continues in Figs. 17 and 18 [16c] until all poles are realized by three inductors and two capacitors. Since only full pole removals were used for the Chebyshev filter, the circuit generated exhibits the minimum number of components.

Figure 18. An LC two-port if $K(s)$ is a polynomial.

So far, from the given matrix A in Eq. (29), the matrix A^* in Eq. (37b)

$$A^* = \begin{pmatrix} kA_{11} & A_{12}^* \\ kA_{21} & A_{22}^* \end{pmatrix} \quad (37b)$$

is realized if we assume that the driving point function D was selected as $D = A_{11}/A_{21}$. In D a common constant factor k may have been canceled. The physical meaning of A_{11} is $A_{11} = V_1/V_2$ for $I_2 = 0$ and of $A_{11}^* = kA_{11} = V_1/V_2^*$ for $I_2^* = 0$, where V_2^* (respectively, I_2^*) are the output voltage (respectively, current) in Fig. 19 at the LC two-port A^* so far realized. The terms are evaluated at an arbitrarily chosen frequency, where $s_0 = 0$ or $s_0 = \infty$ are especially easy to handle. The result is $k = A_{11}^*(s_0)/A_{11}(s_0)$. The correction for $k \neq 1$ is achieved by an ideal transformer in Fig. 19 with matrix T in cascade with A^* providing

$$A^*T = \begin{pmatrix} kA_{11} & A_{12}^* \\ kA_{21} & A_{22}^* \end{pmatrix} \begin{pmatrix} \frac{1}{k} & 0 \\ 0 & k \end{pmatrix} = \begin{pmatrix} A_{11} & kA_{12}^* \\ A_{21} & kA_{22}^* \end{pmatrix} \quad (37c)$$

Figure 19. The intermediate steps A^* , the ideal transformer, and the embedding in R_1 and R_2 during the synthesis of two-ports.

We claim that with this last step the given matrix A is realized. For proof we consider for the matrices A and A^*T the equations

$$\det A = A_{11}A_{22} - A_{12}A_{21} = 1$$

and

$$\det A^*T = A_{11}kA_{22}^* - kA_{12}^*A_{21} = 1$$

The poles of $K(s)$ are given by the denominators of the elements A_{ik} according to Eq. (31). They are already realized by the synthesis procedure and are equal in A and A^* . Therefore, we now concentrate on the numerators of A_{ik} . We assume that A_{11} has the highest degree in s . At the n zeros of A_{11} we obtain $A_{12} = -1/A_{21}$ and $kA_{12}^* = -1/A_{21}$. This means that the numerators of A_{12} and kA_{12}^* of degree $< n$ are identical at n points; hence they are identical for all s . The same applies to A_{22} and kA_{22}^* . Therefore, $A^*T = A$, as desired.

Some remarks about the procedure for synthesizing an LC two-port are necessary:

1. As mentioned previously, a proof has not yet been found that partial pole removal with positive value of the components is always feasible. However, so far there has always been a realizable two-port among all the alternatives for equivalent solutions.
2. If in each element in A the common factors are canceled, then it can be proved that horizontally or vertically adjoining elements exhibit no common zeros. However, for some developments it is necessary to represent all elements with one single common denominator. Then common zeros of adjoining elements may occur. They are also zeros of $K(s)$ and are realized by a partial fraction expansion. The pertinent circuits are added in series of an open-circuit reactance function and in the shunt of a short-circuit reactance function D . This brief remark may suffice.
3. The alternative solutions can differ in the number of inductors and capacitors. Hence a search for a circuit with the minimum number of inductors is worthwhile because capacitors are, as a rule, less costly.
4. Developments with capacitors connected to a common terminal, such as ground, are advantageous since parasitic capacitances can be included in these capacitors.
5. Tuning of the transmission zeros can be carried out by adjusting one element, preferably the capacitor, in the series or parallel resonators.
6. The procedure can be used to generate specific one-ports such as the equivalent circuit for a quartz oscillator in Fig. 20.

The general procedure for the synthesis of an LC filter embedded in R_1 and R_2 from a given $|K(j\omega)|^2$ was pre-

Figure 20. Equivalent circuit of a quartz oscillator.

sented with Chebyshev filters as an example. The procedure will be applied to all further filters discussed in this article.

2.1.4. Further Filters Derived from Chebyshev Polynomials. In the previous section a lowpass was derived from the squared Chebyshev polynomials $T_m^2(\Omega)$, $\Omega = \omega/\omega_c$. Further filters are generated from $1/T_m^2(\Omega)$, $T_m^2(1/\Omega)$, and $1/T_m^2(1/\Omega)$. These functions are depicted in Figs. 21a–21c. In the Figs. 22a–22c the pertaining filters and their $K(s)$ are shown. It can be seen that a highpass with Chebyshev behavior in the stopband (Fig. 22a), a highpass with Chebyshev behavior in the passband (Fig. 22b), and a lowpass with Chebyshev behavior in the stopband (Fig. 22c) can be generated.

2.1.5. The Butterworth Approximation [9]. Contrary to the Chebyshev approximation, the normalizing frequency usually chosen for the Butterworth filters is ω_c^* , the 3 dB frequency, yielding $\Omega = \omega/\omega_c^*$. We again work with the function $K(j\Omega)$ instead of $F(j\Omega) = K(j\Omega)^{-1}$.

The function

$$|K(j\Omega)|^2 = A_0(1 + \Omega^{2n}) = p(\Omega) \geq q^2 = 4R_1/R_2 \quad (38)$$

exhibits $d^v P(\Omega)/d\Omega^v = 0$ for $\Omega = 0$ and $v = 1, 2, \dots, 2n - 1$ and is hence maximally flat at $\Omega = 0$.

The inequality in Eq. (38) is met for $A_0 \geq q^2$. $|K(j\Omega)|$ and $|F(j\Omega)| = |K(j\Omega)|^{-1}$ are plotted in Fig. 23. The 3 dB cutoff frequency is reached at $\Omega = 1$. For large $\Omega \gg 1$, we obtain $|K(j\Omega)| \approx \sqrt{A_0}\Omega^n$ and the attenuation $\alpha(\Omega) = 20 \log |K(j\Omega)| \approx 20n \log \Omega + 20 \log \sqrt{A_0}$, from which an increase in attenuation $\Delta\alpha$ for one frequency decade of $\Delta\alpha = n \cdot 20$ dB/decade can be seen.

According to Eq. (38), we obtain

$$Q(s) = P\left(\frac{s}{j}\right) = A_0(1 + (-1)^n s^{2n}) = K(s)K(-s) \quad (39)$$

The zeros of $Q(s)$ are given by $s^{2n} = (-1)^{n-1} = e^{j\pi(n-1+2k)}$ for $k = 0, 1, 2, \dots, 2n - 1$. This yields the zeros

$$S_k = e^{j(\pi/2n)(n-1+2k)} \quad (40)$$

Obviously, the zeros lie on the unit circle of the complex s plane. If they are complex, they have to be complex conjugate, as $Q(s)$ possesses only real coefficients. For $n = 4$ the zeros are plotted in Fig. 24. The zeros in $\text{Re } s < 0$ are assigned to $K(s)$, yielding a stable two-port. For $n = 4$ we

Figure 21. (a) The polynomial $T_m^2(\omega/\omega_c)$. (b) The polynomial $T_m^2(\omega_c/\omega)$. (c) The polynomial $T_m^2(\omega_c/\omega)$.

obtain

$$K(s) = \pm \sqrt{A_0}(s - e^{j5\pi/8})(s - e^{-j5\pi/8})(s - e^{j7\pi/8})(s - e^{-j7\pi/8})$$

or

$$K(s) = \pm \sqrt{A_0}(s^4 + 2.163s^3 + 3.414s^2 + 2.613s + 1)$$

Table 7 lists $K(s)/\sqrt{A_0}$ for Butterworth filters with degree $n = 1-4$.

The characteristic polynomial is determined due to Eq. (34) by

$$K(s)K(-s) - q^2 = f(s)f(-s) \tag{41}$$

Figure 22. (a) The highpass with $|K(j(\omega/\omega_c))|^2 = q^2 + \epsilon^2 T_m^2(\omega/\omega_c)$ and Chebyshev behavior in the stopband; (b) the highpass with $|K(j(\omega/\omega_c))|^2 = q^2 + \epsilon^2 T_m^2(\omega_c/\omega)$ and Chebyshev behavior in the passband; (c) the lowpass with $|K(j(\omega/\omega_c))|^2 = q^2 + \epsilon^2 T_m^2(\omega_c/\omega)$ and Chebyshev behavior in the stopband.

or

$$A_0(1 + (-1)^n s^{2n}) - q^2 = f(s)f(-s) \tag{42}$$

The zeros are given by

$$s^{2n} = (-1)^{n-1} \left(1 - \frac{q^2}{A_0}\right)$$

Figure 23. The magnitude $|F(j\Omega)|$ of the transfer function and the magnitude $|K(j\Omega)|$ of the inverse transfer function for Butterworth filters.

or

$$s_r = \left(1 - \frac{q^2}{A_0}\right)^{1/2n} e^{j(\pi/2n)(n-1+2k)} \quad (43)$$

where $k=0, 1, \dots, 2n-1$ and hence $r=1, 2, \dots, 2n$.

The $2n$ zeros lie on a circle in the s plane with radius

$$r_0 = \left(1 - \frac{q^2}{A_0}\right)^{1/2n}$$

and are complex conjugate or real. Any complex conjugate pair and any real zero can be assigned to $f(s)$, while the negative locations of these zeros belong to $f(-s)$. This yields

$$f(s) = \pm \sqrt{A_0} \prod_{r=1}^n (s - s_r)$$

With $K(s)$ and $f(s)$ now known, the elements of the chain matrix are calculated by Eqs. (33a)–(33d), followed by the development of the matrix into a two-port with the procedure outlined previously. As an example, the solution for the chain matrix A and for the pertaining two-port is now

Figure 24. The zeros of $Q(s)=K(s)K(-s)$ in Eq. (39) of Butterworth filters for $n=4$.

Table 7. Polynomials $K(s)$ for Butterworth Filters

n	$K(s)/\sqrt{A_0}$
1	$s + 1$
2	$s^2 + \sqrt{2}s + 1$
3	$s^3 + 2s^2 + 2s + 1$
4	$s^4 + 2.613s^3 + 3.414s^2 + 2.613s + 1$

listed for $n=3, A_0=1$, and $R_1=R_2$:

$$A_{11} = 2s^2 + 1; \quad A_{12} = R_2(2s^3 + 2s)$$

$$A_{21} = \frac{2s}{R_2}; \quad A_{22} = 2s^2 + 1$$

As all elements are polynomials in s , the pertaining two-port in Fig. 25 was found by full pole removals and therefore exhibits the minimum number of components.

The solution, based on the normalized frequency $\Omega = \omega/\omega_c^*$, provides the normalized values for the components l_1, l_2 , and c in Fig. 25, where the denormalized values L_1, L_2 , and C are also listed.

2.1.6. The Thomson or Bessel Approximation [11]. A filter with a linear phase $\psi(\omega) = \omega t_0$ provides an ideal delay by t_0 and exhibits the function

$$K\left(j \frac{\omega}{\omega_0}\right) = ae^{j(\omega/\omega_0)\omega_0 t_0}$$

With $\omega_0 t_0 = 1$ and $\Omega = \omega/\omega_0$ we obtain for $s = j\Omega$ extended into the s plane

$$K(s) = ae^s \quad (44)$$

This normalization with ω_0 is different from the one used previously for the comparison of $a(t)$. It is commonly used and emphasizes the delay $t_0 = 1/\omega_0$ as the most important property of Bessel filters.

The group delay $d\psi/d\omega = t_0$ is a constant. We have to approximate the filter with constant group delay by a realizable function $K(s)$. A Taylor series for e^s is no more Hurwitz from the fifth-order term on. A realizable solution is provided by setting $K(s) = ae^s = a(\cosh s + \sinh s)$, where

$$\cosh s = 1 + \frac{s^2}{2!} + \frac{s^4}{4!} + \dots \quad (45a)$$

Figure 25. The Butterworth filter for $n=3, A_0=1$, and $R_1=R_2$.

is an even function and

$$\sinh s = s + \frac{s^3}{3!} + \frac{s^5}{5!} + \dots \tag{45b}$$

is an odd function in s .

A theorem states that if the ratio of the even part of a polynomial over the odd part is an LC driving point function and if the even and odd parts are coprime, then the sum of the even and odd parts is Hurwitz. To check the property of an LC driving point impedance function, we develop the continued fraction based on Eqs. (45a) and (45b):

$$\frac{\cosh s}{\sinh s} = \frac{1}{s} + \frac{1}{\frac{3}{s} + \frac{1}{\frac{5}{s} + \frac{1}{\frac{7}{s} + \dots + \frac{1}{\frac{2N-1}{s} + \dots}}}} = \frac{m(s)}{n(s)} \tag{46}$$

Since all terms in the infinite continued fraction expansion are positive, $h(s) = m(s) + n(s)$ calculated from Eq. (46) truncated at $(2N - 1)/s$ is Hurwitz. For $2N - 1 = 7$, we obtain from Eq. (46)

$$\begin{aligned} \frac{m(s)}{n(s)} &= \frac{s^4 + 45s^2 + 105}{10s^3 + 105s} \quad \text{and} \quad K(s) = aC[m(s) + n(s)] \\ &= aC(s^4 + 10s^3 + 45s^2 + 105s + 105) \end{aligned}$$

The factor C is needed to render $K(0) = a$, as required by Eq. (44). In the example $C = \frac{1}{105}$, $m(s) + n(s)$ can be expressed by modified Bessel polynomials

$$B_\nu(s) = s^\nu B_\nu^*\left(\frac{1}{s}\right) = m(s) + n(s) \tag{47a}$$

with

$$B_\nu^*\left(\frac{1}{s}\right) = \sum_{k=0}^{\nu} \frac{(v+k)!}{(v-k)!k!(2s)^k} \tag{47b}$$

Figure 26. The characteristic $|K(j\Omega)|^2$ of a Cauer filter for n odd in Eq. (49).

$B_0(s) = 1$
$B_1(s) = s + 1$
$B_2(s) = s^2 + 3s + 3$
$B_3(s) = s^3 + 6s^2 + 15s + 15 = (s + 2.322)(s^2 + 3.678s + 6.460)$
$B_4(s) = s^4 + 10s^3 + 45s^2 + 105s + 105 = (s^2 + 5.792s + 9.140) \times (s^2 + 4.208s + 11.488)$
$B_5(s) = s^5 + 15s^4 + 105s^3 + 420s^2 + 945s + 945 = (s + 3.647)(s^2 + 6.704s + 14.272)(s^2 + 4.679s + 18.156)$

A recursion formula is given by

$$B_\nu(s) = (2\nu - 1)B_{\nu-1}(s) + s^2$$

$B_{\nu-2}(s)$. With Eqs. (47a) and (47b), we finally obtain

$$K(s) = aB_\nu(0)^{-1}B_\nu(s) \tag{48}$$

Table 8 lists the Bessel polynomials up to $\nu = 5$ [4].

The constant a is chosen such that the constraint for $|K(j\Omega)|$ is met. The characteristic function is determined by $K(s)K(-s) - q^2 = f(s)f(-s)$. The LC two-port is then calculated by the procedure given previously, applied for polynomials.

2.1.7. Cauer Filters [4,12,21]. These filters exhibit Chebyshev behavior in the passband and in the stopband, as depicted in Fig. 26. They are based on elliptic functions as derived by Cauer and are therefore also called *elliptic filters*. The theory of elliptic filters is very involved. A simpler approach based on the results is given here.

The filter function in Fig. 26 is represented by

$$|K(j\Omega)|^2 = q^2 + \varepsilon^2 F_n^2(\Omega) \tag{49}$$

with

$$F_n(\Omega) = \begin{cases} k \prod_{v=1}^{n/2} \frac{\Omega^2 - \Omega_v^2}{\Omega^2 - (\Omega_s/\Omega_v)^2} & n \text{ even} \end{cases} \quad (50)$$

$$F_n(\Omega) = \begin{cases} k\Omega \prod_{v=1}^{(n-1)/2} \frac{\Omega^2 - \Omega_v^2}{\Omega^2 - (\Omega_s/\Omega_v)^2} & n \text{ odd} \end{cases} \quad (51)$$

The equiripple behavior of $F_n^2(\Omega)$ in $\Omega \in [0, 1]$ in Fig. 27 is guaranteed by the choice of Ω_v according to

$$\Omega_v = \begin{cases} \text{sn} \left(\frac{E \left(\frac{1}{\Omega_s} \right) (2v - 1)}{n} \right) & n \text{ even}, v = 1, 2, \dots, \frac{n}{2} \end{cases} \quad (52a)$$

$$\Omega_v = \begin{cases} \text{sn} \left(\frac{E \left(\frac{1}{\Omega_s} \right) 2v}{n} \right) & n \text{ odd}, v = 1, 2, \dots, \frac{n-1}{2} \end{cases} \quad (52b)$$

where

$$E \left(\frac{1}{\Omega_s} \right) = \int_0^{\pi/2} \frac{d\phi}{\left(1 - \frac{1}{\Omega_s^2} \sin^2 \phi \right)^{1/2}} \quad (53a)$$

is the complete elliptic integral of the first kind and the Jacobi elliptic function $\text{sn}(u) = \sin \phi$ is calculated from the inverse $\phi(u)$ of the incomplete elliptic integral of the first kind

$$u = \int_0^\phi \frac{d\phi}{\left(1 - \frac{1}{\Omega_s^2} \sin^2 \phi \right)^{1/2}} \quad (53b)$$

followed by forming $\sin \phi = \text{sn}(u)$. Ω_s is chosen as $\Omega_s > 1$; Eqs. (52a) and (52b) yield $0 < \Omega_v < 1$, $v = 1, 2, \dots, n/2$, or $(n - 1)/2$. Obviously, the zeros of $F_n^2(\Omega)$ lie in $|\Omega| < 1$ and the poles in $|\Omega| > \Omega_s$. k in Eqs. (50) and (51) is chosen such that $F_n^2(\Omega)$ in Fig. 27 oscillates between 0 and 1 in $\Omega \in [0, 1]$.

Finally, the minimum value B of $F_n^2(\Omega)$ in the stopband in Fig. 27 is given by

$$B = \begin{cases} k \prod_{v=1}^{n/2} \frac{\Omega_s^2 - \Omega_v^2}{\Omega_s^2 - (\Omega_s/\Omega_v)^2} & n \text{ even} \end{cases} \quad (54a)$$

$$B = \begin{cases} k\Omega_s \prod_{v=1}^{(n-1)/2} \frac{\Omega_s^2 - \Omega_v^2}{\Omega_s^2 - (\Omega_s/\Omega_v)^2} & n \text{ odd} \end{cases} \quad (54b)$$

if the degree n of $F_n(\Omega)$ is chosen as

$$n \geq \frac{E(1/\Omega_s)E(\sqrt{1-1/B})}{E(\sqrt{1/B})E(\sqrt{1-(1/\Omega_s)^2})} \quad (55)$$

If the minimum value for n is not an integer, then the next-larger integer has to be chosen. In this case the realized B in Eqs. (54a) and (54b) is larger than the desired B in Eq. (55).

From Eq. (49) and Fig. 27, we derive

$$|K(j1)|^2 = q^2 + \varepsilon^2$$

and

$$|K(j\Omega_s)^2| = q^2 + \varepsilon^2 B$$

For the filter design the desired R_1 and R_2 yield

$$q = 2\sqrt{\frac{R_1}{R_2}},$$

the desired ripple in the passband provides ε , and the minimum $q^2 + \varepsilon^2 B$ of $|K(j\Omega)|^2$ in the stopband yields B in Eqs. (54a) and (54b).

2.1.8. Approximation of $|K(j\Omega)|^2$ by Conformal Mapping [4]. Lowpasses with Chebyshev behavior in the passband and arbitrary characteristics in the stopband can be designed by a conformal mapping. This includes also the case of Chebyshev behavior in the passband and the stopband as a special case.

Figure 27. $F_n^2(\Omega)$ for a Cauer filter in Fig. 26 and in Eqs. (50) and (51).

The procedure is based on the fact that the Hurwitz polynomial

$$h(s) = m(s) + n(s) \tag{56}$$

where $m(s)$ is even and $n(s)$ is odd, provides the reactance function $m(s)/n(s)$. It can be further shown that the driving point impedance function

$$w(s) = \frac{m/n}{1 + \frac{m}{n}} = \frac{m(s)}{m(s) + n(s)} \tag{57}$$

has the property

$$|w(j\Omega)|^2 = \frac{m^2(j\Omega)}{m^2(j\Omega) - n^2(j\Omega)} \in [0, 1] \tag{58}$$

for $\Omega \in [-\infty, \infty]$. This provides the Chebyshev behavior. We investigate

$$f(z^2) = \frac{m^2(z)}{m^2(z) - n^2(z)} \quad \text{with } z = u + jv \tag{59}$$

and the transformation

$$z^2 = 1 + \frac{1}{s^2} \tag{60}$$

providing

$$f(z^2) = f\left(1 + \frac{1}{s^2}\right) = g(s^2) = \frac{m^2\left(\sqrt{1 + \frac{1}{s^2}}\right)}{m^2\left(\sqrt{1 + \frac{1}{s^2}}\right) - n^2\left(\sqrt{1 + \frac{1}{s^2}}\right)} \tag{61}$$

The properties of the transformation in Eq. (60) are investigated in Figs. 28a–28e, where the passband $s = j\Omega$ with $|\Omega| \leq 1$, denoted by dashed lines, and the stopband with $|\Omega| \geq 1$, denoted by solid lines, are step by step mapped into the z plane. The steps from s plane to the z plane in Fig. 28 are $w_1 = s^2$, $w_2 = 1/w_1$, $w_3 = w_2 + 1$, $z = +\sqrt{w_3}$. The result is the following mapping:

$$\Omega \in [-1, 1] \text{ into } v \in [-\infty, \infty] \tag{62a}$$

$$|\Omega| \geq 1 \text{ into } u \in [0, 1] \tag{62b}$$

The complex conjugate pair of poles \times in $|\Omega| \geq 1$ results in a double pole in $u \in [0, 1]$. The consequences of this mapping for $f(z^2) = g(s^2)$ in Eqs. (59) and (61) are as follows. For $z = jv$, $v \in [-\infty, \infty]$, and the pertaining $\Omega \in [-1, 1]$

$$f(-v^2) = g(-\Omega^2) = \frac{m^2(jv)}{m^2(jv) - n^2(jv)} \in [0, 1] \tag{63a}$$

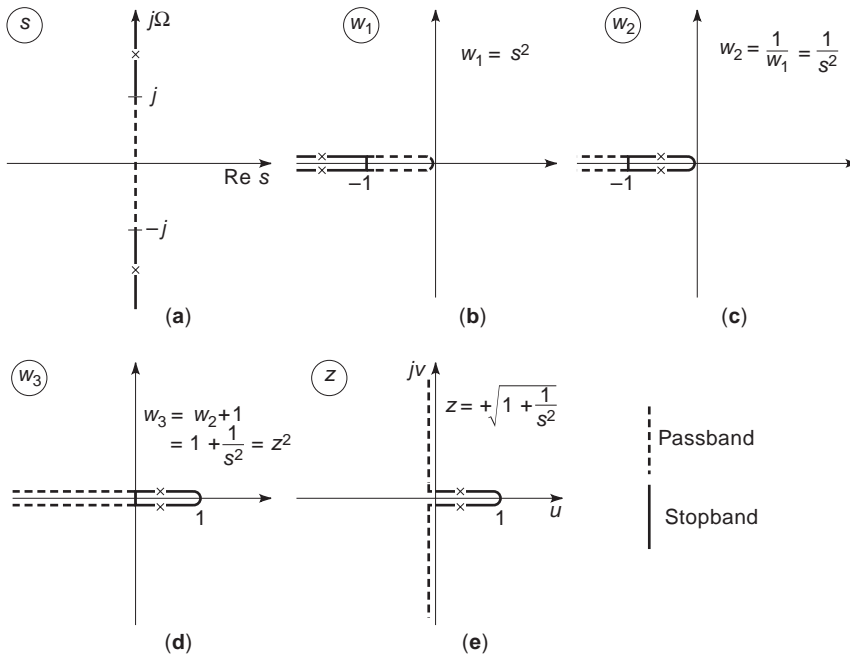

Figure 28. The steps in the conformal mapping $z = +\sqrt{1 + 1/s^2}$ for $s = j\Omega$.

for $z = u, u \in [0, 1]$ and the pertaining $|\Omega| \geq 1$ with the constraint $|m(u)| \geq |n(u)|$ and hence

$$0 \leq \frac{n^2(u)}{m^2(u)} \leq 1$$

$$f(u^2) = g(-\Omega^2) = \frac{m^2(u)}{m^2(u) - n^2(u)}$$

$$= \frac{1}{1 - \frac{n^2(u)}{m^2(u)}} \geq 1 \tag{63b}$$

With these results

$$g(-\Omega^2) = \frac{m^2(\sqrt{1+1/s^2})}{m^2(\sqrt{1+1/s^2}) - n^2(\sqrt{1+1/s^2})} \text{ for } s = j\Omega$$

assumes the shape in Fig. 29. The function $g(-\Omega^2)$ oscillates between 0 and 1 in the passband as long as $m(s)$ is even and $n(s)$ is odd and $h(s) = m(s) + n(s)$ is Hurwitz. The selection of $m(s)$ and $n(s)$ is the freedom for the design of filters.

For the filter, as in all previous cases, we obtain

$$|K(j\Omega)|^2 = q^2 + \varepsilon^2 g(-\Omega^2) \tag{64}$$

with

$$\varepsilon^2 g(s^2) = \varepsilon^2 \frac{m^2(\sqrt{1+1/s^2})}{m^2(\sqrt{1+1/s^2}) - n^2(\sqrt{1+1/s^2})} \tag{65}$$

or

$$\varepsilon^2 g(s^2) = \frac{\varepsilon^2}{2} \left[1 + \frac{1}{2} \frac{m+n}{m-n} + \frac{1}{2} \frac{m-n}{m+n} \right] \tag{66}$$

The dominant term in the stopband, especially around the poles, is

$$|K(j\Omega)|^2 \approx \frac{\varepsilon^2}{4} \frac{m(z) + n(z)}{m(z) - n(z)} \tag{67}$$

Figure 29. The function $g(-\Omega^2)$ of Eq. (63a) in the passband and the stopband.

with $z \in [0, 1]$ and $|\Omega| \geq 1$ in the stopband. The term with the denominator $m(z) + n(z) = h(z)$ in Eq. (66) exhibits no poles in the stopband as $h(z)$ is Hurwitz. Hence the term with the denominator $m(z) - n(z)$ provides the poles. Now we determine m and n from the requirements in the stopband. With the pole locations $z_i \in [0, 1]$ in Eq. (67), which are found later, we obtain

$$m(z) - n(z) = (-z + 1)^\varphi \prod_{i=1}^r (-z + z_i)^2 \tag{68}$$

and by exchanging z with $-z$

$$m(z) + n(z) = (z + 1)^\varphi \prod_{i=1}^r (z + z_i)^2 \tag{69}$$

The term $z = z_i$ in Eq. (68) represents the double pole in $z \in [0, 1]$, while $z = 1$ stands for the pole of multiplicity φ at $\Omega = \infty$. The even part in Eq. (69) provides $m(z)$, whereas the odd part yields $n(z)$. Hence

$$f(z^2) = g(s^2) = \frac{m^2(z)}{m^2(z) - n^2(z)} \tag{70}$$

and $|K(j\Omega)|^2$ in Eq. (67) valid in the stopband are known. The attenuation pertaining to Eqs. (67)–(69) is

$$\alpha(\Omega) = 10 \log |K(j\Omega)|^2$$

$$= 20 \log \varepsilon - 10 \log 4 + \sum_{i=1}^r 10 \log \left(\frac{z + z_i}{-z + z_i} \right)^2$$

$$+ \varphi 10 \log \frac{(z + 1)}{(-z + 1)}$$

The substitution

$$\gamma = \ln z \quad \text{and} \quad \gamma_i = \ln z_i$$

yields

$$r_i = 10 \log \left(\frac{z + z_i}{-z + z_i} \right)^2 = 10 \log \left(\frac{e^{\gamma_i} + e^\gamma}{e^{\gamma_i} - e^\gamma} \right)^2 \tag{71}$$

$$= 10 \log \left(\frac{e^{\gamma_i - \gamma} + 1}{e^{\gamma_i - \gamma} - 1} \right)^2 = 20 \log \coth \left| \frac{\gamma_i - \gamma}{2} \right|$$

For $z_i = 1$ we obtain

$$r_\infty = 10 \log \left(\frac{z + 1}{-z + 1} \right)^\varphi = 10\varphi \log \coth \frac{|\gamma|}{2} \tag{72}$$

The terms r_i and r_∞ can be considered a template in Fig. 30 that can be shifted to all pole locations $\gamma = \gamma_i$ and $\gamma = 0$.

Any given tolerance scheme in the stopband can be met by a sum of the templates in Eqs. (71) and (72). The number of those templates is minimized by shifting them to appropriate locations γ_i . This numerical search procedure

Figure 30. The templates $20 \log \coth |\gamma_i - \gamma|/2$ for the approximation of the given characteristics in the stopband.

is performed either by a computer program or by trials consisting of shifting and adding templates. The result consists of pole locations z_i , their number r , and the multiplicity φ of the poles at $z = 1$.

As all considerations for the conformal mapping have now been discussed, we are ready to list the sequence of the synthesis steps:

1. The given R_1, R_2 and the ripple in the passband yield q and ε .
2. Determine poles z_i .
 - a. If only discrete pilot frequencies

$$z_i = \sqrt{1 - \frac{1}{\Omega_i^2}}$$

have to be suppressed, then these z_i provide Eq. (68).

- b. If a tolerance scheme in the stopband has to be met, templates provide the pole locations z_i together with r and φ in Eq. (68).
3. Form

$$m(z) - n(z) = (-z + 1)^\varphi \prod_{i=1}^r (-z + z_i)^2$$

$$m(z) + n(z) = (z + 1)^\varphi \prod_{i=1}^r (z + z_i)^2$$

and

$$f(z^2) = g(s^2) = \frac{m^2(\sqrt{1+1/s^2})}{m^2(\sqrt{1+1/s^2}) - n^2(\sqrt{1+1/s^2})}$$

4. Form

$$|K(j\Omega)|^2 = q^2 + \varepsilon^2 g(-\Omega^2) = P(\Omega) = P\left(\frac{s}{j}\right) = Q(s)$$

and

$$K(s)K(-s) = Q(s)$$

The zeros and poles of $Q(s)$ provide a stable $K(s)$.

- 5.

$$\begin{aligned} f(s)f(-s) &= Q(s) - q^2 \\ &= \varepsilon^2 \frac{m^2(\sqrt{1+1/s^2})}{m^2(\sqrt{1+1/s^2}) - n^2(\sqrt{1+1/s^2})} \end{aligned}$$

The zeros and poles of $Q(s) - q^2$ determine $f(s)$.

6. With $K(s)$ and $f(s)$, calculate the elements A_{ik} of the chain matrix and synthesize the LC two-ports embedded in R_1 and R_2 .

2.1.9. Transformation of Lowpasses into Other Filters [19].

The synthesis procedures presented were all geared to lowpasses. The standard approach to generate other filter types is a transformation of the lowpass with frequency variable s and $s = j\Omega$ into a new filter with frequency w and $w = j\lambda$. The general transformation is

$$s = f(w) \quad (73)$$

where $f(w)$ is a reactance function. This will also allow transformation of the reactances Ls and Cs into realizable reactances in the w domain.

2.1.9.1. Lowpass Bandpass Transformation. The transformation

$$s = \frac{a}{w} + bw \quad (74)$$

with $a, b > 0$ maps $s = j\Omega$ into $w = j\lambda$ according to

$$\Omega = -\frac{a}{\lambda} + b\lambda \quad (75)$$

as depicted in Fig. 31. The passband of the lowpass with $\Omega \in [-1, 1]$ is translated into the passband with $\lambda \in [\lambda_1, \lambda_2]$ of the bandpass, as indicated by bold lines in Fig. 31. The cutoff frequencies are

$$\lambda_1 = -\frac{1}{2b} + \sqrt{\frac{1}{4b^2} + \frac{a}{b}} \quad (76)$$

$$\lambda_2 = \frac{1}{2b} + \sqrt{\frac{1}{4b^2} + \frac{a}{b}} \quad (77)$$

The center frequency as an image of $\Omega = 0$ is

$$\lambda_0 = \sqrt{\frac{a}{b}} \quad (78)$$

with $\lambda_0^2 = \lambda_1 \lambda_2$ representing the geometric mean of λ_1 and λ_2 . The reactances Ls and Cs translate into the series and parallel resonators in Fig. 32. Due to $f(w)$ in Eq. (73) of second degree, a doubling of the reactances is observed. A transformation $f(w)$ of higher degree provides more than one passband, as outlined by the transformation of sixth

Figure 31. The lowpass bandpass transformation.

degree

$$s = aw + \frac{b}{w} + \frac{cw}{w^2 + \lambda_c^2} + \frac{dw}{w^2 + \lambda_d^2} \quad (79)$$

with $a, b, c, d, \lambda_c^2, \lambda_d^2 > 0$.

The mapping of $s = j\Omega$ into $w = j\lambda$ is shown in Fig. 33, where three passbands are generated. The number of reactances has increased by a factor of 6 due to $f(w)$ of sixth degree.

2.1.9.2. The Lowpass Bandstop Transformation. For the transformation

$$s = \frac{1}{\frac{a}{w} + bw} \quad \text{with } a, b > 0 \quad (80)$$

the function $\Omega = f(\lambda)$ is shown in Fig. 34 with a stopband for $\lambda \in [\lambda_1, \lambda_2]$ with λ_1, λ_2 , and λ_0 , as in Eqs. (76)–(78). The doubling of the reactances is demonstrated in Fig. 35.

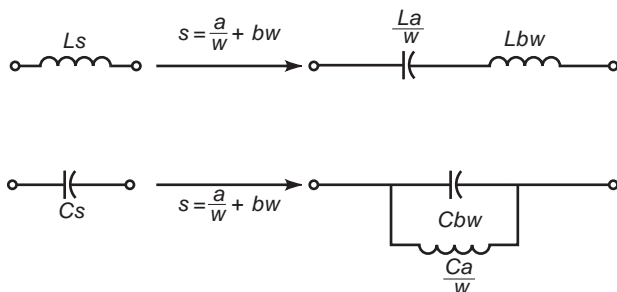

Figure 32. Transformation of reactances for bandpasses.

Figure 33. Transformation of a lowpass into a bandpass with multiple passbands.

2.1.9.3. The Lowpass–Highpass Transformation. The transformation

$$s = \frac{a}{w} \quad (81)$$

$a > 0$ yields

$$\Omega = -\frac{a}{\lambda} \quad (82)$$

which is drawn in Fig. 36.

The cutoff frequency of the highpass is

$$\lambda_1 = a \quad (83)$$

According to Fig. 37, inductors and capacitors are interchanged.

Figure 34. Lowpass bandstop transformation with $\lambda_0 = \sqrt{a/b}$.

Figure 35. Transformation of reactances for bandstops.

Figure 37. Transformation of reactances for highpasses.

2.1.10. Amplitude and Phase Equalizers. Amplitude equalizers generate two-ports with a constant magnitude of the insertion voltage loss function $K(s)$ at least in a limited frequency range. An often encountered solution to this problem is cascading the unequalized two-port with the bridged-T network in Fig. 38. If the impedances Z_1 and Z_2 are chosen according to

$$Z_1 Z_2 = R^2 \tag{84}$$

and if the network is terminated by the resistor R , then the input impedance is also R . This implies that the bridged T terminated by R can replace the load $R_2 = R$ of the original two-port without interaction. The inverse transfer function of the bridged T loaded by R is

$$K_B^*(p) = 1 + \frac{Z_1(p)}{R} \tag{85}$$

For

$$Z_1/R = \frac{1}{G + jY(\omega)}$$

Figure 36. Lowpass-highpass transformation.

we obtain

$$|K_B^*(j\omega)|^2 = \frac{(1 + G)^2 + Y^2(\omega)}{G^2 + Y^2(\omega)}$$

and

$$a(\omega) = 10 \log \frac{(1 + G)^2 + Y^2(\omega)}{G^2 + Y^2(\omega)} \tag{86}$$

The term $a(\omega)$ is the attenuation added to the attenuation of the original two-port in order to equalize the magnitude.

Table 9 lists $a(\omega)$ for various impedances Z_1 and $Z_2 = R^2/Z_1$ [4].

Phase equalizers have the tasks to provide a linear phase or a constant delay for the equalized two-port. They are commonly allpasses. The inverse transfer function of a first-order and of a second-order allpass are

$$K_1^*(p) = \frac{p + \omega_0}{-p + \omega_0} \tag{87}$$

and

$$K_2^*(p) = \frac{p^2 + \frac{2\omega_0}{b}p + \omega_0^2}{p^2 - \frac{2\omega_0}{b}p + \omega_0^2} \tag{88}$$

with the phase $\psi(\omega)$ and the group delay $\tau(\omega)$ as

$$\psi_1(\omega) = \arg K_1(j\omega) = 2 \arctan \frac{\omega}{\omega_0}$$

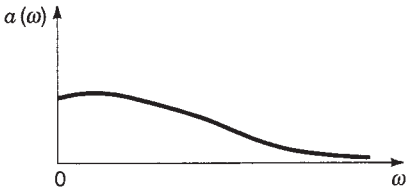

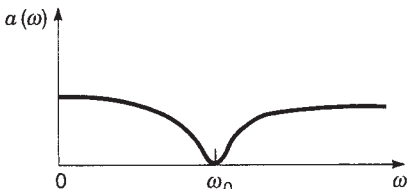

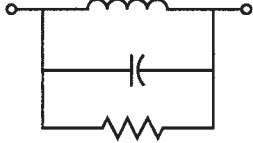

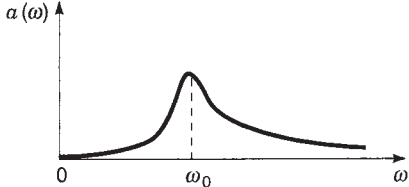

Figure 38. Bridged-T network with $Z_1 Z_2 = R^2$ for amplitude equalization.

Table 9. A List of Impedances Z_1 and Z_2 and the Pertinent $a(\omega)$ for Amplitude Equalization

Z_1	Z_2	Shape of $a(\omega)$ in Eq. (86)
		
		
		
		

and

$$\psi_2(\omega) = \arg K_2(j\omega) = 2 \operatorname{arccot} \frac{b}{2} \left(\frac{\omega_0}{\omega} - \frac{\omega}{\omega_0} \right)$$

$$\tau_1(\omega) = \frac{d \arg K_1(j\omega)}{d\omega} = \frac{\frac{2}{\omega_0}}{1 + \left(\frac{\omega}{\omega_0} \right)^2} \quad (89)$$

$$\tau_2(\omega) = \frac{d \arg K_2(j\omega)}{d\omega} = \frac{b}{\omega_0} \frac{1 + \left(\frac{\omega_0}{\omega} \right)^2}{1 + \left(\frac{b^2}{4} \right) \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right)^2} \quad (90)$$

The group delays $\tau_1(\omega)$ and $\tau_2(\omega)$ are depicted in Figs. 39a and 39b. For $\tau_2(\omega)$ the maximum is approaching $\omega = \omega_0$ depending on increasing values of b . These bell-like curves are added to the nonconstant group delay of the given two-port and thus straighten it out. Several different frequencies ω_0 may be needed for this end. The network in Fig. 40 represents a second-order allpass if it is terminated by R and if the element values are as listed in the figure caption. With the element values given in the figure caption, it exhibits constant input and output impedances and can therefore be cascaded without interaction with the unequaled two-port.

Figure 39. (a) The group delay of a first-order allpass in Eq. (87). (b) The group delay of a second-order allpass in Eq. (88).

3. SURFACE ACOUSTIC WAVE FILTERS

Filters for high frequencies in the megahertz or gigahertz range are difficult to realize as the calculation of a three-

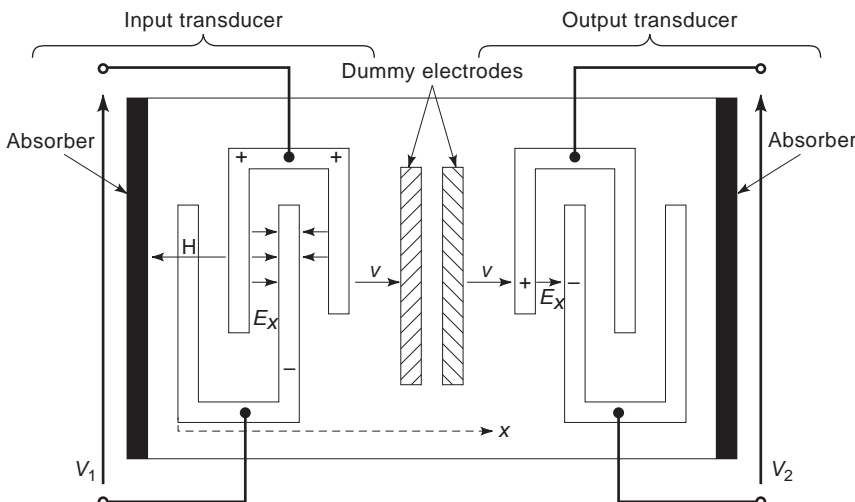

Figure 40. Bridged-T network realizing a second-order allpass with constant input and output impedances R for the element values $L_1 = 2 \frac{R^2 C_1 C_2}{2C_1 + C_2}$, $L_2 = \frac{1}{2} R^2 C_1$ and for a termination by R .

dimensional electromagnetic field is required. To achieve this, one has to resort to numerical methods, which, as a rule, are inaccurate and hence necessitate complicated tuning of the filters. Filters based on surface acoustic waves (SAWs) are somewhat easier to design and build. They are economically one of the most important extensions of classical filters and have reached operating frequencies of more than 10 GHz.

The surface of a piezoelectric substrate such as monocrystalline barium titanate or tantalate carries input and output transducers as shown in Fig. 41. They translate the electric field E stemming from the input voltage V_1 through the piezoelectric effect into a mechanical wave that travels with speed v mainly in the surface of the substrate to the output transducer. Waves traveling backward or through the bulk of the substrate disappear in an absorbing layer in Figs. 41 and 42. The inverse piezo effect changes the mechanical wave in the output transducer back to a charge separation, resulting in the output voltage V_2 .

In its simplest form, the fingers and the gaps of the transducers exhibit all the same width as depicted at the top of Fig. 43. In a more complicated but also more versatile case, they are all unequal, as shown also in Fig. 43. The latter layout provides more degrees of freedom for the filter design. The electrical field in the gaps as response to

Figure 41. Top view on surface acoustic wave filter (SAW filter).

Figure 42. Cross section of SAW filter.

Dirac impulses at the input reaches infinite values in the borders of the fingers, as depicted in Fig. 43. This shape is approximated also by Dirac impulses, as drawn in the last plot in Fig. 43. This so-called δ approximation renders the calculation of the transfer function $F(p)$ rather easy. Each location of a δ impulse is the origin of a mechanical δ im-

pulse traveling with the speed v to the output transducer. Figure 44 shows the distances from the pair of fingers μ in the input transducer to the pair of fingers ν in the output transducer; in Fig. 44 x_0 is the distance between the last fingers of the input transducer and the first fingers of the output transducer. A most important parameter is the overlap h_μ (respectively, g_ν) of a pair of fingers in the transducers. They determine the width of the wave leaving the input and being received by the output. Due to diffraction, the width expands while the wave travels through the substrate. This effect is limited by the dummy electrodes in Fig. 41. They form a surface with equal potential from where the wave again starts with a given width.

The two δ impulses in the edges of the finger pair μ in the input transducer in Fig. 44 reach the center of the gap of the finger pair ν in the output transducer after the

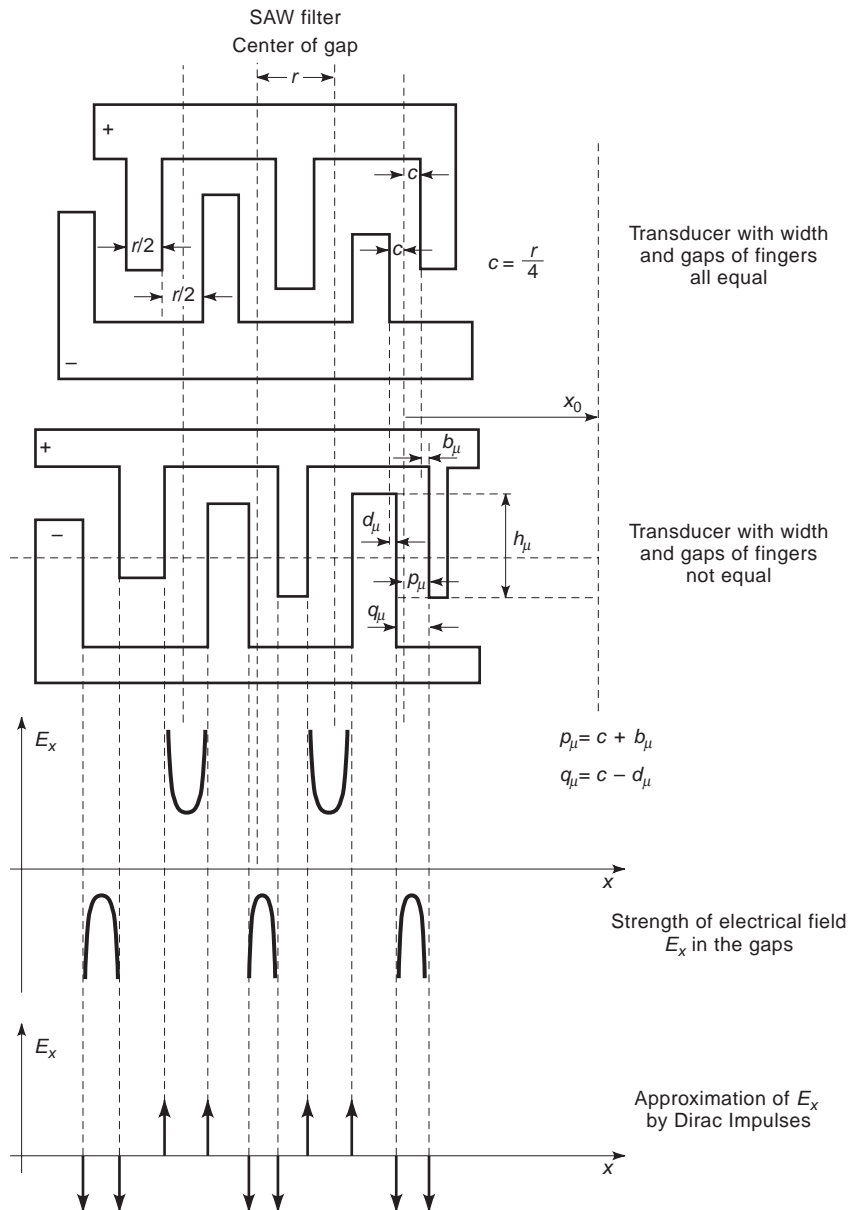

Figure 43. Top view of fingers and electrical field in the gaps.

Figure 44. Top view of input and output transducer with unequal widths and gaps of fingers.

delays

$$t_{L_1} = \frac{x_0 + (v + \mu)r + q_\mu}{v} \quad (91)$$

and

$$t_{L_2} = \frac{x_0 + (v + \mu)r - p_\mu}{v} \quad (92)$$

with

$$p_\mu = c + b_\mu \quad (93a)$$

and

$$q_\mu = c - d_\mu \quad (93b)$$

generating the voltage

$$e_{\mu v}(t) = k(\delta(t - t_{L_1}) + \delta(t - t_{L_2})) \quad (94a)$$

with

$$k = \frac{k_0}{p_\mu + q_\mu} (-1)^v (-1)^\mu \min(h_\mu, g_v) \quad (94b)$$

The factor k describes the strength (area) of the impulse, which is inversely proportional to the width of the gap $1/(p_\mu + q_\mu)$ of the finger pair μ , proportional to the $\min(h_\mu, g_v)$ because the minimum of either the width h_μ of the transmitted wave or the width g_v of the overlap of the receiving finger pair determines the received wave, and, finally, proportional to the alternating sign of E in the gaps represented by $(-1)^v (-1)^\mu$; k_0 is a factor of proportionality representing the transducer constant. As a syn-

thesis with $\min(h_v, g_\mu)$ is hard to achieve, we put

$$\min(h_v, g_\mu) = h_\mu \quad (95)$$

meaning $g_v > h_\mu$ for all v and μ ; thus the output transducer receives the full energy transmitted by the input transducer.

The full impulse response $h(t)$ of the SAW filter is given by adding over all N transmitting finger pairs and over all M receiving pairs, which provides, with Eqs. (91)–(95)

$$h(t) = \sum_{\mu=0}^{N-1} \sum_{v=0}^{M-1} \frac{k_0 (-1)^{v+\mu} h_\mu}{2c + b_\mu - d_\mu} \left(\delta \left(t - \frac{x_0 + (v + \mu)r + c - d_\mu}{v} \right) + \delta \left(t - \frac{x_0 + (v + \mu)r - c - b_\mu}{v} \right) \right) \quad (96)$$

A Laplace transform of Eq. (96) yields the transfer function

$$F^*(j\omega) = k_0 e^{j\omega x_0/v} \sum_{\mu=0}^{N-1} \sum_{v=0}^{M-1} (-1)^{v+\mu} \frac{h_\mu}{2c + b_\mu - d_\mu} e^{-j\omega(v+\mu)r/v} \times \left[e^{-j\omega c/v} e^{j\omega d_\mu/v} + e^{j\omega c/v} e^{j\omega b_\mu/v} \right] \quad (97)$$

This general result is, for practical applications, usually simplified by setting $b_\mu = 0$ and $d_\mu = 0$ for all μ , which means that all fingers have the same width $r/2$, which is

also the width of all gaps. This reduces $F^*(j\omega)$ in Eq. (97) to

$$F^*(j\omega) = \frac{k_0}{c} \cos \frac{c\omega}{v} e^{-j\frac{\omega x_0}{v}} \sum_{\mu=0}^{N-1} (-1)^\mu h_\mu e^{-j\omega \mu r/v} \tag{98}$$

$$\times \sum_{v=0}^{M-1} (-1)^v e^{-j\omega vr/v}$$

In Eq. (98) the term $e^{-j\omega x_0/v}$ stands for the delay x_0/v of the wave between the two transducers; the sum over v is the essentially unwanted contribution of the output transducer, whereas the \cos term stems from the two δ impulses per finger pair. The desired frequency characteristic has to be realized with the individual overlaps h_μ of the input transducer. We set

$$(-1)^\mu h_\mu = h'_\mu \tag{99a}$$

and

$$z = e^{j\omega r/v} \tag{99b}$$

and obtain from Eq. (98)

$$\frac{F^*(j\omega)}{\frac{k_0}{c} \cos \frac{c\omega}{v} e^{-j\omega x_0/v} \sum_{v=0}^{M-1} (-1)^v e^{-j\omega vr/v}} = \sum_{\mu=0}^{N-1} h'_\mu z^{-\mu} \tag{100}$$

$F^*(j\omega)$ is the desired transfer function to be synthesized; the denominator on the left-hand side of Eq. (100) is the unavoidable contribution of the transducers. The ratio of both terms on the left has to be approximated by the right-hand term. This term is the same as the transfer function of digital filters with finite impulse response (FIR filters). Therefore, the synthesis procedures known from FIR filters can be applied [21,22]. Even though SAW filters are continuous time systems, the approximation by δ impulses

Figure 45. Top view of layout of fingers without alternating signs of electric field.

renders them similar to time discrete systems, where r/v in Eq. (99b) plays the role of the sampling time.

We cannot expect the approximation to provide h'_μ with alternating signs. Hence the layout of the fingers must be modified according to Fig. 45, where the alternation of signs is interrupted.

The pitch r in Fig. 46 is chosen such that the output signal is maximum at the center frequency of the passband. This is achieved by a constructive interference of the wave traveling the distance $2r$ in time $2r/v$ and the sin wave with frequency ω_0 imposed by the voltage V_1 exhibiting the period $2\pi/\omega_0$. This yields

$$\frac{2r}{v} = \frac{2\pi}{\omega_0}$$

or

$$r = \frac{v\pi}{\omega_0} = \frac{v}{2f_0} \tag{101}$$

Due to the approximations made, the design of SAW filters as a rule requires a corrective redesign based on the measured deviations from the desired characteristics. Further damaging parasitic effects are the triple transit signals, which are reflected by the fingers at the output transducer and then again reflected back to the output by the input transducer.

Economically important applications of the SAW technology are filters for the intermediate frequency in TV sets and filters for mobile communications.

The bandpass for TV sets possesses a center frequency of 38 MHz; the SAW substrate exhibits $v = 1000$ m/s. This yields, according to Eq. (101), a width of the fingers that equals the gaps of $r/2 = 13 \mu\text{m}$. A shortcoming of SAW filters is the relatively large insertion loss in the passband of around 8 dB, stemming mainly from the loss in the sub-

Figure 46. Construction of superposition of traveling wave and wave fed in by V_1 .

strate material. The loss can be decreased to around 5 dB by employing a second output transducer in Fig. 47, which catches the so far unused backward-traveling wave. However, the placement of the two output transducers both in the distance x_0 has to be accurate in order to maintain the same phase of the waves added in the output transducers.

4. AREAS FOR FUTURE STUDY

Classical filter synthesis is a well-established area for which the first contributions were published more than 70 years ago. Most of the important problems were indeed solved in the meantime. Some remaining unresolved problems will be outlined in this section. There has been increased focus on those problems in recent years because the classical filters serve as models for filter implementations in new technologies, such as digital filters, RC active filters, and switched-capacitors filters.

The following problems need to be resolved:

1. A proof that the synthesis of lossless two-ports with partial and full pole removal is always possible with realizable reactances is still missing. It is a difficult task, as many unsuccessful attempts may testify. However, a proof would certainly offer a deeper insight into one of the most important synthesis procedures. A helpful hint for further investigations would be the fact that negative impedances are also tolerable for partial pole removal, as they can represent the negative component, and inductor or a capacitor, in the equivalent circuit for a transformer with tight couplings.
2. Guidelines on how to find lossless two-ports with a minimum number of the more expensive inductors would be of economic interest. The guidelines could make use of the large number of equivalent solutions.

3. A procedure is needed to control the various possibilities for synthesizing a lossless two-port such that the component values lie in a desired range. This could help in using the components of an advantageous price-performance category and in implementing parasitic components of a given value.

For filters in new miniaturized technologies, the solution to the problem could provide component values that are feasible in the new technology, such as multipliers with values in the raster 2^v , v integer, in digital signal processing or capacitors in the pF range for CMOS technology while still maintaining a closed-loop gain around 1 of the operational amplifiers. The same goal may be reached by a linear transformation into an equivalent two-port either for the time continuous classical filters [12,23] or for digital filters [24].

4. A method is needed to generate equivalent reactance circuits for nonelectric components, such as coupled quartz oscillators, or for other mechanical oscillators during the synthesis procedure for lossless two-ports.
5. In the approximation method based on a conformal mapping, the approximation of arbitrary but realizable requirements in the stopband by a minimum number of $\coth |(\gamma_i - \gamma)/2|$ functions should be achieved by an analytical solution and not by a search procedure, guaranteeing that the minimum number of \coth functions is always reached. This design method would be one of the most powerful.
6. There is a need for synthesis of RLC two-ports that also include lossy two-ports with a complex impedance as a load and as internal impedance of the voltage source. This becomes more important the higher the operating frequencies are, which imply complex impedance loads. The synthesis of either lossy two-ports with resistive loads or of lossless two-ports

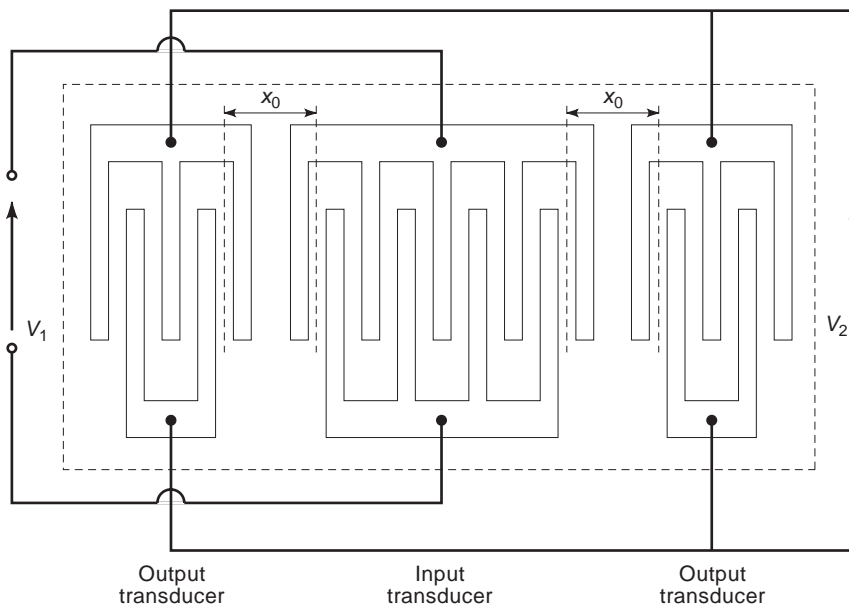

Figure 47. SAW filter with two parallel-connected output transducers in two identical distances x_0 from the input transducer.

with complex impedance loads [25] has been solved. Still unknown is the synthesis of two-ports combining the two properties.

7. There is a need for synthesis of SAW filters based on a more accurate but still easy-to-handle simulation of the device, which should eliminate the need for a corrective redesign.
8. A straightforward synthesis of SAW filters with the large number of geometric parameters in Eq. (69) will save fingers and hence chip area. The synthesis should also compensate for parasitic effects, such as the triple transit signal.
9. Materials science ought to synthesize piezoelectric substrates with a diminished attenuation of the SAW in order to decrease the insertion loss of filters.

FILTER THEORY

ADNAN GÖRÜR
Niğde University
Niğde, Turkey

1. INTRODUCTION

Filters are commonly used to transmit a particular thing and stop everything else. For instance, a car's oil filter passes the oil and rejects the dirt particles, or a pool filter passes the water and stops substances such as dirt, leaves, and twigs. Similarly, the electrical filters also transmit the desired signal or band of signals required for an electrical system and reject spurious signals or harmonics. Electrical filters have been employed in practical applications for more than eight decades, and are currently used in all frequency ranges to provide as nearly perfect transmission as possible for signals falling within desired passband

frequency ranges, together with rejection of those signals and noise outside the desired frequency bands. RF and microwave systems often require means of suppressing unwanted signals and/or separating signals having different frequencies in the microwave region. Naturally, these functions also are performed by electrical filters. RF/microwave filter technology stimulates many microwave applications, such as equalizers, impedance-matching networks, transformers, shaping networks, power dividers, attenuators, and directional couplers. In addition, they are fundamental components in a variety of RF/microwave systems, such as cellular radiocommunications, satellite communications, military applications, and radar.

A paper published in 1937 by Mason and Sykes [1] became a starting point of studies on microwave filters. Much of the foundation of modern filter theory and practice took place during the World War II years and the years immediately following. In particular, the invention of the radar as well as the war itself led to important developments in the area of filter technology. Both theoretical filter design methods and technology employed to realize them have shown a continuous development since World War II. Satellite communications that began in the 1960s stimulated filter transfer functions and network synthesis as well as rapid advances in waveguide and dielectric resonator filters. Later, cellular communications led to further developments in filter technologies such as the dielectric resonator, coaxial resonator, and ceramic and surface acoustic-wave filters, due to the necessity of low-loss high-power-handling selective filters with reduced size and at low cost. Much of developments in microwave filters in historical perspective were surveyed in 1984 by Levy and Cohn [2]. A survey of the significant techniques employed in the design of microwave filters after the first survey published in 1984 is also presented [3]. Additional details on numerous advances in microwave filter technology in the context of their applications may be found in the paper by Hunter et al. [4].

Electrical filters may be classified into several main categories in terms of their general response types: lowpass, bandpass, highpass, and bandstop. Their frequency responses are illustrated in Fig. 1. Lowpass filters transmit all frequencies between zero frequency and some upper frequency limit (cutoff frequency ω_c), while they attenuate all frequencies above the cutoff frequency. In contrast to lowpass filters, highpass filters pass all frequencies above a lower cutoff frequency and attenuate all frequencies below cutoff value. Bandpass filters transmit all frequencies in a specific frequency band (ω_1 to ω_2 , where ω_1 is lower cutoff frequency and ω_2 is upper cutoff frequency as shown in Figs. 1c and 1d, respectively) and reject all frequencies below and above that band. Finally, bandstop filters are complementary to bandpass filters, and reject all frequencies in a frequency band (ω_1 to ω_2) and pass all frequencies outside the band.

The ideal electrical filters are devices that provide perfect transmission for all frequencies in one or more passband regions and infinite attenuation in one or more stopband regions. Since such ideal filters cannot be realized in the practical sense, the aim of filter design is to ap-

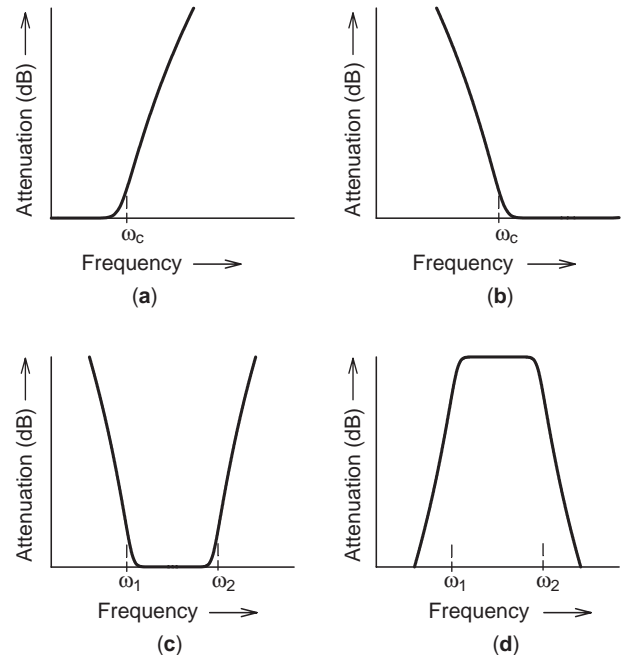

Figure 1. General response types of electrical filters: (a) lowpass; (b) highpass; (c) bandpass; (d) bandstop.

proximate the ideal characteristics within an acceptable tolerance. The electrical filters may also be classified according to their response functions, such as maximally flat or Butterworth, equally ripple or Chebyshev, elliptic function, generalized Chebyshev or pseudoelliptic, and maximally flat time delay or linear phase. These filter responses can be distinguished from each other by examining the locations of the poles and the zeros of their transfer functions. Briefly, the zeros of a transfer function are termed *transmission zeros* (or *attenuation poles*), and its poles, *transmission poles*. Of the filter responses, all the transmission zeros of the Butterworth or maximally flat transfer function are at infinity, and the poles of this function are located on a unit circle in the left-half complex plane. A Butterworth filter that has maximally flat characteristic within the passband is therefore an all-pole filter.

Like the Butterworth response, all the transmission zeros of the Chebyshev transfer function are also at infinity, but the poles of a Chebyshev filter are distributed on an ellipse in the left-half complex plane, where the major and minor axes of the ellipse are the imaginary and real axes of the complex plane. The filter having such a characteristic is often called as an *all-pole Chebyshev filter*, or simply a *Chebyshev filter*. The selectivity (or stopband slope) of a Chebyshev filter is steeper than that of a Butterworth filter of the same degree (the degree or order of a filter is equal to the number of elements used in filter design).

When frequency selectivity or stopband slope and passband loss are considered to be the significant filtering parameters, then Butterworth and Chebyshev filters are not optimum. Therefore, the filters can also be designed such that the transfer function has equal ripples in both passband and stopband. In this particular case, since the transfer function is result in expressions containing elliptic functions, a filter of this type is often called an *elliptic*

function filter or a *Cauer parameter filter* [5,6], or simply an *elliptic filter*. Elliptic filters have the maximum number of poles located at finite frequencies. In comparison to the Chebyshev filter, they show better passband performance and a steeper stopband slope.

On the other hand, if one or more transmission zeros are located at finite frequencies within the stopband of a Chebyshev filter, such a filter is then described as a *generalized Chebyshev* or *pseudoelliptic filter* [7,8]. The use of the generalized Chebyshev filter makes possible filter implementations with the minimum impedance variation, which is considerable for a printed circuit implementation, because when realizing the elliptic function filter, the impedance variation in the filter increases and leads to problems for printed circuit implementation. This filter approach offers high selectivity as the elliptic function filter.

Low loss in the passband and sharp stopband slope at the band edges are typical requirements for RF/microwave filter design. In some applications, however, the other significant characteristic also is behavior of the transmission phase over the passband [9]. For instance, modern microwave communication systems require, especially in satellite communications, filters passing the desired signal with a minimum distortion. In order to prevent the distortion, both the insertion loss and group delay of the filter must be constant within the passband. The group delay remains constant when the transmission phase varies linearly with frequency. Therefore, such a filter is frequently called a *maximally flat time-delay filter*. In addition, although maximally flat time-delay filters generally have a poor selectivity, they have a rather flat group delay within the passband. Since the group delay becomes flat over a wider frequency region as the filter degree n is increased, high-degree maximally flat time-delay filters are often used for obtaining a flat group delay over a large passband. Since the polynomials encountered in the transfer function providing such a filter characteristic are associated with Bessel functions, and as the maximally flat phase approximation was firstly derived by Thomson [10], these filters are also known *Bessel* or *Thomson filters*. The maximal time-delay filters have poles placed on an ellipselike path outside a unit circle in the complex plane, and like Butterworth and Chebyshev filters, they are also all-pole filters.

It is well known that microwave filters can be realized with only lumped elements such as inductors, capacitors, and resistors or only distributed elements such as waveguide sections, coaxial lines, microstrip lines, and strip-lines, or mixed lumped/distributed elements, arranged in a particular configuration. Although lumped-element filters can be utilized up to about Ku band, lumped realizations of the microwave filters with high- Q inductors and capacitors are seldom convenient because the operation wavelength is comparable with the physical size of circuit elements. Consequently, at microwave frequencies, this difficulty in realization of lumped-element filters requires the use of various distributed elements where the size of the elements is comparable with the wavelength. However, the study of lumped-element filters is very important for comprehension of the design of distributed microwave filters based on lumped-element theory. More details on

the role of lumped-element filters in microwave realizations and design may be found in Ref. 3.

The design of microwave filters using two-port lumped-element lowpass prototype networks has been a conventional method because the methods for lumped-element electrical filter design are well established. For this reason, the lowpass prototype filter design is usually a starting point for the design of microwave filters. In such a case, it is not important which media (e.g., transmission line, waveguide, or other media) in which the filter is practically realized. There are two filter theories for design of the lowpass prototype filter: the image parameter theory and the insertion loss theory [11]. The oldest method of filter design is based on the image parameter theory. In the design of lumped-element filters, however, the insertion loss theory is generally preferable because the use of the image parameter theory presents the desired cutoff frequencies and attenuation characteristics, but avoids the specification of a frequency response over the comprehensive operating frequency range. In addition, although this method is relatively simple, it is not an exact procedure and is based on a good deal of cut-and-try procedures for obtaining an adequate overall frequency characteristic. Unlike the image parameter method, the insertion loss theory can produce any possible transfer function and offers a filter design with a completely specified frequency response. Therefore, only insertion loss theory will be discussed here.

In the following paragraphs, the basic concepts and theories for design of general RF/microwave filters are defined. Filter transfer functions, two-port lumped-element lowpass prototype filters, and filter transformations are discussed. Richards' transformation, Kuroda's transformations (or identities), impedance, and admittance inverters are also investigated, which are required for transforming lumped elements to transmission-line sections, for physically separating filter elements and to change impractical elements into more realizable elements in a filter network.

2. BASIC CONCEPTS

2.1. Transfer Function

The transfer function of a linear and time-invariant network as illustrated in Fig. 2 may be expressed in form of a rational function as

$$S_{21}(s) = \frac{N(s)}{D(s)} \quad (1)$$

where $N(s)$ and $D(s)$ are polynomials in a complex frequency variable s . The s plane ($\sigma + j\Omega$) is a particularly convenient representation of a two-port network response as a function of the neper frequency σ and radian frequency Ω , which turns out to be very useful for modern network synthesis. When the network is a lossless passive network, then the neper frequency becomes $\sigma = 0$, and hence $s = j\Omega$. In this case, the transfer function of a lossless two-port network is also expressed as

$$|S_{21}(j\Omega)|^2 = \frac{1}{1 + \epsilon^2 F_n^2(\Omega)} \quad (2)$$

Figure 2. General form of a linear and time-invariant two-port network, where $P_L = P_A$ if the network is lossless, and $P_L = P_{in}$ if the network is lossless and there are no reflections.

where Ω is a frequency variable, ϵ is a ripple constant, and $F_n(\Omega)$ is a filtering function. Thus, to obtain the desired response, the rational transfer function given by (1) can be realized using (2).

The rational transfer function described in (1) is defined on the s -complex plane. The s values that make $S_{21}(s) = 0$ are the zeros of the rational transfer function, and the s values that constitute $S_{21}(s) = \infty$ are the singularities (usually the poles) of the rational transfer function. Briefly, the roots of polynomial $N(s)$ give the zeros of the transfer function $S_{21}(s)$, while the roots of polynomial $D(s)$ give the poles of the transfer function $S_{21}(s)$. These poles and zeros are often called *transmission poles* and *transmission zeros*, respectively, and they can be illustrated on the s -complex plane [12,13]. The poles become the natural frequencies of the filter when its frequency response is represented by the transfer function $S_{21}(s)$. The denominator $D(s)$ is a Hurwitz polynomial [12]. Hurwitz requires that all roots (zeros) of $D(s)$ occur only in the left-half plane, or on the imaginary axis of the s plane. Therefore, for the filter to be a stable and causal network, the transfer function described by (1) must satisfy the following constraints:

- It must be a rational function of complex frequency variable s with a real coefficient.
- The natural frequencies (or poles) of the filter must lie in the left-half complex plane, or on the imaginary axis $j\Omega$.
- The degree of the numerator $N(s)$ must be equal to or less than that of the denominator $D(s)$.

Unlike the denominator $D(s)$, the roots of numerator $N(s)$ may place anywhere on the s -complex plane, and they are defined as *finite-frequency transmission zeros* of the filter.

2.2. Insertion Loss

The transmitted power through a two-port network is characterized as insertion loss. The insertion loss, L_A (measured in decibels), of a two-port network at a particular frequency is defined as

$$L_A(\Omega) = 10 \log \frac{P_{in}}{P_L} = 10 \log \frac{1}{|S_{21}(j\Omega)|^2} \text{ dB} \quad (3)$$

where P_{in} is the power delivered (incident power) to the load when connected directly to the source and P_L is the power delivered to the same load after insertion of the two-port network, as shown in Fig. 2. A typical insertion loss response for a lowpass filter with an equal-ripple passband and stopband is shown in Fig. 3, where Ω_c , Ω_s , and Ω_z are the cutoff frequency, the frequency of the stopband edge, and the frequencies of the transmission zeros, respectively. Insertion loss becomes infinite at transmission zeros (or attenuation poles), while it is zero at reflection zeros (or transmission poles). All transmission zeros must be located in stopband(s) to achieve maximum signal attenuation in these frequency bands. Each transmission zero at infinite frequency increases one the degree of filter while the transmission zeros at finite frequencies appends double degrees.

2.3. Return Loss

The return loss L_R (measured in decibels) characterizes the reflected power and is defined as the ratio of the input to reflected power. Since $|S_{11}|^2 + |S_{21}|^2 = 1$ for a lossless, passive two-port network, the return loss response of the filter is given by

$$\begin{aligned} L_R(\Omega) &= 10 \log \left(\frac{P_{in}}{P_R} \right) = 10 \log \frac{1}{|S_{11}(j\Omega)|^2} \\ &= 10 \log \frac{1}{1 - |S_{21}(j\Omega)|^2} \text{ dB} \end{aligned} \quad (4)$$

Figure 3. Insertion loss and return loss of a lowpass filter with an equal-ripple passband and stopband.

where P_R is the reflected power, as shown in Fig. 2, and $|S_{11}|^2$ is power reflection coefficient. A typical return loss response for a lowpass filter is shown in Fig. 3. Return loss is infinite at reflection zeros but it becomes zero at transmission zeros. In other words, reflected power is an infinite number of decibels (∞ dB) smaller than the incident power at reflection zeros, whereas it is equal to incident power at transmission zeros. It should be known that the return loss becomes infinite at frequencies where insertion loss is zero, and the return loss has minimum value at frequencies where passband ripple has maximum value. All reflection zeros must be located in passband to enable transfer of power to output with minimal reflection. The total number of reflection zeros is equal to the total number of transmission zeros. The degree or order of a filter is also equal to the total number of transmission zeros or reflection zeros.

2.4. Phase Delay

In phase delay, the output signal in relation to the input signal is delayed while a signal is transmitted through a frequency-selective network such as a filter. The phase delay t_p (in seconds) is one of two parameters that play a role in characterizing filter performance related to this delay, and is defined by

$$t_p = \frac{\arg(L_A)}{\Omega} = \frac{\phi_{21}(\Omega)}{\Omega} \tag{5}$$

where ϕ_{21} (in radians) is the phase of the transfer function of the filter and Ω is measured in radians per second. In other words, phase delay is the ratio of the total phase shift (usually expressed in radians) of a sinusoidal signal during transmission through a transducer to the frequency (usually expressed in radians per second) of the signal.

2.5. Group Delay

The second type of signal delay is the group delay described as the negative of the slope of insertion phase. Group delay is defined as

$$t_d = - \frac{d\phi_{21}(\Omega)}{d\Omega} \tag{6}$$

The group delay determines the time required for a signal to pass through a circuit and represents the true signal delay.

3. FILTER CHARACTERISTICS

3.1. The Butterworth (or Maximally Flat) Characteristic

The ideal filter response can be approximated in a number of different ways. A common approximation is the Butterworth or maximally flat response, and its transfer function (or power loss ratio) is commonly described as

$$|S_{21}(j\Omega)|^2 = \frac{1}{1 + \varepsilon^2(\Omega/\Omega_c)^{2n}} \tag{7}$$

where Ω_c is the cutoff frequency or the edge of the passband and n is the degree or the order of filter, which is also

the number of reactive elements required in the lowpass prototype filter. In (7), ε defines the insertion loss at the cutoff frequency $\Omega_c = 1$ and is commonly set equal to 1. Hence, the filter has an insertion loss of $L_{Ar} = 3.01$ dB at the cutoff frequency $\Omega_c = 1$. For $\Omega > \Omega_c$, the insertion loss increases indefinitely with frequency at a rate dependent on the exponent $2n$, as shown in Fig. 4.

3.2. The Chebyshev (or Equal-Ripple) Characteristic

The transfer function that describes this type of filter response is given by

$$|S_{21}(j\Omega)|^2 = \frac{1}{1 + \varepsilon^2 T_n^2(\Omega/\Omega_c)} \tag{8}$$

where $T_n(\Omega/\Omega_c)$ is a Chebyshev polynomial of the first kind of order n and is defined by

$$T_n(\Omega/\Omega_c) = \begin{cases} \cos(n \cos^{-1}(\Omega/\Omega_c)) & |(\Omega/\Omega_c)| \leq 1 \\ \cosh(n \cosh^{-1}(\Omega/\Omega_c)) & |(\Omega/\Omega_c)| \geq 1 \end{cases} \tag{9}$$

Insertion loss responses for Fifth- and Seventh-degree Chebyshev filters are illustrated in Fig. 5. If the passband response is allowed to have ripples between a minimum value and a maximum value and the maximally flat stopband response, then the filter realized using (8) will have a cutoff (or stopband slope) sharper than that of a corresponding Butterworth filter, because the Chebyshev polynomial $T_n(\Omega/\Omega_c)$ oscillates between ∓ 1 for $|\Omega/\Omega_c| \leq 1$, while it increases monotonically for $|\Omega/\Omega_c| \geq 1$. This means that the transfer function oscillates between 1 and $1/(1 + \varepsilon^2)$ in the passband and equals $(1 + \varepsilon^2)$ at cutoff frequency, and increases monotonically for $|\Omega/\Omega_c| \geq 1$. Thus, the ripple constant ε that defines the magnitude of the ripple in the passband is given by

$$\varepsilon = (10^{0.1L_{Ar}} - 1)^{1/2} \tag{10}$$

where the insertion loss L_{Ar} at cutoff frequency is measured in decibels.

Figure 4. Butterworth (or maximally flat) filter characteristic of degrees 5 and 7.

Figure 5. Chebyshev (or equal-ripple) filter characteristic of degrees 5 and 7.

3.3. The Elliptic Function Characteristic

The filter characteristic that can offer an equal-ripple response in both the passband and stopband is known as an *elliptic function response*. The transfer function for elliptic function filter is given by

$$|S_{21}(j\Omega)|^2 = \frac{1}{1 + \varepsilon^2 F_n^2(\Omega/\Omega_c)} \quad (11)$$

where the ripple constant ε is defined by

$$\varepsilon = (10^{0.1L_R} - 1)^{-1/2} \quad (12)$$

and L_R is the minimum return loss level in the passband and is given by

$$L_R = -20 \log |S_{11}| \text{ dB} \quad (13)$$

In (11), the filtering function F_n is an elliptic rational function and can be expressed in terms of its zeros and poles [5,14,15]

$$F_n(\Omega) = \begin{cases} F_0 \frac{\prod_{i=1}^{n/2} (\Omega^2 - \Omega_{z,i}^2)}{\prod_{i=1}^{n/2} (\Omega^2 - \Omega_{p,i}^2)} & \text{for } n \text{ even} \\ F_0 \frac{\Omega \prod_{i=1}^{(n-1)/2} (\Omega^2 - \Omega_{z,i}^2)}{\prod_{i=1}^{(n-1)/2} (\Omega^2 - \Omega_{p,i}^2)} & \text{for } n \text{ odd} \end{cases} \quad (14)$$

where $\Omega_{z,i}$ are the zeros of the elliptic rational function, $\Omega_{p,i}$ are the poles of the elliptic rational function, $\Omega_s > 1$ is frequency at which minimum stopband insertion loss L_{As} (in decibels) occurs, and the scaling constant F_0 that ensures $F_n(1) = 1$, which is described as

$$F_0 = \begin{cases} \frac{\prod_{i=1}^{n/2} (1 - \Omega_{p,i}^2)}{\prod_{i=1}^{n/2} (1 - \Omega_{z,i}^2)} & \text{for } n \text{ even} \\ \frac{\prod_{i=1}^{(n-1)/2} (1 - \Omega_{p,i}^2)}{\prod_{i=1}^{(n-1)/2} (1 - \Omega_{z,i}^2)} & \text{for } n \text{ odd} \end{cases} \quad (15)$$

It should be noted that the poles $\Omega_{p,i}$ are inversely proportional to the zeros $\Omega_{z,i}$ of the elliptic rational func-

tion $F_n(\Omega)$ and the relationship between them is described as

$$\Omega_{p,i} = \frac{\Omega_s}{\Omega_{z,i}} \quad (16)$$

A typical insertion loss response for an elliptic function filter is illustrated in Fig. 6. The elliptic filter provides a much steeper stopband slope for a given degree, and relatively small insertion losses as compared to Butterworth and Chebyshev filters.

3.4. The Generalized Chebyshev (or Pseudoelliptic) Characteristic

Generalized Chebyshev response or pseudoelliptic response is one of the responses used frequently for microwave filters. The responses of these types between the Chebyshev and elliptic function filter characteristics have a pair of transmission zeros at finite frequencies. The transfer function that describes this type of response is given by

$$|S_{21}(j\Omega)|^2 = \frac{1}{1 + \varepsilon^2 F_n^2(\Omega/\Omega_c)} \quad (17)$$

where the ripple constant ε is as given by (12) and the filtering function $F_n(\Omega)$ for the odd-degree generalized Chebyshev characteristic with three transmission zeros at infinity and the remainder at a finite frequency is given as [7]

$$F_n(\Omega) = \cosh \left\{ (n-3) \cosh^{-1} \left[\Omega \left(\frac{\Omega_z^2 - 1}{\Omega_z^2 - \Omega^2} \right)^{1/2} \right] + 3 \cosh^{-1}(\Omega) \right\} \quad (18)$$

where n is the degree of the filter and an odd number. It should be noted that $\Omega = \pm \Omega_z$ ($\Omega > 1$) are the frequency locations of a pair of transmission zeros, and when $\Omega_z \rightarrow \infty$, the filtering function $F_n(\Omega)$ converts to the ordinary Chebyshev filter function. A typical insertion loss response for a generalized Chebyshev filter is illustrated in Fig. 7, where Ω_c , Ω_s , Ω_z , and Ω_m , are the cutoff frequency, the frequency at which minimum stopband insertion loss L_{As} (in decibels) occurs (or the frequency of the stopband

Figure 6. A typical elliptic function filter characteristic.

edge), the frequency of the transmission zero, and the frequency of the minimum insertion loss in the stopband, respectively.

3.5. The Maximally Flat Time-Delay Characteristic

Modern microwave communication systems require, especially in satellite and mobile communications, filters passing the desired signal with a minimum amount of distortion. This problem can be solved successfully when both the insertion loss and the group delay of the filter remains constant within the passband. The group delay will be constant if the transmission phase varies linearly with frequency. Thus, filters of this type are often called *maximally flat time-delay filters*.

For a maximally flat time-delay lowpass prototype filter with the cutoff frequency of $\Omega_c = 1$, the insertion loss is given as [16]

$$L_A(\Omega) = \frac{10\Omega^2}{(2n - 1) \ln 10} \text{ dB} \quad (19)$$

For $n \geq 3$, the 3 dB bandwidth is approximately given by

$$\Omega_{3\text{dB}} \approx \sqrt{(2n - 1) \ln 2} \quad (20)$$

As can be seen from this expression, the 3 dB bandwidth of a maximally flat time-delay filter is a function of the filter degree n only, and it widens as the degree is increased. In addition, the insertion loss responses of the maximally flat time-delay, Butterworth, and Chebyshev lowpass filters, which have identical topologies, are compared in Fig. 8. As can be seen, the insertion loss of the maximally flat time delay gradually increases outside the passband and its stopband rejection is not as good as those of the other two filters.

4. FILTER DESIGN USING THE INSERTION LOSS THEORY

This procedure of the filter design starts with deciding on filter specifications such as frequency range, bandwidth,

Figure 7. A typical generalized Chebyshev (or pseudoelliptic) filter characteristic.

insertion loss, stopband attenuation and frequencies, input and output impedances, VSWR (voltage standing-wave ratio), group delay, and phase linearity. This process is followed by synthesis of a suitable filter network. In this step, the lowpass prototype filter having desired filter characteristics such as Butterworth, Chebyshev, elliptic, pseudoelliptic, or maximally flat time-delay is designed. We shall investigate design of lowpass prototype filters using LC elements here, but the prototype networks can also be designed employing ideal impedance or admittance inverters that will be discussed later on. It should be mentioned that all filters that can be designed with impedance or admittance inverters are also designable employing LC prototype networks. In this article, therefore, only lowpass prototype filters utilizing LC elements will be discussed. For additional information on filter design using prototypes with inverters, the reader is referred to Refs. 13 and 16. The lowpass prototype filter is then transformed to the required type (lowpass, highpass, bandpass, or bandstop) filter with the specified center and/or edge frequencies. Finally, the filter network is realized in terms of lumped- and/or distributed-circuit elements. This filter design procedure is schematically illustrated in Fig. 9.

The design of microwave filters is based principally on transforming the lumped-element lowpass prototype filter network having desired filter characteristics into a physically realizable filter. Lowpass prototype filters are two-port lumped-element networks with an angular cutoff frequency of 1 rad/s and operating in a $1-\Omega$ system that have been synthesized to elicit a desired filter response. The elements of such a prototype filter are composed of inductors and capacitors of the ladder networks as illustrated in Fig. 10. The networks depict the two possible implementations of the lowpass prototype filter topologies providing the same power transfer function. Lowpass filters have characteristics such that they transmit all frequencies between zero frequency and some upper frequency limit (cutoff frequency ω_c) and attenuate all frequencies above the cutoff frequency. These prototype networks are all-pole networks with all their transmission zeros at infinity.

Figure 8. Comparison of characteristics of maximally flat time-delay filter, Butterworth filters, and Chebyshev lowpass filters.

In this section, only the equations and tables needed to determine the basic values of some lowpass prototype filters will be presented. It should be mentioned that the filter synthesis procedures will not be discussed here. (See the article titled FILTER SYNTHESIS.)

4.1. Butterworth (or Maximally Flat) Lowpass Prototype Filters

For Butterworth or maximally flat low-pass prototype filters with an insertion loss of 3.01 dB and at the cutoff frequency of $\Omega_c = 1$, the transfer function is given as

$$|S_{21}(j\Omega)|^2 = \frac{1}{1 + \Omega^{2n}} \quad (21)$$

The element values of such a prototype filter can be calculated using

$$g_0 = 1.0 :$$

$$g_k = 2 \sin\left(\frac{(2k-1)\pi}{2n}\right) \text{ for } k = 1, 2, 3, \dots, n \quad (22)$$

$$g_{n+1} = 1.0$$

The Butterworth filters considered here are always symmetric in network structure, namely, $g_0 = g_{n+1}$, $g_1 = g_n$, $g_2 = g_{n-1}$, and so on. For a normalized lowpass design where the source impedance and the cutoff frequency are 1Ω and $\Omega_c = 1$, respectively, the element values for the ladder-type circuits of Fig. 10 can be tabulated [16]. These circuits may be considered as the dual of each other, and either will offer the same response. For convenience, their element values g_n are given in Table 1 for filter degree n values up to 10, $\Omega_c = 1$ and $L = 3.01$ dB at cutoff frequency Ω_c .

On the other hand, a designer often needs to be able to select the number of elements in filter or the degree of filter to achieve a specified attenuation at the some frequency in the stopband. In such a case, the degree of a Butterworth lowpass prototype filter may be determined as

$$n \geq \frac{\log(10^{0.1L_{As}} - 1)}{2 \log \Omega_s} \quad (23)$$

where L_{As} is the minimum stopband attenuation at a frequency $\Omega = \Omega_s$ in the stopband. For example, if $L_{As} = 35$ dB and $\Omega_s = 1.9$, then $n \geq 6.278$, that is, a Butterworth prototype of degree 7 ($n = 7$) should be selected.

4.2. Chebyshev (or Equal-Ripple) Lowpass Prototype Filters

For a Chebyshev or equal-ripple lowpass prototype filter with a cutoff frequency of $\Omega_c = 1$, the transfer function is

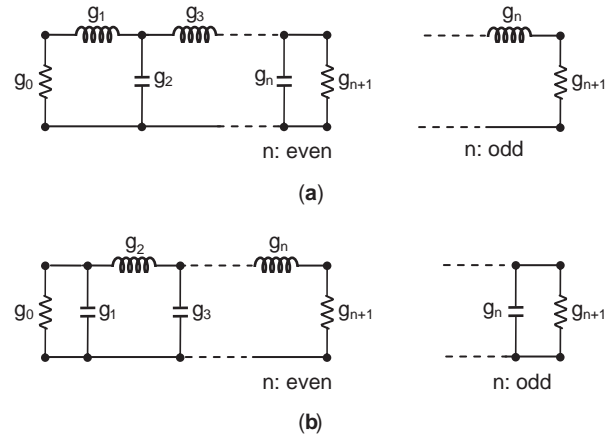

Figure 10. Lumped-element lowpass prototype networks for all-pole filters including Butterworth, Chebyshev, and maximally flat time-delay responses with (a) a ladder network structure and (b) its dual.

given as

$$|S_{21}(j\Omega)|^2 = \frac{1}{1 + \varepsilon^2 T_n^2(\Omega)} \quad (24)$$

The element values of the prototype filters shown in Fig. 10 may be computed using the formulas

$$g_0 = 1.0 \quad (25a)$$

$$g_1 = \frac{2a_1}{\gamma} \quad (25b)$$

$$g_k = \frac{4a_{k-1}a_k}{b_{k-1}g_{k-1}} \text{ for } k = 2, 3, \dots, n \quad (25c)$$

$$g_{n+1} = \begin{cases} 1.0 & \text{for } n \text{ odd} \\ \coth^2(\beta/4) & \text{for } n \text{ even} \end{cases} \quad (25d)$$

with

$$a_k = \sin\left(\frac{(2k-1)\pi}{2n}\right) \text{ for } k = 1, 2, 3, \dots, n \quad (26a)$$

$$b_k = \gamma^2 + \sin^2\left(\frac{k\pi}{n}\right) \text{ for } k = 1, 2, 3, \dots, n \quad (26b)$$

$$\gamma = \sinh\left(\frac{\beta}{2n}\right) \quad (26c)$$

$$\beta = \ln\left[\coth\left(\frac{L_{Ar}}{17.37}\right)\right] \quad (26d)$$

where L_{Ar} is the passband ripple in decibels. Some element values for Chebyshev lowpass prototype filters with a normalized source impedance 1Ω and cutoff frequency $\Omega_c = 1$ for various L_{Ar} and $n = 1-10$ are listed in Table 2 [16].

Figure 9. Filter design procedure.

5	0.6180	1.6180	2.0000	1.6180	0.6180	1.0					
6	0.5176	1.4142	1.9318	1.9318	1.4142	0.5176	1.0				
7	0.4450	1.2470	1.8019	2.0000	1.8019	1.2470	0.4450	1.0			
8	0.3902	1.1111	1.6629	1.9616	1.9616	1.6629	1.1111	0.3902	1.0		
9	0.3473	1.0000	1.5321	1.8794	2.0000	1.8794	1.5321	1.0000	0.3473	1.0	
10	0.3129	0.9080	1.4142	1.7820	1.9754	1.9754	1.7820	1.4142	0.9080	0.3129	1.0

The degree of a Chebyshev lowpass prototype filter may be determined by

$$n \geq \frac{\cosh^{-1} \left(\frac{10^{0.1L_{As}} - 1}{10^{0.1L_{Ar}} - 1} \right)^{1/2}}{\cosh^{-1} \Omega_s} \tag{27}$$

where L_{Ar} is the passband ripple and L_{As} is the minimum stopband attenuation at $\Omega = \Omega_s$. Again, when the filter specifications stipulate $L_{As} = 35$ dB, $L_{Ar} = 0.1$ dB, and $\Omega_s = 1.9$, then $n \geq 5.252$, that is, a Chebyshev prototype of degree 6 ($n = 6$) should be selected to meet this specification.

Since this example is the same as the example given above for the Butterworth prototype, the Chebyshev design has a better frequency characteristic than the Butterworth design, and at microwave frequencies, the Former design is preferred over the latter design.

Moreover, for given minimum return loss L_R or maximum voltage standing-wave ratio (VSWR) in the passband, the corresponding passband ripple L_{Ar} may be calculated as

$$L_{Ar} = -10 \log(1 - 10^{0.1L_R}) \text{ dB} \tag{28}$$

Table 2. Element Values for Chebyshev Prototype Filters ($g_0 = 1.0, \Omega_c = 1$)

or

$$L_{Ar} = -10 \log \left[1 - \left(\frac{VSWR - 1}{VSWR + 1} \right)^2 \right] \text{ dB} \quad (29)$$

where $L_R < 0$ (in decibels) is the minimum return loss given by (13), and VSWR is

$$VSWR = \frac{1 + |S_{11}|}{1 - |S_{11}|} \quad (30)$$

4.3. Elliptic Function Lowpass Prototype Filters

If frequency selectivity and passband loss are considered to be the significant filtering features, the elliptic function filters exhibiting equal-ripple response in both passband and stopband are optimum filters. Lumped-element lowpass elliptic function prototype filters are shown in Fig. 11. For the lowpass prototype filter shown in Fig. 11a, the transmission zeros (or attenuation poles) at finite frequencies in the stopband are produced by the parallel-resonant circuits in the series branches since this resonant circuit is open-circuited at resonance, while the transmission zeros (or attenuation poles) at finite frequencies for the prototype network in Fig. 11b are produced by the series-resonant circuits in the shunt branches since this resonant circuit is short-circuited at resonance.

Unlike the simple method of computing element values for the Butterworth and Chebyshev lowpass prototype filters described above, there are no simple methods for computing element values of the elliptic lowpass prototype filter, but the low-pass prototype element values derived by synthesis [17] have been published for a wide range of passband and, stopband ripple values, and a number of branches. However, the element values for some useful cases are presented in Table 3 [13] for a passband ripple $L_{Ar} = 0.1$ dB, a cutoff $\Omega_c = 1$, various minimum stopband insertion loss L_{As} , and frequency Ω_s at which minimum stopband insertion loss L_{As} occurs. More extensive tables for element values of elliptic filters were offered by Saal and Ulbrich [6].

For an elliptic function lowpass prototype filter with a cutoff frequency of $\Omega_c = 1$, the transfer function is given as

$$|S_{21}(j\Omega)|^2 = \frac{1}{1 + \varepsilon^2 F_n^2(\Omega)} \quad (31)$$

where the filtering function is as given by Eqs. (14) and (15).

The degree equation for an elliptic lowpass prototype filter may be written as

$$n \geq \frac{K(k_s) K(k'_0)}{K(k'_s) K(k_0)} \quad (32)$$

where $K(k)$ is the complete elliptic integral of the first kind, given by

$$\frac{K(k)}{K(k')} = \begin{cases} \frac{1}{\pi} \ln \left(2 \frac{1+k^{1/2}}{1-k^{1/2}} \right) & 0.707 \leq k \leq 1.0 \\ \frac{1}{\pi} \ln \left(2 \frac{1+(k')^{1/2}}{1-(k')^{1/2}} \right)^{-1} & 0 \leq k \leq 0.707 \end{cases} \quad (33)$$

The arguments of the complete elliptic integral of the first kind k_s, k'_s, k_0, k'_0 , are described as

$$k_s = \frac{1}{\Omega_s}, \quad k'_s = (1 - k_s^2)^{1/2} \quad (34)$$

$$k_0 = \varepsilon(10^{0.1L_{As}} - 1)^{-1/2}, \quad k'_0 = (1 - k_0^2)^{1/2} \quad (35)$$

where L_{As} is the minimum stopband attenuation at $\Omega = \Omega_s$. If $L_{As} = 35$ dB and $\Omega_s = 1.9$, then $n \geq 3.957$, namely, an elliptic function prototype network of degree 4 ($n = 4$), should be selected to meet this specification.

4.4. Generalized Chebyshev (or Pseudoelliptic) Lowpass Prototype Filters

The generalized Chebyshev filters have finite-frequency transmission zeros at a single frequency (just outside the edge of the passband) rather than being distributed freely throughout the stopband. When attempting to realize the elliptic function lowpass prototype filter, the impedance variation in the filters becomes large, and this impedance variation leads to problems for printed circuit implementation such as microstrip. The generalized Chebyshev fil-

ter has the advantage of leading to a more suitable range of impedance levels in the filters. Lumped-element lowpass prototype filter networks are shown in Fig. 12. For the prototype filter networks of degrees 5, 7, 9, and 11, the element values for $RL \geq 20$ dB and $RL \geq 26$ dB when $g_0 = 1, \Omega_c = 1$ and $L_{As} \geq 40$ dB are presented in Table 4 [7]. The table also contains the values of Ω_z and Ω_s .

Moreover, apart from the LC prototype networks shown in Fig. 12, a generalized Chebyshev prototype filter using inverters is introduced in Refs. 13 and 18 for any filter degree. However, since we have considered only the LC prototype filter networks, such a network will not be discussed here. For information on the design and characteristics of generalized Chebyshev prototype filters

employing inverters, the reader is referred to Chapt. 10 of Ref. 13 and to Ref. 18.

4.5. Maximally Flat Time-Delay Lowpass Prototype Filters

Lowpass prototype filters for all-pole filters with a ladder network structure as illustrated in Fig. 10 can serve as maximally flat time-delay lowpass prototype filters because these are also all-pole filters. The lowpass prototype element values for filters of this type are often derived by network synthesis. However, for convenience, some element values are provided in Table 5 [11,16]. It should be noted that the first-degree maximally flat time-delay low-

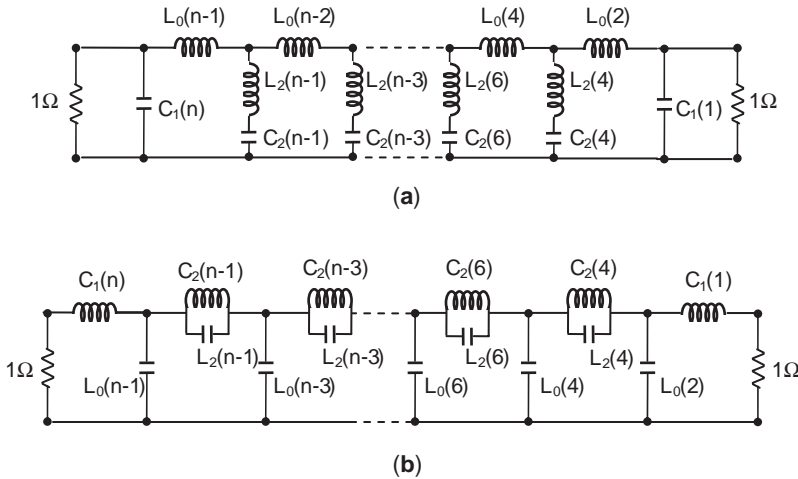

Figure 12. Lumped-element lowpass prototype filters for generalized Chebyshev response with (a) with shunt series-resonant branches and (b) its dual with series-parallel-resonant branches.

pass prototype filter is identical to the first-degree Butterworth lowpass prototype filter.

5. IMPEDANCE AND FREQUENCY SCALING

Lowpass prototype filters are not practical for most applications because they have cutoff frequencies of 1 rad/s and 1 Ω source and load terminations. Therefore, to obtain a practical filter response such as lowpass, highpass, bandpass, and bandstop, these prototypes can be scaled in terms of impedance and frequency.

As mentioned above, the source and load terminations of the prototype network are 1 Ω, except for Chebyshev filters with even n , which have load impedance different from 1 Ω. Therefore, the prototype filter reactances can be considered as normalized by the source impedance Z_0 . The $g_0 = 1$ normalization can be removed by multiplying the impedances of the prototype network by the source impedance Z_0 . Thus, if the component values of the prototype design are represented by g_n , and Z_{PL} , then the new filter

component element values can be obtained as

$$L = Z_0 g_n \quad (\text{for series inductors}) \quad (36)$$

$$C = \frac{g_n}{Z_0} \quad (\text{for shunt capacitors}) \quad (37)$$

$$Z_s = Z_0 \quad (38)$$

$$Z_L = Z_0 Z_{PL} \quad (39)$$

The impedance scaling process has no effect on the filter response.

5.1. Frequency Scaling for Lowpass Filters

To transform the cutoff frequency of a lowpass prototype filter from $\Omega_c = 1$ to ω_c , we can choose a frequency transformation as

$$\Omega = \frac{\omega}{\omega_c} \quad (40)$$

Table 4. Element Values for Generalized Chebyshev Prototype Filters ($g_0 = 1.0$, $\Omega_c = 1$, $L_{As} \geq 40$ dB)

where the angular frequency ω_c is the new cutoff frequency and cutoff occurs when the operation frequency ω is equal to the cutoff frequency ω_c . If we use the frequency transformation given by (40) together with the impedance scaling expressions in (36)–(39), the new component values are obtained as

$$L_n = \frac{Z_0 g_n}{\omega_c} \quad (\text{for series inductors}) \quad (41)$$

$$C_n = \frac{g_n}{Z_0 \omega_c} \quad (\text{for shunt capacitors}) \quad (42)$$

5.1.1. Lowpass-to-Highpass Transformation. To transform a lowpass filter response into a highpass filter response, the frequency transformation is given by

$$\Omega = -\frac{\omega_c}{\omega} \quad (43)$$

If this transformation is applied to the elements of a lowpass prototype network, then, as a result of the negative sign, the inductors and capacitors of the prototype network convert to a capacitors and inductors in the highpass filter, respectively. With impedance transformation, the new element values are obtained as

$$C_n = \frac{1}{Z_0 \omega_c g_n} \quad (\text{for series capacitors}) \quad (44)$$

$$L_n = \frac{Z_0}{\omega_c g_n} \quad (\text{for shunt inductors}) \quad (45)$$

5.1.2. Lowpass-to-Bandpass Transformation. If the angular frequencies ω_1 and ω_2 indicate the edges of the passband, then a practical bandpass response may be found using a frequency transformation as

$$\Omega = \frac{1}{\text{FBW}} \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right) \quad (46)$$

where the fractional bandwidth of the passband FBW and the center frequency ω_0 are, respectively

$$\text{FBW} = \frac{\omega_2 - \omega_1}{\omega_0} \quad (47)$$

$$\omega_0 = \sqrt{\omega_1 \omega_2} \quad (48)$$

The practical bandpass filter elements can be obtained by applying the frequency transformation given in (46) to the lowpass prototype filter elements. In this case, a series inductive element g_n in the prototype network is transformed to a series-connected series-resonant circuit in a practical bandpass filter, while a shunt capacitive element g_n in the prototype network is transformed to a shunt-connected parallel-resonant circuit. Thus, the new elements for the series-connected series-resonant circuit in the bandpass filter and the shunt-connected parallel-resonant circuit in the bandpass filter are, respectively

$$L_{sn} = \frac{Z_0 g_n}{\omega_0 \text{FBW}} \quad (\text{for series inductor in lowpass prototype})$$

$$C_{sn} = \frac{\text{FBW}}{\omega_0 Z_0 g_n} \quad (49)$$

and

$$C_{pn} = \frac{g_n}{Z_0 \omega_0 \text{FBW}} \quad (\text{for shunt capacitor in lowpass prototype})$$

$$L_{pn} = \frac{Z_0 \text{FBW}}{\omega_0 g_n} \quad (50)$$

Since both series- and parallel-resonant circuits have a resonant frequency of ω_0 , the resonant frequency ω_0 is $\omega_0^2 = 1/L_{sn}C_{sn}$ and $\omega_0^2 = 1/L_{pn}C_{pn}$.

5.1.3. Lowpass-to-Bandstop Transformation. A practical bandstop response may be found using a frequency transformation as

$$\Omega = \frac{\text{FBW}}{(\omega_0/\omega - \omega/\omega_0)} \quad (51)$$

where FBW and ω_0 are as given in (47) and (48), respectively. It should be noted that this transformation is opposite to the bandpass transformation described above. In the case of (51), the series inductors of the lowpass prototype filter are, respectively, transformed to series-connected

parallel-resonant circuits using

$$L_{pn} = \frac{g_n Z_0 \text{FBW}}{\omega_0}$$

(for series inductor in lowpass prototype)

$$C_{pn} = \frac{1}{Z_0 g_n \omega_0 \text{FBW}} \tag{52}$$

and shunt capacitors to shunt-connected series-resonant circuits using

$$L_{sn} = \frac{Z_0}{g_n \omega_0 \text{FBW}}$$

(for shunt capacitor in lowpass prototype)

$$C_{sn} = \frac{g_n \text{FBW}}{\omega_0 Z_0} \tag{53}$$

Again, since both series- and parallel-resonant circuits have a resonant frequency of ω_0 , the resonant frequency ω_0 is $\omega_0^2 = 1/L_{sn}C_{sn}$ and $\omega_0^2 = 1/L_{pn}C_{pn}$. All the transformations from lowpass prototype filters to other types of filters are summarized in Table 6.

6. FILTER REALIZATION

Distributed filters, including combline, interdigital, hair-pin-line, parallel-coupled-line, stepped-impedance, loop, and patch filters can be realized in a variety of media such as waveguide, coaxial lines, dielectric resonators, microstrip, stripline, and suspended substrate depending on the desired application. The transformation of lumped elements to transmission-line sections can be realized in

terms of Richards' transformation [19], while Kuroda's transformations or identities [20,21] can be employed to physically separate filter elements, to convert series elements into parallel elements or vice versa, and to change impractical elements into more realizable elements in a filter network. In addition, to convert a filter network composed of both series elements and parallel elements into one that contains either only series-resonant elements or only parallel-resonant elements, impedance or admittance inverters are especially useful, particularly for bandpass or bandstop having narrow (<10%) bandwidths.

6.1. Richards' Transformation

Richards' frequency transformation is defined as

$$S = j\Omega = j \tan \beta\ell = j \tan \frac{\omega\ell}{v_p} = j \tan \frac{\pi\omega}{2\omega_0} \tag{54}$$

where Ω is the distributed frequency variable, β is the phase constant, ℓ is transmission-line length, ω is the usual angular frequency, v_p is the phase velocity independent of frequency, and ω_0 is the angular frequency at which the lengths of all transmission lines are a quarter-wavelength long (or $\beta\ell = \pi/2$). This transformation maps the ω plane to the Ω plane. As the frequency ω changes from 0 to ω_0 , the new variable Ω changes from 0 to ∞ . Therefore, by applying Richards' transformation of (54), the entire frequency response of a lumped-element prototype is reproduced over a finite portion of the frequency band. Responses of a typical lumped-element filter and a corresponding transmission-line filter are illustrated in Fig. 13. Note that the response of a transmission-line filter repeats with a period of $2\omega_0$, which is due to repeated increments of $\lambda/2$ in the electrical length of the transmission-line sections. Under Richards' transformation, there is a

Table 6. Transformation Relations

Lowpass Prototype	Lowpass Filter	Highpass Filter	Bandpass Filter	Bandstop Filter
	 $L_n = Z_0 g_n / \omega_c$	 $C_n = 1 / Z_0 \omega_c g_n$	 $L_{sn} = Z_0 g_n / \omega_0 \text{FBW}$ $C_{sn} = \text{FBW} / \omega_0 Z_0 g_n$	 $L_{pn} = g_n Z_0 \text{FBW} / \omega_0$ $C_{pn} = 1 / Z_0 g_n \omega_0 \text{FBW}$ $\omega_0^2 = 1 / L_{pn} C_{pn}$
	 $C_n = g_n / Z_0 \omega_c$	 $L_n = Z_0 / \omega_c g_n$	 $C_{pn} = g_n / Z_0 \omega_0 \text{FBW}$ $L_{pn} = Z_0 < \text{FBW} / \omega_0 g_n$	 $L_{sn} = Z_0 / g_n \omega_0 \text{FBW}$ $C_{sn} = g_n \text{FBW} / \omega_0 Z_0$ $\omega_0^2 = 1 / L_{sn} C_{sn}$
$\text{FBW} = \frac{\omega_2 - \omega_1}{\omega_0}, \quad \omega_0 = \sqrt{\omega_1 \omega_2}$				

Figure 13. (a) Richards' transformation (b) Chebyshev lowpass filter characteristic using the Richards transformation.

relation between the lumped elements and the quarter-wave lines. The input impedance of short-circuited transmission line is

$$Z = jZ_0 \tan \beta \ell = jZ_0 \tan \left(\frac{\pi \omega}{2\omega_0} \right) = j\Omega Z_0 \quad (55)$$

where Z_0 is the characteristic impedance of the line and the length ℓ is $\lambda/4$ at ω_0 . Similarly, the input admittance of an open-circuited line is

$$Y = jY_0 \tan \left(\frac{\pi \omega}{2\omega_0} \right) = j\Omega Y_0 \quad (56)$$

where $Y_0 = 1/Z_0$ is the characteristic admittance of the line. According to Eqs. (55) and (56), since the impedance of a lumped inductor and the admittance of a lumped capacitor are, respectively, $j\omega L$ and $j\omega C$, a lumped inductor corresponds to a short-circuited line of $\lambda/4$ at ω_0 with an input impedance $Z = j\Omega Z_0$, while a lumped capacitor corresponds to an open-circuited line of $\lambda/4$ at ω_0 with an input admittance $Y = j\Omega Y_0$. These equivalences are illustrated in Fig. 14. In addition, note that the lumped resis-

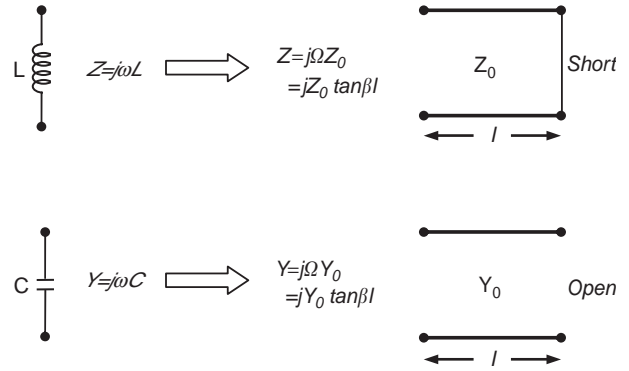

Figure 14. Correspondence between short-circuited and open-circuited transmission-line sections and lumped elements.

tors are unaffected by Richards' transformation because they are independent of frequency. As a result, Richards' transformation can be utilized for realizing transmission-line filters consisting of commensurate (equal electrical length) transmission-line sections.

6.2. Kuroda's Transformations (or Identities)

Since the realization of series-connected stubs in transmission-line filters leads to complexity, certain network equivalences without compromising filter performance may be desirable to realize filter networks. Such network equivalences are known as *Kuroda's transformations* or *identities* [20,21]. Kuroda's transformations have properties such as effecting physical separation between stubs, mapping series stubs into parallel stubs or vice versa, and changing impractical elements into more realizable elements in a filter network. Four network equivalences known as *Kuroda's transformations of the first and second kinds* are illustrated in Fig. 15, where the commensurate line sections having the same electrical length $\theta = \beta \ell$ are assumed for each identity. Kuroda's transformations, as well as the unit element, were also discussed in Ref. 22. The unit element labeled "UE" in Fig. 15 is simply a lossless transmission-line section with characteristic impedance Z_0 , and its length is a quarter-wavelength at frequency ω_0 . Levy [21] has generalized the Kuroda transformations to include any two-port network and unit element.

6.3. Impedance and Admittance Inverters

At microwave frequencies, it is desirable to convert a filter network composed of both series- and parallel-resonant elements into one that contains only one type of these elements. This can be achieved by using impedance and admittance inverters. Impedance inverters are also known as *K inverters* and admittance inverters, as *J inverters*. Ideal *K* and *J* inverters are defined in Fig. 16, where *K* (*J*) is real and is the characteristic impedance (admittance) of the inverter. These inverters have a phase shift of $\pm 90^\circ$ [16,23].

Briefly, lowpass filters can be implemented by employing only one sort of reactance, while bandpass filters can be implemented by employing series (parallel) *LC* series

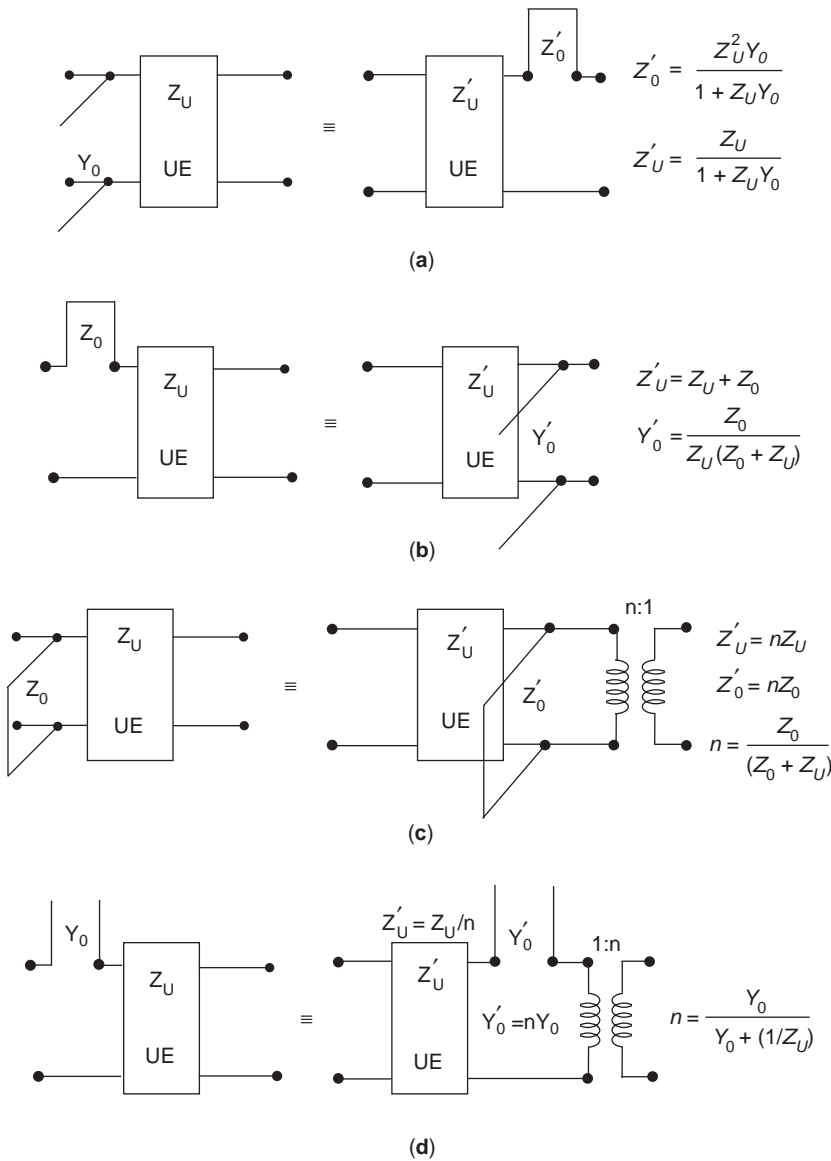

Figure 15. (a,b) Kuroda's transformations of the first kind; (c,d) Kuroda's transformations of the second kind.

(shunt) resonant circuits separated by impedance (admittance) inverters. Thus, the lowpass prototype filters in Fig. 10 can be transformed into the filter networks with the impedance and admittance inverters shown in Fig. 17. In this case, both the prototype filters and the filters with inverters will have the same frequency responses, provid-

ed the inverter parameters K and J are computed by the equations given in Fig. 17.

On the other hand, by applying suitable element transformations, the impedance and admittance inverters can also be utilized to convert the lowpass filters shown in Fig. 17 into two bandpass filter or into other types of filters commonly employed because impedance and admittance inverters are frequency-invariable. Two bandpass filters with the impedance and admittance inverters are illustrated in Fig. 18. The expressions for element transformation as well as for impedance and admittance of the inverters are also given in the figures. It should be noted that the source impedances are assumed to be the same for the networks in Figs. 17 and 18, and again, since no impedance transformation is required, the impedance Z_0 in (49) and (50) is assumed to be 1.0. Figure 18a illustrates a bandpass filter composed of only series resonators, while the filter in Fig. 18b includes only shunt parallel resonators.

Figure 16. Definition of (a) impedance (K) and (b) admittance (J) inverters.

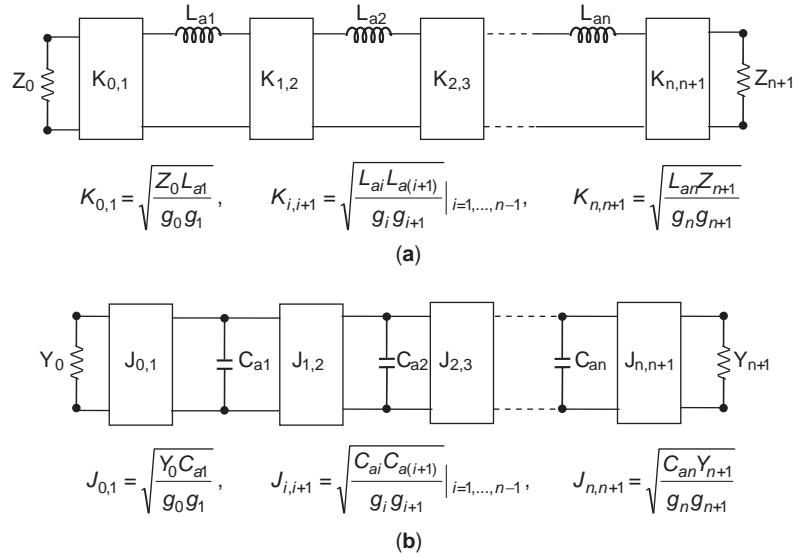

Figure 17. Lowpass prototype filter with (a) impedance inverters and (b) admittance inverters.

As mentioned previously, difficulties in realization of lumped-element microwave filters require the use of distributed elements such as waveguide sections, coaxial lines, microstrip lines, striplines, and dielectric resonators. Consequently, it is generally desirable to employ distributed-element resonators instead of lumped-element ones to realize microwave filters. Under ideal circumstances, the reactances or susceptances of lumped and distributed resonators should be equal to each other, but they approximate each other only near resonance. So, for narrowband distributed filters, the distributed resonator reactance (susceptance) and the reactance (susceptance) slope are determined by equating to those of their corresponding

lumped resonator at resonant frequency, and it is convenient to introduce their reactance and susceptance slope parameters. The reactance slope parameter for any resonator having zero reactance at resonant frequency ω_0 (such a resonator exhibits series resonance properties) is given by

$$x = \frac{\omega_0}{2} \frac{dX}{d\omega} \Big|_{\omega=\omega_0} \quad \Omega \tag{57}$$

where X is the reactance of the distributed resonator. For a lumped series LC resonator, this expression reduces to $x = \omega_0 L = 1/\omega_0 C$. The susceptance slope parameter for any resonator having zero susceptance at resonant frequency ω_0 (such a resonator exhibits shunt resonance properties)

Table 7. Practical Impedance and Admittance Inverters

Lumped-Element Inverters	Lumped- and Distributed-Element Inverters			
	<i>Impedance Inverters</i>			
<p style="text-align: center;">$K = \omega L$</p>	<p style="text-align: center;">$K = 1/\omega C$</p>	<p style="text-align: center;">$\phi < 0$ for $X > 0$ $K = Z_0 \tan \phi/2 ,$</p>	<p style="text-align: center;">$\phi > 0$ for $X < 0$ $\phi = -\tan^{-1}(2X/Z_0)$</p>	
	$\left \frac{X}{Z_0} \right = \frac{K/Z_0}{1 - (K/Z_0)^2}$			
	<i>Admittance Inverters</i>			
<p style="text-align: center;">$J = 1/\omega L$</p>	<p style="text-align: center;">$J = \omega C$</p>	<p style="text-align: center;">$\phi > 0$ for $B < 0$ $J = Y_0 \tan \phi/2 ,$</p>	<p style="text-align: center;">$\phi < 0$ for $B > 0$ $\phi = -\tan^{-1}(2B/Y_0)$</p>	
	$\left \frac{B}{Y_0} \right = \frac{J/Y_0}{1 - (J/Y_0)^2}$			

is defined by

$$b = \frac{\omega_0}{2} \left. \frac{dB}{d\omega} \right|_{\omega=\omega_0} \Omega^{-1} \quad (58)$$

where B is the susceptance of the distributed resonator. For a lumped shunt LC resonator, this expression reduces to $b = \omega_0 C = 1/\omega_0 L$ (see article titled RESONATORS).

To transform the filters including lumped resonance elements with K and J inverters in Fig. 18 into the filters including distributed resonance elements with K and J inverters in Fig. 19, we can add $\omega_0 L_{si} = x_i$ and $\omega_0 C_{pi} = b_i$ to the expressions indicated in Fig. 18. As a result, generalized bandpass filters composed of distributed resonators with impedance inverters and admittance inverters are derived as shown in Fig. 19.

Essentially, an ideal quarter-wave impedance transformer can be used as an impedance inverter. Besides a quarter-wave transformer, there are various other circuits that have properties of K and J inverters. Such types of practical K and J inverters are summarized in Table 7. More details on impedance and admittance inverters and their applications may be found in the literature [13,16,21].

7. CONCLUSION

As mentioned previously, distributed filter topics including lowpass, bandpass, highpass, and bandstop constructed in a variety of media, such as waveguide, coaxial line, microstrip, stripline, and dielectric resonators, are generally based on lumped-element filters. Many filter designs commence with a lumped-element lowpass prototype filter. Therefore, the objective of this study was to present the basic topics of filter theory for newcomers to the area and to point out how a filter may be designed. Various filter characteristics generally used, such as Butterworth, Chebyshev, elliptic, pseudoelliptic, and maximally flat time delay, were discussed. Insertion loss theory only for lowpass prototype filter design was investigated because of its superior to image parameter theory. Although the image parameter theory is the oldest method of filter design, it has hardly ever been used.

Note that the subject here is not to discuss the microwave filter technologies, such as waveguide, coaxial, combline, interdigital, parallel-coupled, hairpin, patch and ring, ceramic resonator, dielectric resonator, suspended substrate stripline, and superconducting filters from an applications perspective or a historical perspective. However, the topics of microwave filters are extensively investigated in the classic book of Matthaei et al. [16]. This book, even in its first edition, has been a milestone in the history of microwave filters. Although it has become a classic for microwave filters, it was published in 1980 and somewhat dated. The book by Hong and Lancaster [13] may be considered as an alternative of this classic. It provides a comprehensive treatment of RF and microwave filters based on microwave structures and also discusses advanced microwave filters. The

1984 survey by Levy and Cohn [2] and the 2002 surveys by Levy et al. [3] and Hunter et al. [4] may also be considered as good reference sources for newcomers to the field.

FINITE-DIFFERENCE TIME-DOMAIN ANALYSIS

ALLEN TAFLOVE
Northwestern University

SUSAN C. HAGNESS
University of Wisconsin-
Madison
Madison, Wisconsin

Prior to 1990, numerical modeling of electromagnetic engineering systems was implemented primarily using solution techniques for the sinusoidal steady-state (frequency-domain) Maxwell's equations. Principal computational approaches included high-frequency asymptotic methods and integral equation techniques. However, while asymptotic analyses are well suited for modeling the scattering properties of electrically large complex shapes, such methods have difficulty treating nonmetallic material composition and volumetric complexity of a structure. Conversely, while integral equation methods can deal with material and structural complexity, their need to construct and solve systems of linear equations limits the electrical size of possible models, especially those requiring detailed treatment of geometric details within a volume, as opposed to just the surface shape.

While significant progress has been made in solving the large systems of equations generated by frequency-domain integral equations, the capabilities of even the latest such technologies are exhausted by many volumetrically complex structures of engineering interest. This also holds for frequency-domain finite-element techniques. Further, incorporation of material and device nonlinearities into frequency-domain solutions of Maxwell's equations poses difficult problems as engineers seek to design active electromagnetic, electronic, and/or quantum-optical systems such as high-speed digital circuits, microwave and millimeter-wave amplifiers, and lasers.

Realization of the limitations of frequency-domain solutions of Maxwell's equations led to exploration of alternative approaches aimed at direct time-domain solutions of Maxwell's differential (curl) equations on spatial grids or lattices. The finite-difference time-domain (FDTD) method introduced by Yee in 1966 [1] was the first technique in this class. FDTD has remained the subject of continuous active development and expanding application areas [2] with numerous available software packages (e.g., see the list of WWW links to such softwares provided in

Ref. 3). Two related numerical approaches for solving Maxwell's equations, the finite integration technique (FIT) introduced by Weiland [4,5] and the transmission-line matrix (TLM) technique introduced by Johns [6,7], have also been studied for many years and are also the basis of commercial software packages. FIT and TLM techniques will not be discussed in this article, which focuses on the foundation and illustrative applications of the FDTD method.

There are six primary reasons for the expansion of interest in FDTD and related grid-based time-domain numerical solution techniques for Maxwell's equations:

1. *FDTD uses no linear algebra.* Being a fully explicit computation, FDTD avoids the difficulties with linear algebra that limit the size of frequency-domain integral equation and finite-element electromagnetics models to generally fewer than 10^7 field unknowns. FDTD models with as many as 10^9 field unknowns have been run. There is *no intrinsic upper bound* to this number.
2. *FDTD is accurate and robust.* The sources of error in FDTD calculations are well understood and can be bounded to permit accurate models for a very large variety of electromagnetic wave interaction problems.
3. *FDTD treats impulsive behavior naturally.* FDTD directly calculates the impulse response of an electromagnetic system. For a linear system, a single FDTD simulation can provide both the ultrawideband temporal response and (via discrete Fourier transformation) the sinusoidal steady-state response at any frequency within the excitation spectrum. For a nonlinear system, FDTD avoids the need to perform harmonic balance calculations that are required when using frequency-domain analyses.
4. *FDTD is systematic and simple to implement.* With FDTD, specifying a new structure to be modeled is reduced to a problem of mesh generation rather than the potentially complex reformulation of an integral equation. For example, FDTD requires no calculation of structure-dependent Green functions.
5. *Computer memory capacities are increasing rapidly.* While this trend positively influences all numerical techniques, it is of particular advantage to FDTD methods which are founded on discretizing space over a volume, and therefore inherently require a large random access memory.
6. *Computer visualization capabilities are increasing rapidly.* While this trend positively influences all numerical techniques, it is of particular advantage to FDTD methods that generate time-marched arrays of field quantities suitable for use in color videos to illustrate the field dynamics.

An indication of the expanding level of interest in FDTD Maxwell's equations solvers is the hundreds of papers currently published in this area worldwide each year, as opposed to fewer than 10 as recently as 1985 [8]. This expansion continues as engineers and scientists in

nontraditional electromagnetics-related areas such as digital systems and integrated optics become aware of the power of such direct solution techniques for Maxwell's equations.

1. CHARACTERISTICS OF FDTD TECHNIQUES

FDTD and related space-grid time-domain techniques are direct solution methods for Maxwell's curl equations. These methods employ no potentials. Rather, they are based on volumetric sampling of the unknown electric and magnetic fields within and surrounding the structure of interest, and over a period of time. The sampling in space is at subwavelength resolution set by the user to properly sample the highest near-field spatial frequencies thought to be important in the physics of the problem. Typically, 10–20 samples per wavelength are needed. The sampling in time is selected to ensure numerical stability of the algorithm.

Overall, FDTD and related techniques are marching-in-time procedures that simulate the continuous actual electromagnetic waves in a finite spatial region by sampled-data numerical analogs propagating in a computer data space. Timestepping continues as the numerical wave analogs propagate in the space lattice to causally connect the physics of the modeled region. For simulations where the modeled region must extend to infinity, absorbing boundary conditions are employed at the outer lattice truncation planes, which ideally permit all outgoing wave analogs to exit the region with negligible reflection. Phenomena such as induction of surface currents, scattering and multiple scattering, aperture penetration, and cavity excitation are modeled timestep by timestep by the action of the numerical analog to the curl equations. Self-consistency of these modeled phenomena is generally assured if their spatial and temporal variations are well resolved by the spacetime sampling process. In fact, the goal is to provide a self-consistent model of the mutual coupling of all the electrically small-volume cells constituting the structure and its near field, even if the structure spans tens of wavelengths in three dimensions and there are hundreds of millions of space cells.

Timestepping is continued until the desired late-time pulse response is observed at the field points of interest. Prolonged “ringing” of the computed field waveforms due to a high Q factor or large electrical size of the structure being modeled requires a combination of extending the computational window in time and extrapolation of the windowed data before Fourier transformation.

2. CLASSES OF FDTD SPACE LATTICES

Current FDTD and related space-grid time-domain algorithms are fully explicit solvers employing highly vectorizable and parallel schemes for time-marching the six components of the electric and magnetic field vectors at each of the space cells. The explicit nature of the solvers is usually maintained by employing a leapfrog timestepping scheme. Current methods differ primarily in how the space lattice is set up. In fact, gridding methods can be

categorized according to the degree of structure or regularity in the mesh cells:

1. *Almost Completely Structured.* In this case, the space lattice is organized so that its unit cells are congruent wherever possible. The most basic example of such a mesh is the pioneering work of Yee [1], who employed a uniform Cartesian grid having rectangular cells. Staircasing was used to approximate the surface of structural features not parallel to the grid coordinate axes. Later work showed that it is possible to modify the size and shape of the space cells located immediately adjacent to a structural feature to conformally fit its surface [9,10]. This is accurate and computationally efficient for large structures because the number of modified cells is proportional to the surface area of the structure. Thus, the number of modified cells becomes progressively smaller relative to the number of regular cells filling the structure volume as its size increases. As a result, the computer resources needed to implement a fully conformal model approximate those required for a staircased model. However, a key disadvantage of this technique is that special mesh generation software must be constructed.

2. *Surface-Fitted.* In this case, the space lattice is globally distorted to fit the shape of the structure of interest. The lattice can be divided into multiple zones to accommodate a set of distinct surface features [11]. The major advantage of this approach is that well-developed mesh generation software of this type is available. The major disadvantage is that, relative to the Yee algorithm, there is substantial added computer burden due to (a) memory allocations for the position and stretching factors of each cell and (b) extra computer operations to implement Maxwell's equations at each cell and to enforce field continuity at the interfaces of adjacent cells. Another disadvantage is the possible presence of numerical dissipation in the timestepping algorithm used for such meshes. This can limit the range of electrical size of the structure being modeled due to numerical wave attenuation artifacts.

3. *Completely Unstructured.* In this case, the space containing the structure of interest is completely filled with a collection of lattice cells of varying sizes and shapes, but conforming to the structure surface [12]. As for the case of surface-fitted lattices, mesh generation software is available and capable of modeling complicated three-dimensional shapes possibly having volumetric inhomogeneities. A key disadvantage of this approach is its potential for numerical inaccuracy and instability due to the unwanted generation of highly skewed space cells at random points within the lattice. A second disadvantage is the difficulty in mapping the unstructured mesh computations onto the architecture of either parallel vector computers or massively parallel machines. The structure-specific irregularity of the mesh mandates a robust preprocessing algorithm that optimally assigns specific mesh cells to specific processors.

At present, the best choice of computational algorithm and mesh remains unclear. In the near future, we expect

continued progress in this area as various groups develop their favored approaches and perform validations.

3. SOURCES OF ERROR

FDTD techniques have four primary sources of numerical error. Each error source represents a type of behavior of the numerical waves within the FDTD grid that differs from that of the desired physical electromagnetic waves being modeled. The error sources are as follows:

1. *Imperfect Absorbing Boundary Conditions.* For open-region simulations wherein the FDTD lattice would ideally extend throughout all of space, outgoing numerical waves are spuriously reflected back toward the lattice interior at the outermost grid boundaries.
2. *Wave Propagation Speed Errors.* Numerical waves in the FDTD space lattice have propagation speeds that differ from that of light, as they are a function of the lattice resolution and the propagation direction. The resulting positional and/or phase errors of the numerical waves are cumulative and can be significant for lattices that extend over many wavelengths of the numerical modes.
3. *Spurious Numerical Wave Reflections.* A space lattice region with position-dependent resolution and/or unit cell shape causes numerical waves to propagate with position-dependent speeds within its interior. This generates spurious internal wave reflections even if the lattice region has otherwise uniform electrical properties.
4. *Inaccurate Rendering of Surface Shapes.* The shape and/or size of the space lattice cells may not permit fully conformal modeling of the surface of the wave interaction structure being modeled.

Error source 1 has been practically eliminated for many problems due to the development of highly effective absorbing boundary conditions such as Berenger's perfectly matched layer [13]; the anisotropic perfectly matched layer [14,15], and the complementary operator method [16]. Error sources 2 and 3 are being attacked by a new generation of low-dispersion algorithms including the wavelet-based multiresolution time-domain technique [17] and the pseudospectral time-domain technique [18]. Finally, error source 4 is being attacked by a new generation of conformal-surface FDTD algorithms [10].

4. SCALING TO VERY LARGE PROBLEM SIZES

Using FDTD, we can model electromagnetic wave interaction problems requiring the solution of considerably more than one-billion field vector unknowns. At this level of complexity, it is possible to develop high-resolution, volumetric, three-dimensional models of complete physical and engineering systems, including the following:

- The entire Earth-ionosphere cavity for extremely low-frequency wave propagation
- Entire aircraft and missiles illuminated by radar at 1 GHz and above
- Entire multilayer circuit boards and multichip modules for digital signal propagation, crosstalk, and radiation
- Entire microwave and millimeter-wave amplifiers, including the active and passive circuit components and packaging
- Entire integrated optical structures, including lasers, waveguides, couplers, and resonators

A key goal for such large models is to achieve algorithm/computer architecture scaling such that for N field unknowns to be solved on M processors, we approach an order(N/M) scaling of the required computational resources.

We now consider the factors involved in determining the computational burden for the class of FDTD and related space-grid time-domain solvers.

1. *Number of Volumetric Grid Cells N .* The six-vector electromagnetic field components located at each lattice cell must be updated at every timestep. This yields by itself an order(N) scaling.
2. *Number of Timesteps n_{\max} .* A self-consistent solution in the time domain mandates that the numerical wave analogs propagate over timescales sufficient to causally connect each portion of the structure of interest. Therefore, n_{\max} must increase as the maximum electrical size of the structure. In three dimensions, it can be argued that n_{\max} is a fractional power function of N such as $N^{1/3}$. Further, n_{\max} must be adequate to step through "ring-up" and "ringdown" times of energy storage features such as cavities. These features vary from problem to problem and cannot be ascribed a dependence relative to N .
3. *Cumulative Propagation Errors.* Additional computational burdens may arise because of the need for either progressive mesh refinement or progressively higher-accuracy algorithms to bound cumulative positional or phase errors for propagating numerical modes in progressively enlarged meshes. Any need for progressive mesh refinement would feed back to factor 1.

For most free-space problems, factors 2 and 3 are weaker functions of the size of the modeled structure than factor 1. This is because geometric features at increasing electrical distances from each other become decoupled as a result of radiative losses by the electromagnetic waves propagating between these features. Further, it can be shown that replacing second-order accurate algorithms by higher-order versions sufficiently reduces numerical dispersion error to avoid the need for progressive mesh refinement for object sizes up to the order of 100 wavelengths. Overall, a computational burden of order($N \cdot n_{\max}$) = order($N^{4/3}$) is estimated for very large FDTD and related models.

5. THE BASIS OF FDTD: MAXWELL'S TIME-DEPENDENT CURL EQUATIONS

Using MKS units, the time-dependent Maxwell's curl equations in three dimensions are given in differential equation form for general materials by

$$\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times \mathbf{E} - \mathbf{M} \quad (1)$$

$$\frac{\partial \mathbf{D}}{\partial t} = \nabla \times \mathbf{H} - \mathbf{J} \quad (2)$$

where

- \mathbf{E} = electric field intensity (V/m)
- \mathbf{D} = electric flux density (C/m²)
- \mathbf{H} = magnetic field intensity (A/m)
- \mathbf{B} = magnetic flux density (Wb/m²)
- \mathbf{J} = electric current density (A/m²)
- \mathbf{M} = equivalent magnetic current density (V/m²)

are the space- and time-dependent vectors that constitute the electromagnetic field and its associated current densities.

The constitutive relations between the field vector pairs (\mathbf{B}, \mathbf{H}) and (\mathbf{D}, \mathbf{E}) which describe the macroscopic interaction of the electromagnetic field with materials are given in a general form by

$$\mathbf{H} = f(\mathbf{B}) \quad (3a)$$

$$\mathbf{E} = g(\mathbf{D}) \quad (3b)$$

where f and g can be scalar, polynomial, matrix, time-derivative, time-integral, or time-convolution operators. Appropriate selection of f and g provides the description of material anisotropies, frequency dispersions, and nonlinearities. For the simplest case of an isotropic, nondispersive, linear material, f and g are multiplicative scalars and (3a) and (3b) reduce to

$$\mathbf{H} = \frac{\mathbf{B}}{\mu} \quad (4a)$$

$$\mathbf{E} = \frac{\mathbf{D}}{\varepsilon} \quad (4b)$$

where μ and ε are, respectively, the material's magnetic permeability (in henries per meter) and electric permittivity (in farads per meter).

When expressed in a desired global or local spatial coordinate system, Eqs. (1)–(3) directly form the basis of the FDTD numerical algorithm for modeling electromagnetic wave phenomena. For example, implementation of (1) and (2) in Cartesian coordinates yields the following system of six coupled differential equations for the vector components of the fields:

$$\frac{\partial B_x}{\partial t} = \frac{\partial E_y}{\partial z} - \frac{\partial E_z}{\partial y} - M_x \quad (5a)$$

$$\frac{\partial B_y}{\partial t} = \frac{\partial E_z}{\partial x} - \frac{\partial E_x}{\partial z} - M_y \quad (5b)$$

$$\frac{\partial B_z}{\partial t} = \frac{\partial E_x}{\partial y} - \frac{\partial E_y}{\partial x} - M_z \quad (5c)$$

$$\frac{\partial D_x}{\partial t} = \frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} - J_x \quad (6a)$$

$$\frac{\partial D_y}{\partial t} = \frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x} - J_y \quad (6b)$$

$$\frac{\partial D_z}{\partial t} = \frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} - J_z \quad (6c)$$

In this example, we would (1) numerically approximate the spatial partial derivatives of (5) and (6) with finite-differences implemented in a Cartesian coordinate system, (2) numerically integrate the resulting system of spatial difference equations with respect to time by a finite-difference approximation of the time partial derivatives, and (3) concurrently numerically implement the constitutive relations of (3) to relate the Cartesian components of the field-vector pairs (\mathbf{B}, \mathbf{H}) and (\mathbf{D}, \mathbf{E}) appearing separately in (5) and (6). This yields a means to evolve each vector component of the electromagnetic field in space and time in a manner that mimics nature.

We note that the FDTD method involves only finite-difference approximations of Maxwell's curl equations, and not Gauss' laws for the electric and magnetic fields. This is because FDTD space grids *implicitly* enforce Gauss' laws by properly (1) positioning the E - and H -field vector components about each unit cell of the grid and (2) defining the finite-difference approximations of the space partial derivatives. Yee's space grid and timestepping method [1], which is the foundation of the FDTD method in Cartesian coordinates, satisfies these criteria [2].

6. YEE'S SPACE GRID AND TIMESTEPPING METHOD

Yee [1] originated a system of finite-difference approximations of the time-dependent Maxwell's curl equations of (5) and (6). Consider first his *central-difference* approximations of the spatial partial derivatives comprising the curl operators. Referring to Fig. 1, this is based on centering the Cartesian components of \mathbf{E} and \mathbf{H} about rectangular unit cells of size Δx , Δy , and Δz so that every \mathbf{E} component is surrounded by four "looping" \mathbf{H} components and every \mathbf{H} component is surrounded by four "looping" \mathbf{E} components. Then, for example, the value of $\partial H_z / \partial y$ observed at the E_x component located at the centerpoint of the front-face of the unit cell, $[i\Delta x, (j+0.5)\Delta y, (k+0.5)\Delta z]$, is calculated at the timepoint $(n+0.5)\Delta t$ as

$$\begin{aligned} & \frac{\partial H_z}{\partial y} [i\Delta x, (j+0.5)\Delta y, (k+0.5)\Delta z, (n+0.5)\Delta t] \\ &= \frac{H_z|_{i,j+1,k+0.5}^{n+0.5} - H_z|_{i,j,k+0.5}^{n+0.5}}{\Delta y} + O[(\Delta y)^2] \end{aligned} \quad (7)$$

where Δt is the timestep and i, j, k , and n are integers. This calculation is *second-order accurate* in Δy . For example, halving Δy reduces the error in the numerical

Figure 1. Position of the electric and magnetic field vector components about a cubic unit cell of the Yee space lattice [1].

approximation of $\partial H_z/\partial y$ by 4:1. Central-difference approximations analogous to (7) can be written for all the spatial partial derivatives of the Cartesian components of \mathbf{E} and \mathbf{H} in (5) and (6).

Consider next Yee's central-difference approximations of the temporal partial derivatives in (5) and (6). The following is a sample calculation of a field component time derivative, $\partial D_x/\partial t$ as observed at grid location $[i\Delta x, (j+0.5)\Delta y, (k+0.5)\Delta z]$ and at timepoint $(n+0.5)\Delta t$:

$$\begin{aligned} \frac{\partial D_x}{\partial t} [i\Delta x, (j+0.5)\Delta y, (k+0.5)\Delta z, (n+0.5)\Delta t] \\ = \frac{D_x|_{i,j+0.5,k+0.5}^{n+1} - D_x|_{i,j+0.5,k+0.5}^n}{\Delta t} + O[(\Delta t)^2] \end{aligned} \quad (8)$$

Referring to Fig. 2, this approach to time-differentiation permits a fully explicit, second-order accurate, *leapfrog* (alternating) calculation of the field vector pairs (\mathbf{B}, \mathbf{H}) and (\mathbf{D}, \mathbf{E}) in time. Specifically, this permits the set $\{\mathbf{B}\}$ of all magnetic flux density vector components in the space grid to be calculated at a particular timepoint by having (5) operate on the existing set $\{\mathbf{E}\}$ of electric field intensity vector components. Then, (3a) operates on the newly obtained $\{\mathbf{B}\}$ to yield the updated set $\{\mathbf{H}\}$ of all magnetic field intensity vector components. Next, the set $\{\mathbf{D}\}$ of all electric flux density vector components can be calculated by having (6) operate on the updated $\{\mathbf{H}\}$. Then, (3b) operates on the newly obtained $\{\mathbf{D}\}$ to yield the updated set $\{\mathbf{E}\}$. The computational cycle now begins again with the updating of $\{\mathbf{B}\}$ based on the newly calculated $\{\mathbf{E}\}$. This process continues until timestepping is concluded. A key point to note is that the numerical time evolution of the electromagnetic fields with this approach requires no usage of simultaneous equations and matrix inversion.

Figure 2. Spacetime chart of the Yee algorithm for a one-dimensional wave propagation example showing the use of central differences for the space derivatives and leapfrog for the time derivatives [2]. Initial conditions for both electric and magnetic fields are zero everywhere in the grid.

7. APPLICATION TO MAXWELL'S EQUATIONS IN CARTESIAN COORDINATES

On applying the abovementioned ideas and notation, and referring to Figs. 1 and 2, we proceed as follows:

1. We implement the following FDTD approximation of Maxwell's curl equation (5) to obtain $\{\mathbf{B}^{n+0.5}\}$ from $\{\mathbf{E}^n\}$:

$$\begin{aligned} B_x|_{i-0.5,j+1,k+1}^{n+0.5} &= B_x|_{i-0.5,j+1,k+1}^{n-0.5} + \Delta t \\ &\times \left(\frac{E_y|_{i-0.5,j+1,k+1.5}^n - E_y|_{i-0.5,j+1,k+0.5}^n}{\Delta z} \right. \\ &- \frac{E_z|_{i-0.5,j+1.5,k+1}^n - E_z|_{i-0.5,j+0.5,k+1}^n}{\Delta y} \\ &\left. - M_x|_{i-0.5,j+1,k+1}^n \right) \end{aligned} \quad (9a)$$

$$\begin{aligned} B_y|_{i,j+0.5,k+1}^{n+0.5} &= B_y|_{i,j+0.5,k+1}^{n-0.5} + \Delta t \\ &\times \left(\frac{E_z|_{i+0.5,j+0.5,k+1}^n - E_z|_{i-0.5,j+0.5,k+1}^n}{\Delta x} \right. \\ &- \frac{E_x|_{i,j+0.5,k+1.5}^n - E_x|_{i,j+0.5,k+0.5}^n}{\Delta z} \\ &\left. - M_y|_{i,j+0.5,k+1}^n \right) \end{aligned} \quad (9b)$$

$$\begin{aligned}
 B_z|_{i,j+1,k+0.5}^{n+0.5} &= B_z|_{i,j+1,k+0.5}^{n-0.5} + \Delta t \\
 &\times \left(\frac{E_x|_{i,j+1.5,k+0.5}^n - E_x|_{i,j+0.5,k+0.5}^n}{\Delta y} \right. \\
 &\left. - \frac{E_y|_{i+0.5,j+1,k+0.5}^n - E_y|_{i-1/2,j+1,k+0.5}^n}{\Delta x} \right. \\
 &\left. - M_z|_{i,j+1,k+0.5}^n \right)
 \end{aligned} \tag{9c}$$

2. We implement constitutive relation (3a) to obtain $\{\mathbf{H}^{n+0.5}\}$ from $\{\mathbf{B}^{n+0.5}\}$ (and possibly earlier values):

$$\begin{aligned}
 H_x|^{n+0.5} &= f_{H_x}(\mathbf{B}^{n+0.5}, \mathbf{B}^{n-0.5}, \mathbf{B}^{n-1.5}, \dots; \\
 &H_x|^{n-0.5}, H_x|^{n-1.5}, H_x|^{n-2.5}, \dots)
 \end{aligned} \tag{10a}$$

$$\begin{aligned}
 H_y|^{n+0.5} &= f_{H_y}(\mathbf{B}^{n+0.5}, \mathbf{B}^{n-0.5}, \mathbf{B}^{n-1.5}, \dots; \\
 &H_y|^{n-0.5}, H_y|^{n-1.5}, H_y|^{n-2.5}, \dots)
 \end{aligned} \tag{10b}$$

$$\begin{aligned}
 H_z|^{n+0.5} &= f_{H_z}(\mathbf{B}^{n+0.5}, \mathbf{B}^{n-0.5}, \mathbf{B}^{n-1.5}, \dots; \\
 &H_z|^{n-0.5}, H_z|^{n-1.5}, H_z|^{n-2.5}, \dots)
 \end{aligned} \tag{10c}$$

3. We implement the following FDTD numerical approximation of Maxwell's curl equation (6) to obtain $\{\mathbf{D}^{n+1}\}$ from $\{\mathbf{H}^{n+0.5}\}$:

$$\begin{aligned}
 D_x|_{i,j+1,k+0.5}^{n+1} &= D_x|_{i,j+0.5,k+0.5}^n + \Delta t \\
 &\times \left(\frac{H_z|_{i,j+1,k+0.5}^{n+0.5} - H_z|_{i,j,k+0.5}^{n+0.5}}{\Delta y} \right. \\
 &\left. - \frac{H_y|_{i,j+0.5,k+1}^{n+0.5} - H_y|_{i,j+0.5,k}^{n+0.5}}{\Delta z} \right. \\
 &\left. - J_x|_{i,j+0.5,k+0.5}^{n+0.5} \right)
 \end{aligned} \tag{11a}$$

$$\begin{aligned}
 D_y|_{i-0.5,j+1,k+0.5}^{n+1} &= D_y|_{i-0.5,j+1,k+0.5}^n + \Delta t \\
 &\times \left(\frac{H_x|_{i-0.5,j+1,k+1}^{n+0.5} - H_x|_{i-0.5,j+1,k}^{n+0.5}}{\Delta z} \right. \\
 &\left. - \frac{H_z|_{i,j+1,k+0.5}^{n+0.5} - H_z|_{i-1,j+1,k+0.5}^{n+0.5}}{\Delta x} \right. \\
 &\left. - J_y|_{i-0.5,j+1,k+0.5}^{n+0.5} \right)
 \end{aligned} \tag{11b}$$

$$\begin{aligned}
 D_z|_{i-0.5,j+0.5,k+1}^{n+1} &= D_z|_{i-0.5,j+0.5,k+1}^n + \Delta t \\
 &\times \left(\frac{H_y|_{i,j+0.5,k+1}^{n+0.5} - H_y|_{i-1,j+0.5,k+1}^{n+0.5}}{\Delta x} \right. \\
 &\left. - \frac{H_x|_{i-0.5,j+1,k+1}^{n+0.5} - H_x|_{i-0.5,j,k+1}^{n+0.5}}{\Delta y} \right. \\
 &\left. - J_z|_{i-0.5,j+0.5,k+1}^{n+0.5} \right)
 \end{aligned} \tag{11c}$$

4. Finally, we implement constitutive relation (3b) to obtain $\{\mathbf{E}^{n+1}\}$ from $\{\mathbf{D}^{n+1}\}$ (and possibly earlier values):

$$E_x|^{n+1} = g_{E_x}(\mathbf{D}^{n+1}, \mathbf{D}^n, \mathbf{D}^{n-1}, \dots; \tag{12a}$$

$$E_x|^{n-1}, E_x|^{n-2}, \dots)$$

$$E_y|^{n+1} = g_{E_y}(\mathbf{D}^{n+1}, \mathbf{D}^n, \mathbf{D}^{n-1}, \dots; \tag{12b}$$

$$E_y|^{n-1}, E_y|^{n-2}, \dots)$$

$$E_z|^{n+1} = g_{E_z}(\mathbf{D}^{n+1}, \mathbf{D}^n, \mathbf{D}^{n-1}, \dots; \tag{12c}$$

$$E_z|^{n-1}, E_z|^{n-2}, \dots)$$

The computational cycle now repeats with implementation of (9).

With the system of (9)–(12), the new value of an electromagnetic field vector component at any space lattice point depends only on previously calculated values of field vector components in the lattice and known electric and magnetic current sources. Therefore, at any given time-step, the computation of a field vector can proceed either one point at a time, or, if p parallel processors are employed concurrently, p points at a time.

We note that constitutive relations (10) and (12) are stated here in a very general form. In fact, for modeling dispersive and nonlinear materials, a significant literature exists that describes specific means to implement (10) and (12). There are three primary techniques: recursive convolution [19], auxiliary differential equations [20], and z transforms [21]. Currently, multiple Debye and Lorentzian dielectric dispersions can be efficiently modeled by any of these approaches. For nonlinear dispersive materials, this has led to the ability to use FDTD to model the propagation and interaction of temporal and spatial optical solitons [22].

8. NUMERICAL DISPERSION

The FDTD algorithm for Maxwell's curl equations reviewed above causes nonphysical dispersion of the simulated waves in a free-space computational lattice; that is, the phase velocity of numerical wave modes can differ from c by an amount varying with the wavelength, direction of propagation in the grid, and grid discretization. This artifact causes propagating numerical waves to accumulate delay or phase errors that can lead to

nonphysical results such as broadening and ringing of pulsed waveforms, imprecise cancellation of multiple scattered waves, anisotropy, and pseudorefraction. Numerical dispersion is a factor that must be accounted to understand the operation of FDTD algorithms and their accuracy limits, especially for electrically large structures.

Following the procedure discussed in Ref. 2, arbitrary numerical waves propagating in the FDTD space lattice can be considered as being fundamentally consisting of a sum of plane, monochromatic, and sinusoidal traveling waves ("Fourier modes"). For example, a general Fourier mode of free-space wavelength λ_0 for the E_z component in a Cartesian space lattice is given by $E_z|_{I,J,K}^n = E_{z0} \exp[j(\omega_F n \Delta t - k_{F_x} I \Delta x - k_{F_y} J \Delta y - k_{F_z} K \Delta z)]$, where (I, J, K) is the observation point in the space lattice; k_{F_x} , k_{F_y} , and k_{F_z} are the components of the Fourier mode wavevector \mathbf{k}_F ; and ω_F is the angular frequency of the Fourier mode. Substituting this and similar expressions for the other electromagnetic field components into the system of (9)–(12) yields, after simplification, the following relation between ω_F and \mathbf{k}_F for the linear, lossless, isotropic, nondispersive material case:

$$\left[\frac{1}{c\Delta t} \sin\left(\frac{\omega_F \Delta t}{2}\right) \right]^2 = \left[\frac{1}{\Delta x} \sin\left(\frac{k_{F_x} \Delta x}{2}\right) \right]^2 + \left[\frac{1}{\Delta y} \sin\left(\frac{k_{F_y} \Delta y}{2}\right) \right]^2 + \left[\frac{1}{\Delta z} \sin\left(\frac{k_{F_z} \Delta z}{2}\right) \right]^2 \quad (13)$$

where $c = (\mu\epsilon)^{-1/2}$ is the speed of light in the material being modeled. Equation (13) is the *numerical dispersion relation* of the Yee algorithm for the three-dimensional case. In contrast to (13), the dispersion relation for a physical electromagnetic plane wave propagating in three dimensions in a homogeneous lossless medium is simply $(\omega/c)^2 = (k_x)^2 + (k_y)^2 + (k_z)^2$.

We consider the important special case of a cubic cell space lattice having $\Delta x = \Delta y = \Delta z = \Delta$, and assume a real-valued $\omega_F = \omega$ (indicating a numerically stable algorithm, as discussed later). Then, defining the *Courant stability factor* $S = c\Delta t/\Delta$ and the *spatial sampling density* $N_\lambda = \lambda_0/\Delta$, we can solve (13) analytically for \mathbf{k}_F and the corresponding Fourier mode phase velocity $v_F = \omega/\mathbf{k}_F$ for a few special cases of wave propagation direction in the lattice, for example:

Propagation parallel to the x -, y -, or z -coordinate axes of the space lattice

$$v_F = \frac{\pi}{N_\lambda \sin^{-1}\left[\frac{1}{S} \sin\left(\frac{\pi S}{N_\lambda}\right)\right]} c \quad (14a)$$

Propagation along a 45° diagonal within any $(x-y)$, $(x-z)$, or $(y-z)$ plane of the space lattice

$$v_F = \frac{\pi}{2^{1/2} N_\lambda \sin^{-1}\left[\frac{1}{2^{1/2} S} \sin\left(\frac{\pi S}{N_\lambda}\right)\right]} c \quad (14b)$$

As an example, assume a space lattice having $S = 0.5$ and $N_\lambda = 20$. Then (14a) and (14b) provide unequal v_F values of

0.996892 c and 0.998968 c , respectively. The implication is that a sinusoidal numerical wave propagating obliquely within any $(x-y)$, $(x-z)$, or $(y-z)$ plane of this lattice has a speed that is $0.998968/0.996892 = 1.00208$ times that of a wave propagating along the x , y , or z axis of the same lattice. This represents a velocity anisotropy of about 0.2% between oblique and along-axis numerical wave propagation. Reference 2 demonstrated that this theoretical anisotropy of the numerical phase velocity appears in actual FDTD simulations.

It would be very useful to derive closed-form expressions for v_F analogous to (14a) and (14b) for any wave-propagation direction within the space lattice. However, for this general case, the underlying dispersion relation (13) is a transcendental equation. Reference 2 provides a means to calculate sample values of v_F by applying Newton's method to solve (13) for k_F . Figure 3 graphs results obtained using this procedure that illustrate the variation of v_F with propagation direction ϕ within any $(x-y)$, $(x-z)$, or $(y-z)$ plane of the space lattice. Here, for the Courant factor fixed at $S = 0.5$, three different grid sampling densities N_λ are examined: $N_\lambda = 5$ points per λ_0 , $N_\lambda = 10$, and $N_\lambda = 20$. We see that $v_F < c$ and is a function of both ϕ and N_λ . It is clear that v_F is maximum for waves propagating obliquely within the plane ($\phi = 45^\circ$), and is minimum for waves propagating along either major axis ($\phi = 0^\circ, 90^\circ$).

It is useful to quantify the algorithmic dispersive error performance by defining two normalized error measures: (1) the physical phase velocity error Δv_p , and (2) the phase velocity anisotropy error Δv_a . These are given by

$$\Delta v_p = \frac{\min[v_F(\phi)] - c}{c} \times 100\% \quad (15a)$$

$$\Delta v_a = \frac{\max[v_F(\phi)] - \min[v_F(\phi)]}{\min[v_F(\phi)]} \times 100\% \quad (15b)$$

The first velocity error measure, Δv_p , provides an upper bound on the phase error that numerical modes suffer

Figure 3. Variation of the numerical phase velocity with wave propagation angle in a 2D FDTD grid for three sampling densities of the square unit cells [2]; $S = c\Delta t/\Delta = 0.5$ for all cases.

relative to physical modes propagating at c . For example, from (14a) and (15a), $\Delta v_p = -0.31\%$ for $N_\lambda = 20$. This means that a sinusoidal numerical wave traveling parallel to the x -, y -, or z -coordinate axes of this space lattice over a $10\lambda_0$ distance (200 cells) develops a lagging phase error of 11° . We note further that Δv_p is a function of N_λ . Since the mesh cell size Δ is fixed, for an impulsive wave propagation problem there exists a spread of effective N_λ values for the Fourier spectral components constituting the pulse. This causes a spread of Δv_p over the pulse spectrum, which in turn yields a temporal dispersion of the pulse evidenced in the spreading and distortion of its waveform as it propagates. Figure 4 plots the variation of Δv_p versus N_λ within any x - y , x - z , or y - z plane of the space lattice for on-axis and oblique wave propagation for a sample Courant factor $S = 0.5$. Here, we see that a mesh resolution $N_\lambda > 20$ is required for any particular Fourier component to limit its physical velocity error to less than 0.3%.

The second velocity error measure, Δv_a , provides an upper bound on the wavefront distortion. For example, a circular cylindrical wave would suffer progressive distortion of its wavefront since the portions propagating along the grid diagonals would travel slightly faster than the portions traveling along the major grid axes. For example, from (14a), (14b), and (15b), $\Delta v_a = 0.208\%$ for $N_\lambda = 20$. The wavefront distortion due to this anisotropy would total about 2.1 cells for each 1000 cells of propagation distance.

Liu [23] has shown that, for $N_\lambda > 10$, Δv_a is virtually independent of the timestep size and can be approximated by the following simple expression:

$$\Delta v_a \cong \frac{\pi^2}{12(N_\lambda)^2} \times 100\% \quad (16)$$

For example, (16) yields $\Delta v_a \cong 0.206\%$ for $N_\lambda = 20$. This is very close to the 0.208% value previously obtained using the complete dispersion relation.

We note that errors due to inaccurate numerical wave velocities are cumulative, increasing linearly with the wave propagation distance. These errors represent a

Figure 4. Percent physical phase velocity error relative to the free-space speed of light as a function of the mesh sampling density for on-axis and oblique wave propagation [2]; $S = 0.5$ is assumed.

fundamental limitation of all grid-based time-domain Maxwell equation algorithms, and can be troublesome when modeling electrically large structures. A positive aspect is that both Δv_p and Δv_a decrease as the square of the sampling density N_λ . Therefore, finer meshing is one way to control the dispersion error.

There are ongoing active investigations of means to reduce the dispersion error of FDTD algorithms with the goal of allowing electrically very large structures to be modeled in a computationally efficient manner [17,18]. Specifically, with emerging pseudospectral time-domain algorithms [18], Δv_a can be reduced to very low levels approaching zero. In this case, residual errors involve primarily the dispersion of Δv_p with N_λ , which can be optimized by the proper choice of Δt . However, the new approaches presently have limitations regarding their ability to model material discontinuities, and require more research.

9. NUMERICAL STABILITY

We have seen that the choice of Δ and Δt can affect the propagation characteristics of numerical waves in the FDTD space lattice, and therefore the numerical error. In addition, Δt must be bounded to ensure numerical stability. This can be seen from the following discussion, which summarizes the primary results on this topic reported in Ref. 2. We solve dispersion relation (13) for a potentially complex-valued numerical angular frequency ω_F , obtaining:

$$\omega_F = \frac{2}{\Delta t} \sin^{-1}(\xi) \quad (17a)$$

where

$$\xi = c\Delta t \left[\frac{1}{(\Delta x)^2} \sin^2\left(\frac{k_{F_x}\Delta x}{2}\right) + \frac{1}{(\Delta y)^2} \sin^2\left(\frac{k_{F_y}\Delta y}{2}\right) + \frac{1}{(\Delta z)^2} \sin^2\left(\frac{k_{F_z}\Delta z}{2}\right) \right]^{1/2} \quad (17b)$$

and k_{F_x} , k_{F_y} , and k_{F_z} are assumed to be real numbers. With a general field component V propagating in the space lattice as $V_{I,J,K}^n = V \exp[j(\omega_F n \Delta t - k_{F_x} I \Delta x - k_{F_y} J \Delta y - k_{F_z} K \Delta z)]$, we see that V grows exponentially with time (i.e., is numerically unstable) if $\text{Im}(\omega_F) < 0$. From (17), it can be shown that this condition is avoided if

$$\Delta t \leq \frac{1}{c \left[\frac{1}{(\Delta x)^2} + \frac{1}{(\Delta y)^2} + \frac{1}{(\Delta z)^2} \right]^{1/2}} \quad (18)$$

For a cubic cell space lattice with $\Delta x = \Delta y = \Delta z = \Delta$, (18) reduces to

$$\Delta t \leq \frac{\Delta/c}{3^{1/2}} \quad (19a)$$

which is equivalent to the following upper bound on the Courant stability factor $S = c\Delta t/\Delta$:

$$S_{3D} \leq 3^{-1/2} \quad (19b)$$

If S exceeds S_{3D} uniformly at all points within the space lattice, Ref. 2 shows that the following multiplicative growth factor occurs each timestep for the computed field components:

$$q_{3D} = \left\{ 3^{1/2}S + (3S^2 - 1)^{1/2} \right\}^2 \quad \text{for } S > 3^{-1/2} \quad (20)$$

For example, if S exceeds S_{3D} by only 0.05% (i.e., $S = 1.0005 \times 3^{-1/2}$), then (20) indicates a growth factor of 1.0653 every timestep. This is equivalent to field growth by 1.8822 every 10 timesteps, 558.7 every 100 timesteps, and 2.96×10^{27} every 1000 timesteps.

Similarly, Ref. 2 shows for a two-dimensional, square cell Yee grid the stability requirement

$$S_{2D} \leq 2^{-1/2} \quad (21a)$$

and the multiplicative growth factor per timestep

$$q_{2D} = \left\{ 2^{1/2}S + (2S^2 - 1)^{1/2} \right\}^2 \quad \text{for } S > 2^{-1/2} \quad (21b)$$

if the stability limit is exceeded. For a one-dimensional Yee grid, [2] shows the stability requirement

$$S_{1D} \leq 1 \quad (22a)$$

and the multiplicative growth factor per timestep

$$q_{1D} = \left\{ S + (S^2 - 1)^{1/2} \right\}^2 \quad \text{for } S > 1 \quad (22b)$$

if the stability limit is exceeded.

We note that numerical instability can arise if the Courant stability condition is violated at only a *single* point in a space lattice. In this case, a rapidly oscillating and growing noise component due to numerical instability originates at this point, rather than everywhere within the lattice. Despite this localization of the source of the instability, the numerical noise grows exponentially with timestep number n , ultimately filling and corrupting the entire grid.

There are ongoing active investigations of means to surmount the numerical stability constraints of standard FDTD methods based on Yee leapfrog timestepping. Techniques being considered fall into two primary categories: (1) unconditionally stable alternating-direction-implicit (ADI) formulations [24,25] wherein explicit Yee timestepping is replaced by a sequence of implicit field updates along linear cuts through the space grid and (2) novel "one-step" matrix exponential techniques, which, in principle, can eliminate timestepping altogether [26,27]. Thus far, the ADI approaches proposed in Refs. 24 and 25 have the limitation of progressively reduced accuracy as their

timestep is increased well beyond the normal FDTD stability limit [28]. Further, the one-step approaches proposed by De Raedt et al. [26,27] have not yet been able to incorporate absorbing outer grid boundaries, which are essential for the modeling of open-region electromagnetic wave interaction problems (see the following section). Advances in both ADI and one-step techniques for FDTD can be expected soon since the potential reward of greatly reduced computer running time per model is so attractive.

10. INTRODUCTION TO ABSORBING BOUNDARY CONDITIONS

Many electromagnetic wave interaction problems are defined on "open" regions where the spatial domain is partially or completely unbounded. Since no computer can store an unlimited dataset, FDTD space lattices for such problems must somehow be truncated without introducing error due to spurious reflection of outward-propagating numerical waves. Grid truncation conditions of this type are popularly called *absorbing boundary conditions* (ABCs) because of their requirement to absorb outward-propagating numerical modes with negligible reflection.

ABCs cannot be directly obtained from the Yee algorithm since it requires field data on both sides of an observation point, and hence cannot be implemented at the outermost planes of a space lattice. Although backward finite differences could be used, these are generally of lower accuracy for a given spatial resolution and have not been used in any major FDTD software.

Research in this area since 1970 has resulted in two principal categories of computationally efficient ABCs for FDTD simulations:

1. *Analytical*. Boundary conditions are imposed on the electromagnetic field and its spatial and temporal derivatives at the outermost planes of the space lattice [2]. Small numerical wave reflection coefficients in the order of 10^{-2} to 10^{-3} can be attained.
2. *Perfectly Matched Layer (PML)*. Specially formulated wave absorbing media are located within the space lattice adjacent to its outer planes, by analogy with the treatment of the walls of an anechoic chamber [13–15]. Extremely small numerical wave reflection coefficients in the order of 10^{-5} – 10^{-6} can be attained.

PML ABCs have proved to be significantly more effective than analytical ABCs, and are used in virtually all current commercial FDTD software. There are two primary categories of PML ABCs: (1) Berenger's split-field formulation [13] and (2) the anisotropic formulation [14,15]. These are now reviewed, following the more detailed discussion in Ref. 2.

11. BERENGER'S SPLIT-FIELD PML ABC

Consider implementing an ABC by using an impedance-matched electromagnetic wave absorbing layer adjacent to the outer planes of the FDTD space lattice. Ideally, the

absorbing medium is only a few lattice cells thick, reflectionless to all impinging waves over their full frequency spectrum, highly absorbing, and effective in the near field of a source or a scatterer. An early attempt at implementing such an absorbing material boundary condition was reported [29] utilizing a conventional lossy, dispersionless, absorbing medium. The difficulty with this tactic is that such an absorbing layer is matched only to normally incident plane waves.

Berenger [13] provided the seminal insight that a non-physical PML ABC can be implemented at the outer boundary of an FDTD grid to effectively absorb outgoing waves virtually regardless of their frequency, angle of incidence, and polarization, assuming that the interior medium is lossless, isotropic, and nondispersive. The key is to exploit additional degrees of freedom arising from a novel split-field formulation of Maxwell's equations. Here, each field vector component is split into two orthogonal components. For example, in Cartesian coordinates in three dimensions we have [30]

$$H_x = H_{xy} + H_{xz}; \quad H_y = H_{yx} + H_{yz}; \quad (23)$$

$$H_z = H_{zx} + H_{zy}$$

$$E_x = E_{xy} + E_{xz}; \quad E_y = E_{yx} + E_{yz}; \quad (24)$$

$$E_z = E_{zx} + E_{zy}$$

The 12 resulting field components are expressed as satisfying the following set of coupled partial-differential equations that are modifications of Maxwell's equations in source-free space:

$$\left(\mu \frac{\partial}{\partial t} + \sigma_y^*\right) H_{xy} = -\frac{\partial}{\partial y} (E_{zx} + E_{zy}) \quad (25a)$$

$$\left(\mu \frac{\partial}{\partial t} + \sigma_z^*\right) H_{xz} = \frac{\partial}{\partial z} (E_{yx} + E_{yz}) \quad (25b)$$

$$\left(\mu \frac{\partial}{\partial t} + \sigma_x^*\right) H_{yx} = \frac{\partial}{\partial x} (E_{zx} + E_{zy}) \quad (25c)$$

$$\left(\mu \frac{\partial}{\partial t} + \sigma_z^*\right) H_{yz} = -\frac{\partial}{\partial z} (E_{xy} + E_{xz}) \quad (25d)$$

$$\left(\mu \frac{\partial}{\partial t} + \sigma_x^*\right) H_{zx} = -\frac{\partial}{\partial x} (E_{yx} + E_{yz}) \quad (25e)$$

$$\left(\mu \frac{\partial}{\partial t} + \sigma_y^*\right) H_{zy} = \frac{\partial}{\partial y} (E_{xy} + E_{xz}) \quad (25f)$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_y\right) E_{xy} = \frac{\partial}{\partial y} (H_{zx} + H_{zy}) \quad (26a)$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_z\right) E_{xz} = -\frac{\partial}{\partial z} (H_{yx} + H_{yz}) \quad (26b)$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_x\right) E_{yx} = -\frac{\partial}{\partial x} (H_{zx} + H_{zy}) \quad (26c)$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_z\right) E_{yz} = \frac{\partial}{\partial z} (H_{xy} + H_{xz}) \quad (26d)$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_x\right) E_{zx} = \frac{\partial}{\partial x} (H_{yx} + H_{yz}) \quad (26e)$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_y\right) E_{zy} = -\frac{\partial}{\partial y} (H_{xy} + H_{xz}) \quad (26f)$$

Here, σ_x , σ_y , and σ_z denote electric conductivities, and σ_x^* , σ_y^* , and σ_z^* denote magnetic losses.

Equations (25) and (26) represent a generalization of the electrodynamics of physical media. In the normal case, if $\sigma_x = \sigma_y = \sigma_z = \sigma$ and $\sigma_x^* = \sigma_y^* = \sigma_z^* = \sigma^*$, then (25) and (26) describe a physically realizable isotropic medium having a combination of electric and magnetic losses. Additional possibilities present themselves, however. For example, if $\sigma_x \neq 0$ and $\sigma_x^* \neq 0$ but $\sigma_y = \sigma_y^* = 0$ and $\sigma_z = \sigma_z^* = 0$, then (25) and (26) describe a nonphysical medium that can attenuate waves propagating along the $\pm x$ directions but not along the $\pm y$ or $\pm z$ directions.

It is the latter situation that permits the PML ABC to be established. Continuing with the example above, assume that the interior of the FDTD space lattice is filled with a homogeneous, lossless, isotropic medium characterized by the electrical properties (ε_1, μ_1) . Berenger showed that, to effectively absorb waves propagating out of the lattice in the $\pm x$ directions, it is sufficient to locate adjacent to the x_{\min} and x_{\max} lattice outer boundaries layers of material that have the same (ε_1, μ_1) as the lattice interior and are subject to (25) and (26) with the constraint that σ_x and σ_x^* satisfy the "perfect" matching condition

$$\frac{\sigma_x}{\varepsilon_1} = \frac{\sigma_x^*}{\mu_1} \quad (27a)$$

At the interface between the lattice interior and the PML, this yields theoretically zero wave reflection for incident angles $-90^\circ < \phi < 90^\circ$ relative to the $\pm x$ axis regardless of the wave frequency. Within the PML, the transmitted wave propagates with the same speed and direction as the impinging wave while simultaneously undergoing exponential decay along the $\pm x$ axis. Choosing the PML thickness appropriately permits negligible overall wave reflection from the lattice terminations at x_{\min} and x_{\max} , which are usually assumed to be perfect electric conductors (PECs) having tangential electric field components set to zero for all timesteps.

In a similar manner, PML absorbers can be established adjacent to the other lattice outer-boundary planes. Adjacent to y_{\min} and y_{\max} , the PMLs again have the same (ε_1, μ_1) as the lattice interior, but here are subject to (25) and (26) with $(\sigma_x = \sigma_x^* = 0, \sigma_z = \sigma_z^* = 0)$ and $(\sigma_y \neq 0, \sigma_y^* \neq 0)$ satisfying

$$\frac{\sigma_y}{\varepsilon_1} = \frac{\sigma_y^*}{\mu_1} \quad (27b)$$

Adjacent to z_{\min} and z_{\max} , the PMLs again have the same (ε_1, μ_1) as the lattice interior, but here are subject to (25)

and (26) with $(\sigma_x = \sigma_x^* = 0, \sigma_y = \sigma_y^* = 0)$ and $(\sigma_z \neq 0, \sigma_z^* \neq 0)$ satisfying

$$\frac{\sigma_z}{\epsilon_1} = \frac{\sigma_z^*}{\mu_1} \quad (27c)$$

Figure 5 illustrates the structure of a two-dimensional FDTD grid employing the Berenger PML ABC in this manner. Note that the electric and magnetic losses defined in any overlapping PMLs in the grid corners are continued into the overlap regions.

12. ANISOTROPIC PML (APML) ABC

The split-field PML introduced by Berenger is a hypothetical, nonphysical medium based on a mathematical model. Because of the coordinate dependence of the loss terms, if such a physical medium exists, it must be anisotropic. Indeed, a physical model based on an anisotropic, perfectly matched medium can be formulated. This was first discussed by Sacks et al. [14]. For a single interface, the anisotropic medium is uniaxial and is composed of both electric and magnetic constitutive tensors. This anisotropic PML, or APML, performs as well as Berenger's PML while avoiding its nonphysical field splitting. Further, as summarized in Ref. 2, the APML has capabilities exceeding those of Berenger's PML by providing additional degrees of freedom which permit it to attenuate evanescent waves and terminate conductive and dispersive materials.

We first summarize the analytical formulation of the APML. Following Ref. 2, this can be most easily done in the phasor (sinusoidal steady-state) domain, where we can write Maxwell's curl equations in a three-dimensional APML medium as

$$\nabla \times \mathbf{H} = j\omega\epsilon\mathbf{E}; \quad \nabla \times \mathbf{E} = -j\omega\mu\mathbf{H} \quad (28)$$

Here, the field vectors are complex-valued phasors, and s is the tensor defined by

$$s = \begin{bmatrix} s_x^{-1} & 0 & 0 \\ 0 & s_x & 0 \\ 0 & 0 & s_x \end{bmatrix} \begin{bmatrix} s_y & 0 & 0 \\ 0 & s_y^{-1} & 0 \\ 0 & 0 & s_y \end{bmatrix} \begin{bmatrix} s_z & 0 & 0 \\ 0 & s_z & 0 \\ 0 & 0 & s_z^{-1} \end{bmatrix} \quad (29)$$

$$= \begin{bmatrix} s_y s_z s_x^{-1} & 0 & 0 \\ 0 & s_x s_z s_y^{-1} & 0 \\ 0 & 0 & s_x s_y s_z^{-1} \end{bmatrix}$$

Allowing for a nonunity real part κ , the multiplicative components of the diagonal elements of s are given by

$$s_x = \kappa_x + \frac{\sigma_x}{j\omega\epsilon}; \quad s_y = \kappa_y + \frac{\sigma_y}{j\omega\epsilon}; \quad (30)$$

$$s_z = \kappa_z + \frac{\sigma_z}{j\omega\epsilon}$$

If desired, the APML medium can be specialized to apply throughout the entire FDTD space lattice. The following lists all of the possible special cases.

Lossless, Isotropic Interior Zone. s is the identity tensor realized by setting $s_x = s_y = s_z = 1$ in (29). This requires $\sigma_x = \sigma_y = \sigma_z = 0$ and $\kappa_x = \kappa_y = \kappa_z = 1$ in (30).

APML Absorbers at x_{\min} and x_{\max} Lattice Outer-Boundary Planes. We set $s_y = s_z = 1$ in (29). This requires $\sigma_y = \sigma_z = 0$ and $\kappa_y = \kappa_z = 1$ in (30).

APML Absorbers at y_{\min} and y_{\max} Lattice Outer-Boundary Planes. We set $s_x = s_z = 1$ in (29). This requires $\sigma_x = \sigma_z = 0$ and $\kappa_x = \kappa_z = 1$ in (30).

Figure 5. Structure of a two-dimensional FDTD grid employing the Berenger PML absorbing boundary condition [13].

APML Absorbers at z_{\min} and z_{\max} Lattice Outer-Boundary Planes. We set $s_x = s_y = 1$ in (29). This requires $\sigma_x = \sigma_y = 0$ and $\kappa_x = \kappa_y = 1$ in (30).

Overlapping APML Absorbers at x_{\min} , x_{\max} and y_{\min} , y_{\max} Dihedral Corners. We set $s_z = 1$ in (29). This requires $\sigma_z = 0$ and $\kappa_z = 1$ in (30).

Overlapping APML Absorbers at x_{\min} , x_{\max} and z_{\min} , z_{\max} Dihedral Corners. We set $s_y = 1$ in (29). This requires $\sigma_y = 0$ and $\kappa_y = 1$ in (30).

Overlapping APML Absorbers at y_{\min} , y_{\max} and z_{\min} , z_{\max} Dihedral Corners. We set $s_x = 1$ in (29). This requires $\sigma_x = 0$ and $\kappa_x = 1$ in (30).

Overlapping APML Absorbers at all Trihedral Corners. We use the complete general tensor in (29).

We next summarize the efficient implementation of the APML in a Cartesian FDTD formulation. Following the derivation discussed in detail in Ref. 2, explicit timestepping of the components of \mathbf{E} in the APML requires two steps in sequence: (1) updating the values of the components of an auxiliary-defined field variable \mathbf{D} and (2) using these new \mathbf{D} components to obtain updated values of the \mathbf{E} components. For example, the D_x update is given by

$$D_x|_{i+1/2,j,k}^{n+1} = \left(\frac{2\varepsilon\kappa_y - \sigma_y\Delta t}{2\varepsilon\kappa_y + \sigma_y\Delta t} \right) D_x|_{i+1/2,j,k}^n + \left(\frac{2\varepsilon\Delta t}{2\varepsilon\kappa_y + \sigma_y\Delta t} \right) \times \left(\frac{H_z|_{i+1/2,j+1/2,k}^{n+1/2} - H_z|_{i+1/2,j-1/2,k}^{n+1/2}}{\Delta y} - \frac{H_y|_{i+1/2,j,k+1/2}^{n+1/2} - H_y|_{i+1/2,j,k-1/2}^{n+1/2}}{\Delta z} \right) \quad (31a)$$

The subsequent E_x update is given by

$$E_x|_{i+1/2,j,k}^{n+1} = \left(\frac{2\varepsilon\kappa_z - \sigma_z\Delta t}{2\varepsilon\kappa_z + \sigma_z\Delta t} \right) E_x|_{i+1/2,j,k}^n + \left[\frac{1}{(2\varepsilon\kappa_z + \sigma_z\Delta t)\varepsilon} \right] \times \left[(2\varepsilon\kappa_x + \sigma_x\Delta t)D_x|_{i+1/2,j,k}^{n+1} - (2\varepsilon\kappa_x - \sigma_x\Delta t)D_x|_{i+1/2,j,k}^n \right] \quad (31b)$$

A similar two-step procedure is required to implement an explicit timestepping of the components of \mathbf{H} in the APML: (1) updating the values of the components of an auxiliary-defined field variable \mathbf{B} and (2) using these new \mathbf{B} components to obtain updated values of the \mathbf{H} components. For example, the B_x update is given by

$$B_x|_{i,j+1/2,k+1/2}^{n+3/2} = \left(\frac{2\varepsilon\kappa_y - \sigma_y\Delta t}{2\varepsilon\kappa_y + \sigma_y\Delta t} \right) B_x|_{i,j+1/2,k+1/2}^{n+1/2} - \left(\frac{2\varepsilon\Delta t}{2\varepsilon\kappa_y + \sigma_y\Delta t} \right) \times \left(\frac{E_z|_{i,j+1,k+1/2}^{n+1} - E_z|_{i,j,k+1/2}^{n+1}}{\Delta y} - \frac{E_y|_{i,j+1/2,k+1}^{n+1} - E_y|_{i,j+1/2,k}^{n+1}}{\Delta z} \right) \quad (32a)$$

The subsequent H_x update is given by

$$H_x|_{i,j+1/2,k+1/2}^{n+3/2} = \left(\frac{2\varepsilon\kappa_z - \sigma_z\Delta t}{2\varepsilon\kappa_z + \sigma_z\Delta t} \right) H_x|_{i,j+1/2,k+1/2}^{n+1/2} + \left[\frac{1}{(2\varepsilon\kappa_z + \sigma_z\Delta t)\mu} \right] \left[(2\varepsilon\kappa_x + \sigma_x\Delta t)B_x|_{i,j+1/2,k+1/2}^{n+3/2} - (2\varepsilon\kappa_x - \sigma_x\Delta t)B_x|_{i,j+1/2,k+1/2}^{n+1/2} \right] \quad (32b)$$

Nehrbass et al. [31] showed that such an algorithm is numerically stable within the Courant limit. Further, Abarbanel and Gottlieb [32] showed that the resulting discrete fields satisfy Gauss' law, and the APML is well posed. Finally, Ref. 2 discussed how the APML formulation in both the frequency and the time domains can be extended to terminate material regions in the FDTD space grid that are either electrically lossy or have frequency-dispersive dielectric parameters.

13. PML PERFORMANCE

Consider a PML of thickness T used to terminate the FDTD space lattice, which is assumed to have PEC outermost planes. There are two primary contributors to nonphysical wave reflections generated by this ABC configuration: (1) the PEC wall backing the PML and (2) the interface between the interior lattice medium and the PML.

Minimizing wave reflection due to the PEC backing wall calls for the greatest possible PML thickness and/or electrical loss. However, blindly increasing the PML loss can actually lead to degraded overall performance due to increased wave reflections at the interior PML interface. The latter represent a numerical artifact arising from the finite spatial sampling inherent in the FDTD algorithm. To reduce this artifact, Berenger [13] proposed that PML losses gradually increase with depth d within the PML along the w direction normal to the PML interface. Subsequently, several such profiles have been investigated. One of the most successful uses a simple polynomial variation of the PML loss:

$$\sigma_w(d) = \left(\frac{d}{T} \right)^m \sigma_{w,\max} \quad (33a)$$

$$\kappa_w(d) = 1 + (\kappa_{w,\max} - 1) \cdot \left(\frac{d}{T} \right)^m \quad (33b)$$

This increases the value of the PML σ_w from zero at $d = 0$ (the interior surface of the PML) to $\sigma_{w,\max}$ at $d = T$ (the PEC outer boundary of the space lattice). Similarly, for the APML, κ_x increases from one at $d = 0$ to $\kappa_{w,\max}$ at $d = T$.

For a fixed PML thickness T , the polynomial grading of (33a) provides two adjustable parameters: polynomial order m and $\sigma_{w,\max}$. Through extensive numerical experimentation [2], $3 \leq m \leq 4$ has been found to be nearly optimal for many FDTD simulations. Furthermore, for many applications, an optimal value of $\sigma_{w,\max}$ for

10-cell-thick PML is estimated to be [2]

$$\sigma_{w,\max} \approx \frac{0.8(m+1)}{\eta\Delta} \quad (34)$$

where η is the wave impedance of the PML medium. For detailed discussions and examples of PML performance over a wide range of possible loss profiles, see Ref. 2.

14. WAVE SOURCES

In this section, we consider means to introduce into the FDTD space lattice electromagnetic wave excitations appropriate for modeling engineering problems. Six numerical wave sources are reviewed: (1) \mathbf{E} and \mathbf{H} hard sources, (2) \mathbf{J} and \mathbf{M} current sources, (3) total-field/scattered-field lattice zoning, (4) the all-scattered-field formulation, (5) waveguide sources, and (6) interface with linear and nonlinear electronic circuits.

14.1. \mathbf{E} and \mathbf{H} Hard Sources

\mathbf{E} and \mathbf{H} hard sources are set up simply by assigning desired time functions to specific components of \mathbf{E} and/or \mathbf{H} in the FDTD space lattice. The time functions are independent of anything else in the model. Hard sources radiate numerical waves having time waveforms corresponding to the source functions.

While hard sources are very easy to implement, they cause spurious, nonphysical reflections of any numerical waves propagating in their vicinity. This is because hard sources effectively enforce nonphysical field boundary conditions. One way to time-limit the reflective nature of an impulsive hard source is simply to replace it with a normal free-space Yee field update after its pulse time waveform has decayed essentially to zero. However, this is not appropriate for source waveforms such as continuous sinusoids that have extended durations.

In FDTD models where hard sources can be used, analysis has shown that such sources do not behave as pointwise emitters of numerical waves. In fact, hard sources have a finite effective radius of approximately 0.2 lattice cell [33].

14.2. \mathbf{J} and \mathbf{M} Current Sources

\mathbf{J} and \mathbf{M} current sources are set up simply by assigning desired time functions to specific components of \mathbf{J} and/or \mathbf{M} in the FDTD space lattice. Similar to \mathbf{E} and \mathbf{H} hard sources, \mathbf{J} and \mathbf{M} current sources radiate numerical waves having time waveforms corresponding to the source functions. However, unlike hard sources, \mathbf{J} and \mathbf{M} current sources cause *no* nonphysical reflections of numerical waves propagating in their vicinity. This is because such current sources behave in an additive manner relative to the ambient electromagnetic field and set no field boundary conditions whatsoever.

A key nuance is that \mathbf{J} and \mathbf{M} current sources can deposit charge and generate charge-associated fields in three-dimensional FDTD space lattices. These fields, which are required to satisfy the continuity equation,

can persist indefinitely and hence remain in the computational domain even after all of the radiated fields have exited [34].

14.3. Total-Field/Scattered-Field Lattice Zoning

Total-field/scattered-field (TF/SF) lattice zoning permits implementation of a numerical plane-wave source in the FDTD space lattice. Such a wave source is characterized by

- Arbitrary wave propagation direction, polarization, time waveform, and duration
- Constant field amplitude along planes perpendicular to the direction of propagation
- Invisibility relative to any other numerical waves in the space lattice

The TF/SF formulation is based on the linearity of Maxwell's equations. It assumes that the physical (measurable) total electric and magnetic fields $\mathbf{E}_{\text{total}}$ and $\mathbf{H}_{\text{total}}$ can be decomposed as

$$\mathbf{E}_{\text{total}} = \mathbf{E}_{\text{inc}} + \mathbf{E}_{\text{scat}} \quad (35a)$$

$$\mathbf{H}_{\text{total}} = \mathbf{H}_{\text{inc}} + \mathbf{H}_{\text{scat}} \quad (35b)$$

Here \mathbf{E}_{inc} and \mathbf{H}_{inc} are the values of the incident-wave fields, assumed to be known at all points of the space lattice at all timesteps. These are the fields that would exist in vacuum, that is, if there were no materials of any sort in the modeling space. \mathbf{E}_{scat} and \mathbf{H}_{scat} are the values of the scattered-wave fields, which are initially unknown. These result from the interaction of the incident wave with any materials in the space lattice.

We note that the finite-difference operations of the Yee algorithm can be applied with equal validity to the incident field, the scattered field, and the total field. As shown in Fig. 6, this property permits zoning of the Yee space lattice into two distinct regions:

- *Region 1*—the inner zone of the space lattice. Here, total fields are assumed to be stored in the computer memory and operated on by the Yee algorithm. The interacting structure of interest is embedded within this region.
- *Region 2*—the outer zone of the space lattice surrounding region 1. Here, scattered fields are assumed to be stored in the computer memory and operated on by the Yee algorithm. There is no incident wave in region 2. The outer lattice planes bounding region 2 truncate the computation space and serve to implement an absorbing boundary condition, as discussed in the previous section.

Regions 1 and 2 are separated by the TF/SF interface, a virtual surface connecting the fields in each region that generates the incident numerical plane wave. The algorithms that implement the TF/SF interface for one-, two-, and three-dimensional FDTD space lattices are discussed in detail in Ref. 2.

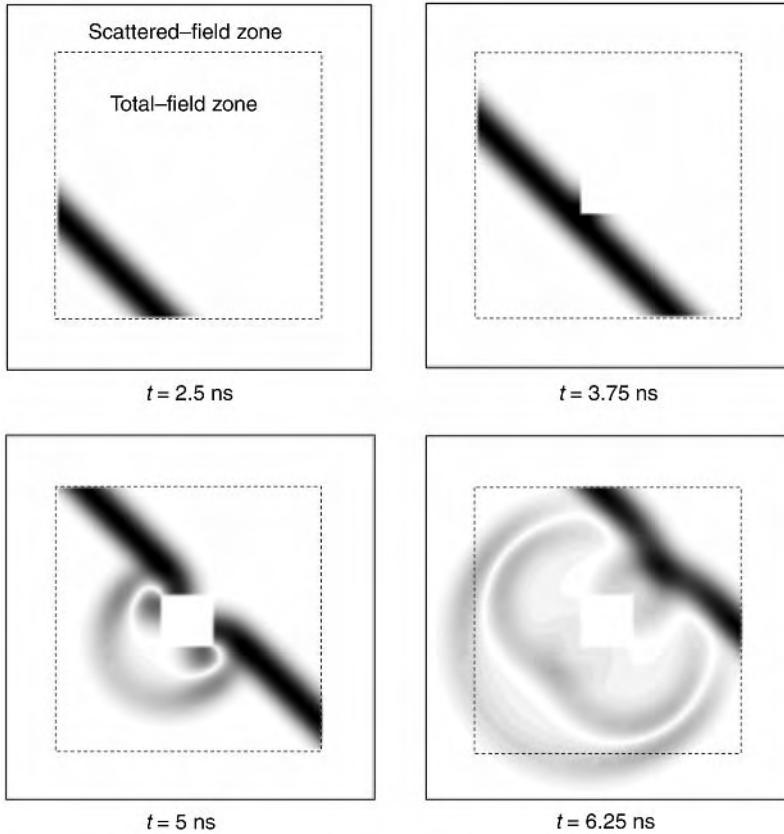

Figure 7. Action of total-field/scattered-field grid zoning for a plane wave propagating obliquely within a transverse electric grid impinging on a square perfectly conducting cylinder [2]. The H_z field is visualized in four successive snapshots as the wave propagates through the total-field zone.

technique. Incident fields can be calculated *exactly* using an analytical expression, rather than via numerical propagation through the FDTD space lattice. This eliminates phase/delay errors in the incident wave excitation caused by numerical dispersion, an increasingly important consideration as the electrical size of the modeled structure increases.

Holland et al. [36] reported the initial application of the all-scattered-field formulation of FDTD to lossy dielectric structures showing that Maxwell's equations could be written for isotropic nondispersive dielectrics as

$$\mu \frac{\partial \mathbf{H}_{\text{scat}}}{\partial t} + \sigma^* \mathbf{H}_{\text{scat}} = -\nabla \times \mathbf{E}_{\text{scat}} - \sigma^* \mathbf{H}_{\text{inc}} - (\mu - \mu_0) \frac{\partial \mathbf{H}_{\text{inc}}}{\partial t} \quad (37)$$

$$\varepsilon \frac{\partial \mathbf{E}_{\text{scat}}}{\partial t} + \sigma \mathbf{E}_{\text{scat}} = \nabla \times \mathbf{H}_{\text{scat}} - \sigma \mathbf{E}_{\text{inc}} - (\varepsilon - \varepsilon_0) \frac{\partial \mathbf{E}_{\text{inc}}}{\partial t} \quad (38)$$

Equations (37) and (38) can be numerically implemented in the conventional manner using Yee differences. The additional computational burden is that the incident fields and/or their time derivatives must be calculated at all lattice locations where $\sigma^* \neq 0$, $\sigma \neq 0$, $\mu \neq \mu_0$, or $\varepsilon \neq \varepsilon_0$.

14.5. Waveguide Sources

FDTD models of waveguides can be excited in ways analogous to those discussed above for the free-space case [2]. In certain cases, the transverse field distribution of the desired propagating waveguide mode is known analytically, allowing the numerical wave that is launched to immediately represent the desired mode without generating undesired propagating modes or below-cutoff reactive fields. In other cases, the transverse distribution of the desired mode is initially unknown or can be only approximated. There are two options in this situation:

- *Implement an approximation of the true mode.* An example is the excitation of a collinear array of \mathbf{E} or \mathbf{J} components in the FDTD space lattice to simulate a probe extending from a waveguide wall and dead ending in air at a point halfway to the opposing wall. Depending on the frequency content of the excitation, this can generate a spectrum of numerical waves including the desired mode, undesired high-order modes, and nonpropagating (cutoff) reactive fields. A substantial buffer length of waveguide may be required in the model to permit any reactive fields to decay.
- *Use "bootstrapping."* This involves running a preliminary FDTD model of the waveguide that is designed to propagate only the desired fundamental mode and is sufficiently long to decay undesired reactive fields.

The complete normalized transverse field distribution at the far end of this preliminary model is stored in a data file and is subsequently used in all production runs as a compact \mathbf{E} hard source or \mathbf{J} current source. (In the case of a dielectric waveguide, this includes the significant transverse fields located both internal and external to the waveguide.) Effectively, the preliminary FDTD run is used to solve for the correct transverse modal field distribution.

14.6. Interface with Linear and Nonlinear Electronic Circuits

An emerging sixth type of wave source involves interfacing a passive FDTD space lattice with a time-domain numerical model of an active linear or nonlinear electronic device or circuit. Here, potential excitation sources include discrete transistors and logic gates, and even complete circuits composed of many such discrete devices. Hybrid FDTD/electronic circuit models are increasingly useful in constructing self-consistent simulations of high-speed circuits embedded within electromagnetic wave transmission and radiation systems. A summary of techniques in this area is provided in Ref. 2.

15. NEAR-FAR-FIELD TRANSFORMATION

The provision of a scattered-field region in the FDTD space lattice via either total-field/scattered-field lattice zoning or an all-scattered-field lattice (as described in the previous section) permits a systematic *near-far-field transformation*. In other words, there is *no* need to extend the FDTD space lattice to the far field to obtain far-field data.

The near-far-field transformation is based on the surface equivalence theorem [37], illustrated in Fig. 8. This theorem permits electromagnetic fields in an exterior region to be rigorously calculated from equivalent non-physical currents properly defined over an arbitrary virtual surface S that completely encloses the original antenna or scatterer, even if S is located in the near field.

Figure 8a depicts schematically the most general case dealing with an arbitrary three-dimensional structure. Following the notation of Balanis [37], we assume that a field $(\mathbf{E}_1, \mathbf{H}_1)$ filling all of space is generated by the action of the physical electric and magnetic currents \mathbf{J}_1 and \mathbf{M}_1 associated with the antenna or scatterer of interest. In Fig. 8b, we assume that \mathbf{J}_1 and \mathbf{M}_1 are removed, and that there now exists a new field (\mathbf{E}, \mathbf{H}) inside virtual surface S

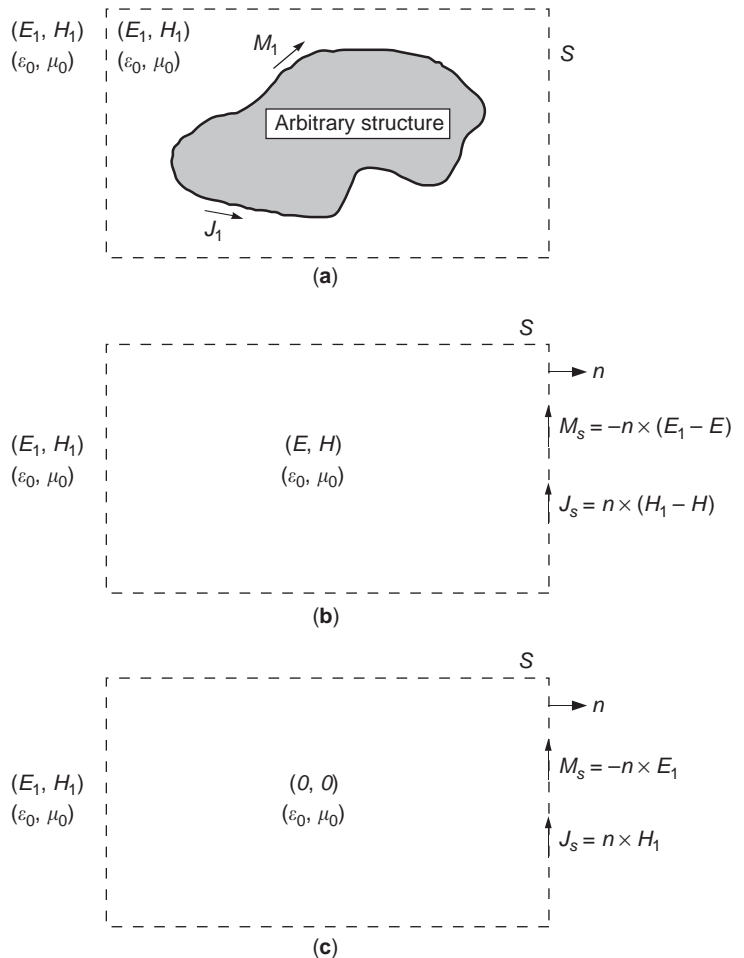

Figure 8. Definition of electromagnetic fields and equivalent electric and magnetic virtual currents for the surface equivalence theorem: (a) original interaction geometry; (b) intermediate equivalent problem; (c) final equivalent problem [37].

that completely encloses the structure. However, we wish to observe the original field $(\mathbf{E}_1, \mathbf{H}_1)$ outside S . For this desired situation to satisfy the required electromagnetic field boundary conditions on the tangential \mathbf{E} - and \mathbf{H} -field components at S , there must exist the following virtual electric and magnetic currents flowing tangentially along S :

$$\mathbf{J}_S = \mathbf{n} \times (\mathbf{H}_1 - \mathbf{H}) \quad (39a)$$

$$\mathbf{M}_S = -\mathbf{n} \times (\mathbf{E}_1 - \mathbf{E}) \quad (39b)$$

where \mathbf{n} is the unit outward normal vector to S . The virtual electric and magnetic currents of (39) radiate into free space everywhere (inside and outside S), and generate the original field $(\mathbf{E}_1, \mathbf{H}_1)$ in the unbounded free-space region outside S . Since the fields within S can be anything (and we are not concerned with this region anyway with regard to developing far-field information), it is useful to assume that $\mathbf{E} = 0$ and $\mathbf{H} = 0$ inside S . Then, the equivalent problem of Fig. 8b reduces to Fig. 8c, with equivalent current densities equal to

$$\mathbf{J}_S = \mathbf{n} \times (\mathbf{H}_1 - \mathbf{H})|_{\mathbf{H}=0} = \mathbf{n} \times \mathbf{H}_1 \quad (40a)$$

$$\mathbf{M}_S = -\mathbf{n} \times (\mathbf{E}_1 - \mathbf{E})|_{\mathbf{E}=0} = -\mathbf{n} \times \mathbf{E}_1 \quad (40b)$$

Using the surface equivalence theorem, a phasor-domain near-far-field transformation can be efficiently implemented for Cartesian FDTD models of arbitrary three-dimensional structures. Here, S is a six-sided rectangular “box” that completely encloses the structure of interest in the scattered-field zone of the FDTD space lattice. Along each face of S , distributions of the equivalent phasor electric current \mathbf{J}_S and phasor magnetic current \mathbf{M}_S are calculated from (40) using discrete Fourier transformations (DFTs) that are applied to the FDTD-computed tangential \mathbf{H} and \mathbf{E} fields, respectively, “on the fly” during timestepping. Then, as introduced in Ref. 38 and discussed in detail in Ref. 2, these equivalent currents are integrated with a free-space Green’s function weighting to obtain the desired normalized far-field patterns of the scattered or radiated power.

In this manner, a single FDTD run that models the impulsive plane-wave illumination of a scattering object provides sufficient data to calculate the complete far-field bistatic radar cross-sectional pattern of the object at *multiple* sinusoidal frequencies for the incidence and polarization angles of the illuminating wave used in the modeling run. Similarly, a single FDTD run that models the impulsive excitation of an antenna provides sufficient data to calculate the complete far-field radiation pattern of the antenna at multiple sinusoidal frequencies.

An alternative time-domain near-far-field transformation is discussed by Luebbers et al. [39]. While FDTD timestepping proceeds in a particular modeling run, this transformation allows calculation of the evolving time waveforms of the scattered or radiated \mathbf{E} and \mathbf{H} fields at selected angular locations in the far field. Phasor-domain

results can be obtained in a subsequent postprocessing step via Fourier transformation of the calculated time waveforms.

16. EXAMPLES OF FDTD MODELING APPLICATIONS

Current examples of FDTD modeling applications span much of the electromagnetic spectrum. A worldwide FDTD developer/user community is involved in numerical simulation of electrodynamic phenomena ranging from extremely low-frequency (ELF) propagation about the entire Earth to the lasing behavior of aggregates of micrometer-scale particles exhibiting four-level quantum system characteristics. Such applications of FDTD vividly illustrate the principle that “Maxwell’s equations work from DC to light.” This section provides examples of current and emerging FDTD applications that literally span this range.

16.1. Global ELF Propagation within the Earth-Ionosphere Waveguide

Global propagation of extremely low-frequency (ELF: 3 Hz–3 kHz) and very low-frequency (VLF: 3 kHz–30 kHz) electromagnetic waves within the Earth-ionosphere waveguide has been the subject of recurring theoretical and experimental interest for decades. ELF/VLF propagation phenomena form the physics basis of submarine communications and remote-sensing investigations of lightning and sprites, global temperature change, subsurface structures, and potential earthquake precursors.

Most theoretical techniques for modeling ELF/VLF propagation are based on frequency-domain waveguide-mode theory. However, these techniques cannot account for arbitrary horizontal as well as vertical geometric and electrical inhomogeneities of the ionosphere, continents, and oceans. Recently, a full-vector, three-dimensional, spherical coordinate FDTD model has been used to calculate impulsive ELF propagation within the entire Earth-ionosphere waveguide. All features of the lithosphere and ionosphere located within ± 100 km of sea level are modeled with a resolution of approximately $40 \times 40 \times 5$ km [40]. Periodic boundary conditions are used in conjunction with a variable-cell grid that wraps around the complete Earth sphere. The model is verified by numerical studies of frequency-dependent propagation attenuation with distance, antipodal propagation, and the Schumann resonance. Figure 9 visualizes the results of one such model, which illustrates the propagation about Earth of an ELF electromagnetic pulse generated by a vertical lightning stroke off the coast of South America.

16.2. High-Speed Electronics

High-speed electronic circuits have been traditionally grouped into two classes: analog microwave circuits and digital logic circuits.

1. Microwave circuits typically process bandpass signals at frequencies above 3 GHz. Common circuit features include microstrip transmission lines,

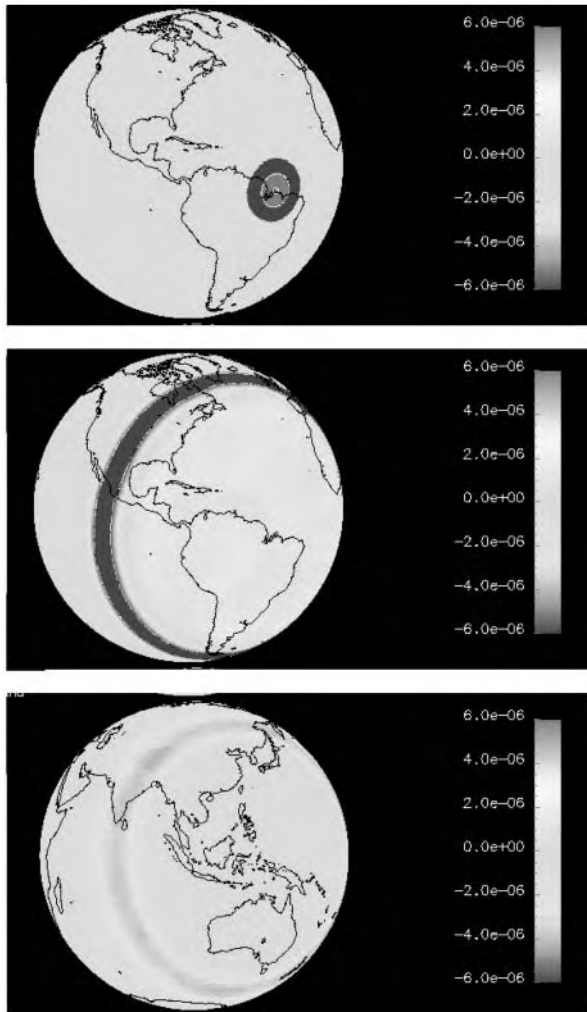

Figure 9. Snapshot visualizations of the FDTD-computed global propagation of an ELF electromagnetic pulse generated by a lightning strike off the coast of South America [40]. All features of the lithosphere and atmosphere located within ± 100 km of sea level are modeled in three dimensions with a resolution of approximately $40 \times 40 \times 5$ km. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

directional couplers, circulators, filters, matching networks, and individual transistors. Circuit operation is fundamentally based on electromagnetic wave phenomena.

2. Digital circuits typically process lowpass pulses requiring a DC return. Typical circuits include multiple planes of metal traces for signal transmission, power supply, and ground return. Via pins provide electrical connections between the planes. Circuit operation is nominally not based on electromagnetic wave effects.

However, the distinction between the design of these two classes is blurred. The rise of everyday computer clock speeds above 3 GHz implies digital signal bandwidths above 10 GHz, well into the microwave range. Electromagnetic wave effects that, until now, were in the domain of the microwave engineer are becoming a limiting factor in

digital circuit operation. For example, hard-won experience has shown that high-speed digital signals can spuriously

- Distort as they propagate along the metal circuit paths
- Couple (create crosstalk) from one circuit path to another
- Radiate and create interference to other circuits and systems

An example of electromagnetic field effects in a digital circuit is shown in Fig. 10, which illustrates the results of FDTD modeling of an ultra-high-speed logic pulse entering a microchip embedded within a conventional dual in-line package [41]. The fields associated with the logic pulse are not confined to the metal circuit paths and, in fact, smear out and couple to all adjacent circuit paths. We note that FDTD modeling permits incorporation of (1) a very high level of detail of the geometry and materials of the chip packaging and (2) the nonlinear active circuit components within the chip that terminate the metal

Figure 10. Snapshot visualization of the FDTD-computed coupling and crosstalk of a high-speed logic pulse entering and leaving a microchip embedded within a conventional dual in-line integrated circuit package [41]. The fields associated with the logic pulse are not confined to the metal circuit paths and, in fact, smear out and couple to all adjacent circuit paths. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

connections. These attributes provide the engineer with robust modeling capabilities to accurately assess the crosstalk problem and test potential remedies involving redesign of the microchip packaging.

16.3. Microwave Penetration and Coupling

FDTD computational electromagnetics has played an important role in helping to assess and mitigate the effects of electromagnetic wave coupling into sensitive electrical and electronic equipment. The primary sources of such waves include lightning, nuclear electromagnetic pulses (NEMPs), and high-power microwaves (HPMs).

NEMP can burn out electrical and electronic equipment on Earth's surface located many hundreds of miles away from the detonation of a nuclear bomb above Earth's atmosphere. Equipment failures on this geographic scale could leave a nation largely defenseless against subsequent attack. HPM can neutralize electronics in the manner as NEMP, but can be applied on a more selective basis for either tactical or strategic applications. For both NEMP and HPM, FDTD modeling has been used to understand the complex electromagnetic wave penetration and coupling mechanisms into potential targets, and means to mitigate these mechanisms. FDTD is particularly useful for these purposes since it can model extremely complicated three-dimensional structures in a straightforward manner. As an example, Fig. 11 illustrates the results of applying FDTD modeling to calculate the penetration of a pulsed 10-GHz microwave beam into a missile radome containing a horn antenna [42].

16.4. Ultrawideband Microwave Imaging for Early-Stage Breast Cancer Detection

Several researchers have conducted theoretical investigations of the use of ultrawideband microwave pulses for early-stage breast cancer detection. In principle, this technique could detect much smaller tumors over larger regions of the breast than is currently possible using X-ray mammography, and further avoid exposing the patient to potentially hazardous ionizing radiation. In this proposed technique, an array of small antennas would be placed on the surface of the breast to emit and then receive a short electromagnetic pulse lasting less than 100 ps. Signal processing techniques would then be applied to the received pulses at each antenna element to form the breast image.

In work to date, FDTD modeling has provided crucial simulated test data and allowed optimization of the imaging algorithms. As shown in Fig. 12, these simulations indicate promise for imaging small, deeply embedded malignant breast tumors in the presence of the background clutter due to the complicated surrounding normal tissues [43]. In this figure, the simulated 2-mm-diameter tumor has a volume that is about one order of magnitude smaller than that needed for reasonably reliable detection by X-ray mammography.

16.5. Photonic Integrated Circuits

Microcavity ring and disk resonators are proposed components for filtering, routing, switching, modulation, and

Figure 11. Snapshot visualizations of the FDTD-computed penetration of a short microwave pulse into a missile radome containing a horn antenna [42]. The impinging plane wave propagates from right to left at the speed of light and is obliquely incident at 15° from boresight. Complicated electromagnetic wave interactions visible within the radome structure require FDTD Maxwell's equations solutions to permit effective design. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

multiplexing/demultiplexing tasks in ultra-high-speed photonic integrated circuits. Figure 13 is a scanning electron microscope image of a prototype photonic circuit consisting of 5.0- μm -diameter aluminum gallium arsenide (AlGaAs) microcavity disk resonators coupled to 0.3- μm -wide optical waveguides across airgaps spanning 0.1–0.3 μm [44].

FDTD solutions of Maxwell's equations permit calculation of the optical coupling, transmission, and resonance behavior of the microoptical structures in Fig. 13. This permits effective engineering design. For example, Fig. 14 shows visualizations of the FDTD-calculated sinusoidal steady-state optical electric field distributions for a typical microdisk in Fig. 13 [45]. In the upper left panel, the optical excitation is at a nonresonant frequency, 193.4 THz (an optical wavelength λ of 1.55 μm). Here, 99.98% of the rightward-directed power in the incident signal remains in the lower waveguide. In the upper right panel, the excitation is at the resonant frequency of the first-order radial whispering-gallery mode of the microdisk, 189.2 THz ($\lambda = 1.585 \mu\text{m}$). Here, there is a large field enhancement within the microdisk, and 99.79% of the incident power switches to the upper waveguide in the reverse (leftward) direction. This yields the action of a passive, wavelength-selective switch.

Figure 12. Top: 2D FDTD breast model derived from magnetic resonance imaging containing a 2-mm-diameter malignant lesion at a depth of 3.1 cm. The black dots along the surface of the breast represent positions from which an antenna transmits low-power ultrawideband pulses into the breast. Bottom: Image showing the backscattered energy as a function of location in the breast. The image was reconstructed from FDTD-computed backscattered waveforms using a spacetime beamforming approach. Note that the tumor signature is almost 100 times stronger than the backscattering clutter generated by the surrounding heterogeneous normal tissue [43]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The lower left and right panels of Fig. 14 are visualizations at, respectively, the resonant frequencies of the second- and third-order whispering-gallery modes, 191.3 THz ($\lambda = 1.567 \mu\text{m}$) and 187.8 THz ($\lambda = 1.596 \mu\text{m}$). A goal of current design efforts is to suppress higher-order modes to allow the use of microdisks as passive wave-

Figure 13. Scanning electron microscope image of a prototype photonic integrated circuit [44]. The photonic circuit is composed of 5.0- μm -diameter aluminum gallium arsenide (AlGaAs) microcavity disk resonators coupled to 0.3- μm -wide AlGaAs optical waveguides across airgaps spanning as little as 0.1 μm .

length-division multiplexing devices having low crosstalk across a wide spectrum, or as active single-mode laser sources.

16.6. Applications in Microcavity Laser Design

FDTD solutions of Maxwell's equations are being used to design the world's smallest microcavity laser sources for use in ultra-high-speed photonic integrated circuits. These sources are based on the physics of photonic crystals, which are artificial structures having a periodic variation of the refractive index. Photonic crystals have a frequency stopband over which there is no transmission of electromagnetic waves. However, a defect introduced into the periodic structure creates a resonant mode at a frequency that lies inside the bandgap. This defect behaves as a microcavity resonator to trap light.

Figure 15 (top) illustrates how light is contained inside a laser microcavity in a photonic crystal structure [46]. First, a half-wavelength thick high-refractive-index slab (consisting of indium gallium arsenic phosphide) is used to trap light in the vertical direction by total internal reflection. Then, light is localized in plane by the action of a two-dimensional photonic crystal consisting of a hexagonal array of submicrometer-radius airholes etched into the slab. In the simplest structure, a single airhole is removed from the photonic crystal,

Figure 14. Visualizations of the FDTD-computed sinusoidal steady-state optical electric field distributions in a 5.0- μm -diameter AlGaAs microdisk resonator coupled to straight 0.3- μm -wide AlGaAs optical waveguides for single-frequency excitations propagating to the right in the lower waveguide [45]. Upper left: off-resonance signal. Upper right: on-resonance signal, first-order radial mode. Lower left: second-order radial-mode resonance. Lower right: third-order radial-mode resonance. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

thereby forming a resonant microcavity which traps light energy.

Figure 15 (bottom) visualizes along a planar cut through the middle of the slab the magnitude of the optical electric field calculated from a three-dimensional FDTD solution of Maxwell's equations. Nearly all of the laser power is emitted vertically. Experimental realization of this microcavity laser design indicates a lasing wavelength within 0.3% of the FDTD-predicted value. Ongoing research involves optimizing this and similar laser cavities by performing FDTD simulations to reduce the required pump power and facilitate room-temperature operation.

16.7. Incorporation of Quantum Effects

The final modeling example illustrates one of the most interesting current frontiers in FDTD theory and applications that may lead to significant advances in overall electrical engineering technology. This frontier involves the self-consistent modeling of a system of nanometer-scale sources (originating from quantum phenomena) interacting with each other and with external material geometries via electromagnetic wave energy transport over micrometer-distance scales.

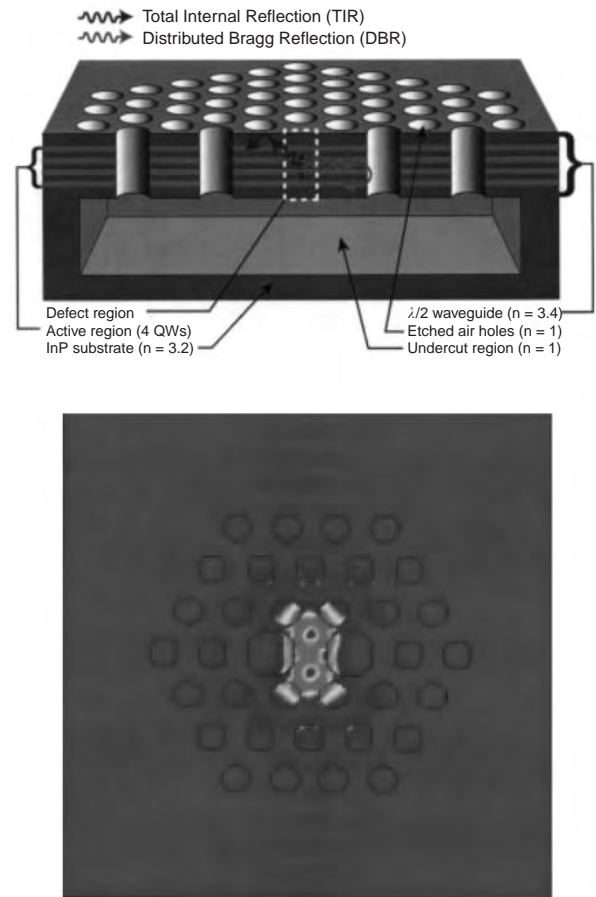

Figure 15. Photonic crystal microcavity laser [46]. Top: geometry. Bottom: visualization of the FDTD-computed optical electric field along a horizontal planar cut through the middle of the laser geometry. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 16 shows a specific problem where this type of modeling is being pursued: the exploration of the physics of lasing in random clusters of zinc oxide (ZnO_2) nanoparticles [47]. Here, quantized electron energy states in ZnO_2 are described by a four-level two-electron model consisting of a system of six simultaneous time-domain differential equations for the electron population densities and resulting induced polarizations. This system is coupled to a conventional two-dimensional FDTD Maxwell equation solver. Quantum phenomena such as the excitation of electrons to higher energy states, population inversion, and photon emission/stimulated emission are modeled concurrently with the classical phenomena of multiple scattering of optical electromagnetic waves within the particle cluster leading to light localization and potential lasing action.

As computing capabilities advance, the extension of such a multiphysics quantum/classical electrodynamics model to three dimensions will enable the development of robust and comprehensive engineering design tools for active photonic and quantum nanostructures. Nanostructures of these types may become the basis of much of mid-21st century communications and computing technologies in our society.

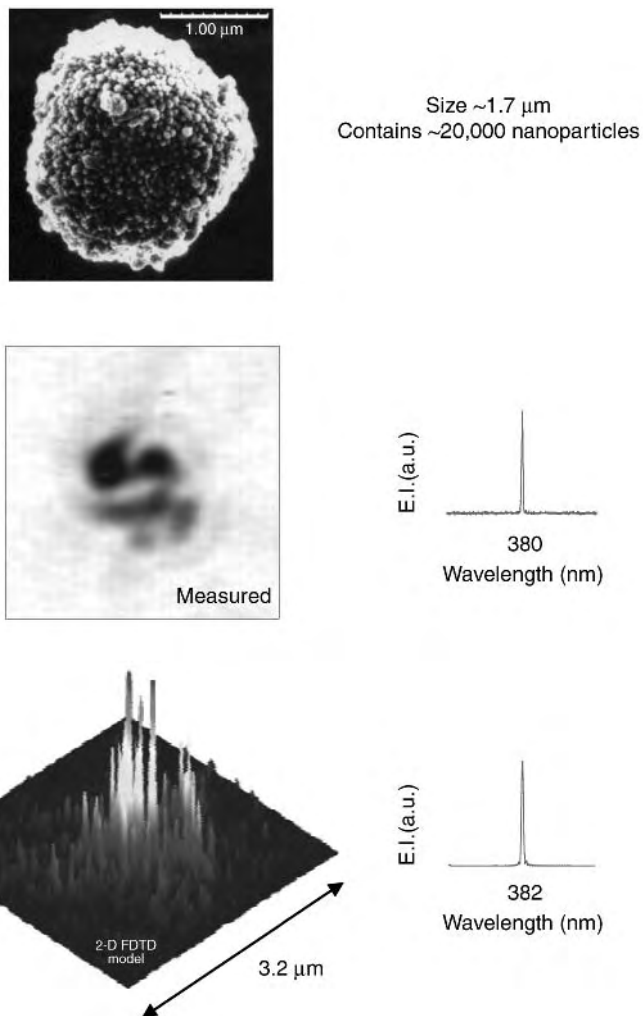

Figure 16. FDTD model of lasing in a random clump of zinc oxide (ZnO_2) nanoparticles. Population inversion and stimulated emission can be modeled using a four-energy-level, two-electron quantum model for ZnO_2 [47]. 1. INTRODUCTION

The finite-element method is a numerical procedure used to obtain approximate solutions to boundary value problems of mathematical physics. The method was first proposed by Courant in 1943 to solve variational problems in potential theory [1]. Thereafter, the method was developed and applied extensively to problems of structural analysis and increasingly to problems in other fields. Today, the finite-element method is recognized as a general, preeminent method applicable to a wide variety of engineering and mathematical problems, including those in RF and microwave engineering.

The first application of the finite-element method to microwave engineering and electromagnetics appeared in 1969, when Silvester employed it to analyze wave propagation in a hollow waveguide [2]. The importance of the method was quickly recognized, and successful applications were achieved for the analysis of electrostatic, magnetostatic, and dielectric-loaded waveguide problems. In 1974, Mei developed a technique that combined the finite-element method with eigenfunction expansion to deal with open-region electromagnetic problems such as antenna and scattering analysis [3]. In 1982, Marin developed an alternative method to deal with open-region scattering problems, which combined the finite-element method and a boundary integral equation [4].

An important breakthrough in the finite-element analysis of vector field problems occurred in the 1980s with the development of edge-based vector elements [5–7]. These new elements accurately model the nature of the electric and magnetic fields and eliminate much of the problems associated with traditional node-based scalar elements. Since the development of the vector elements, the finite-element method has become a very powerful numerical technique in computational electromagnetics. Today, the method is used as a major design tool for RF and microwave devices. Its basic principle and a variety of applications have been described in many books, such as those by Silvester and Ferrari [8], Jin [9], and Volakis et al. [10].

2. FINITE-ELEMENT ANALYSIS OF SCALAR POTENTIAL PROBLEMS

To illustrate the basic principle of the finite-element method, consider the problem of calculating the static electric potential ϕ due to electric charge density ρ distributed in domain Ω . The domain can be either two- or three-dimensional and is filled with a medium having a permittivity ϵ . On the basis of electromagnetic theory, the problem is to solve the following Poisson equation

$$-\nabla \cdot (\epsilon \nabla \phi) = \rho \quad \text{on } \Omega \tag{1}$$

subject to given boundary conditions. Typical boundary conditions include the Dirichlet type, which specifies the value of the potential on the boundary, and the Neumann type, which prescribes the normal derivative of the potential. To illustrate the treatment of both boundary conditions, the following boundary conditions are assumed for this example

$$\phi = \phi_D \quad \text{on } \Gamma_D \tag{2}$$

$$\hat{n} \cdot (\epsilon \nabla \phi) = \kappa_N \quad \text{on } \Gamma_N \tag{3}$$

where ϕ_D denotes the specified value of the potential on the Dirichlet boundary Γ_D and κ_N denotes the prescribed value for the normal derivative of the potential on the Neumann boundary Γ_N . The entire boundary of domain Ω consists of Γ_D and Γ_N and is denoted by Γ .

The boundary value problem expressed by Eqs. (1)–(3) is usually too complex to allow a closed-form solution. This

is particularly true when Ω has an irregular shape and the medium, characterized by ϵ , is inhomogeneous. In this case, a numerical solution is the only alternative. Among numerical methods, the finite-element method is very powerful because of its ability to deal with arbitrary shapes and inhomogeneous media. The basic principle of the finite-element method is to divide the entire domain into many small subdomains, called *finite-elements*, and then seek an approximate solution in each of the subdomains. The commonly used subdomains are triangular elements in two dimensions and tetrahedral elements in three dimensions (Fig. 1) because of their flexibility in modeling complex shapes, although other elements can also be used for special problems.

Once the domain Ω is divided into small elements, the potential in each element can be approximated as a simple function, such as linear, quadratic, and cubic functions. This approximation can be obtained by interpolating the potential values at a set of discrete points on the element. For example, the potential in a triangular element (Fig. 2) can be approximated as

$$\phi^e(x, y) = N_1^e(x, y)\phi_1^e + N_2^e(x, y)\phi_2^e + N_3^e(x, y)\phi_3^e \tag{4}$$

where ϕ_1^e , ϕ_2^e and ϕ_3^e denote the values of the potential at nodes 1, 2, and 3, respectively, and $N_1^e(x, y)$, $N_2^e(x, y)$, and $N_3^e(x, y)$ are the corresponding interpolation functions. These interpolation functions are completely determined by the coordinates of the three nodes. The interpolation functions, also known as *basis functions* or *expansion functions*, determine the order of the elements. An important requirement for the interpolation functions is that they guarantee the continuity of the interpolated potential.

When the potential in each element is interpolated using its values at discrete points, the potential in the entire

Figure 1. Finite-element mesh with (a) triangular and (b) tetrahedral elements.

Figure 2. Linear triangular element.

domain can be expressed as

$$\phi = \sum_{i=1}^N N_i \phi_i + \sum_{i=1}^{N_D} N_i^D \phi_i^D \quad (5)$$

where N denotes the total number of nodes, at which the potential is unknown, and N_D denotes the number of nodes on Γ_D , where the potential is as given by (2). Furthermore, ϕ_i denotes the value of the potential at node i and N_i is the corresponding interpolation or basis function (the superscript “D” denotes the quantities on Γ_D). This interpolation function consists of the corresponding interpolation functions in all the elements that are directly connected to the associated node. Figure 3 shows the linear interpolation function in a two-dimensional triangular mesh.

Expression (5) can now be substituted into (1) to determine the unknown potentials ϕ_i , using the method of weighted residuals. It should be noted that the method of weighted residuals is only one of the methods for the finite-element formulation. Another commonly used method is the so-called variational method, which starts from the variational representation of the boundary value problem defined in (1)–(3). The method of weighted residuals is used here for its simplicity. In this method, a suitable testing or weighting function w is applied to (1) and the resulting equation is integrated over the problem domain, yielding

$$-\int_{\Omega} [\nabla \cdot (\varepsilon \nabla \phi)] w \, dV = \int_{\Omega} \rho w \, dV \quad (6)$$

Figure 3. Basis function N_i for linear triangular elements. (After Jin [9], ©2002 Wiley.)

Using the well-known vector identity $\nabla \cdot (w \varepsilon \nabla \phi) = [\nabla \cdot (\varepsilon \nabla \phi)] w + \varepsilon \nabla \phi \cdot \nabla w$ and Gauss theorem

$$\int_{\Omega} \nabla \cdot f \, d\Omega = \oint_{\Gamma} \hat{n} \cdot f \, d\Gamma \quad (7)$$

(6) can be written as

$$\int_{\Omega} \varepsilon \nabla \phi \cdot \nabla w \, d\Omega = \int_{\Omega} \rho w \, d\Omega + \oint_{\Gamma} (\hat{n} \cdot \varepsilon \nabla \phi) w \, d\Gamma \quad (8)$$

where one of the del operators is now transferred from ϕ to w . Substituting (3) into (8), one obtains

$$\begin{aligned} & \int_{\Omega} \varepsilon \nabla \phi \cdot \nabla w \, d\Omega \\ &= \int_{\Omega} \rho w \, d\Omega + \int_{\Gamma_D} [\hat{n} \cdot (\varepsilon \nabla \phi)] w \, d\Gamma + \int_{\Gamma_N} \kappa_N w \, d\Gamma \end{aligned} \quad (9)$$

This equation is called the weak-form representation of the boundary value problem defined by (1)–(3). The corresponding solution is called the weak-form solution, which satisfies (1) in the weighted average sense.

Next, a suitable weighting function needs to be chosen for w . A popular choice is

$$w = N_i \quad i = 1, 2, \dots, N \quad (10)$$

where N_i is the interpolation function associated with unknown ϕ_i . The resulting formulation is known as Galerkin’s formulation. Doing so, one obtains

$$\begin{aligned} \sum_{j=1}^N \phi_j \int_{\Omega} \varepsilon \nabla N_i \cdot \nabla N_j \, d\Omega &= \int_{\Omega} \rho N_i \, d\Omega + \int_{\Gamma_N} \kappa_N N_i \, d\Gamma \\ &\quad - \sum_{j=1}^{N_D} \phi_j^D \int_{\Omega} \varepsilon \nabla N_i \cdot \nabla N_j^D \, d\Omega \end{aligned} \quad (11)$$

and it is noted that the integral over Γ_D in (9) disappears here since N_i vanishes on Γ_D . Equation (11) can be written more compactly as

$$\sum_{j=1}^N K_{ij} \phi_j = b_i \quad i = 1, 2, \dots, N \quad (12)$$

where

$$K_{ij} = \int_{\Omega} \varepsilon \nabla N_i \cdot \nabla N_j \, d\Omega \quad (13)$$

$$\begin{aligned} b_i &= \int_{\Omega} \rho N_i \, d\Omega + \int_{\Gamma_N} \kappa_N N_i \, d\Gamma \\ &\quad - \sum_{j=1}^{N_D} \phi_j^D \int_{\Omega} \varepsilon \nabla N_i \cdot \nabla N_j^D \, d\Omega \end{aligned} \quad (14)$$

Equation (12) represents a set of linear equations, which can also be written in matrix form as

$$[K]\{\phi\} = \{b\} \tag{15}$$

where $[K]$ is an $N \times N$ square and symmetric matrix, $\{\phi\}$ is an $N \times 1$ column vector containing the unknown potential values at all the nodes except those on Γ_D , and $\{b\}$ is the $N \times 1$ known vector contributed by the known charge density and the Dirichlet and Neumann boundary conditions. The matrix equation (15) can be solved using one of the many standard matrix solvers, and its solution yields the potential values at all the nodes. The potential elsewhere can then be obtained by interpolation in (5).

A very important property of the finite-element method is that its matrix $[K]$ is extremely sparse. This becomes obvious from (13), which is nonzero only when N_i and N_j overlap with each other. Since N_i is nonzero only within the elements directly connected to node i , it overlaps with N_j only when nodes i and j belong to the same element. Hence, in each row of matrix $[K]$, there are only a few nonzero elements no matter how large the dimension of the matrix is. Therefore, the memory required to store $[K]$ is proportional to $\mathcal{O}(N)$, and the solution can also be made very efficient by using special solvers that exploit the property of sparsity. Such solvers are often referred to as *sparse solvers*. As a result, the finite-element method is very suitable for large-scale applications, where one has to deal with a very large number of unknowns.

In the actual implementation of the finite-element method described above, it might prove difficult to find the explicit expressions of N_i and N_j to evaluate K_{ij} , since a node may be connected to a different number of elements, each having a different shape. To alleviate this difficulty, (13) is rewritten as

$$K_{ij} = \sum_{e=1}^M \int_{\Omega_e} \epsilon \nabla N_i \cdot \nabla N_j \, d\Omega \tag{16}$$

where Ω_e denotes the domain of element e and M denotes the total number of elements in Ω . Using (16), one can process elements one by one and calculate its contribution to $[K]$. This process, called *assembly*, is described in detail in Ref. 9 using a specific example.

3. FINITE-ELEMENT ANALYSIS OF VECTOR FIELD PROBLEMS

The finite-element method described in Section 2 can be extended to deal with problems involving vector fields. For this, consider the problem of calculating the electric field intensity \mathbf{E} due to electric current density \mathbf{J} in a domain Ω characterized by relative permittivity ϵ_r and relative permeability μ_r . Maxwell's equations for this case can be converted into the vector Helmholtz equation

$$\nabla \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) - k_0^2 \epsilon_r \mathbf{E} = -jk_0 Z_0 \mathbf{J} \quad \text{on } \Omega \tag{17}$$

where k_0 denotes the free-space wavenumber and Z_0 denotes the free-space intrinsic impedance. Typical boundary conditions for the electric field include the homogeneous Dirichlet condition on a perfectly conducting surface and the mixed boundary condition on an impedance surface. To illustrate the treatment of these two conditions, the following are assumed for this example

$$\hat{n} \times \mathbf{E} = 0 \quad \text{on } \Gamma_D \tag{18}$$

$$\hat{n} \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) + \frac{jk_0}{\eta} \hat{n} \times (\hat{n} \times \mathbf{E}) = \mathbf{K}_N \quad \text{on } \Gamma_N \tag{19}$$

where η denotes the normalized surface impedance on Γ_N and \mathbf{K}_N is a known function introduced to make (19) more general.

Similar to the scalar problem discussed in Section 2, instead of solving the boundary value problem (17)–(19) directly, one can seek its weak-form solution by multiplying (17) by an appropriate weighting function \mathbf{W} and integrating over the problem domain, which yields

$$\begin{aligned} & \int_{\Omega} \mathbf{W} \cdot \left[\nabla \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) - k_0^2 \epsilon_r \mathbf{E} \right] d\Omega \\ & = -jk_0 Z_0 \int_{\Omega} \mathbf{W} \cdot \mathbf{J} \, d\Omega \end{aligned} \tag{20}$$

By invoking the vector identity

$$\begin{aligned} \mathbf{W} \cdot \left[\nabla \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) \right] & = -\nabla \cdot \left[\mathbf{W} \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) \right] \\ & \quad + \frac{1}{\mu_r} (\nabla \times \mathbf{W}) \cdot (\nabla \times \mathbf{E}) \end{aligned} \tag{21}$$

and Gauss theorem (7), one obtains

$$\begin{aligned} & \int_{\Omega} \left[\frac{1}{\mu_r} (\nabla \times \mathbf{W}) \cdot (\nabla \times \mathbf{E}) - k_0^2 \epsilon_r \mathbf{E} \cdot \mathbf{W} \right] d\Omega \\ & = \int_{\Gamma_D} \frac{1}{\mu_r} (\nabla \times \mathbf{W}) \cdot (\hat{n} \times \mathbf{E}) \, d\Gamma \\ & \quad - \int_{\Gamma_N} \left[\frac{jk_0}{\eta} (\hat{n} \times \mathbf{W}) \cdot (\hat{n} \times \mathbf{E}) + \mathbf{K}_N \cdot \mathbf{W} \right] d\Gamma \\ & \quad - jk_0 Z_0 \int_{\Omega} \mathbf{J} \cdot \mathbf{W} \, d\Omega \end{aligned} \tag{22}$$

after the boundary condition (19) is applied.

To find a numerical solution of (22) using the finite-element method, the entire domain Ω is first divided into small elements. Within each small element, \mathbf{E} can be interpolated using a set of discrete values. One approach is to assign \mathbf{E} at a few points on the element and then interpolate \mathbf{E} elsewhere using a set of scalar interpolation functions. This approach turns out to be very problematic because of the difficulty in applying correct boundary conditions to the interpolated field \mathbf{E} . A better approach is to assign the tangential component of \mathbf{E} at each edge of the

element and then interpolate \mathbf{E} elsewhere using a set of vector basis functions. For example, the field in a triangular element can be interpolated as

$$\mathbf{E}^e(x, y) = \mathbf{N}_1^e(x, y)E_1^e + \mathbf{N}_2^e(x, y)E_2^e + \mathbf{N}_3^e(x, y)E_3^e \quad (23)$$

where $E_1^e, E_2^e,$ and E_3^e denote the tangential component of \mathbf{E} at edges 1, 2, and 3, respectively, and $\mathbf{N}_1^e(x, y), \mathbf{N}_2^e(x, y),$ and $\mathbf{N}_3^e(x, y)$ are the corresponding interpolation or basis functions. Different from those in (4), these functions are vector functions and the corresponding element is called the *vector element* or *edge element*, in contrast to the previous scalar element or nodal element. Figure 4 shows the vector basis functions for a triangular element. Clearly, such basis functions ensure the tangential continuity of the interpolated field while allowing the normal component to be discontinuous. Hence, they accurately model the nature of the vector field \mathbf{E} .

When the field \mathbf{E} is interpolated in each element using its tangential values at the edges of the element, the field \mathbf{E} in the entire domain Ω can be expressed as

$$\mathbf{E} = \sum_{i=1}^{N_e} \mathbf{N}_i E_i \quad (24)$$

where N_e denotes the total number of edges excluding those on Γ_D , E_i denotes the tangential component of \mathbf{E} at the i th edge, and \mathbf{N}_i is the corresponding basis function. Obviously, for an edge inside Ω , \mathbf{N}_i spans over two neighboring elements that share the common edge, and for an edge on Γ_N , \mathbf{N}_i spans over only one element. Figure 5 shows \mathbf{N}_i for an interior edge.

By substituting (24) into (22) and using the same \mathbf{N}_i as the weighting function \mathbf{W} , one obtains

$$\sum_{j=1}^{N_e} K_{ij} E_j = b_i \quad i = 1, 2, \dots, N_e \quad (25)$$

where

$$K_{ij} = \int_{\Omega} \left[\frac{1}{\mu_r} (\nabla \times \mathbf{N}_i) \cdot (\nabla \times \mathbf{N}_j) - k_0^2 \epsilon_r \mathbf{N}_i \cdot \mathbf{N}_j \right] d\Omega \quad (26)$$

$$+ jk_0 \int_{\Gamma_N} \left[\frac{1}{\eta} (\hat{\mathbf{n}} \mathbf{N}_i) \cdot (\hat{\mathbf{n}} \times \mathbf{N}_j) \right] d\Gamma$$

$$b_i = -jk_0 Z_0 \int_{\Omega} \mathbf{J} \cdot \mathbf{N}_i d\Omega - \int_{\Gamma_N} \mathbf{K}_N \cdot \mathbf{N}_i d\Gamma \quad (27)$$

Figure 4. Vector basis functions \mathbf{N}_i^e for a linear triangular element. (After Jin [9], © 2002 Wiley.)

Figure 5. Vector basis function \mathbf{N}_i for linear triangular elements.

Note that the integral over Γ_D in (22) disappears here since $\hat{\mathbf{n}} \times \mathbf{N}_i = 0$ on Γ_D . Equation (25) can be written compactly as

$$[K]\{E\} = \{b\} \quad (28)$$

which can be solved for $\{E\}$. Similar to the scalar case, $[K]$ is a sparse and symmetric matrix, which can be solved efficiently using a sparse solver. Once $\{E\}$ is obtained, the field everywhere in Ω can be calculated using (24).

4. COMPUTATIONAL ASPECTS

When solving a problem using the finite-element method, one first sets up the mesh, then fills the matrix equation based on the mesh together with the boundary conditions, and finally solves the resulting system of linear equations. The computational issues of mesh generation and matrix solvers are discussed in this section.

4.1. Mesh Generation

The finite-element method assumes the availability of a mesh on the structure under consideration. However, obtaining this mesh is not trivial. Finite-element meshes can be split into two main categories: structured and unstructured meshes. Structured meshes have the property that all elements have the same number of neighbors, while unstructured meshes have no such constraint. When using rectangular or brick elements, structured meshes usually result, while unstructured meshes most often consist of triangles or tetrahedrons. Unstructured meshing with

triangles and tetrahedrons is much more general, since any polygonal/polyhedral domain may be represented by such a mesh.

The quality of an unstructured mesh is determined by the shape regularity of its elements, which is defined on an elemental basis as the ratio between the radius of the largest inscribed circle/sphere and the maximum dimension of the element. Among the most widely used approaches to unstructured meshing are "Octree," "Delaunay," and "Advancing front." The first approach breaks the structure into blocks until a desired resolution is obtained, and then the blocks are meshed. The second approach actually refers to a criterion for ensuring shape regularity when creating a mesh from a given set of nodes. The third approach relies on an already meshed boundary, to which elements are progressively added toward the interior.

As various requirements are placed on the meshing algorithm, such as continuity between different regions and variations in element size, the process becomes increasingly complicated. See [11,12] and the references therein for further discussions on mesh generation.

4.2. Matrix Solvers

An efficient solution of the finite-element matrix equation is very important, since in the course of solving a problem with finite-elements most computer resources (memory and time) are usually expended on this step. The important issues are matrix storage schemes, matrix solvers (direct or iterative), and matrix preconditioners (in the iterative case).

The matrices produced by the finite-element method are sparse with only a very small percentage of nonzero elements. By storing only the nonzero entries, the matrix storage requirement is reduced from $\mathcal{O}(N^2)$ to $\mathcal{O}(N)$. Popular approaches to sparse storage are compressed row and compressed column storage.

The choice of matrix solver can have a significant impact on computational efficiency, so it is important to choose a solver that best suits the properties of the matrix. There are two types of matrix solvers. The first type is direct solvers based on Gaussian elimination or *LU* decomposition. These solvers are commonly used for full matrices, but are also applicable to sparse matrices stored in a band format, or even a fully sparse format in the case of the frontal and multifrontal methods [13,14]. The alternative to direct solvers are iterative solvers, where very little extra memory is required, since they are based on calculating successive matrix-vector products according to an iterative algorithm to converge to the solution [15]. The main drawback of such algorithms is that they might require a prohibitive amount of iterations to converge, depending mainly on the locations of the eigenvalues of the matrix; if the eigenvalues are all located close to unity, convergence is usually rapid. This problem is addressed by using a preconditioner to move the eigenvalues closer to unity and thereby reduce the iteration count. Construction of a preconditioner can be based on physical insight into the problem or on the structure of the original matrix.

4.3. Fast Frequency Sweep

Many RF and microwave engineering applications require computation of frequency responses over a broad band rather than at one or a few isolated frequencies. Such calculations can be very time-consuming when a traditional frequency-domain numerical method is used because a set of algebraic equations must be solved repeatedly at many frequencies. The number of calculations is proportional to the electrical size of the problem and can be large for most applications. Therefore, there is a need to find approximate solution techniques that can efficiently simulate a frequency response over a broad band. This can be accomplished by the method of asymptotic waveform evaluation [16]. In this method, the unknown solution vector, the right-hand vector, and the system matrix are first expanded into Taylor series at a chosen frequency. The expansion coefficients of the solution vector are then determined by moment matching. The Taylor series of the solution vector is then converted into a Padé rational function to broaden the radius of convergence. With this approach, one obtains a solution that is accurate at frequencies near the point of expansion. The accuracy of the solution decreases when the frequency moves away from the point of expansion. In many practical applications, one is often required to find the solution over a specified frequency band, where one point of expansion may not be sufficient, and multiple points of expansion become necessary. These points can be selected automatically using a simple binary search algorithm [9].

5. APPLICATIONS OF THE FINITE-ELEMENT METHOD

The finite-element method has been widely applied to the analysis of problems in RF and microwave engineering. A few typical applications are discussed here to illustrate the treatment of various problems commonly encountered in the finite-element analysis.

5.1. Cavity Analysis

Typical cavity analysis involves finding the resonant frequencies and modal distributions of a given cavity. Mathematically, it translates to solving the homogeneous vector Helmholtz equation

$$\nabla \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) - k_0^2 \epsilon_r \mathbf{E} = 0 \quad \text{on } \Omega \quad (29)$$

for a set of discrete values of k_0^2 that yield nontrivial solutions for \mathbf{E} . Application of the finite-element analysis described in Section 3 to (29) yields a generalized eigenvalue problem

$$[A]\{E\} = k_0^2[B]\{E\} \quad (30)$$

where

$$A_{ij} = \int_{\Omega} \frac{1}{\mu_r} (\nabla \times \mathbf{N}_i) \cdot (\nabla \times \mathbf{N}_j) d\Omega \quad (31)$$

$$B_{ij} = \int_{\Omega} \epsilon_r \mathbf{N}_i \cdot \mathbf{N}_j d\Omega \quad (32)$$

The eigenvalues solved for in (30) yield the resonant frequencies of the cavity modes, and the corresponding eigenvectors $\{E\}$ provide the modal distributions.

5.2. Waveguide Analysis

Typical waveguide analysis involves finding the propagation constants and field distributions of the propagation modes in an infinitely long waveguide. Since the waveguide is assumed to be uniform in its longitudinal direction, say, the z direction, it is sufficient to consider (29) over the cross section of the waveguide.

For all the propagating modes, the electric field can be written as

$$\mathbf{E}(x, y, z) = \left[\frac{1}{\beta} \mathbf{e}_t(x, y) + j\hat{z}e_z(x, y) \right] e^{-j\beta z} \quad (33)$$

where β represents the propagation constant, \mathbf{e}_t represents the transverse component, and e_z represents the longitudinal component. The coefficients of \mathbf{e}_t and e_z are introduced to cast the final result in a more desirable form [17]. By introducing the weighting function

$$\mathbf{W}(x, y, z) = \left[\frac{1}{\beta} \mathbf{w}_t(x, y) - j\hat{z}w_z(x, y) \right] e^{j\beta z} \quad (34)$$

the weak form of (29) can be found as

$$\int_{\Omega} \left\{ \frac{1}{\mu_r} (\nabla_t \times \mathbf{e}_t) \cdot (\nabla_t \times \mathbf{w}_t) - k_0^2 \epsilon_r \mathbf{e}_t \cdot \mathbf{w}_t + \beta^2 \left[\frac{1}{\mu_r} (\nabla_t e_z + \mathbf{e}_t) \cdot (\nabla_t w_z + \mathbf{w}_t) - k_0^2 \epsilon_r e_z w_z \right] \right\} d\Omega = 0 \quad (35)$$

where ∇_t denotes the transverse del operator.

When edge elements are used for \mathbf{e}_t and nodal elements are employed for e_z , (35) can be converted into a generalized eigenvalue problem

$$\begin{bmatrix} A_{tt} & 0 \\ 0 & 0 \end{bmatrix} \begin{Bmatrix} e_t \\ e_z \end{Bmatrix} = -\beta^2 \begin{bmatrix} B_{tt} & B_{tz} \\ B_{zt} & B_{zz} \end{bmatrix} \begin{Bmatrix} e_t \\ e_z \end{Bmatrix} \quad (36)$$

in which

$$A_{ttij} = \int_{\Omega} \left[\frac{1}{\mu_r} (\nabla_t \times \mathbf{N}_i) \cdot (\nabla_t \times \mathbf{N}_j) - k_0^2 \epsilon_r \mathbf{N}_i \cdot \mathbf{N}_j \right] d\Omega \quad (37)$$

$$B_{ttij} = \int_{\Omega} \frac{1}{\mu_r} \mathbf{N}_i \cdot \mathbf{N}_j d\Omega \quad (38)$$

$$B_{tzij} = \int_{\Omega} \frac{1}{\mu_r} \mathbf{N}_i \cdot \nabla_t N_j d\Omega \quad (39)$$

$$B_{ztij} = \int_{\Omega} \frac{1}{\mu_r} \nabla_t N_i \cdot \mathbf{N}_j d\Omega \quad (40)$$

$$B_{zzij} = \int_{\Omega} \left[\frac{1}{\mu_r} \nabla_t N_i \cdot \nabla_t N_j - k_0^2 \epsilon_r N_i N_j \right] d\Omega \quad (41)$$

where the indices of \mathbf{N}_i and \mathbf{N}_j run from 1 to N_e and those of N_i and N_j run from 1 to N .

From (36), one can solve for a set of eigenvalues β^2 and the corresponding eigenvectors $\{e_t, e_z\}^T$ for a given value of k_0 . These eigenvalues and eigenvectors give the propagation constant and field distribution of each waveguide mode. Figure 6 shows the dispersion curves for an insulated image guide, calculated using the method described here.

5.3. Microwave Device Analysis

A microwave device has typically one or more ports, and it is usually characterized by its s parameters. To perform the finite-element analysis of a microwave device, it is necessary to terminate each port to limit the volume of analysis. A boundary condition is then required at each port to uniquely define the boundary value problem.

To derive such a boundary condition, one needs to know the propagation constants and field distributions of the waveguide modes. For most waveguides such as rectangular, circular, and coaxial waveguides, the propagation constants and modal fields can be obtained analytically. For other waveguides such as partially filled waveguides and microstrip lines, they can be calculated using the finite-element method described in Section 5.2. Once the waveguide modes are known, the total electric field

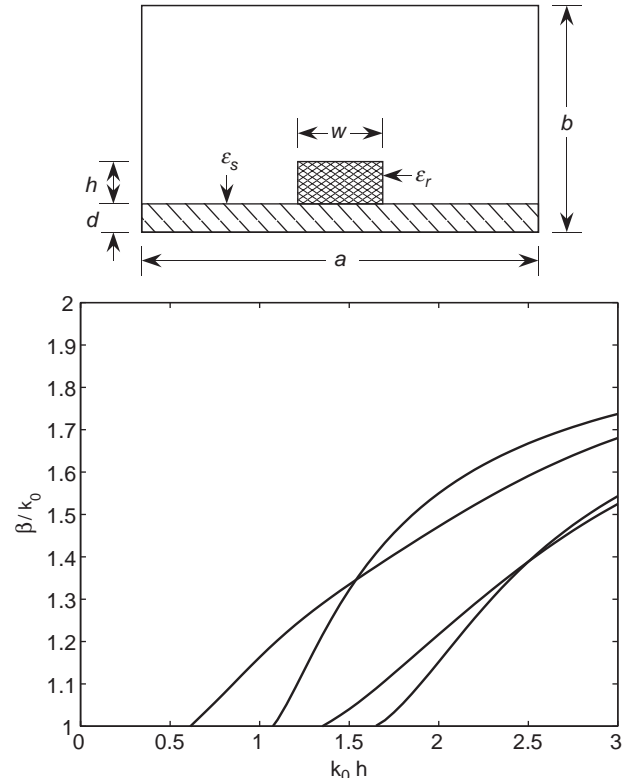

Figure 6. Dispersion characteristics of an insulated image guide ($w/h = 2.25$, $d/h = 0.5$, $a/h = 13.5$, $b/h = 8.0$, $\epsilon_r = 3.8$, and $\epsilon_s = 1.5$). (After Jin [9], ©2002 Wiley.)

at a port can be written as

$$\mathbf{E}(x, y, z) = \mathbf{E}^{\text{inc}}(x, y, z) + \sum_{n=1}^{\infty} a_n \left[\frac{1}{\beta_n} \mathbf{e}_{tn}(x, y) + j\hat{z}e_{zn}(x, y) \right] e^{-j\beta_n z} \quad (42)$$

where n denotes the mode number, (x, y, z) are the local coordinates (where z denotes the axis of the waveguide), and \mathbf{E}^{inc} represents the incident field at the port. Using the orthonormality property of the modes, one finds

$$a_n = \beta_n e^{j\beta_n z_0} \int_{\Gamma_A} \mathbf{e}_{tn}(x, y) \cdot [\mathbf{E} - \mathbf{E}^{\text{inc}}]_{z=z_0} d\Gamma \quad (43)$$

where Γ_A denotes the aperture of the port and z_0 denotes its position. From (42), it can be shown that

$$\hat{n} \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) + P(\mathbf{E}) = \mathbf{U}^{\text{inc}} \quad \text{at } z = z_0 \quad (44)$$

where

$$P(\mathbf{E}) = -\frac{j}{\mu_r} \sum_{n=1}^{\infty} \beta_n (\mathbf{e}_{tn} + \nabla_t e_{zn}) \int_{\Gamma_A} \mathbf{e}_{tn} \cdot \mathbf{E} d\Gamma \quad (45)$$

$$\mathbf{U}^{\text{inc}} = \hat{n} \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E}^{\text{inc}} \right) + P(\mathbf{E}^{\text{inc}}) \quad (46)$$

Equation (44) can be considered as a generalized mixed boundary condition and can be treated in a manner similar to that for (19).

Once the field inside the device and at its ports has been obtained, the s parameters can be calculated in a straightforward manner. Figure 7 shows the transmission coefficient $|S_{12}|$ for a cylindrical cavity resonator. The input and output ports are WR75 waveguides, coupled to the internal resonator through two rectangular slots.

5.4. Antenna Analysis

Most antennas are used to radiate electromagnetic waves into an open space. An antenna is typically characterized by its radiation pattern and input impedance. For multiple antennas such as an antenna array, the mutual coupling is also important. The main difficulty in the finite-element analysis of antennas is how to deal with the surrounding open space. A common approach is to introduce an artificial surface to truncate the infinite solution domain into a finite one. A boundary condition is then required at this surface for a unique solution of the electromagnetic fields. This boundary condition should be transparent to the radiated field; that is, it should permit the radiated field to pass through without any reflection. Unfortunately, there is no simple boundary condition that meets this requirement. Over the years, a variety of approximate boundary conditions, also called *absorbing boundary conditions*, have been developed to approximately satisfy this requirement. The simplest absorbing boundary condition is the well-known Sommerfeld radiation boundary condition, which states that if the truncation surface is sufficiently

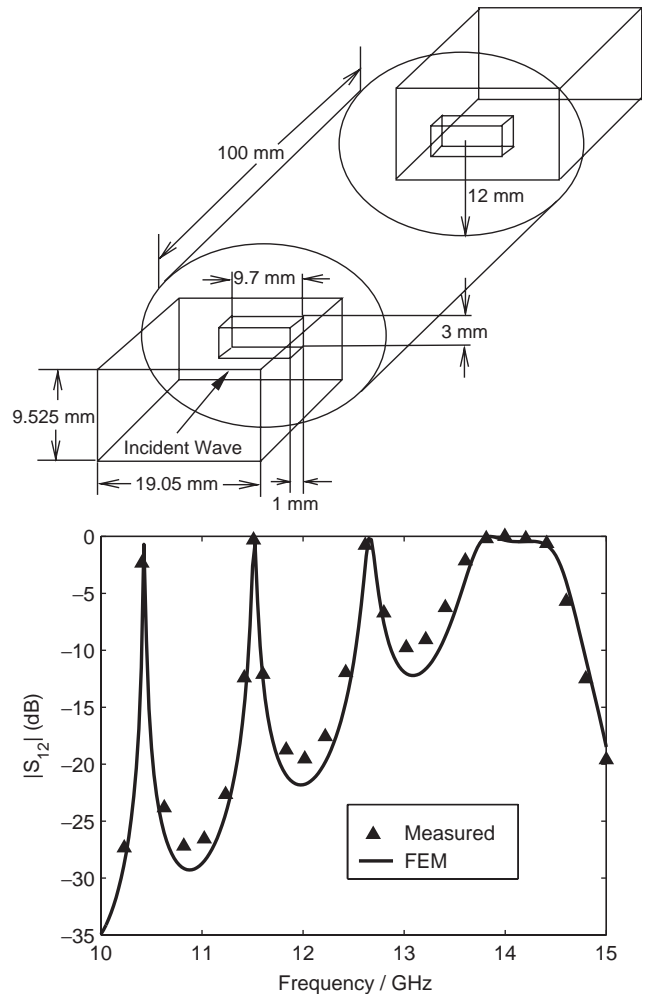

Figure 7. Transmission coefficient S_{12} of a cylindrical cavity resonator. (After Liu et al. [18], ©2002 Wiley.)

far away from the radiation source, the radiated field satisfies

$$\hat{n} \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) + jk_0 \hat{n} \times (\hat{n} \times \mathbf{E}) \approx 0 \quad (47)$$

This equation is simply the homogeneous version of the mixed condition (19), the treatment of which is discussed in Section 3.

Another issue in the finite-element analysis of antennas is the modeling of the antenna feeds. If the antenna feeds can be modeled approximately as electric current sources, they can be treated as \mathbf{J} in (17). If a more accurate modeling is desired, they can be modeled as waveguide ports, the treatment of which is described in Section 5.3.

It must be noted again that (47) is approximate; hence, the analysis result is also approximate. Although the accuracy can be improved by placing the truncation surface farther away from the antenna, one then has to deal with a very large computational domain, which makes the analysis inefficient. A better alternative is to use an exact boundary integral equation as a boundary condition at the truncation surface. This allows the truncation surface to

be placed as close to the antenna as possible. This approach is briefly described in Section 6.3.

Figure 8 shows the input impedance of a microstrip patch antenna, which consists of a 5.0×3.4 -cm rectangular patch residing on a substrate having thickness $t = 0.08779$ cm, relative permittivity $\epsilon_r = 2.17$, and a loss tangent of 0.0015. The antenna is excited by a current probe applied at $(x_f = 1.22, y_f = 0.85)$ cm and has a $50\text{-}\Omega$ resistor placed at $(x_L = -2.2, y_f = -1.5)$ cm, assuming that the patch is centered at the origin.

5.5. Scattering Analysis

The finite-element analysis of electromagnetic wave scattering by an object is similar to the analysis of antennas. An artificial surface is first introduced to enclose the entire object and to truncate the infinite solution domain to a finite one. An absorbing boundary condition is then

employed to permit the scattered field to leave the truncation surface without significant reflection. If the Sommerfeld radiation condition is used as the absorbing boundary condition, it can be written as

$$\hat{n} \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E}^{\text{sc}} \right) + jk_0 \hat{n} \times (\hat{n} \times \mathbf{E}^{\text{sc}}) \approx 0 \quad (48)$$

where \mathbf{E}^{sc} denotes the scattered field, which is the difference between the total and the incident fields ($\mathbf{E}^{\text{sc}} = \mathbf{E} - \mathbf{E}^{\text{inc}}$).

Since the absorbing boundary condition applies only to the scattered field, the formulation for scattering analysis is slightly different from that for the antenna analysis formulation. There are two approaches to formulating the scattering problem. One approach uses the total field that satisfies (29). The absorbing boundary condition (48) is then written in terms of the total field as

$$\hat{n} \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) + jk_0 \hat{n} \times (\hat{n} \times \mathbf{E}) = \mathbf{U}^{\text{inc}} \quad (49)$$

where

$$\mathbf{U}^{\text{inc}} = \hat{n} \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E}^{\text{inc}} \right) + jk_0 \hat{n} \times (\hat{n} \times \mathbf{E}^{\text{inc}}) \quad (50)$$

Another approach is to work on the scattered field using (48) directly. In this case, (29) can be written for the scattered field as

$$\nabla \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E}^{\text{sc}} \right) - jk_0 \epsilon_r \mathbf{E}^{\text{sc}} = \mathbf{F}^{\text{inc}} \quad (51)$$

where

$$\mathbf{F}^{\text{inc}} = \nabla \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E}^{\text{inc}} \right) - jk_0 \epsilon_r \mathbf{E}^{\text{inc}} \quad (52)$$

and the boundary conditions on conducting surfaces become

$$\hat{n} \times \mathbf{E}^{\text{sc}} = -\hat{n} \times \mathbf{E}^{\text{inc}} \quad (53)$$

Both approaches are mathematically equivalent. They differ in the numerical implementation, specifically, in the implementation of the excitation. In the first approach, the excitation is introduced as a boundary source on the truncation surface; in the second approach, it is introduced on the conducting surface and over the object. Numerical experiments show that the second approach is slightly more accurate since the wave travels a shorter distance in the finite-element mesh, resulting in a smaller dispersion error.

Figure 9 shows the VV-polarized monostatic radar cross section of a metallic double ogive at 9 GHz, which is formed by joining two different half-ogives. The top piece has a half-length of 12.7 cm, a maximum radius of 2.54 cm, and a half-angle of 22.62° at the tip, and the bottom has a half-length of 6.35 cm, a maximum radius of

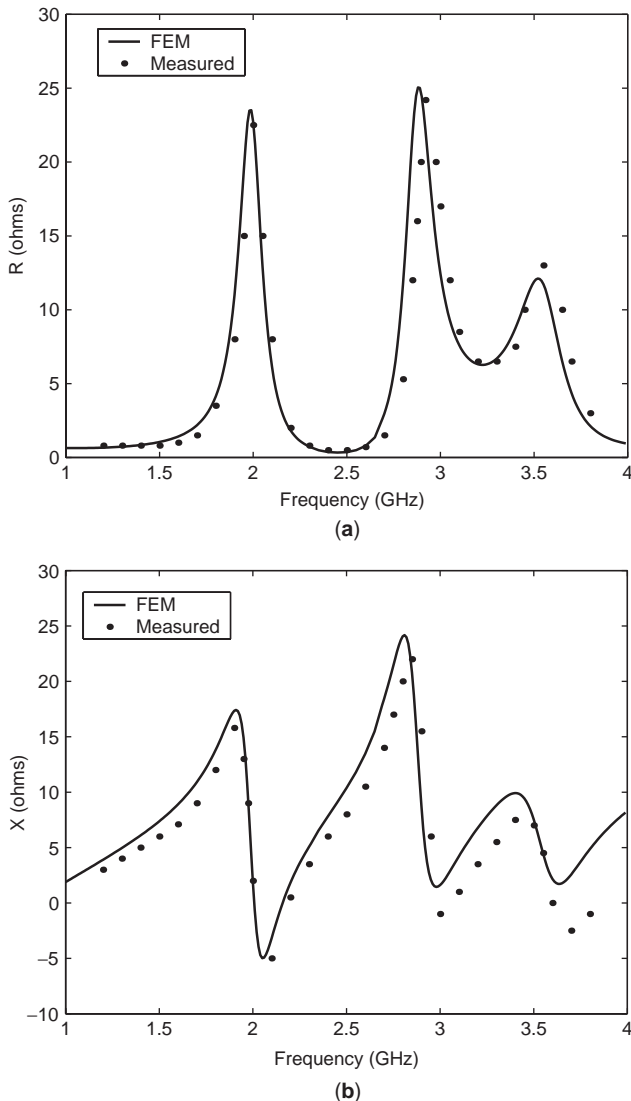

Figure 8. Input impedance of a loaded microstrip patch antenna: (a) resistance; (b) reactance. (After Jin and Volakis [19], ©1991 IEEE.)

2.54 cm, and a half-angle of 46.4° at the tip. The calculated results are compared with measured data.

6. ADVANCED FINITE-ELEMENT ANALYSIS

There are many advanced methods that build on and complement the basic finite-element method framework as illustrated in Sections 2 and 3. A few of the most prominent of these methods are discussed here.

6.1. Higher-Order Elements

Most finite-element methods use basis functions that vary linearly within every element (see Figs. 3 and 5). However, it is also possible, and often very advantageous, to consider basis functions of higher polynomial orders. Such basis functions are defined for scalar nodal elements in Refs. 8 and 9 and for vector elements in Refs. 21 and 22.

Higher-order basis functions can be categorized into two classes: interpolatory and hierarchical. *Interpolatory* basis functions relate to a set of elemental points, such that every basis function is of the same order, and is equal to unity at one point and zero at all others. On the other hand, hierarchical basis functions are formed by adding new higher-order basis functions to the lower-order ones; thus the elemental solution is expanded in terms of basis functions of differing polynomial orders. Both approaches have the same accuracy, but one may be favored over the other, depending on the application. Interpolatory basis functions generally lead to better conditioned matrices, while hierarchical basis functions permit the use of different elemental orders in a single finite-element solution.

Since higher-order basis functions interpolate the solution field much more accurately, the finite-element method may be expected to yield much more accurate results, as the elemental order is increased. Specifically, for smooth functions it can be shown that if p is the order of the basis functions, h denotes the elemental size divided by the order of the element, and λ denotes the excitation wavelength, the interpolation error is of the order $\mathcal{O}((h/\lambda)^{p+1})$. Therefore, in the case of smooth solutions, the finite-element solution error may be reduced accord-

ingly by using higher-order basis functions. If the true solution to the finite-element analysis contains a singularity, this interpolation error estimate does not hold anymore and it becomes more advantageous to use smaller elements of low polynomial order around the singularity.

When the finite-element method is applied to the Helmholtz equations (scalar as well as vector cases), the simulated wave propagates at a speed slightly different from the exact value. Consequently, there is a numerical error in the phase of the numerical solution, which is called *dispersion error*. Analysis based on the finite-element discretization of plane wave propagation in a uniform medium shows that the dispersion error per wavelength is proportional to $\mathcal{O}((h/\lambda)^{2p})$. From this result follows the very important conclusion that phase errors may be decreased exponentially by increasing the order of the elements. Therefore, higher-order elements are especially suitable for simulating large-scale wave propagation problems.

6.2. Curvilinear Elements

In the same way that elemental basis functions can be defined to arbitrary polynomial order, the geometric representation of the elements can also be defined to arbitrary polynomial order. The elements shown in Figs. 3 and 5 are of linear geometric order since all edges and faces are straight and flat, and can thus be described by linear functions of position. Such elements are termed *rectilinear*. Elements of higher geometric polynomial order may be defined by modeling elemental edges and faces with higher-order polynomial functions of position. For example, one may require the edge of a triangular element to pass through two of its vertex nodes together with an additional node that may not lie on the straight line connecting the vertices. In this case, a second-order geometric representation would suffice. Such elemental representations are very useful when modeling curved boundaries and are termed *curvilinear*. When the order of geometric representation is the same as the order of basis functions, the element is called *isoparametric*. Otherwise, it is called either *subparametric* (when the order of geometric modeling is lower) or *superparametric* (when the order of geometric modeling is higher).

6.3. Finite-Element/Boundary Integral Method

As mentioned in Section 5.4, instead of using an absorbing boundary condition to approximate an infinite exterior volume to the finite-element domain, one may use a boundary integral equation as a boundary condition such that the infinite exterior region is modeled exactly through the Green function [9]. This approach, called the *finite-element/boundary integral method*, allows complete freedom in choosing the truncation surface enclosing the region of interest.

For example, consider the case of solving (17) on a truncated mesh with infinite exterior free space. The truncation surface, denoted by S , is closed, and given the electric and magnetic fields on such a surface, one can calculate the electric and magnetic fields to its exterior using the electric and magnetic field integral equations,

which are defined as follows

$$\mathbf{E} = \mathbf{E}^{\text{inc}} - Z_0 \mathcal{L}(S, \mathbf{J}_S) + \mathcal{K}(S, \mathbf{E} \times \hat{\mathbf{n}}) \quad (54)$$

$$Z_0 \mathbf{H} = Z_0 \mathbf{H}^{\text{inc}} - Z_0 \mathcal{K}(S, \mathbf{J}_S) - \mathcal{L}(S, \mathbf{E} \times \hat{\mathbf{n}}) \quad (55)$$

where \mathbf{E}^{inc} and \mathbf{H}^{inc} represent the exterior incident fields and

$$\mathcal{L}(S, \mathbf{v}) = jk_0 \oint_S \left[\mathbf{v}(\mathbf{r}') G_0(\mathbf{r}, \mathbf{r}') + \frac{1}{k_0^2} \nabla' \cdot \mathbf{v}(\mathbf{r}') \nabla G_0(\mathbf{r}, \mathbf{r}') \right] dS' \quad (56)$$

$$\mathcal{K}(S, \mathbf{v}) = \oint_S \mathbf{v}(\mathbf{r}') \times \nabla G_0(\mathbf{r}, \mathbf{r}') dS' \quad (57)$$

in which $G_0(\mathbf{r}, \mathbf{r}')$ denotes the scalar, free-space Green function [9,23] and $\mathbf{J}_S = \hat{\mathbf{n}} \times \mathbf{H}$ on S . For the finite-element region one may then use the simple boundary condition

$$\hat{\mathbf{n}} \times \left(\frac{1}{\mu_r} \nabla \times \mathbf{E} \right) = -jk_0 Z_0 \mathbf{J}_S \quad \text{on } S \quad (58)$$

and solve it together with a numerical system obtained by applying Galerkin's method to either (54) or (55) (or linear combinations of these), in terms of both \mathbf{E} and \mathbf{J}_S . This approach has been widely used, with various modifications to improve robustness and efficiency [9,24].

The finite-element/boundary integral method generally leads to sparse matrices with fully populated subblocks, corresponding to the unknowns associated with the exterior boundary. This aspect implies increased computational resource requirements, but on the other hand, the method enables one to reduce the computational domain's size to a minimum. More importantly, the method is accurate and reliable since its formulation involves no approximation other than numerical discretization.

6.4. Time-Domain Finite-Element Method

The finite-element method for electromagnetic fields may be formulated in the time domain, rather than the frequency domain, so that transient responses may be calculated directly. This is especially useful when data over a wide frequency band are required or when nonlinear devices are considered. In the time domain, the vector wave equation (17) takes the following form:

$$\nabla \times \left(\frac{1}{\mu} \nabla \times \mathbf{E} \right) + \varepsilon \frac{\partial^2 \mathbf{E}}{\partial t^2} + \sigma \frac{\partial \mathbf{E}}{\partial t} = - \frac{\partial \mathbf{J}}{\partial t} \quad \text{on } \Omega \quad (59)$$

In order to solve (59) with the finite-element method, both spatial and temporal discretization is required. The spatial discretization follows the procedure described in Section 3 by using vector elements to represent the fields, which yields the following system in terms of the time variable:

$$[T] \frac{d^2 \{E\}}{dt^2} + [R] \frac{d \{E\}}{dt} + [S] \{E\} + \{f\} = \{0\} \quad (60)$$

This equation represents a set of second-order ordinary differential equations in terms of the time-dependent

spatial unknowns $\{E\}$. This equation is solved numerically by first dividing the time axis into discrete intervals of length Δt . Next, the time derivatives are approximated such that $\{E\}$ can be calculated at successive timesteps, $t = n\Delta t$, $n = 1, 2, 3, \dots$. For this purpose, various timestepping schemes are available, such as central differencing and the Newmark β method [9,25]. The Newmark β method, when applied to (60), takes the following form:

$$\begin{aligned} & \left\{ \frac{1}{(\Delta t)^2} [T] + \frac{1}{2\Delta t} [R] + \beta [S] \right\} \{E\}^{n+1} \\ & = \left\{ \frac{2}{(\Delta t)^2} [T] - (1 - 2\beta) [S] \right\} \{E\}^n \\ & - \left\{ \frac{1}{(\Delta t)^2} [T] - \frac{1}{2\Delta t} [R] + \beta [S] \right\} \{E\}^{n-1} \\ & - [\beta \{f\}^{n+1} + (1 - 2\beta) \{f\}^n + \beta \{f\}^{n-1}] \end{aligned} \quad (61)$$

This method has a very important characteristic that when the parameter β is set to $\beta \geq 0.25$, it becomes unconditionally stable, which means that it can be used with a timestep independent of spatial discretization size. Usually the stability of a timestepping scheme is tied to the minimum size of the spatial discretization, given a fixed Δt .

When considering open-region problems, the time-domain equivalents of the absorbing boundary condition and the finite-element/boundary integral method can be employed [9].

6.5. Adaptive Finite-Element Method

Associated with any finite-element solution is an error due to the approximate representation of the solution on the mesh. Quantifying this error is an important extension to the finite-element method, since it opens up the possibility of adaptive finite-element analysis, which can enhance the efficiency of the finite-element method significantly.

The goal of an adaptive finite-element analysis is to optimize the mesh size (designated by h) and element orders (designated by p) with which a given accuracy can be obtained with the minimum number of unknowns. This is accomplished in the following way. Choose an initial discretization and solve the problem. On the basis of the solution, estimate the error distribution and the global solution error, as measured in a relevant quantity such as energy, impedance or scattering cross section. On the basis of the error distribution, refine the solution representation selectively with respect to h and/or p . Resolve the problem using the new discretization and repeat the process. Iterate in this way until the global error measure drops below a required level.

The core component of this process is the error estimation, which is termed a *posteriori error estimation*, since an existing solution is required. Many different approaches to a posteriori error estimation exist [26,27]. Usually the error estimator is derived mathematically, based on the finite-element formulation at hand and the output quantity of interest, but sometimes one can construct it on

the basis of physical insight alone. For example, for vector field problems one can use the residues of (17) and (19) to estimate the error over each element. The field continuity condition across each element edge or face can also be incorporated into the error estimation.

7. CONCLUSION

This article has described the basic principle, the numerical formulation, and some applications of the finite-element method for analysis of electromagnetic problems in RF and microwave engineering. It also has discussed briefly some computational aspects and advanced topics associated with the method. The finite-element method is a powerful analysis and design tool because it can model very complex geometries and can deal with a variety of media, including inhomogeneous and anisotropic cases. Moreover, the method yields a very sparse matrix that can be generated, stored, and solved efficiently.

The finite-element method in RF and microwave engineering, and electromagnetics in general, has undergone several important developments. For example, the development of vector elements enabled the correct modeling of the electric and magnetic vector fields for the first time. The development of higher-order versions of the vector elements permitted accurate and efficient modeling of large-scale field problems, especially wave propagation problems, because of the reduced interpolation and dispersion errors. The development of absorbing boundary conditions and perfectly matched layers [28,29] allowed fast, approximate analysis of wave radiation, scattering, and propagation problems. The development of the hybrid finite-element/boundary integral method provided a more reliable and robust approach to deal with these problems. It also created a mechanism to incorporate fast integral solvers into the finite-element simulations, such as FFT-based methods and the fast multipole method [30]. The hybridization with asymptotic methods [31] made it possible to analyze electrically very large scatterers with small and complex features. The development of adaptive methods [32] further enhanced the efficiency of the finite-element method and provided an error-controllable solution. The development of the time-domain finite-element method [33] enabled numerical modeling of nonlinear devices and materials and made efficient broadband simulation possible.

The material covered in this article represents only a fraction of the theory and application of the finite-element method in electromagnetics. With its continuous advancement and the rapid development of computer technology, RF and microwave devices will in future be designed routinely on computers in the same way as is done today with electronic circuit designs.

FINLINE COMPONENTS

WOLFGANG S. MENZEL
University of Ulm
Ulm, Germany

1. INTRODUCTION

The finline has been intensively investigated since 1970 as a planar transmission-line medium for millimeter-wave components. The electromagnetic wave is guided by slots in a metallization printed on a thin dielectric substrate. All passive circuit functions are realized by these slotline structures, partly in combination with other types of planar transmission lines, such as microstrips or coplanar lines printed on the same substrate. These circuits are correctly known as E -plane circuits, but the terms *finline* and E -plane circuits are often used interchangeably. Semiconductor devices, preferably beam-lead devices, can eas-

ily be soldered, glued, or bonded across the slot. The complete transmission line is held and shielded by a metal housing that most often has the (inner) dimension of the respective metal waveguide (Fig. 1). The transition from metal waveguide to finline can be achieved by tapering the finline slot to the waveguide height as shown in Fig. 1. Therefore, finline components can easily be combined with waveguide circuits. Because the circuit functions are determined by the planar structure, the tolerance requirements for this housing are considerably relaxed; thus this housing may be fabricated by low-cost methods such as metal casting or even plastic injection molding and electroplating.

Because of the relatively large transmission-line cross section, finline losses typically are lower than for microstrip or coplanar lines, but higher than those for metal waveguide. Typical finline types, cross sections, and propagation properties are described in detail in Ref. 1.

2. PASSIVE FINLINE COMPONENTS

2.1. Filters

Finline filters, especially band-pass and low-pass filters are based on transmission-line structures [2]. Bandpass filters typically are realized using either side-coupled (Fig. 2a) or end-coupled (Fig. 2b) resonators. To reduce losses, end-coupled filters may degenerate to pure E -plane waveguide filters as shown in Fig. 2c. In this case, the “slot width” is equal to the waveguide height, and no taper to waveguide is necessary; even the dielectric substrate material may be omitted, resulting in simple metal insert filters. For better stopband attenuation, bilateral finline or several side-by-side metal inserts may be used. These arrangements strongly suppress higher-order mode coupling and therefore improve the stopband behavior. Detailed descriptions of these kinds of filters, together with duplexers, are presented by Shih et al. [3] and Dittloff and Arndt [4].

Lowpass filters typically are based on low- and high-impedance line sections (Fig. 2d) or stub structures (Fig. 2e). High impedances are easily realized with wide slots. For uniplanar finline, the lowest impedance value is determined by the minimum slot width that can be technologically realized; for bilateral or antipodal finline, overlapping of the metallization may further reduce the characteristic impedance of the respective line segment. The discontinuities involved have to be included in the design procedure, especially for large steps in impedance.

Figure 1. Cross section of a (unilateral) finline and metallization pattern for a transition from waveguide to finline.

Figure 2. Typical metallization patterns of different finline filters: (a) side-coupled bandpass filter; (b) end-coupled bandpass filter; (c) end-coupled bandpass filter (the slot width has been increased to the waveguide height, losses are lower, and no taper to waveguide is required); (d) high-low impedance lowpass filter; (e) stub-type lowpass filter.

2.2. Directional Couplers

The design of a directional coupler in conjunction with finline was first reported by Meier [8] based on printed metal probes between two adjacent metal waveguides, placed in between two thin substrate layers in the E plane. Finline couplers, however, are designed mostly on the basis of coupled slots. Such a coupled transmission-line structure supports two modes; one is similar to the normal finline mode with the electric fields in the same direction, and the other one is a coplanar-type mode with zero cutoff frequency. The coupler design shown in Fig. 3a relies on a quarter-wave section of coupled lines. The fundamental principles of operation are comparable to those of respective couplers in the microstrip or microstrip/slot-line technique. The center strip may alternatively be replaced by a bond wire, or the metallization section containing the strip may be placed on the backside of the substrate (antipodal finline), thus achieving an increased design flexibility. Another coupler principle is based solely on the different phase velocity of the two modes on the coupled transmission line (Fig. 3b). Feeding a wave to one of the ports, an increasing part of the electromagnetic field couples from one slot to the other with increasing propagation distance; that is, the amount of coupling depends on the length of the coupled-line section.

Figure 3. Metallization patterns of two different finline couplers.

This length will be several wavelengths, but in the millimeter-wave range, this problem is reduced because of the short wavelength. In contrast to the coupler design shown in Fig. 3a, a smooth transition from the feedline to the coupled-line section with minimum reflections is mandatory. Furthermore, the coupling of the transition region contributes to the coupler performance. With both types of couplers, broadband performance over a complete waveguide band is achieved [5–7].

2.3. Nonreciprocal Components

Some effort has been made to develop circulators and isolators in finline or by a compatible E -plane technique. A ferrite sphere or a small cylinder is placed in the center of a finline Y junction to realize circulators [9,10]. For a field displacement type of isolator, an additional layer of ferrite substrate together with an absorbing sheet is added to the finline on a standard substrate [11]; optimization is done by full-wave calculations of the composite structure. Both approaches, however, lead to rather complex and therefore mechanically sensitive structures, so these are rarely used in practical applications.

A more successful approach is the realization of waveguide-type circulators in a metal waveguide, Y junction in the E plane [12]. A ferrite disk is placed into the junction. The diameter of the disk is equal to the inner diameter of the waveguide Y junction. The center frequency is determined by the height of the disk. A permanent magnet is placed into a hole in the waveguide mount close to the ferrite disk. This type of circulator, therefore, is fabricated easily, and is integrated into the E -plane split block together with single or integrated finline components, as

Figure 4. Waveguide mount and metallization pattern of a finline antenna. The planar substrate with the finline metallization protrudes out of the waveguide mount and acts as a slotline-type antenna.

shown later. Circulators of this type are even built up to the 140 GHz frequency range.

2.4. Finline Antennas

Extending the finline substrate out of the waveguide mount allows the realization of slotline or “Vivaldi”-type endfire antennas (Fig. 4). Beamform, sidelobe level, and bandwidth can be determined, to some extent, by the form of the tapered metallization structure and by a proper choice of the substrate thickness and its dielectric constant. Beamwidth, however, remains relatively wide associated with low gain. Applications of finline antennas are found in the integration of several antennas as an antenna array or as a feed cluster to form multiple beams in conjunction with lens or reflector antennas [13].

3. DIODE-BASED FINLINE COMPONENTS

Schottky diodes, pin diodes, and varactor diodes have been fabricated as beam-lead devices for many years and are ideally suited for integration into finline circuits. Because of their low parasitic capacitances and inductances, high-performance components with wide bandwidth can be built.

3.1. Detectors

For a finline detector, a low-barrier Schottky diode is placed across the finline slot. One of the finline metallizations has to be isolated from the metal mount by a thin dielectric sheet (10–20 μm). Alternatively, an oxidized aluminum mount is used. For broadband operation, some absorber material is placed behind the diode. Figure 5 is a

Figure 5. Basic setup of a finline detector. One of the finline metallizations is DC-isolated from the waveguide mount to allow extraction of the rectified output signal.

sketch of the detector layout. Detectors of this type are capable of zero-bias operation over one or two waveguide bands with sensitivities of several hundred millivolts (mV/mW) per milliwatt, and are even designed for frequencies up to 200 GHz and above [7,14].

3.2. pin Diode Attenuators and Switches

In the same way as with the detector, one or more beam-lead pin diodes can easily be placed across a finline slot. With bias applied to the pin diodes, these exhibit a low series resistance together with some parasitic inductance. Thus they basically short-circuit the finline slot. Without or with reverse bias, pin diodes load the finline slot only with their fairly low capacitance. Basically, two types of attenuator or switch have been developed. The first one uses diodes in the shunt configuration shown in Fig. 6a. Placing two or more diodes approximately a quarter-wavelength apart results in some compensation of the diode capacitance in the ON state of the switch, that is, without biasing the diodes or with reverse bias. Attenuators (the attenuation is controlled by the amount of diode bias) or switches of this type typically have an insertion loss of 0.5 dB in the Ka band (26–40 GHz) up to 1.5 dB in the W

Figure 6. Metallization patterns of finline shunt-type (a) and series-type (b) attenuator or switch, and single-pole double-throw (SPDT) switch with shunt diode configuration (c).

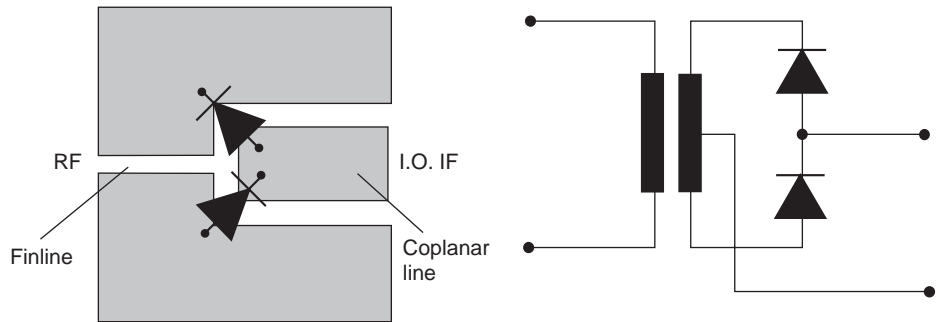

Figure 7. Basic principle of a balanced finline mixer and its equivalent circuit. The combination of finline and coplanar line forms an inherently broadband 180° hybrid junction.

band (75–110 GHz) over a nearly complete waveguide band. Maximum attenuation amounts to 15 dB per diode. For attenuation values higher than ~ 50 dB, parasitic power leakage along the DC isolation between the metallization pattern on the substrate and the waveguide mount is a concern, and absorbing isolating foils must be used to prevent this problem. For attenuators operating over even two waveguide bands, the finline can be placed in a ridged waveguide mount.

The second type of pin diode switch is based on a series configuration of the diode (Fig. 6b). A diode is placed across a lateral slot in the metallization. This slot is short-circuited for RF signals by the wall of the waveguide mount. Together with the diode capacitance, this stub forms a parallel resonator in the OFF position of the attenuator, whereas the stub is short-circuited in the ON position. Accordingly, this attenuator has a more narrow-band performance, but with increased attenuation for a single diode. Furthermore, it presents some advantages with respect to DC isolation from other components in integrated finline circuits. In the case of a single diode, the metallization at one side of the stub has to be DC-isolated from the waveguide mount. With two cascaded structures of this type, only the metallization between the stubs needs to be DC isolated (see also Section 5).

Two or three switches as described above, preferably those with the diodes in a shunt configuration, can also be arranged for single-pole double-throw (SPDT) or single-pole triple-throw (SPTT) switches, as shown in Fig. 6c. This results in performance similar to the single switches except for slightly increased losses due to the additional transmission line(s) loading. Further details and numerous results are described by Callsen et al. [15].

3.3. Finline Mixers

Although single-ended mixers are easily realized placing a beam-lead Schottky diode across the finline slot [8], much more effort has been put into the design of a balanced mixer based on a combination of finline and coplanar line as shown in Fig. 7. This structure gives an ideal combination for forming an inherently broadband, 180° , hybrid junction. The Schottky diodes are placed across the junction, in series with respect to the finline and antiparallel with respect to the coplanar line. The RF signal is fed to the diodes via the finline and the local oscillator (LO) signal via the coplanar line. Then the intermediate frequency

(IF) is also extracted from the coplanar line. Therefore, some diplexing circuit must be added to the coplanar line. This single balanced mixer design has inherent high mutual isolation between RF and LO ports (and RF and IF ports, respectively), but in practice this is limited by asymmetries in the circuit structure or the diodes.

Many mixers based on this configuration have been developed. Basic differences were found mainly in the LO/IF feeding arrangement. Some mixers use a transition from finline to coplanar line via an antipodal finline, as sketched in Fig. 8, possibly together with an end-coupled band-pass filter for the LO signal and a microstrip lowpass filter for the IF. A typical Ka-band finline filter of this type was presented by Ball and Bui [16] and is shown in the photograph in Fig. 9. Another design [7,17] uses a transition from finline to coplanar line based on magnetic coupling, as shown in Fig. 10. Very broadband performance and operating frequencies up to 150 GHz are reported [18] with this type of mixer. A photograph of a 140–150 GHz mixer is shown in Fig. 11.

Because sufficient LO power in the millimeter-wave frequency range is sometimes difficult or too expensive to generate, efforts have been undertaken to design subharmonically pumped mixers. For mixing with even harmonics of the LO frequency, two diodes are used in an antiparallel configuration. For odd harmonics, a circuit and diode configuration as used for the balanced mixer and shown in Fig. 7 can be employed. Together with suitable filter configurations (Fig. 12), mixers with a LO frequency at about half the RF frequency [19,20] and at much lower frequencies, for example, $f_{LO} \approx f_{RF}/8$ [21], have been realized.

Until the late 1990s, a major problem in the design of finline mixers was determination of the actual nonlinear

Figure 8. Layout of a transition from finline to coplanar line via an antipodal finline and a microstrip line.

Figure 9. Photograph of a Ka-band balanced finline mixer [16] (courtesy of Academic Press).

diode impedances for signal, LO, and IF frequency. The problem is even more challenging as the diodes are placed in a major discontinuity (Fig. 7) where parasitic capacitances and inductances affect the impedances seen by input and output transmission lines. This problem now has been solved applying a full-wave finite difference in time-domain (FDTD) field solver, including lumped nonlinear elements such as the mixer diodes [22]. The mixer diodes are represented by a suitable equivalent circuit (valid up to the respective frequency of operation) and embedded into the FDTD computation. In the millimeter-wave range,

the actual size of the beam-lead diodes can be accounted for by distributing the equivalent circuit over several cells of the FDTD grid. The nonlinear response of the diodes to the LO power is calculated by a harmonic excitation of the diodes, including the actual power level. Following this, a

small-signal, modulated Gaussian pulse is fed to the signal port of the mixer (with the LO signal still present). From the reflected signals, the return loss at the respective ports is computed, and the conversion loss is extracted from the input signal and the IF output signal. On the basis of these calculations, a matching and an optimization of (harmonic) mixers are possible. An example of a harmonic mixer with the LO frequency at about one-third of the signal frequency is shown in Fig. 13. A conversion loss of down to 15 dB for a 60-GHz third-harmonic mixer is achieved using low-cost silicon Schottky diodes (Fig. 14).

3.4. Phase Shifters

Finline phase shifters are based on two different principles. The first one uses a 3-dB coupler described earlier in this article together with pin diode switches to modify the two output port loads [6]. The other principle uses a

Figure 13. Layout of the key section of a third-harmonic 60-GHz mixer that has been optimized using a FDTD calculation. The steps in widths of slot and strips as well as the backside metallization under the LO/IF line provide the impedance matching for the different ports.

Figure 14. Conversion loss of the third-harmonic 60-GHz mixer. As a result of the full-wave calculation, even resonances can be predicted and shifted to uncritical frequencies.

configuration very similar to that of the balanced mixer (see Figs. 7 and 10 and (Refs. 23 and 24)). For the phase shifter, either pin or Schottky diodes are alternatively switched to the ON or OFF state via a bias applied to the coplanar line. With an appropriate matching of the circuitry, signal transmission between the finline port (RF port in the mixer case) and the coplanar port (LO port of the mixer) undergoes a phase differences of 180° depending on the sign of the control voltage, that is, depending on which diode is in the ON (biased) state.

4. FINLINE OSCILLATORS AND AMPLIFIERS

A number of efforts have been made to realize oscillators by the integrated finline technique. A basic problem is always heat removal from the active elements. Therefore, Gunn elements are usually used screwed directly into the broadside of the waveguide mount. Then the diode cap is soldered directly to one side of the finline metallization, which contains the necessary resonance and matching circuits (Fig. 15). Final tuning is typically done with a backshort in the metal waveguide behind the diode. A more detailed review of finline oscillators is given by Hofer [25]. Although some oscillators are used in integrated finline front ends (see next section), they have not proved suitable for high-volume and low-cost applications.

Some authors published designs of “finline” amplifiers [25,26]. Their arrangements, however, basically are microstrip FET amplifiers with transitions to finline, and

Figure 15. Basic setup of a finline Gunn oscillator. The Gunn element is screwed directly into the waveguide mount; resonance and matching structures are integrated into the planar structure.

they use the waveguide mount as some kind of package. Furthermore, because finline does not lend itself easily to a monolithic integration, amplifier design in finline was not pursued further.

5. INTEGRATED FINLINE COMPONENTS AND FRONT ENDS

The major advantages of planar components are exploited by integrating several components to “supercomponents” or complete front ends. With respect to finline, this can be done in two different ways. Because finline circuits consist of planar circuits and waveguide mounts, a first step is to integrate several finline circuits in a single waveguide mount, although each circuit still has its own transition(s) to waveguide. This concept allows optimizing and testing all finline circuits separately and combining them with waveguide circuits like oscillators, waveguide filters, or circulators realized in a waveguide mount split in the E plane. The complete waveguide mount can be fabricated using computer-controlled milling or, for high-production quantities, using plastic injection molding and electroplating. Some disadvantages of this arrangement are increased losses due to the repeated tapers from waveguide to finline and possibly some problems with interaction of components over greater distances causing an increased ripple in transmission and return loss behavior. Integrated front ends of this type have been realized for communication equipment in the Ka band [27], for military surveillance receivers [28], and for radar front ends for military seeker heads [29] or automotive radars for intelligent cruise control [30]. For example, Barnes et al. [27], describe a transmitter front end for a 29-GHz communication system that includes an E -plane waveguide circulator, two couplers, a pin diode biphase modulator, and a pin diode attenuator. The power is generated by an external Gunn oscillator. An E -plane, metal insert, bandpass filter is added to this unit with an additional waveguide mount.

An even higher degree of integration is achieved by integrating several components on a single substrate with direct finline interconnects, that is, without transitions from finline to waveguide and back to finline. This technique results much smaller components with reduced losses. Furthermore, the single components are placed close together, thus avoiding strong phase variations from mutual interactions as a function of frequency. On the other hand, the single components in such a supercomponent can no longer be tested separately.

A number of integrated front ends of this type have been realized by the author and his group, starting with the integration of balanced mixer and pin diode attenuators acting as sensitivity time control (STC) for radar applications [31] or as Dicke switch for a radiometer [32].

Figure 16 shows the opened waveguide mount with a quartz substrate containing a 94-GHz mixer and a SPDT switch. Two diodes in each of the two input arms of the circuit are mounted with opposite polarities. Thus only a single control input for the Dicke switch is necessary. Efforts were also made to integrate Gunn oscillators as shown previously (Fig. 15). In Ref. 32, the integration of

Figure 16. Photograph of a 94-GHz integrated finline circuit including a balanced mixer and a pin diode SPDT. The waveguide split block is opened to observe the quartz substrate with the planar circuit.

a mixer with a two-diode series type of pin diode attenuator (Fig. 6b) and a Gunn oscillator as LO is demonstrated (see photograph of Fig. 17). In this example, the series type of pin diode attenuator is used favorably for bias isolation; only the finline metallization between the two stubs loaded with the diodes must be DC-isolated.

Even the integration of a Ka-band pulse radar sensor on a single substrate including pulse oscillator and LO, an SPDT switch as a transmit/receive switch, a series type pin diode STC, and a balanced mixer were demonstrated [31].

Figure 17. Photograph of a 60-GHz integrated finline receiver consisting of a Gunn oscillator as LO, a balanced mixer, and a series-type pin diode attenuator. The Gunn element is screwed into a copper heatsink in the waveguide mount; the series pin diode attenuator allows a DC isolation with respect to the other components.

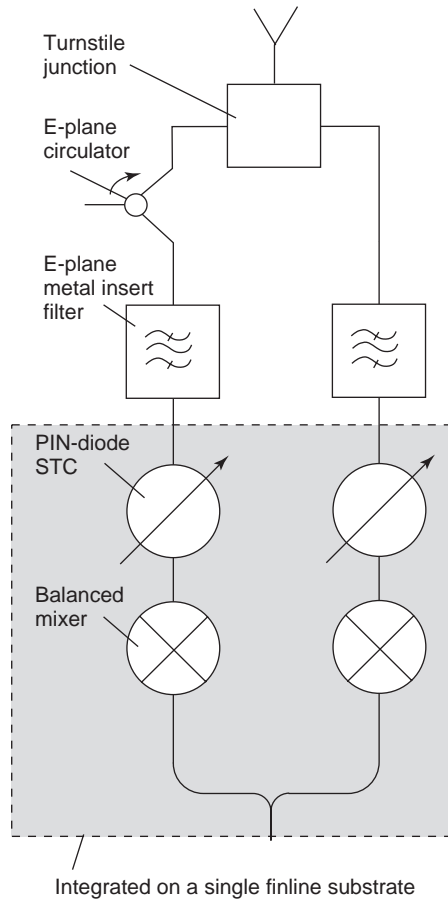

Figure 18. Block diagram of an integrated dual-channel 94-GHz radar receiver front end. All components (except for the turnstile junction) are combined in a single *E*-plane split-block mount. Balanced mixers, pin diode STCs, and the LO power divider are integrated on a single substrate.

For a 94-GHz dual-polarization radar, an integrated receiver front end was realized using both an integrated finline circuit (2 mixers, 2 pin diode STCs, and a power

 Höchstfrequenztechnik

Finlines are guiding structures for electromagnetic waves that consist of one or several metallic fins suspended in

the *E* plane of a waveguide enclosure. They are the basic transmission media for the so-called integrated *E*-plane circuit technology. The fins can either be suspended freely (metallic *E*-plane lines) or supported by dielectric substrates of low permittivity. The general term “finline” usually applies to the latter type, and there exist many variations that are classified according to the manner in which the metallization is placed on the substrate, and how the planar structure is mounted in the enclosure.

Finlines are applied predominantly in the frequency range between 10 and 100 GHz; but some applications at frequencies up to 170 GHz have been realized. Having losses of typically 0.1 dB per wavelength, finlines are not suitable for long-distance transmission. However, they excel as a circuit medium for millimeter-wave components and systems due to their low manufacturing cost, wide single-mode bandwidth, compatibility with discrete active and passive devices, and suitability for integration with other hybrid circuit techniques as well as with standard rectangular waveguides. Manufacturing costs are moderate for two reasons: (1) the planar insert can be fabricated using printed-circuit batch processing; (2) since the circuit characteristics are dominated by the topology of the printed insert, dimensional tolerances for the waveguide enclosure can be greatly relaxed (typically by a factor of 5 compared with standard waveguide). The enclosure also prevents radiation losses, reduces susceptibility to outside interference, and may act as a heatsink for active devices. Unfortunately, there is a price to pay for the technological advantages of finlines; their analysis and design are difficult because of the metallic edges that lead to field singularities, the presence of two or more different dielectrics in the structure giving rise to hybrid modes of propagation, and to structural complications necessary for mounting the substrate and for biasing of devices.

1. A BRIEF HISTORY

Since the early 1940s it has been known that one or two metallic ridges in the *E* plane of a rectangular waveguide increased its single-mode bandwidth and lowered its characteristic impedance. In particular, Cohn [1] pointed out the potential of this feature for realizing impedance transformers, tapers, filters, slow-wave structures, and broadband matched loads by simply changing the ridge depth; Hopfer [2] published extensive and accurate data for the cutoff frequencies, characteristic impedances and power-handling capability of ridged waveguides. While the ridge waveguide is not truly quasiplanar, its early theoretical treatment and the manner in which circuit functions were realized have laid the groundwork for the design and realization of finline circuits. In 1955, Robertson [3] built the first truly planar finline component. It was a circular-to-rectangular waveguide coupler fitted with a pair of thin metal fins. Robertson recognized that this technique was suitable for very broadband hybrids, directional and polarization-sensitive couplers. Sixteen years later, Konishi and Hoshino [4] reported a 100-GHz converter featuring a planar metallic circuit in a waveguide. However, the major development in the evolution of *E*-plane technology was

Meier's invention of the "integrated finline" in 1972 [5–7], for which he received the Microwave Application Award of the IEEE-MTT society in 1984. By supporting the planar conducting fins with a thin, low-permittivity substrate, Meier extended thin-film fabrication techniques to E -plane circuitry and gained additional advantages such as DC isolation of the fins for bias purposes, intermediate-frequency (IF) and modulation connections, and mechanical support for discrete devices mounted in parallel or in series with the fins.

Meier's invention spurred intense international research activities and product development. First commercial finline products were announced in the late 1970s. They included mixers, broadband switches, attenuators, detectors, and complete integrated radar front ends for frequencies up to 140 GHz [8–12].

2. CLASSIFICATION OF FINLINES

Finline structures can be viewed as derivatives of the four generic structures shown in Fig. 1. In fact, they share some of their characteristics and can be reduced to any of them. A finline is thus created either by placing a slotline into the E plane of a rectangular waveguide, by partially loading a ridge waveguide with dielectric, or by partially metallizing the dielectric in a slab-loaded waveguide. Four basic types of finlines may result; their simplified cross sections are shown in Figs. 2a–2d. Insulated, unilateral, bilateral, and antipodal finlines can be distinguished by the way in which their fins are arranged on the substrate. Further variations of each type are obtained by moving the substrate or the slot away from the symmetric position, or by adding further planar inserts, strips, or slots. For example, Figs. 2e and 2f show cross sections of asymmetric finlines.

3. CONSTRUCTION OF FINLINES

A finline consists of printed metallic fins on a substrate (the planar insert) and a metallic housing that holds the insert and confines the electromagnetic fields. Both soft and hard substrate materials may be used. Fiberglass-reinforced Teflon (RT Duroid, $\epsilon_r = 2.2$) is the most widely

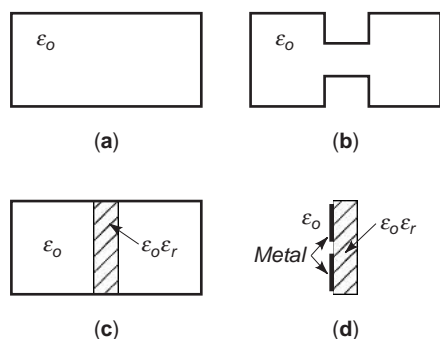

Figure 1. The four generic waveguides from which finlines can be derived: (a) rectangular waveguide; (b) double-ridged waveguide; (c) slab-loaded waveguide; (d) slotline.

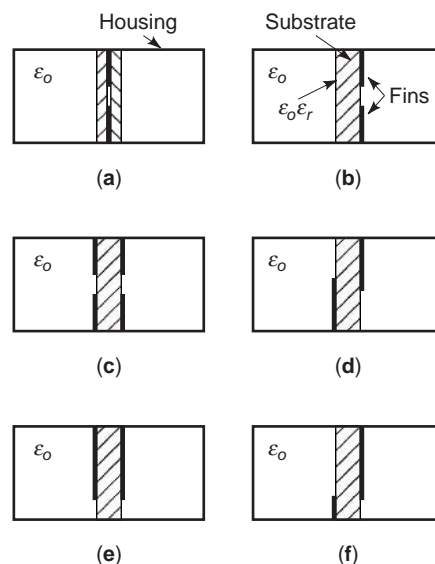

Figure 2. The four basic finline types and some of their variants: (a) insulated finline; (b) unilateral finline; (c) bilateral finline; (d) antipodal finline; (e) asymmetric bilateral finline; (f) asymmetric antipodal finline.

used soft substrate material. It is easily processed and cut, costs little, and has low dielectric permittivity and losses. It is employed mostly at lower millimetric frequencies; a thickness of 0.01 in. (0.254 mm) is suitable for components up to 40 GHz, and 0.005 in. (0.127 mm) is used for frequencies up to 90 GHz. Finline components and circuits of highest quality and for frequencies beyond 90 GHz call for quartz substrates ($\epsilon_r = 3.75$) which are more expensive, fragile, and difficult to process, but provide better mechanical support for delicate semiconductor devices. The housing is usually machined from brass or aluminum in the form of a split block. Metallized Plexiglas has also been used with mixed results because of adhesion problems. Three housing configurations (Fig. 3) can be found in practice.

The first type has been proposed by Meier [6]. Two Π -shaped metal pieces clamp the planar insert (Fig. 3a) held in place by nylon screws. Since the substrate extends beyond the confines of the inner waveguide channel, this configuration is partially open. To minimize RF leakage, the clamping region is made $\lambda_d/4$ wide, where λ_d is the wavelength in the dielectric substrate at midband frequency. Furthermore, to suppress the excitation of TEM-type modes in the slot region, longitudinal current flow must be impeded by serrating the substrate metallization in the slot region [42]. On the other hand, since one of the fins can be isolated from the housing with a dielectric insert, bias is easily supplied to embedded semiconductor devices.

The second type has been proposed by Adelseck et al. [8]. Here, the two halves of the split block touch each other, thus completely shielding the finline (Fig. 3b). A shallow groove is machined into one of the blocks to accommodate the substrate. However, stringent mechanical tolerances (typically $\pm 10\mu\text{m}$) must be maintained

Figure 3. Three types of finline construction: (a) finline mount proposed by Meier; (b) finline mount proposed by Adelseck et al. (c) combination of (a) and (b) for hard substrates and high frequencies. (After Meier [6], copyright © 1974 IEEE, reprinted with permission.)

here. If the groove is too wide, poor contact between the fins and the housing can introduce considerable attenuation. If the groove is too narrow, hard substrates may break, and soft substrates may be compressed and pushed out into the waveguide channel, causing bending and possibly rupture of delicate leads of devices. Bias can be fed locally to the clamping region through the metal block, and fins can be insulated from the housing by inserting a thin Mylar sheet into the groove.

The third type combines the features of both approaches (Fig. 3c). It is suitable for quartz substrates at high frequencies (90 GHz and above), where machining tolerances become prohibitive because of the small size of the groove. As in type 1, the walls of the waveguide channel are made $\lambda_d/4$ wide to form a choke, but the substrate protrudes on either side into a secondary channel that contains RF absorbing material. In this way the finline is sealed. Fins can be biased by inserting a thin insulating sheet between fins and housing, and by contacting the fins through a feed connection.

All three techniques have been used successfully in the realization of finline components. Acceleration tests have shown that components of types 2 and 3 with hard substrates can survive up to 30,000 *g* for 2 ms, while components with soft substrates withstand 2000 *g* for 0.5 ms or shocks of up to 4000 *g* [9].

4. BASIC ELECTROMAGNETIC PROPERTIES OF FINLINES

The most important properties are the propagation constant and the characteristic impedance associated with the dominant mode of propagation. These depend on the geometry of the cross section, the substrate permittivity, and the frequency of operation. Furthermore, the single-mode bandwidth is proportional to the separation between the cutoff frequencies of the dominant and the first higher-order mode. If finline discontinuities are to be analyzed using mode matching in the longitudinal direction, a significant number of higher-order modes must be characterized as well. While the generic topologies in Fig. 2 yield the characteristics of real finlines quite accurately at lower frequencies, the influence of the geometric details shown in Fig. 3, such as the substrate mounting grooves and the finite thickness of the metal fins, must be included in the analysis and design of practical components, particularly at higher frequencies where the size of these features is not negligible vis-à-vis the dimensions of the waveguide channel and the substrate thickness.

Similar to regular waveguides, finlines are dispersive; that is, their guided wavelength λ_g changes nonlinearly with frequency. In waveguides without partial dielectric filling, the guided wavelength λ_g (or propagation constant β) at any frequency above cutoff can be calculated from the knowledge of the cutoff wavelength λ_c with the well-known formula

$$\lambda_g = \frac{\omega}{\beta} = \frac{\lambda}{\sqrt{1 - (\lambda/\lambda_c)^2}} \quad (1)$$

However, as soon as the waveguide is partially filled with a dielectric material, this formula no longer applies. With increasing frequency, more of the wave energy tends to concentrate inside the material with the higher permittivity, slowing down the propagation velocity. This effect is not included in Eq. (1). To accurately determine the guided wavelength in a finline at any frequency above cutoff, the field problem must be solved separately for each frequency.

As in all waveguides carrying non-TEM waves, voltage and characteristic impedance are not uniquely defined. While the voltage is usually obtained by integrating the electric field in the slot along the shortest path on the substrate surface, impedance definitions vary with the application, and the most appropriate definition must be established on a case-by-case basis. Meinel and Rembold [10] found that the voltage-current definition $Z_{v,i} = (\text{voltage across the slot})/(\text{current in the fins})$ was most appropriate for predicting the interaction of finlines with discrete devices, while Knorr and Shayda [14] reported best results with the ridged waveguide definition and Willing and Spielmann [15] preferred the voltage-power definition $Z_{v,p} = (\text{voltage across the slot})/(2 \times \text{average power transmitted})$.

There exist a variety of techniques for the computation of finline parameters, ranging from approximate analytical expressions to sophisticated numerical procedures. They will be outlined briefly in the following. For detailed information the reader is invited to consult to the appropriate references given in the bibliography.

4.1. Approximate Methods of Finline Analysis

Since most finlines are made with low-permittivity substrates such as RT Duroid ($\epsilon_r = 2.2$) or quartz ($\epsilon_r = 3.75$) that occupies only a small fraction of the waveguide cross section, their dispersion characteristics can be approximated by the behavior of commensurate waveguides that are filled uniformly with a fictitious frequency-independent dielectric of permittivity $\epsilon_0 \epsilon_{re}$ (Fig. 4). (The permittivity of this fictitious dielectric ϵ_{re} is called the equivalent dielectric constant to distinguish it from the so-called effective dielectric constant $\epsilon_{eff} = (\lambda/\lambda_g)^2$ of a finline.) The uniformly filled ridge waveguide obeys a rather simple dispersion formula for the guided wavelength λ_g and the characteristic impedance Z_0 :

$$\lambda_g = \frac{\lambda}{\sqrt{\epsilon_{re} - (\lambda/\lambda_c)^2}}; \quad Z_0 = \frac{Z_\infty}{\sqrt{\epsilon_{re} - (\lambda/\lambda_c)^2}} \quad (2)$$

According to Meier [6], these expressions agree with measurements within $\pm 2\%$ when λ_c and Z_∞ are the cutoff wavelength and characteristic impedance at infinite frequency of an air-filled ridge waveguide of identical dimensions (available from Cohn’s [1] or Hopfer’s [2] paper, or from other published data), and ϵ_{re} has been determined by measuring the guided wavelength of a test structure at a single frequency in mid-band [6].

Figure 4. Insulated finline and its equivalent ridged waveguide with identical cross section and uniform dielectric filling of permittivity $\epsilon_0 \epsilon_{re}$.

More accurate results can be obtained by the transverse resonance approach that has previously been applied by Cohn [16] and other researchers to analyze ridge waveguides, slab-loaded waveguides, and slotlines. In the simplest formulation, the dominant mode in the finline is considered to be a TE mode in the transverse direction that resonates between the two sidewalls of the enclosure. In transverse direction, the finline thus appears as a chain of piecewise homogeneous waveguide sections of width $\lambda_g/2$ (λ_g is the wavelength in longitudinal direction of the finline and corresponds to the cutoff wavelength of the transverse waveguide sections). The fins form a capacitive transverse discontinuity. The characteristic admittances and propagation constants of the subsections are those of homogeneous waveguides. The corresponding equivalent circuit is shown in Fig. 5; its transverse resonance condition is obtained by setting the total admittance in the plane of the fins equal to zero

$$\frac{B}{Y_a} - \cot \beta_a h - \frac{Y_d}{Y_a} \cot \beta_d \left\{ d + \frac{1}{\beta_d} \tan^{-1} \left[\frac{Y_d}{Y_a} \tan \beta_a (a - d - h) \right] \right\} = 0 \quad (3)$$

where

$$\beta_a = \frac{2\pi}{\lambda} \sqrt{1 - (\lambda/\lambda_g)^2},$$

$$\beta_d = \frac{2\pi}{\lambda} \sqrt{\epsilon_r - (\lambda/\lambda_g)^2} \quad \text{and} \quad \frac{Y_d}{Y_a} = \frac{\beta_d}{\beta_a}$$

By fixing the guided wavelength λ_g and solving Eq. (3) for λ , one obtains the frequencies at which the dominant and higher-order modes propagate down the finline with that wavelength λ_g . The accuracy of the solution depends essentially on the accuracy of the capacitive susceptance B , and the various transverse resonance approaches reported in the literature differ in the way in which this susceptance is determined. They range from quasistatic approximations to variational expressions and mode-matching solutions [17–20]. The group of approximate methods also comprises the empirical closed-form equations that are essentially formulas fitted to more accurate numerical results [21,22]. Their advantage resides in their simplicity and their suitability for synthesis, but they are limited to certain combinations of parameters and have lost some of their attractiveness due to the proliferation of high-performance computers that yield more rigorous numerical solutions almost instantly.

Figure 5. (a) Unilateral finline; (b) and its equivalent transverse network.

4.2. Rigorous Methods of Finline Analysis

Rigorous methods yield field solutions by solving Maxwell's equations subject to the boundary conditions imposed by the finline geometry. Several are based on the method of moments, from the first formulation in the space domain by Hofmann [23] to the spectral domain approaches described by Itoh [24], Knorr and Shayda [14], and Schmidt and Itoh [25]. A mode-matching solution was proposed by Beyer and Wolff [61], and a modified mode-matching approach was presented by Vahldieck and Bornemann [26,27]. A singular integral equation formulation was proposed by Omar and Schuenemann [28].

In all these approaches the fields in the dielectric and air-filled subregions of the finline are expressed in terms of rectangular waveguide TE and TM modes resonating in transverse direction, also called *longitudinal section electric* (LSE) and *longitudinal section magnetic* (LSM) modes. In fact, each of these modes must satisfy a condition similar to Eq. (3). The modal coefficients are determined such that their superposition satisfies all boundary and interface conditions, in particular, the edge condition at the metal fins where most of the energy in the structure is concentrated. Approaches differ in the way in which the relationship between slot field and fin current distributions is formulated. In the space domain formulation, this relationship takes the form of integral equations. Their kernels are the Green functions of the housing and substrate without the metal fins. These integral equations are then solved with the method of moments and Galerkin's procedure (identical basis and testing functions are used).

By performing a spatial Fourier transformation of all fields and currents with respect to the coordinates parallel to the substrate plane, one can transform the integral equations into a set of algebraic equations. The resulting spectral-domain formulation leads to a very efficient algorithm for the dominant and first higher-order finline eigensolutions and eigenvectors, especially when the slot fields or fin currents are developed into physically realistic basis functions that individually satisfy all the boundary and edge conditions in the plane of the fins. In fact, only a single constant basis function for the slot field is sufficient to determine the dominant wavenumber within 2–3%. However, the spectral-domain method is restricted to idealized finline geometries (no mounting grooves, zero metallization thickness). It is also less suitable than the singular integral formulation for determining eigensolutions of high order because the set of required basis functions for the slot field or fin current grows quickly in size and complexity.

The general mode matching approach that enforces conservation of tangential field components or complex power across all boundaries between subregions can take these realistic features into account more readily, as can the well-known family of space discrete solution methods, such as the finite-difference, finite-element, and TLM methods of analysis, in both their frequency and time-domain formulations, or the method of lines. A detailed description of these methods with extensive bibliographies can be found in Refs. 29 and 30. However, the salient features of the most frequently employed rigorous methods of

finline analysis, namely, the spectral-domain and the mode-matching methods, will be summarized in the following, together with some typical results.

4.2.1. Spectral-Domain Analysis of Finline. In the spectral-domain formulation the Fourier transform of the Green functions $\tilde{\mathbf{G}}_{ij}$ in the finline (expressed in terms of LSE and LSM modes) relates the transforms of the electric field in the slot with those of the current density on the fins via the equation

$$\begin{bmatrix} \tilde{\mathbf{G}}_{11}(\alpha_n, \beta, k_0) & \tilde{\mathbf{G}}_{12}(\alpha_n, \beta, k_0) \\ \tilde{\mathbf{G}}_{21}(\alpha_n, \beta, k_0) & \tilde{\mathbf{G}}_{22}(\alpha_n, \beta, k_0) \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{E}}_x(\alpha_n) \\ \tilde{\mathbf{E}}_z(\alpha_n) \end{bmatrix} = \begin{bmatrix} \tilde{\mathbf{J}}_x(\alpha_n) \\ \tilde{\mathbf{J}}_z(\alpha_n) \end{bmatrix} \quad (4)$$

$$\tilde{\mathbf{G}}_{11} = -(\alpha_n^2 Z_{\text{LSE}} + \beta_n^2 Z_{\text{LSM}})/(\alpha_n^2 + \beta_n^2)$$

$$\tilde{\mathbf{G}}_{12} = \tilde{\mathbf{G}}_{21} = -\alpha_n \beta_n (Z_{\text{LSE}} - Z_{\text{LSM}})/(\alpha_n^2 + \beta_n^2)$$

$$\tilde{\mathbf{G}}_{22} = -(\alpha_n^2 Z_{\text{LSE}} + \beta_n^2 Z_{\text{LSM}})/(\alpha_n^2 + \beta_n^2)$$

where Z_{LSE} and Z_{LSM} are the impedances seen from the nodes of the current source, looking into the respective equivalent circuits of Fig. 6b and 6c. α_n is the Fourier variable, $\beta = 2\pi/\lambda_g$ is the propagation constant in the axial direction, and k_0 is the free-space wavenumber; $\tilde{\mathbf{E}}_x$, $\tilde{\mathbf{E}}_z$, $\tilde{\mathbf{J}}_x$, and $\tilde{\mathbf{J}}_z$ are the electric fields in the slot and the current densities on the fins, respectively. This relationship is most readily formulated using Itoh's [24] immittance approach. Figure 6 shows the cross section of a unilateral finline, together with the equivalent transverse modal circuits for the immittance formulation of the Green functions. The slot fields and fin currents are expressed in terms of known basis functions with unknown coefficients. Applying Galerkin's procedure and Parseval's theorem results in a set of algebraic equations. The roots of the characteristic equation yield the eigenvalues of the finline.

The method is particularly efficient when basis functions are selected that satisfy already the edge condition at the fins. Thus, only a few basis functions are necessary to accurately describe the field in the slot or the current density on the fins. Once the coefficients of the basis

Figure 6. Cross section of a unilateral finline (a) and its equivalent transverse modal circuits for LSE (b) and LSM (c) modes.

functions are determined, the field functions inside the structure can be derived, and quantities such as slot voltage, fin current and characteristic impedances can be determined by appropriate integration over the field functions. Figure 7 shows the effective dielectric constant and voltage–power impedance of the unilateral finline in Fig. 6, computed with a single constant basis function for E_x in the slot. The enclosure is a standard WR-28 rectangular waveguide.

As mentioned earlier, geometric details such as the substrate mounting grooves and finite metallization thickness must be accounted for in practical realizations, particularly at higher frequencies. These can easily be included in the mode-matching analysis. Representative finline characteristics obtained with this approach will be presented in the following as well.

Two typical finline structures with realistic geometric details are presented in Fig. 8. Depending on the application, structures that support quasi-TEM modes (Fig. 8a) or configurations with pure slotline layout (Fig. 8b) are utilized. The principal difference between the two types is that in the first the dominant mode of propagation is the quasi-TEM mode without a lower cutoff frequency, while in the slotline structure the dominant mode is limited by a cutoff frequency that is determined mainly by the width of the slot(s).

Both types of finlines carry hybrid modes due to the presence of the dielectric substrate that supports the fins. Hybrid modes are neither TE nor TM but a combination of both, denoted as either HE or EH modes with all six field components present; HE modes are those with a predominant H_z field component, while EH modes exhibit a stronger E_z field component. Only at cutoff are these modes purely of type TE or TM. These modes often carry the same indices as TE and TM modes, such as HE_{nm} or EH_{nm} , indicating that the latter two originate from the corresponding TE or TM modes at cutoff. At frequencies

Figure 7. Effective dielectric constant and voltage–power impedance of the unilateral finline shown in Fig. 6, computed with the spectral–domain method using a single constant basis function for the slot field E_x . The dimensions are: $a = 7.112$ mm; $b = 3.556$ mm; $h = 3.429$ mm; $d = 0.254$ mm; $\epsilon_r = 2.2$.

Figure 8. Two basic finline structures with finite metallization and substrate mounting grooves (t = finite metallization thickness, e = depth of mounting grooves, a = waveguide width, b = waveguide height): (a) edge-coupled unilateral finline; (b) asymmetric bilateral finline.

above cutoff, the field configuration of the individual hybrid modes can differ significantly from the TE and TM modes. Therefore, hybrid modes are equally often numbered according to the sequence at which they occur, such as HE_n and EH_m .

In the mode-matching approach, the finite metallization thickness and substrate mounting grooves are taken into account from the outset. It yields a somewhat longer guided wavelength than spectral domain analysis since a higher percentage of the electric field travels in air within the slot region. The hybrid modes are derived from the z components of the magnetic and electric vector potentials $\vec{\phi}_h$ and $\vec{\theta}_e$, respectively

$$\begin{aligned} \vec{E} &= \nabla \times \vec{\phi}_{hz} + \frac{1}{j\omega\epsilon} \nabla \times \nabla \times \vec{\theta}_{ez} \\ \vec{H} &= \nabla \times \vec{\theta}_{ez} - \frac{1}{j\omega\epsilon} \nabla \times \nabla \times \vec{\phi}_{hz} \end{aligned} \quad (5)$$

where

$$\begin{aligned} \phi_{hz} &= \sum_n Q_n^h(x) f_n(y) e^{-j\beta_n z} \\ \theta_{ez} &= \sum_n P_n^e(x) g_n(y) e^{-j\beta_n z} \end{aligned} \quad (6)$$

Q , P , f and g denote transverse eigenfunctions defined in each subregion of the finline cross section (i.e., regions 1, 2a, 2b, 3, 4 in Fig. 8a). The electric and magnetic fields tangential to the interfaces between the subregions are proportional to the vector potentials and their derivatives

$$E_y \propto \frac{dQ^h}{dx} = P^h, E_z \propto P^e, H_z \propto Q^h, H_y \propto \frac{dP^e}{dx} = Q^e \quad (7)$$

Matching the tangential field components at each interface and utilizing the orthogonality of modes leads to one coupling matrix (C_μ for $\mu = 1, 2a, 2b, 3, 4$) per interface. The coupling matrices can be linked successively by transferring the electric and magnetic fields from one boundary of a subregion to the opposite one. These transfer matrices (T_μ for $\mu = 1, 2a, 2b, 3, 4$) are the generalized (fundamental and higher-order modes) transmission-line equations in

each subregion. The resulting matrix equation yields

$$\begin{bmatrix} P^h = 0 \\ P^e = 0 \\ Q^h \\ Q^e \end{bmatrix}_{x=0} = \underbrace{\prod_{n=1}^{n=3} T^n C^n T^d}_G \begin{bmatrix} P^h = 0 \\ P^e = 0 \\ Q^h \\ Q^e \end{bmatrix}_{x=a} \quad (8)$$

From the resonance condition in Eq. (8) the characteristic equation G_{12} is obtained. Solving for $\det(G_{12})=0$ yields the propagation constant β or guided wavelength λ_g . Typical dispersion characteristics obtained in this way for the first six eigenmodes in a unilateral finline are shown in Fig. 9. The modes that are not excited by an incident TE_{10} mode are dashed. The first important higher-order mode is thus HE_3 ; the single-mode bandwidth of the dominant mode is situated between the cutoff frequencies of HE_1 and HE_3 (frequencies at which the curves intersect the frequency axis). Note that these dispersion curves change with both the groove depth e and the metallization thickness t as shown in the following.

4.2.2. Effect of Mounting Grooves. Mounting grooves are required to hold the substrate in the waveguide housing. A detailed analysis of the effect of the groove depth on the modes is given in Refs. 26 and 31. It was found that for unilateral finlines the cutoff frequencies of higher-order modes react very sensitively to the groove depth (e in Fig. 8), which for one-fifth of the waveguide height reduces the cutoff frequency of higher-order modes to such an extent that the finline is useless for most practical purposes. This is due to modes that originate from the TE_{20} (HE_3) and TE_{01} (HE_2) modes of the empty waveguide. Both modes appear to be coupled, are highly concentrated between the metallization within the substrate, and are thus very sensitive to changes in the groove depth. This effect is particularly pronounced in Fig. 10. The asymmetric bilateral finline carries an additional metallic strip inside the

Figure 9. Dispersion characteristics of the first six hybrid eigenmodes in a unilateral finline. The dashed curves indicate modes that are not excited by the incident TE_{10} mode. The dimensions are $a = 1.65$ mm; $b = a/2$, $e = 0.5$ mm; $t = 5$ μ m, $\epsilon_r = 3.75$. (After Vahldieck [26], copyright © 1984 IEEE, reprinted with permission.)

Figure 10. Dispersion characteristics of an asymmetric bilateral finline with an additional metallic strip in the gap on the right-hand side of the substrate. The modes appear to be strongly coupled and are very sensitive to changes in the groove depth. The dimensions are $a = 7.112$ mm; $b = 3.556$ mm; $e = 0.7$ mm; $t = 71$ μ m, $\epsilon_r = 10$. (After Vahldieck and Bornemann [27], copyright © 1985 IEEE, reprinted with permission.)

gap on the right-hand side of the substrate. For centered fin-lines this interaction between modes is greatly reduced since some of them will not be excited. This is not the case for unilateral finlines. However, since the metallization is only on one side of the substrate, the problem is not as pronounced.

4.2.3. Effect of Finite Metallization Thickness. The effect of finite metallization on the propagation constant and the characteristic impedance has been investigated by several researchers [26,31–33,62]. A typical behavior of the dominant mode in a unilateral finline with three different values of metallization thickness is shown in Fig. 11. The effect of mounting grooves is not included here. The characteristic impedance is reduced throughout the operating bandwidth when the metallization becomes thicker. This is consistent with the behavior of the ridge waveguide [1,2], where the capacitive loading of the waveguide increases when the ridge becomes wider. However, the propagation constant is not affected in the same way at lower and at higher frequencies. While the cutoff frequency is reduced by thicker metallization for the same reason as the characteristic impedance, the effect is reversed at higher frequencies; because of the wider airgap between thicker fins, more of the field energy travels in the airgap and less is concentrated in the dielectric, leading to a higher phase velocity. As a result, there is a crossover of the dispersion curves at midband. In conclusion, the effect

Figure 11. Effect of metallization thickness on the dispersion characteristics and the characteristic impedance of a unilateral finline. The dimensions are $a = 4.776$ mm; $b = 2.388$ mm; $d = 0.127$ mm; $w = 0.2b$; $\epsilon_r = 3.8$. (After Kitazawa and Mittra [32], copyright © 1984 IEEE, reprinted with permission.)

of finite metallization on the propagation constant is minimal around the center of the operating bandwidth.

5. FINLINE DISCONTINUITIES

Discontinuities in the finline geometry form the building blocks of finline circuits. Given the many degrees of freedom in the design of finlines, the possibilities are endless, and it would be impossible to give a complete treatment of this subject. Nevertheless, one can identify some generic types of finline discontinuities and provide some basic characteristics. Some of the most important are inductive strips, step changes in gap width, notches, dents, and series stubs. The shapes of typical discontinuities are shown in Fig. 12, together with their equivalent lumped-element networks. Note that, in contrast to similar waveguide discontinuities, the circuit elements are determined solely by the metallization pattern of the planar insert, while the geometry of the enclosure remains unchanged. This results in a considerable reduction in the manufacturing cost, as the discontinuities are realized using printed-circuit techniques rather than machining.

The effect of discontinuities on the guided wave in the finline can be represented either by generalized scattering parameters (S parameters) or by equivalent lumped networks. These are not determined solely by the local changes of the dominant waveguiding parameters, but include the effects of mode conversion, energy storage, and possibly multimode interactions between neighboring discontinuities. Within the single-mode propagation range, dominant-mode S parameters are sufficient to describe the behavior of discontinuities, provided that they have been determined at reference planes beyond the reach of evanescent higher-order modes.

The theoretical characterization of finline discontinuities is a challenge for the same reasons as the computation of finline characteristics. Inhomogeneous dielectric

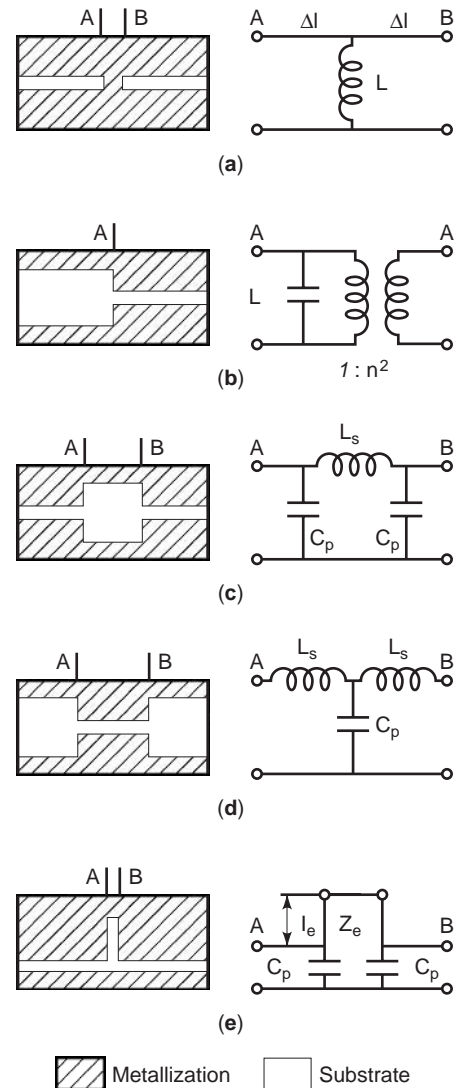

Figure 12. Profile of some important finline discontinuities and their equivalent lumped-element circuits: (a) inductive strip; (b) impedance step (step change in gap width); (c) inductive notch; (d) capacitive strip; (e) series stub. Note that the distance between planes A and B is short compared to the wavelength.

filling and edge singularities call for special approaches, ranging from experimental [6,34–36] over variational [37] and spectral domain techniques [35,38,39] to mode matching in longitudinal [40–42] as well as transversal [43] directions.

5.1. Inductive Strips

Inductive strips are important elements of bandpass filters. Meier [6] has determined the equivalent shunt inductance of strips from insertion loss measurements and from the resonant frequency of a one-section filter. Pic and Hoefler [34] have characterized strips and impedance steps by measuring the shift they caused in the resonant frequencies of an oversized cavity. The resulting empirical formulas for the strip inductance were confirmed by spectral-domain evaluations performed by Koster and Jansen

[39]. Further methodologies for the characterization of inductive strips and related discontinuities can be found in papers by Knorr and Deal [35], Zhang and Itoh [38], Saad and Schuenemann [44], and Omar and Schuenemann [45]. To achieve maximum Q factors in bandpass filters formed by inductive strips, the gap width of the resonant sections is usually maximized to the full height b of the enclosure. Such full-height strips and their interactions have been analyzed extensively with mode-matching techniques by Arndt et al. [46] and Shih et al. [47], leading to highly accurate CAD programs for E -plane bandpass filters.

5.2. Single and Interacting Impedance Steps

These discontinuities are formed by sudden changes in the gap width and come in many shapes and forms (Figs. 12b–12d). They serve as impedance transformers, tuning and matching elements, mounting platforms for semiconductor devices, or constitutive elements of filters. Besides empirical characterization [34], most systematic analytical approaches employ the representation of fields near the discontinuities by eigenmodes of either the adjacent uniform finline subsections (mode matching in longitudinal direction) or of transverse homogeneous waveguide subsections. As mentioned earlier, the former approach requires the determination of the eigensolutions of the finline subsections. It has been pointed out by Omar and Schuenemann [45] that the spectrum of finline modes can contain pairs of complex eigensolutions, and that their omission in the modal decomposition of the fields at the discontinuity can lead to significant errors. Various analyses and properties of impedance steps have also been described by El Hennawy and Schuenemann [40,41], Heilard et al. [42], Sorrentino and Itoh [43], and Beyer [48].

5.3. Narrow Series Slots

The series slot (Fig. 12e) is a popular tuning element in the design of oscillators and lowpass filters. It can be represented by a series-connected transmission line of effective length l_e and two stray capacitances that account for the field energy stored in the stray field at the junction. The effective length includes the stray effect at the end of the slot. Burton and Hooper [49] have characterized such slots experimentally and have given closed-form expressions for the elements of the equivalent circuit in Fig. 2e. These expressions are valid over an entire waveguide band and are independent of the dimensions of the enclosure. This indicates that narrow slots in the finline metallization behave essentially like slotline elements [16].

6. TRANSITIONS TO OTHER TRANSMISSION MEDIA

Most practical finline circuits include one or several types of transitions, either between different types of finlines or between finlines and other transmission media such as rectangular waveguides, coaxial line, or microstrip. Of particular importance and interest is the transition between finline and the commensurate rectangular waveguide due to the need to interface finline circuits with

measurement systems and conventional components. Transitions between different finline types and also between finlines and other planar circuits are needed to combine them and to take advantage of their respective properties in an integrated design. The topologies and properties of such transitions will be summarized in the following.

6.1. Transitions Between Finline and Waveguide

Transitions between finline and the commensurate rectangular waveguide are realized by varying in some way the slot between the full height of the waveguide and the final slot width. The bandwidth and the VSWR of the transition depend entirely on the profile of the fin contour and the length of the transition. The geometrically simplest transition is a linear taper extending over at least three guided wavelengths, as used by Cohen and Meier [13]. More sophisticated designs that are shorter than a wavelength employ single or double exponential profiles, cosine profiles, parabolic and circular profiles, as well as other profiles derived by nonuniform transmission-line theory [50–53]. Figure 13 shows some typical taper profiles employed for the realization of finline-to-waveguide transitions.

The problem of taper optimization amounts to realizing the lowest possible insertion loss over a given frequency band with a taper of minimum length. A rigorous treatment of the tapered transition leads to a nonlinear differ-

Figure 13. Profile of typical finline tapers and matching elements for the reduction of reflections from the dielectric slab interface: (a) linear taper with quarter-wave substrate protrusion; (b) exponential taper with quarter-wave substrate notch; (c) exponential taper with printer quarter-wave section; (d) double circular profile taper with triangular substrate protrusion.

ential equation of the Riccati type that must be solved numerically. Approximate solutions can be found, however, yielding the so-called Dolph–Chebyshev taper [51]. This taper has impedance discontinuities at its extremities that introduce parasitic reactances. However, since it is impossible to uniquely define the local characteristic impedance of a tapered finline, one might as well select a profile that approximates the “optimal” contour. Indeed, most researchers who have measured the characteristics of such tapers agree that the profile is not very critical, especially when the taper is about a wavelength long or more.

Detailed formulas and instructions for the synthesis of finline tapers have been reported by Hinken [50], Schieblich et al. [51], Beyer and Wolff [52], and Pramanick and Bhartia [53]. A transition comprising a short finline taper with a circular contour and matching capacitive discontinuities has been proposed by de Ronde [54], who claims that its performance is similar to that of an optimized taper, but its length does not exceed $\frac{3}{8}$ ths of λ_{\max} . Typical finline tapers have a return loss better than 20 dB over a standard waveguide band.

One feature that cannot be neglected in most applications is the discontinuity introduced by the finline substrate itself.

When the slotwidth is equal to the waveguide height, the finline becomes a dielectric slab-loaded waveguide. The reflection due to the substrate alone deteriorates the return loss of a subsequent taper typically by 5 dB. Cohen and Meier [13] reduced these spurious reflections by cutting a quarter-wave notch into the dielectric substrate with dimensions determined experimentally. Verver and Hoefer [55] later developed a closed-formed expression for the design of such notches and their dual, dielectric protrusions. Drawings by Piotrowski and Wojtasiak [56] and Beyer et al. [36] show transitions with triangular protrusions of the substrate, but no design information is given. For hard substrates that are difficult to cut (quartz), a printed transformer structure consisting of one or even two quarterwave sections in front of the taper is more appropriate [57]. Figure 13 shows how such matching elements can be incorporated in the design of a finline taper.

6.2. Transitions between Finline and Other Planar Media

Many transitions between various types of finlines [58] as well as between finlines and other planar media such as microstrip, coplanar waveguide, and suspended and inverted microstrip have been developed. A good survey of such transitions can be found in by Bhat and Koul [11]. The topologies are rather difficult to analyze and thus have been optimized empirically. Care must be taken not to excite unwanted modes and to avoid resonances that can considerably affect the transfer function of such transitions [59].

7. CONCLUSION

The principal advantages of finline technology at millimetric frequencies are wide single-mode bandwidth, moderate insertion loss, freedom from radiation and

interference, suitability for batch processing and low-cost production in both small and large quantities, potential for circuit integration, and compatibility with waveguide instrumentation. When properly constructed, finline components are rugged and reliable, withstanding considerable thermal and mechanical stress. Practically all imaginable circuit functions have been realized thanks to the many advances in the field-theoretic modeling of quasiplanar circuits. While early design efforts relied mostly on approximate and empirical characterization of finlines, rigorous formulations of the field problem and their numerical implementations have made it possible to design, optimize, and fabricate finline components entirely by computer.

The major drawback of the finline is its limited compatibility with transistors. On the other hand, active and passive diodes are easily embedded into a finline; oscillators, frequency converters, switches, phase shifters and attenuators with excellent performance have thus been realized. Entire integrated millimeter-wave radar front ends for frequencies up to 140 GHz have been built by the finline technique, demonstrating the potential and versatility of this technology that favorably combines the high electrical quality of the waveguide with the advantages of planar circuitry. When paired with the available computer-based design tools, finline stands out as an important and versatile technology in the arsenal of the modern microwave and millimeter-wave engineer.

8. LITERATURE

The literature on finlines is quite extensive; only a small number of key references could be cited here. The reader in search for more detailed information is referred to the comprehensive survey papers by Solbach [9] and Meier [60]. Bhartia and Pramanick [12] have assembled a collection of reprints of key papers on *E*-plane integrated circuits. Finally, in their book on the analysis, design, and applications of finlines, Bhat and Koul [11] have gathered and organized a wealth of design information, methods, and references on the subject. Further details on numerical techniques for the analysis of microwave circuits and electromagnetic wave problems can be found in two volumes edited by Itoh [29] and Yamashita [30].

FRACTAL-SHAPED ANTENNAS: A REVIEW

JAUME ANGUERA
 CARLES PUENTE

1. INTRODUCTION

Among the different telecommunications systems, mobile communication systems have experimented the fastest relative growth. A wireless system requires an antenna to radiate and receive electromagnetic waves. The antenna is therefore an essential component. Antenna performance is usually very sensitive to the antenna's geometric

form and size-wavelength ratio. This has two important consequences:

1. Once the antenna has been designed to operate at a particular wavelength, it will rarely be useful at other wavelengths. Since telecommunication systems operate at separate frequency bands to avoid mutual interference, one usually must account for an individual antenna for every single system.
2. Given a particular service band, the antenna cannot be made arbitrarily small owing to the same constraint.

In this sense, the present article deals with the investigation of antennas presenting small properties and multifunctionality features. The aim is to describe fractal techniques and their applications to design miniature, multifrequency, and high-directivity antennas. Fractal techniques have been chosen as their geometric properties are useful in designing miniature, multifrequency, and high-directivity antennas.

An overview of fractal-shaped antennas summarizes most of the work carried out since the early 1990s.

2. FRACTAL GEOMETRY

Since the early days of mathematics and Euclidian geometry, objects have been classified as one-, two-, or three-dimensional (1D, 2D, or 3D). The full stop we use to separate sentences in a written paper is 1D (i.e., point/line); the paper we use to write on can be considered approximately 2D (i.e., a plane/an area); while the ballpen we use to write these words is a 3D object (i.e., a cube/volume). However, we are surrounded by other objects (clouds, cost lines, arm trees, etc.) that are best described not by using Euclidian geometry but by using fractal geometry [1].

Among the several properties that characterize fractals, two are of interest in terms of antenna design: self-similarity/self-affinity and space-filling/fractal dimension properties. We will briefly define these properties and in the next section we will relate such geometric properties to the antenna field.

Some fractals are *self-similar*, which roughly implies that there are copies of the whole structure within the structure at different scales. For example, the futuristic tree of Fig. 1 can be understood in a loose sense to be self-similar; if we cut one branch, we will see that it is a reduced simplified copy of the whole structure. If such a scale factor is different for several directions, the structure is no longer self-similar but self-affine.

A characteristic feature of fractals is their space-filling property. To characterize such space-filling properties, the concept of fractal dimension is used. There are several definitions of fractal dimension. What really matters here is that a fractal object can have a fractional dimension or a larger dimension than its topological one [2], as it is the case of the Hilbert curve used to obtain a small monopole antenna presented in the next section.

Finally, two more definitions are presented here: mass fractals and boundary fractals. *Mass fractals* implies that

Figure 1. Futuristic vision of a tree. Every arm can be considered a scaled-down copy of the whole tree. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the internal structure is fractal, as in the Sierpinski gasket presented next. *Boundary fractals* implies that the perimeter is fractal-like, as in the Koch island patch presented in the next section.

3. FRACTAL-SHAPED ANTENNAS

3.1. The Concept

Having seen the geometric properties of fractal geometry, it is interesting to explain what benefits are derived when such geometry is applied to the antenna field.

Fractals are abstract objects that cannot be physically implemented. Nevertheless, some related geometries can be used to approach an ideal fractal that are useful in constructing antennas. Usually, these geometries are called *prefractals* or *truncated fractals*. In other cases, other geometries such as multitriangular or multilevel configurations [3,4] can be used to build antennas that might approach fractal shapes and extract some of the advantages that can theoretically be obtained from the mathematical abstractions. In general, the term *fractal antenna technology* is used to describe those antenna engineering techniques that are based on such mathematical concepts that enable one to obtain a new generation of antennas with some features that were often thought impossible in the mid-1980s.

After all the work carried out thus far, one can summarize the benefits of fractal technology in the following way:

- *Self-Similarity.* This property is useful in designing multifrequency antennas, as, for instance, in the examples based on the Sierpinski gasket [5–10]. Another interesting application of the self-similar property

has been applied in designing multiband arrays [11,12].

- *Fractal Dimension.* It is useful to design electrically small antennas, such as the Hilbert and Koch monopoles, fractal loops, and microstrip antennas [13–17].
- *Mass Fractals and Boundary Fractals.* These fractals are useful in obtaining high-directivity elements [18–20] and undersampled arrays [21–23]. They have also been useful for designing low-sidelobe arrays [8,11,24,25].

The next section explores fractal techniques used to obtain multifrequency antennas and arrays; miniature, high-directivity antennas; and undersampled and low-sidelobe arrays.

3.2. Applications of the Self-Similar Property: Multifrequency Antennas and Arrays

3.2.1. Multifrequency Antenna Elements. The first reported multifrequency fractal-shaped antenna was designed by C. Puente at the Universitat Politècnica de Catalunya (UPC) in the early 1990s and was named the *Sierpinski monopole* (Fig. 2) [5,7,26]. This monopole is a five-iteration Sierpinski gasket that features five operating bands (as many bands as fractal iterations) spaced logperiodically by a factor of 2 (the same scale factor used to generate the fractal). At the five operating bands, this antenna presents a good level of return loss (around –10 dB) (Fig. 3) and similar radiation patterns across the bands (Fig. 4).

The antenna depicted in Fig. 2 was extensively studied [26] and first patented in May 1995 [27].

Besides the experimental work, numerical computation using the finite-difference time-domain (FDTD) and method-of moments (MoM) codes were also used to fully understand the antenna behavior. Perhaps the most interesting analysis is that related to the current distribution on the conductor surface. Figure 5 shows the electrical current distribution at each of the five operating bands, where it can be observed that the current is concentrated in several regions called *active regions*. At the lowest operating frequency, the active region is extended

Figure 2. The Sierpinski monopole on a square ground plane.

Figure 3. Measured and computed return loss for the Sierpinski monopole of Fig. 2. Numerical simulations agree fairly well with measurements. The antenna is matched at -10 dB return loss at five bands, as many as the iterations (five). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

throughout the whole structure; on the other hand, for the highest operating frequency, the active region is concentrated in the smallest iteration number near the feed-point.

Figure 6 shows an iterative method that has been used to predict the return loss of the Sierpinski monopole and Sierpinski patch antennas. Such a method as well as the segmentation method is interesting because it enables parametric analysis to be performed in a very short time and allows us to understand what occurs if the scale factor is changed. The S matrix is the S parameter of interconnected transmission lines, where one can factor in the radiation loss mechanism by considering transmission

line with losses. The present method as well as the segmentation method have been used to predict input parameters of the Sierpinski monopole as well as other fractal-shaped antennas [28–31].

Another analytical method called the *multiperiodic traveling-wave “vee” model* has also been used to predict the radiation patterns as depicted in Fig. 7 [26]. Such a model is able to predict the radiation pattern of a Sierpinski monopole if the current along the edge is known.

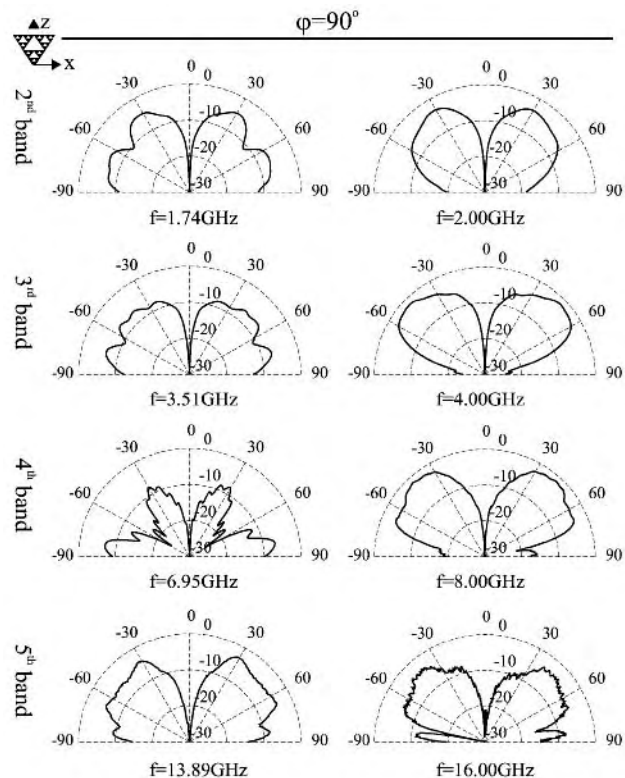

Figure 4. Measured radiation cuts at the four upper bands for $\phi = 90^\circ$ plane for the Sierpinski monopole of Fig. 2.

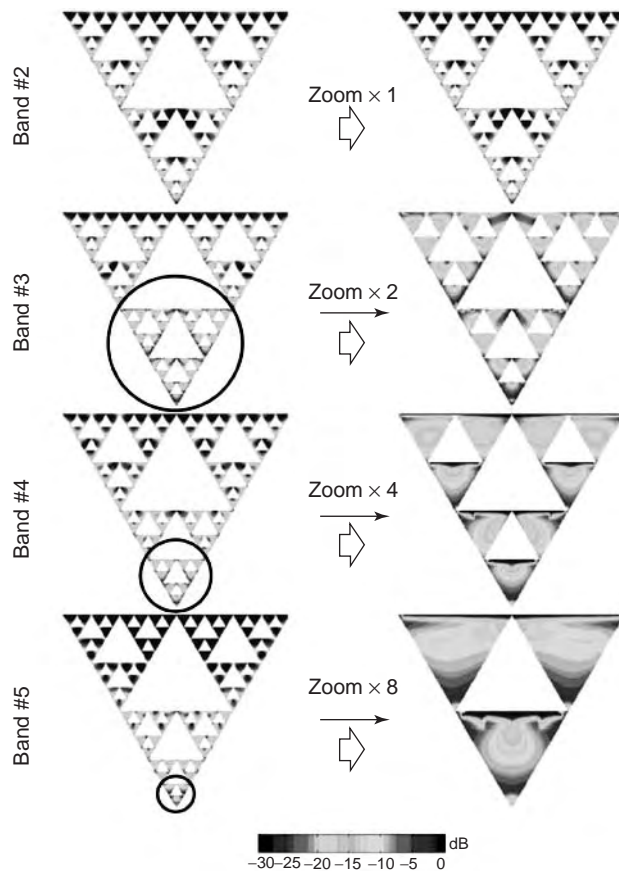

Figure 5. FDTD electrical current simulations on the conductor surfaces. An active region is observed (circled in the left column). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

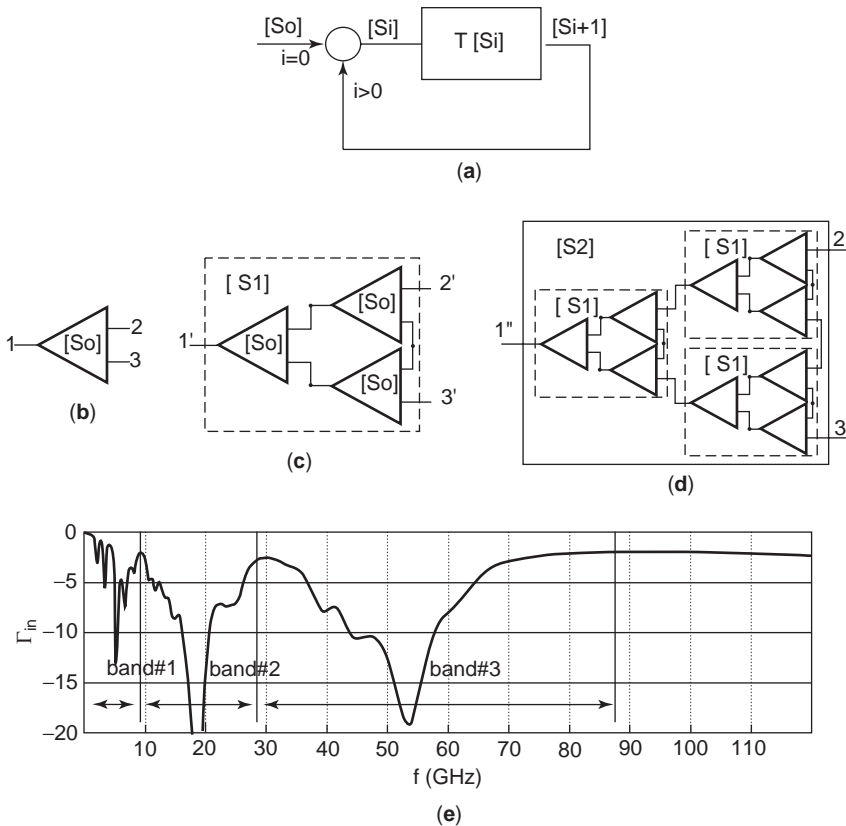

Figure 6. (a) Iterative method to calculate the input impedances of fractal-shaped antennas; (b–d) cascading the S parameters—in this case, the model is useful for predicting the evolution of the operating bands with the number of iterations; (e) result for a three-fractal-iterated Sierpinski antenna.

The model has been extended not only to better understand the physical radiation of the classic Sierpinski monopole [32,33] but also to obtain the radiation pattern of Mod-P Sierpinski monopoles [34,35].

For a fractal-shaped antenna operating at the highest frequency, the antenna is electrically very large. If the MoM is used for example, this requires a small discretization elements resulting in a large number of unknowns (N). If N is large enough, the matrix impedance Z of MoM does not fit in the computer memory (N^2) and moreover, large computation time is needed (time is proportional to N^3). Therefore, advanced numerical methods and other strategies are required to correctly model fractal-shaped antennas such as the multilevel matrix decomposition algorithm (MLMDA) and multilevel fast multipole method (MLFMM). MLFMM is very efficient for 3D problems, while MLMDA is very efficient for planar antennas, as is the case with microstrip patches or dipoles. Other methods such as adaptive meshes can be used (Fig. 8). For example, one can use a fine mesh for the active zone related to the highest frequency, while coarse meshes can be used to the lowest frequencies [36].

Genetic algorithms have also been used to optimize the fractal antenna geometry [37,38], as is the case of a dual-band dipole antenna having a SWR (standing-wave ratio) below 2 at 1.225 and 1.575 GHz and small monopole antennas [39].

For the numerical experiments, we have shown that an active zone is associated with the fractal Sierpinski

monopole antennas (Fig. 5). One can observe the same effect using experimental procedures [40]. Figure 9 photographically illustrates the temperature elevation on the antenna surface. A magnetron operating at 2.45 GHz was used. In order to observe the active region, several Sierpinski prototypes printed in fiberglass have been built. The losses on the fiberglass allow one to acquire thermic images. The antennas have been scaled to obtain the active region at 2.45 GHz.

Following those results, one can conclude that at each operating frequency, only some part of the structure is responsible for radiation. As these parts present approximately the same electrical height and shape, the antenna radiates similar at each band (Fig. 4).

After the successful result described above, research on the Sierpinski monopole continued and variation of the flare angle and geometric perturbation based on self-affine transformations were explored to study how one could control the input impedance and frequency allocation [41–44]. Those experiments were really interesting because they clarified the design of practical monopole antennas for base station systems such as GSM 900, GSM 1800, and UMTS [45–47]. Another interesting modification when changing the flare angle is to obtain a dual-band antenna with bidirectional pattern [48].

The Sierpinski gasket was also used to design a dipole antenna (Fig. 10), and it was used by Romeu and Rahmat-Samii [49–51] to implement a frequency-selective surface

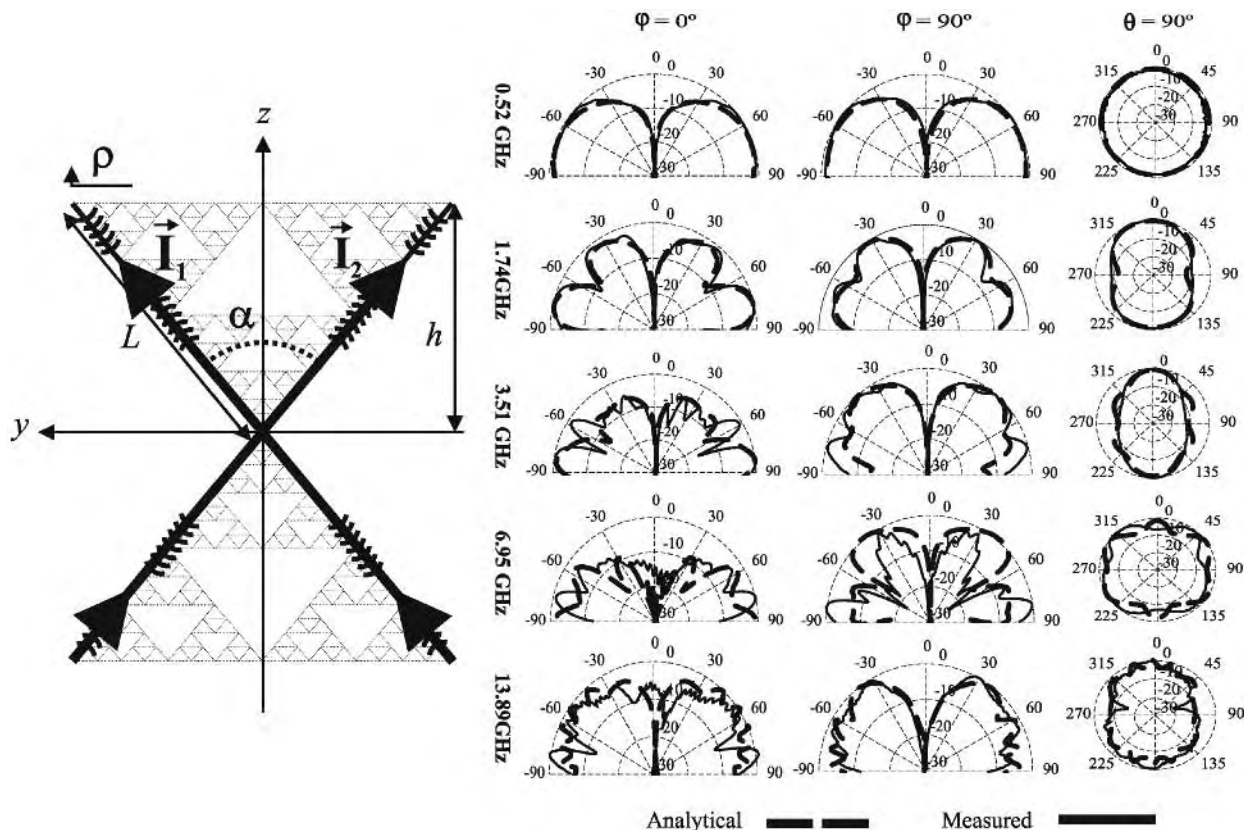

Figure 7. Multiperiodic traveling-wave V (“vee”) model is useful for predicting the radiation patterns of fractal-shaped antennas such as the Sierpinski monopole.

(FSS) operating at two bands. Other fractal shapes have also been studied to create FSS [52,53].

Novel geometries based on the Sierpinski triangle are investigated in Soler’s thesis [54] to control the num-

ber of bands and also to control the frequency separation (Fig. 11). These antennas are based on Pascal’s triangle [34,35]. By using the Mod-P Sierpinski structures, the frequency separation between bands can be larger than that obtained for the classic Sierpinski gasket [55].

In addition, fractal-related antenna structures can be top-loaded as shown in Fig. 12 in order to control the spacing between bands and the input resonances at each resonance [56,57].

In general, depending on the feeding scheme used for the antenna, the ground plane becomes a useful contributor in the radiating process [58]. The fractal geometry has been also used not only to shape the antenna but also to design ground planes inspired on the Sierpinski fractal shape [59] (Fig. 13).

It has been shown that by means of Sierpinski fractal and other related shapes, it is possible to obtain several matched bands with a similar radiation pattern [60–62]. To improve the radiation pattern, a 3D arrangement has been proposed [63] and is shown in Fig. 14.

The Sierpinski gasket was reexplored as a microstrip patch as well [64,65]. In Borja’s thesis [66,67], an in-depth study is devoted to analysis of the Sierpinski patch in order to obtain several bands with broadside radiation patterns. For the patch version, it is more difficult to obtain a multifrequency behavior, although several proposals have been already made [66,68]. Figure 15 shows a particular

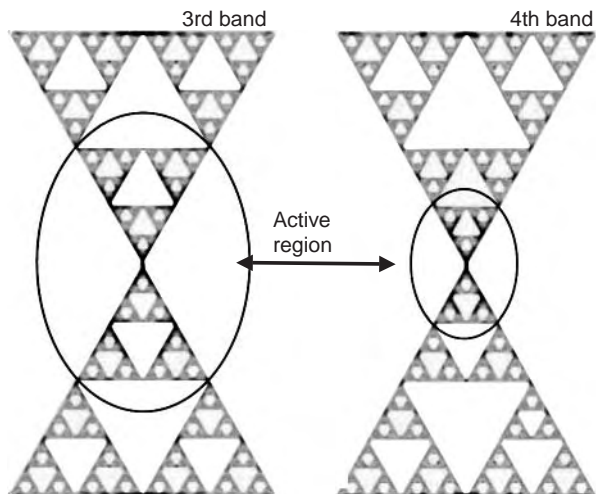

Figure 8. A fractal-shaped antenna becomes and electrically large structure at the highest operating bands. Advanced methods are required to model these complex structures. Adaptive meshing can be used to mesh properly the active regions.

Figure 9. Temperature elevation on the antenna surface measured in operating bands 2–4 using an infrared camera. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 10. The Sierpinski gasket was also used to design a dipole antenna.

Figure 11. The Sierpinski monopole mod-3 and mod-5.

solution where some junctions are broken in order to eliminate undesired higher modes that degrade the radiation patterns.

By modifying the scale factor and fractal geometry, a dual-band dual-polarized microstrip antenna was designed to operate at GSM 900 and 1800 [69]. Moreover, such an element was the basic radiating element of a prototype for a dual-band dual-polarized array for mobile communications (Fig. 16). The feeding scheme is based on an etched capacitor designed to cancel the inductance effect of the coaxial probe [70].

In this sense, research continues with the aim to go a further step: investigate multifrequency microstrip antennas using fractal-based geometries (Fig. 17), while introducing a broadband behavior at each frequency band employing bandwidth enhancement techniques [6,71].

The current distributions of the multistacked antenna are calculated at the central operating frequencies as shown in Fig. 18. It is important to observe that when the antenna is excited at $f = 1.612$ GHz, the bottom parasitic patch remains nonexcited; that is, it seems to be transparent to the stated frequency, and only the top parasitic patch is operating. By contrast, when the antenna is excited at $f = 2.697$ GHz, the bottom patch is excited while the top patch is almost totally disconnected. Therefore, for the first operating frequency, the top parasitic patch is responsible for enhancing the bandwidth of the active patch while the bottom parasitic patch is responsible for broadening the second band. The measured prototype shows a $BW = 4.7\%$ and $BW = 6.8\%$ ($SWR = 2$) for the first and second operating bands, respectively, with similar radiation patterns for the entire bandwidth and similar for both bands, confirming the dual-broadband performance.

Figure 14. 3D antenna solution used to tailor the antenna patterns at different frequency bands. The antenna is built with two planar structures based on the Sierpinski fractal.

3.2.2. Antenna Arrays. The self-similar property of some fractals has been useful in designing multiband arrays [11,72]. This can be achieved if the array factor is a self-similar curve such as, for example, the Koch curve (Fig. 19). In Fig. 19, an array factor following the self-similar curve is shown. If the progressive phase $\beta = kd$, the same shape is obtained at $f, f/3, f/9$ and so on. Although the same radiation pattern is maintained at several frequencies, the radiation parameters such as gain, radiation resistance, and efficiency are not maintained because the pattern magnitude is reduced when the frequency increases.

Other functions as the Weierstrass function can be used as well to synthesize fractal arrays with self-similar properties [73].

Werner takes advantage profit of the self-similar property of fractal-based arrays to develop fast algorithms for calculating the impedance matrix of such arrays [74]. The self-similar property is also useful for developing rapid beamforming algorithms [75,76].

Having reviewed some of the work on multifrequency antennas and arrays using fractals, in the next section we

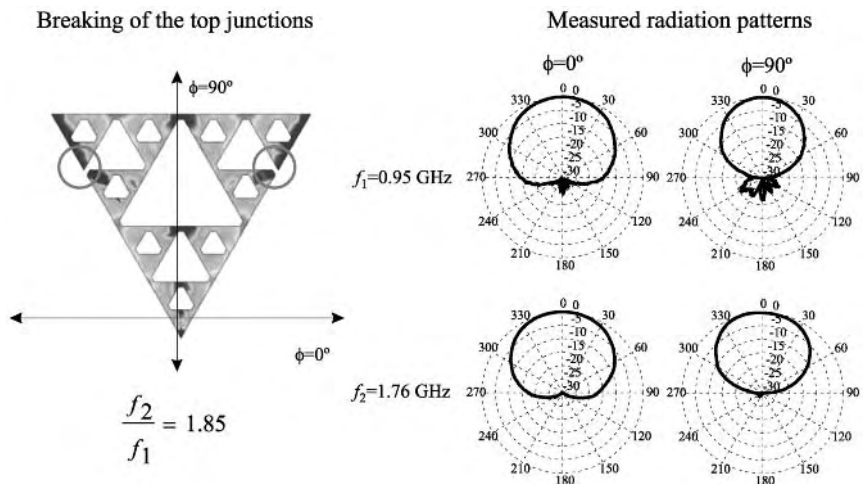

Figure 15. The Sierpinski patch with the top junction broken in order to obtain a dual-band antenna with broadside radiation patterns.

Figure 17. A multistacked microstrip patch antenna based on the modified Sierpinski fractal.

present some of the research related to electrically small antennas.

3.3. Applications of the Fractal Dimension Property: Electrically Small Antennas

Antenna size is a critical parameter because antenna behavior depends on antenna dimensions in terms of wavelength (λ). In many applications, space is a constraint factor; therefore an antenna cannot be comparable to the wavelength but smaller (i.e., a small antenna). An antenna is said to be small when its larger dimension is less than twice the radius of the radian sphere; its radius is $\lambda/2\pi$. Wheeler and Chu were the first who investigated the fundamental limitations of such antennas [77–79]. The goal of this section is to present the miniature features of the Hilbert monopole [14,80,81] and compare it with the Koch monopole studied previously [13,26,27]. Some new advancements are also presented. It should be pointed out that at the limit, the Koch and Hilbert curves feature fractal dimensions of 1.23 and 2, respectively.

Figure 20 shows a $\lambda/4$ monopole and the first five iterations of the Hilbert monopole where the total height for all antennas is $h = 7$ cm. The antennas are etched on a 1-mm FR4 substrate acting merely as an antenna support. The copper used is 0.4 mm wide. As the total length of the Hilbert monopole increases as iteration increases, the resonant frequency will decrease. Thus, the antenna becomes electrically smaller as the iteration number increases.

For the fifth iteration, the length is 65 times h . One might think that the resonant frequency for a fifth-iteration Hilbert monopole would be 65 times less than the resonant frequency of a linear monopole with height h , which will be an extraordinary frequency reduction. Obviously, this is not true since coupling between turns provides a shorter path for currents flowing from one tip to the other. However, even with the coupling effect, the resonant frequency reduction or compression factor (CF), which is defined as the ratio between the resonant frequency for the vertical monopole and the Hilbert resonant frequency, can achieve values up to 10, taking into account the negligible effect of the dielectric support. Large CF are interesting for designing miniature antennas where space is a constraint factor such as, for instance, integrated low-frequency antennas in automotive applications [82].

Finally, a new concept called *compression efficiency* (CE) is introduced. CE is defined as the ratio between the first resonant frequency of the equivalent vertical linear monopole with a height equal to the total length of a Hilbert (Koch) monopole and the first resonant frequency of the Hilbert (Koch) antenna. CE is an important parameter for comparing different space-filling geometries to determine which structure can decrease the resonant frequency with less wirelength.

Figure 21 shows CE as a function of the fractal iteration, showing that CE decreases as the iteration number increases. In the same figure, the CE for the Koch monopole is shown [14]. It is clearly seen that the CE decreases more rapidly for the Koch monopole. For example, for the same height (h) of the vertical monopole, the Hilbert 1 and the Koch 5 monopoles have approximately the same length; however, CE is 70% for the Hilbert monopole and only 40% for the Koch monopole, indicating that the Hilbert monopole (with a larger fractal dimension) achieves a larger frequency reduction with the same wirelength.

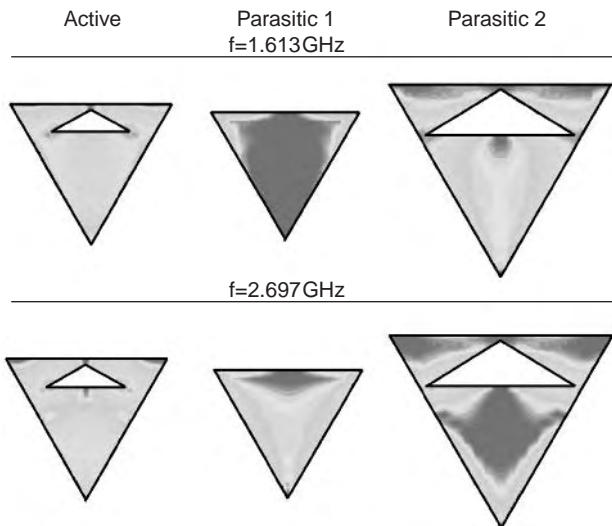

Figure 18. Simulated current distribution. It can be observed that only one parasitic patch contributes significantly to radiation depending on the operating frequency. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

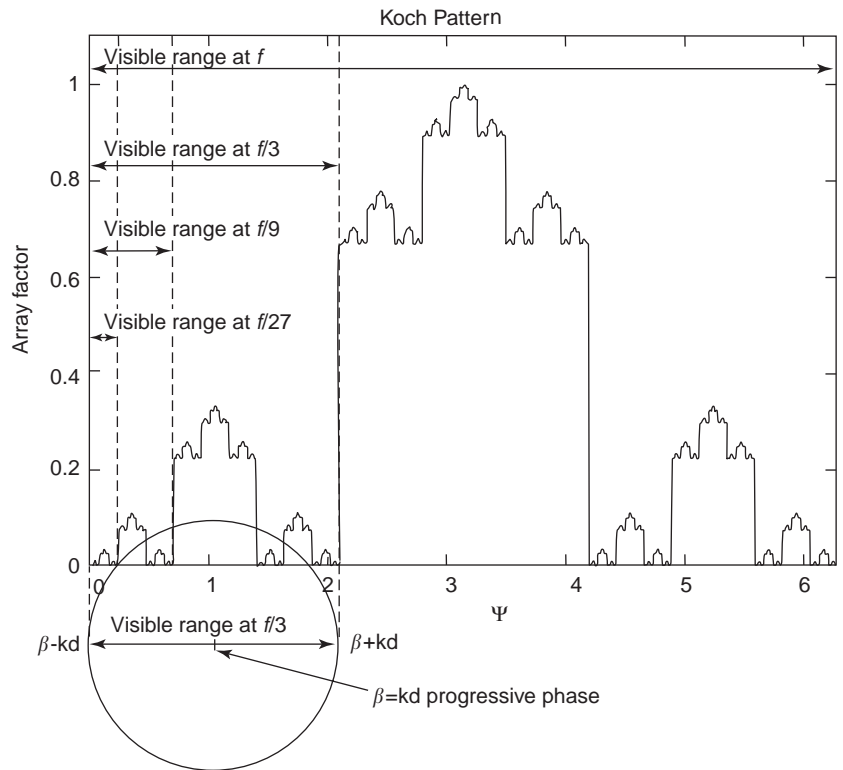

Figure 19. The Koch array factor. The curve retains its similarity at six different scales. By adding a progressive phase $\beta = kd$, the visible range is always centered at a secondary lobe that has the same shape as the total pattern. The frequency change by a factor $\frac{1}{3}$ reduces the visible range around this similar subpattern [11].

Analytical models have been proposed by Vinoy et al. to predict the resonant frequency of the Hilbert-based antenna [83]. Modifications of the feeding point have been investigated in order to match the antenna [84]. Methods for fast calculation of the input impedance of a Koch fractal dipole have also been proposed [85].

The Hilbert curve have also been useful in designing small microstrip patch antennas. In Ref. 86, a microstrip patch is loaded with a transmission line to reduce the resonant frequency of the fundamental mode of the unloaded patch [82]. The Hilbert curve has also been used to construct metamaterials, in particular to design artificial magnetic conductors as proposed by McVay, Engheta, and Hoorfar [87].

The classic miniature technique of short-circuited monopoles has been combined with fractal technology, as is the case of a shorted monopole inspired in the Sierpinski fractal in Song’s thesis [88,89].

Another advantage of miniature antennas is that they tend to reduce mutual coupling in an antenna array as studied in Gianvittorio’s thesis [90]. By reducing the mutual coupling, the scan-blindness effect can be reduced to shift the blind angle toward larger angles near the horizon [16,17,91].

In order to overcome the problem of miniature microstrip antennas, that is, small bandwidth and radiation efficiency, parasitic techniques have been combined with fractal techniques to obtain miniature and wideband antennas with improved efficiency [68,92,93]. Figure 22 shows a modified Sierpinski-based microstrip antenna consisting of an active patch and a parasitic patch. Using such a geometry, the resonant frequency of the antenna is 1.26 GHz while it is 2 GHz for the filled version. By adding the parasitic patch, the bandwidth with respect to the single active element is increased by a factor of 15, resulting in a bandwidth of $BW = 2.7\%$ at $SWR = 2$; the radiation efficiency for this antenna is 84% [68]. Similar approaches of stacking elements can be found in Ref. 94.

Figure 20. (a) Vertical monopole; (b) Hilbert 1; (c) Hilbert 2; (d) Hilbert 3; (e) Hilbert 4; (f) Hilbert 5. The antennas are etched on a FR4 substrate acting as a support.

3.4. Application of Mass and Boundary Fractals: High-Directivity Antennas and Undersampled and Low-Sidelobe Arrays

3.4.1. High-Directivity Antennas. Another interesting feature of fractal-based microstrip antennas is the existence of localized modes called *fractons* and *fractinos*

Figure 21. Compression efficiency for the Hilbert and Koch monopoles.

depending on whether the structure is based on mass fractals or boundary fractals [66,68,95–98]. Figure 23 shows a Koch-island patch where the current distribution for the fundamental mode and fractino mode are shown [18,99]. It is worth noting that for the fractino mode there are zones of high current density (localized mode). Moreover, such zones are coherent; that is, they radiate in

phase, and thus the radiation pattern is broadside. This feature is rarely obtained with classical Euclidian geometries such as squares, circles, and triangles. Other geometries presenting localized modes have been investigated [66,68].

The fracton-mode behavior of the Sierpinski bowtie patch has been investigated [100]. The fracton-mode properties are studied as a function of the iteration number.

Besides fracton and fractino modes, microstrip antennas supporting several fracton modes have also been studied. Figure 24 shows an example of the Sierpinski bowtie fractal-based antenna, which supports as many fracton modes as iterations [101–103]. It is interesting to note that the directivity of the fracton mode increases with the mode order.

Figure 22. A miniature microstrip antenna inspired in the Sierpinski fractal. Current distributions on the patch surfaces are shown. The parasitic patch enhances the bandwidth when the input impedance loop is correctly centered at the center of the Smith chart.

3.4.2. Undersampled Arrays. Operating in such a fracton or fractino mode, one can obtain a larger directivity than that for a fundamental mode. In this sense, Anguera [68] has investigated structures supporting fracton modes for microstrip arrays (Fig. 25); this type of array is called an *undersampled array* [22,23,104,105]. Such a novel method presents an advantage over conventional designs in that one can obtain in the same electrical area of a conventional array using Euclidian-based elements, with the same directivity but using fewer elements. Other advantages are that the feeding network complexity decreases and there is more available space to integrate other microwaves devices such as, for example, amplifiers, filters, and matching networks. This reduces the antenna cost, volume and weight, which can be an enormous advantage for satellite antenna applications [21,106].

Figure 26 shows the radiation pattern in the upper space for the Euclidian and fractal arrays of Fig. 25. Both

Figure 23. Current distribution for the fundamental and localized modes of a Koch microstrip patch. The localized mode presents high current density on the boundary with coherent radiation; a broadside radiation pattern with a directivity larger than that of the fundamental mode can be obtained. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

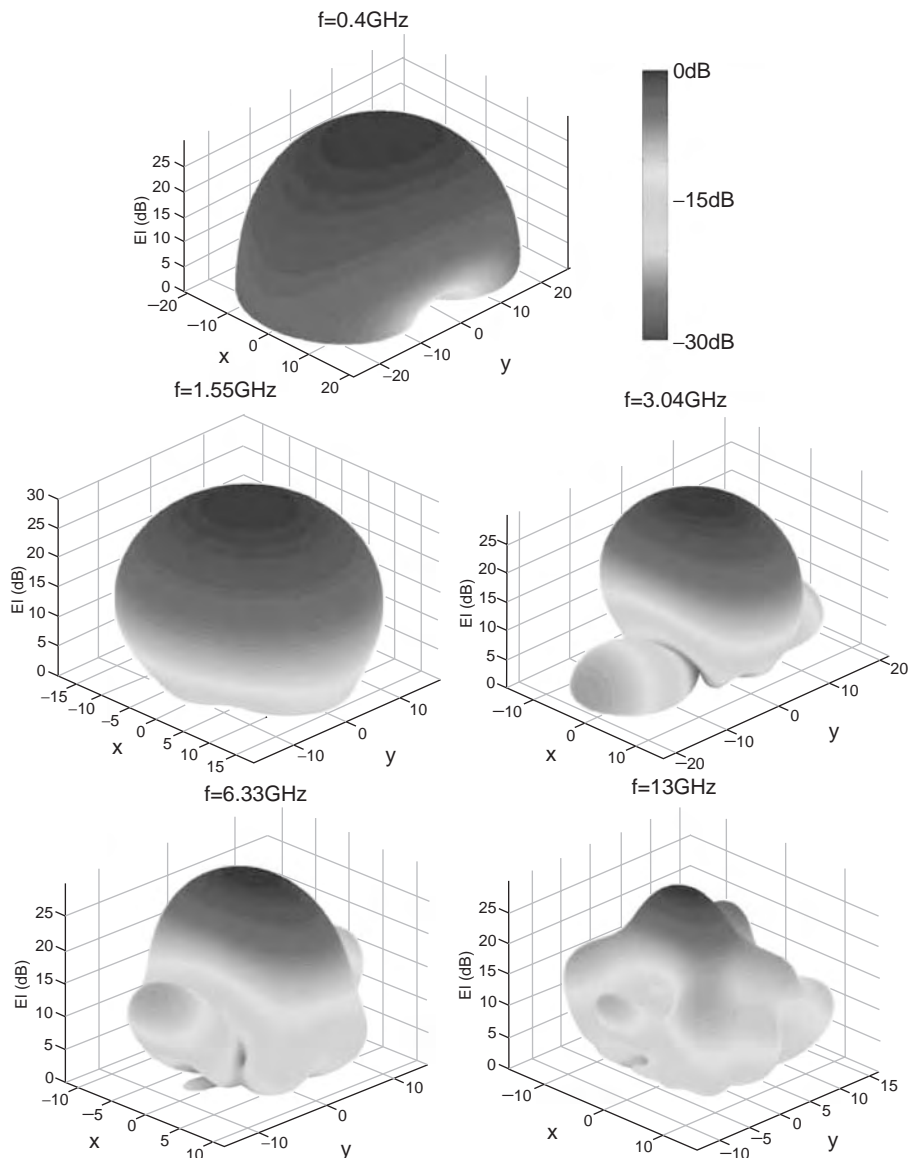

Figure 24. 3D-simulated radiation patterns for the Sierpinski bowtie 4: the fundamental and four fracton modes are shown. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 25. The classical microstrip array with circular patches and the novel scheme with fractal-shaped microstrip antennas.

arrays present the same electrical area; however, for the fractal array operating in a fracton mode, the number of elements is 2.8 times less (14×13 for the Euclidian and only 8×8 for the fractal one).

3.4.3. Low-Sidelobe Arrays. The fractal spatial arrangement of array elements have been useful for designing low-sidelobe arrays with equally weighted current elements, which is advantageous current element for practical purposes because the feeding network is easier than those used when different current amplitudes are required in order to reduce sidelobes.

Kim and Jaggard first proposed a nonuniform random fractal spacing for improving the sidelobe level of random arrays in 1986 [24]. The Cantor array has also been

Figure 26. Normalized simulated radiation patterns for the arrays shown in Fig. 25. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

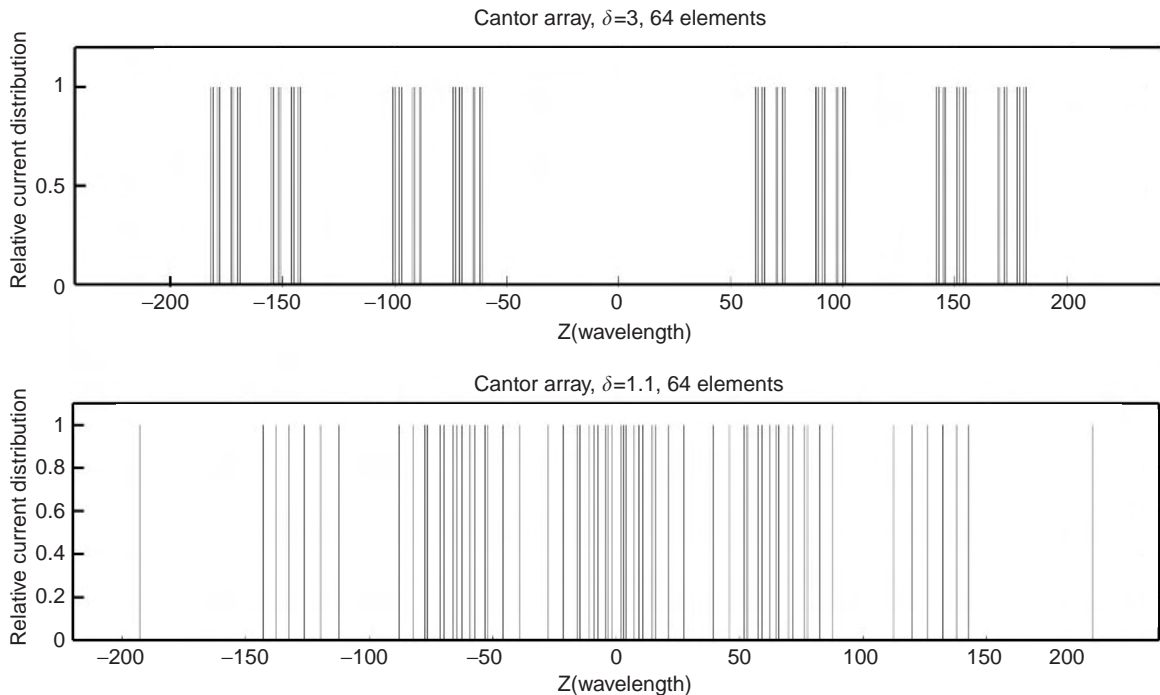

Figure 27. Cantor array constructed with 64 array elements from a 2^δ generator and a logperiod $\delta = 3$ (top) and $\delta = 1.1$ (bottom).

Figure 28. Array pattern of a binomial distribution and a Cantor distribution with a logperiod of $\delta=1.1$, both having the same number of array elements: 64.

analyzed [11,107,108]. Mathematically, the generalized Cantor distribution can be obtained by convoluting two delta function as

$$c(z) = \prod_{n=-\infty}^{\infty} \{f(z \cdot \delta^n)\} \quad (1)$$

where $f(z)$ is a 2δ function and δ is the scaling factor.

Figure 27 shows two cantor arrays formed by 64 array elements and scale factors of $\delta=3$ and $\delta=1.1$, respectively. For the Cantor array having a logperiod of $\delta=1.1$, the corresponding pattern looks very similar to a binomial distribution: sidelobe level below -65 dB (Fig. 28). The main advantage is that although the sidelobe level is close to the binomial distribution, the current excitation is uniform with drastically simplifies the feeding network.

An array with a low sidelobe level has been investigated by small position offsets of fractal elements [109].

4. CONCLUSIONS

Research and applications of fractal-shaped antennas is increasing [110,111]. So far, we can divide the applications into six main groups:

1. *Multifrequency Antennas, FSS, and Arrays.* The early work was dedicated to the Sierpinski dipole. Nowadays, fractal technology is also being applied to the design of multifrequency microstrip patches. Moreover, multifrequency FSS and arrays can be designed using the fractal technology.
2. *Electrically Small Antennas.* Koch and Hilbert curves have been used so far and are inspiring many researchers to search for new space-filling curves to optimize antenna performance.
3. *High-Directivity Elements.* Fractal-based antennas supports fracton and fractino modes. As we have shown, these modes present a broadside radiation pattern with a directivity larger than the fundamental mode.
4. *Low Sidelobe Array.* Using fractal arrangements, arrays with very low sidelobes can be achieved

with a uniform excitation. This is an advantage compared with nonuniform excitations, which required a complex feeding network.

5. *Undersampled Arrays.* With this novel application, microstrip arrays use a fewer elements than in the classic approach using Euclidian radiators. This reduction of the number of elements potentially reduces the feeding network complexity and might become a very interesting application for satellite antennas, where space, cost, and volume are constrain factors.
6. *Fast Computational Methods.* Taking advantage of the fractal geometry, rapid algorithms to calculate antenna parameters and beamforming are being developed.

FREQUENCY CONVERTERS AND MIXERS

ILTCHO ANGELOV
 ERIK L. KOLLBERG
 HERBERT ZIRATH
 Chalmers University of
 Technology
 Göteborg, Sweden

An essential part of most microwave receivers is the frequency converter, a device that converts the frequency of an incoming signal to another frequency. The output frequency may be *downconverted*, *upconverted*, *multiplied*, or *divided*. Important and common is the *mixer*, which downconverts a high-frequency input signal f_s to a much lower and more manageable signal f_{IF} , preserving information concerning the amplitude, frequency, and phase of the input signal. The devices used are nonlinear (i.e., the relationship between current and voltage is not

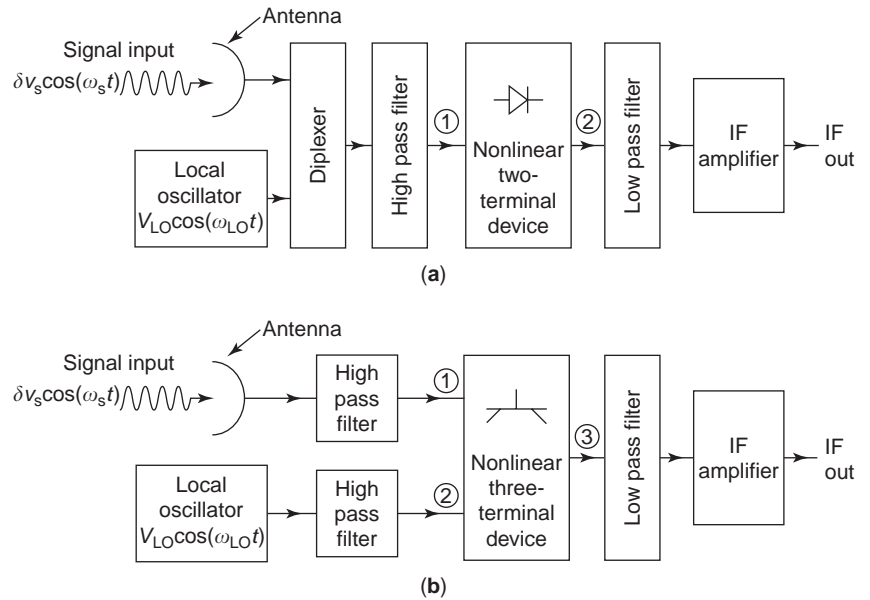

Figure 1. Typical mixer block diagram showing layouts for a two-terminal device (diode) (a) and a three-terminal device (transistor) (b). At the input there is a highpass filter that will prevent any low-frequency IF power from escaping to the mixer input (left). The lowpass filter will stop any input signal or LO power from going to the IF circuit (right).

linear). The devices may have either two terminals (diodes) or three terminals (transistors).

Mixers are important for very high frequencies, where amplifiers are not available and direct amplitude or phase detection is difficult. A mixer can be used to downconvert, say, a terahertz frequency signal to a microwave frequency one, where electronic methods are readily available for amplification and any kind of demodulation. In fact, in almost any radio set or mobile telephone receiver or base station, there are several mixers and other types of frequency converters.

Both two-terminal devices (diodes) and three-terminal devices (transistors) are used in mixers. The frequency conversion is accomplished by using the *nonlinear* properties of the device. Virtually all semiconductor devices, such as diodes and transistors, show nonlinear properties in certain bias ranges. Common devices for microwave mixer applications are the Schottky diode, the field-effect transistor (FET), and the bipolar transistor. There are many other devices available as well, for example, the superconducting tunneling device (SIS) and the superconducting hot-electron device for low-noise (high-sensitivity) millimeter- and sub-millimeter-wave receivers. For infrared wavelengths, metal-insulator-metal (MIM) devices and, for optical frequencies, photoconducting devices have been used. Note that ordinary resistors, capacitances, and inductances are linear components.

Figure 1 gives an example of how mixers are used in a receiving system. The antenna is connected directly to the

Figure 2. A rectifying diode circuit. If the capacitance C and the resistance R are large enough, $v_R(t)$ will follow the envelope of $v(t)$ (see Fig. 3).

mixer. For example, in a TV satellite receiver, an amplifier is placed just after the antenna to increase the signal amplitude. In reality there are many other systems (e.g., radar, radio, measurement systems) where mixers are used to frequency downconvert the input signal.

To give a simple illustration of how a diode mixer may work, consider the detector circuit shown in Fig. 2 using an ideal diode (zero resistance in the forward direction and infinite resistance in the backward direction). If a sinusoidal voltage $V(t) = V_{LO} \cos(2\pi f_{LO} t)$ is applied, it will be “rectified” (detected) by the diode. The voltage over the resistance $v_R(t)$ will be a constant DC voltage proportional to V_{LO} . Next, add a *small* signal voltage $\delta v_s \cos(2\pi f_s t)$, that is, $V(t) = V_{LO} \cos(2\pi f_{LO} t) + \delta v_s \cos(2\pi f_s t)$. Assuming that $\delta v_s / V_{LO} \ll 1$, the resulting voltage $V(t)$ will become amplitude-modulated, as shown in Fig. 2. The detected voltage $v_R(t)$ over the load resistance R will be proportional to the envelope $V_R(t)$ (assuming $\tau = RC \ll 1/\omega_{IF}$) (see Fig. 3),

Figure 3. An example with a drive voltage $v(t)/V_{LO} = \cos(\omega_{LO} t) + (\delta v_s / V_{LO}) \cos(\omega_s t)$, where $\delta v_s / V_{LO} = 0.2$ and $\omega_{LO} / \omega_s = 1.18$. The IF is $0.18 \omega_{LO}$.

that is

$$v_R(t) = V_{\text{LO}} \left(1 + \frac{\delta v_s}{V_{\text{LO}}} \cos(2\pi f_{\text{IF}} t) \right) \quad (1)$$

where $f_{\text{IF}} = |f_{\text{LO}} - f_s|$ is the intermediate frequency (IF). The DC part of Eq. (1) is the “detected local oscillator (LO),” and the alternating part is identical to the IF voltage and, in this example, is equal in amplitude to the input signal. This IF signal is fed into an amplifier as described in Fig. 1.

Note that in the simplified example above we have not correctly accounted for a number of parameters, such as the impedances of the LO and signal sources. This means that the IF voltage will not become equal to δv_s . A more detailed description of a more correct calculation is given in the Section 3. For details concerning microwave mixers, see Refs. 1 and 2.

1. GENERAL PROPERTIES OF TWO-TERMINAL NONLINEAR DEVICES

Below we describe some general results obtained when a two-terminal device such as the Schottky diode is excited with a sinusoidal signal. The impedance of the Schottky diode is voltage-dependent. The speed of this device is indeed high. It shows a nonlinear behavior up to several terahertz.

1.1. Frequency Multiplication

Consider a nonlinear diode device exposed to LO (or pump) power yielding a large voltage swing $V(t) = V_{\text{LO}} \cos(\omega_{\text{LO}} t)$ over the diode. (Note: Below we use $\omega = 2\pi f$.) Since the relation between current and voltage is not linear (i.e., $I \neq \text{const.} \times V$), the resulting current will *not* have a sinusoidal shape like that of the input voltage. However, the current in this case is still a *periodic* function versus time with the same periodicity, $\tau = 2\pi/\omega_{\text{LO}}$, as the LO frequency and can consequently be expressed as a Fourier series with harmonics of the LO, $n\omega_{\text{LO}}$:

$$I(t) = \sum_{n=0}^{\infty} i_n \cos(n\omega_{\text{LO}} t + \varphi_n) \quad (2)$$

The component i_0 is the DC component. To obtain power at a particular harmonic, for example, the third harmonic, it

is required that the current component at $3\omega_{\text{LO}}$ pass through a resistance R_3 delivering a power of $\frac{1}{2}i_3^2 R_3$. To avoid any power being delivered at other harmonics, it is necessary to ensure that the device is reactively terminated at these harmonics.

In reality, the impedance of most nonlinear devices is complex with both the *real* and the *imaginary* parts voltage (or current)-dependent. For a more detailed theory, see Section 3.2.

1.2. Frequency Conversion

If two signal voltages at ω_{LO} and ω_s are simultaneously interacting with the nonlinear diode impedance, the resulting current can be expressed in a more complex Fourier series:

$$I(t) = \sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{+\infty} i_{m,n} \cos((m\omega_{\text{LO}} + n\omega_s)t + \varphi_{m,n}) \quad (3)$$

In the case when both the signal voltage and the local oscillator voltage are large, a large number of frequency conversion products are obtained. Obviously it is possible to generate power at any frequency $m\omega_{\text{LO}} \pm n\omega_s$. If for $m = n = 1$ the required output frequency is higher than the signal frequency, one has *frequency upconversion*, and if the output frequency is lower than the signal frequency, one has *frequency downconversion*.

1.3. Linear Mixing

As already mentioned, a mixer receiver usually handles “small signals.” We have a small signal case if the amplitude of the signal at ω_s is much smaller than the LO amplitude at ω_{LO} . In this case only harmonics of ω_{LO} are important, and we are left with

$$I(t) \approx \sum_{m=-\infty}^{+\infty} i_m \cos[(m\omega_{\text{LO}} + \omega_s)t + \varphi_m] \quad (4)$$

In most mixer applications, we are interested in the “intermediate frequency,” $\omega_{\text{IF}} = |\omega_{\text{LO}} - \omega_s|$. An IF load resistance in the circuit will allow power at the IF frequency to be extracted (compare with Fig. 2). Equation (4) suggests that power may go not only to the IF but also to *harmonic sidebands*, as illustrated in Fig. 4. The only way to prevent this power loss is to make sure that the

Figure 4. Power flow in a lower sideband mixer. The input signal power is distributed not only to the IF but also to the harmonic sidebands.

harmonic sideband current components are facing impedances that are purely reactive.

Note that an IF signal (Fig. 4) will be created if either $\omega_{su} = \omega_{LO} + \omega_{IF}$ or $\omega_{sl} = \omega_{LO} - \omega_{IF}$. The former frequency ω_{su} is the upper sideband, and the latter ω_{sl} the lower sideband. For a *lower sideband mixer* the upper sideband is denoted the *image frequency*, and vice versa for an *upper sideband mixer*. For a lower or upper sideband case, some signal power may go to the image frequency. In an *image-reject mixer* a filter prevents the image frequency from entering the mixer. In the *image-enhanced mixer*, the image terminal is terminated reactively so that the conversion loss is reduced.

At high signal powers, there may be confusion because the mixer may produce output signals in the IF band (see Section 1.5 below) for

$$|m\omega_{LO} - n\omega_s| = \omega_{IF} \tag{5}$$

1.4. Harmonic Mixer

In a harmonic and small-signal linear mixer one has $\omega_{IF} = |n\omega_{LO} - \omega_s|$. A spectrum analyzer always uses a harmonic mixer to analyze the signal, and the harmonic number n can be very high (> 10). The power flow in a harmonic mixer is shown in Fig. 5.

1.5. Intermodulation

All mixer products created by two or more signals are called *intermodulation* (IM) products. Most IM products are unwanted.

For example, if two signals at slightly different frequencies ω_{s1} and ω_{s2} and with a power of the same order of magnitude as the LO are interacting with the nonlinear device, the current will contain frequency products as shown in the following equation:

$$I(t) = \sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} i_{m,n} \cos[(m\omega_{LO} + n\omega_{s1} + k\omega_{s2})t + \varphi_{m,n,k}] \tag{6}$$

All signals at frequencies fulfilling the requirement

$$\omega_{s1} \approx |m\omega_{LO} + n\omega_{s2} \pm \omega_{IF}| - \infty < m, n < \infty \tag{7}$$

may create IM products in the IF band. Indeed, intermodulation must be considered a potentially serious problem in all applications where strong signals may occur.

2. SYSTEMS ASPECTS

In a system, the following properties are important: (1) conversion loss, (2) noise properties, and (3) intermodulation properties.

2.1. Conversion Loss

An important property of a mixer is the conversion loss L , defined as

$$L = \frac{P_s}{P_{IF}} = \frac{\text{signal power available at the input}}{\text{IF power delivered to the IF load}} \tag{8}$$

In most practical mixers the conversion loss is larger than one. However, it is possible to obtain gain owing to parametric amplification caused by a nonlinear capacitance. In certain configurations using transistors (see Ref. 1 or 4) conversion gain can be obtained. Superconducting mixers, however, due to quantum phenomena, can show stable conversion gain.

There are several loss mechanisms causing the conversion loss:

1. Losses due to absorption in the nonlinear device
2. Losses due to power lost to harmonic sidebands
3. Losses due to reflection at the input port
4. Losses due to reflection at the IF output port

See also Section 3.

2.2. Mixer Receiver Noise

The important noise measure in practical applications is always the total receiver noise temperature. The contributions approximately in order of importance are (1) mixer device noise, (2) the IF amplifier noise, (3) thermal noise from the mixer circuit, and (4) LO noise. There are two different noise measures usually cited in the literature: the *single sideband* (SSB) noise temperature and the *double sideband* (DSB) noise temperature.

When calculating the noise temperature of a mixer, it is advisable to always start adding up all noise contributions at the IF amplifier input (see Fig. 6). The temperature

Figure 5. Power flow in a second-harmonic lower sideband mixer.

Figure 6. Receiver configuration for calculating the receiver noise. For the calculation it is wise to determine the noise temperature at the input of the IF amplifier T_{in} .

then becomes

$$T_{in} = \frac{T_1}{L_s} + \frac{T_1}{L_i} + \sum_{n=2}^{\infty} \left(\frac{T_1}{L_{n+}} + \frac{T_1}{L_{n-}} \right) + T_{M\ out} + T_{IF} \quad (9)$$

where L_s , L_i , L_{n+} , and L_{n-} are the conversion losses at the signal, image, and upper harmonic sidebands and lower harmonic sidebands, respectively. T_1 is the noise temperature of the input resistance, $T_{M\ out}$ is the noise from the mixer diode entering the IF amplifier. As the next step, identify the signal to noise ratio:

$$\frac{P_s}{P_{in}} = \frac{P_s/L_s}{kT_{in}\Delta f} = \frac{P_s}{kT_{syst}\Delta f} \quad (10)$$

where T_{syst} is by definition the system noise temperature for a *single-sideband* receiver. It is assumed that the useful and interesting signal enters only one sideband. Hence

$$T_{syst,SSB} = T_{in}L_s = T_1 \left[1 + \frac{L_s}{L_i} + \sum_{n=2}^{\infty} \left(\frac{L_s}{L_{n+}} + \frac{L_s}{L_{n-}} \right) \right] + T_{MXR,SSB} + L_s T_{IF} \quad (11)$$

where we have defined the equivalent noise temperature of the mixer itself, $T_{MXR,SSB} = T_{M\ out} L_s$.

For the double-sideband case, one assumes a useful signal to enter both the upper and the lower sidebands. Hence the signal-to-noise ratio for this case should be defined as

$$\frac{P_s}{P_n} = \frac{P_s(1/L_s + 1/L_i)}{kT_{in}\Delta f} = \frac{P_s}{kT_{syst}\Delta f} \quad (12)$$

that is,

$$T_{syst,DSB} = \frac{T_{in}}{1/L_s + 1/L_i} = T_1 \left[1 + \frac{L_s L_i}{L_s + L_i} \sum_{n=2}^{\infty} \left(\frac{1}{L_{n+}} + \frac{1}{L_{n-}} \right) \right] + T_{MXR,DSB} + \frac{L_s L_i}{L_s + L_i} T_{IF} \quad (13)$$

where the double sideband noise temperature of the mixer itself is defined as

$$T_{MXR,DSB} = T_{M\ out} \frac{L_s L_i}{L_s + L_i} \quad (14)$$

Note that if $L_s = L_i$, both the single-sideband mixer and system noise temperatures are twice as large as for the double-sideband case. The LO noise (if important) can be taken into account by adding a certain amount at the input port. Also note that the noise entering the mixer at the harmonic sidebands may considerably influence the total receiver performance.

3. SCHOTTKY DIODE MIXERS

The Schottky diode mixer is the most common type of mixer for frequencies from megahertz to terahertz.

3.1. Schottky Diode for Mixer Applications

A schematic diagram of a common design of millimeter-wave Schottky barrier diode is shown in Fig. 7. Note that the radiofrequency (RF) current is flowing from the diode contact at the surface of the diode chip to the back contact. Hence the RF series resistance is slightly larger for RF than for DC. The current-voltage (I - V) characteristic of the junction itself can be calculated from

$$i_d = I_0 \left[\exp\left(\frac{qV_j}{\eta kT}\right) - 1 \right] \quad (15)$$

where I_0 is the saturation current, V_j the junction voltage, q the charge of the electron, k Boltzmann's constant, T the physical temperature, and η the ideality factor, which for good diodes at room temperature is between, say, 1.03 and 1.10.

The small-signal RF junction properties of a Schottky diode can be modeled as a nonlinear resistance r_j in parallel with a nonlinear capacitance C_j

$$r(i_d) = \frac{\partial V_j}{\partial i_d} = \frac{k\eta T}{qi_d} \quad C(V_j) = \frac{C_0}{\sqrt{1 - \frac{V_j}{V_b}}} \quad (16)$$

where C_0 is the zero bias capacitance and V_b is the built-in voltage of the diode. For more details, see Ref. 3.

Figure 7. Simple design of a GaAs Schottky barrier diode and the corresponding equivalent circuit. The higher the frequency, the smaller the diodes required.

A common measure of the high-frequency properties is the cutoff frequency, which is defined for the diode at zero bias,

$$f_c = \frac{1}{2\pi R_s C_0} \quad (17)$$

where R_s is measured using the DC I - V characteristic. For good mixer performance this cutoff frequency must be much larger than the signal frequency. The series resistance uses up signal power and should for obvious reasons be made as small as possible. For the conversion efficiency the nonlinear capacitance is of much less importance than the nonlinear resistance. The diode is typically designed as a thin n-doped active layer of 1000 Å (Mott diode), which leaves one with a diode with reduced capacitance variation and a minimum series resistance.

GaAs is preferred for millimeter-wave diodes. The main reason is that the high mobility of GaAs yields a low series resistance and consequently a high cutoff frequency. Another advantage (to silicon) is that carriers do not freeze out when the diode is cooled to cryogenic temperatures in order to improve the mixer noise properties [see Eq. (7)].

The noise performance and the conversion efficiency are the prime properties of the diode for use in mixer applications. Noise properties are discussed next.

3.1.1. Shot Noise. The shot noise is due to fluctuations in the electron particle current between cathode and anode of the diode [3]. The root-mean-square (RMS) fluctuations in the current are $\delta i^2 = 2eI\Delta f$, where Δf is a small frequency interval. The noise power of the Schottky diode can then be calculated as

$$P_n = \frac{\delta i^2}{4 \frac{\partial I_d}{\partial V_j}} = \frac{1}{2} k\eta T \Delta f \quad (18)$$

Identifying this equation with the ordinary Johnson noise expression, $P_n = kT \Delta f$, it is seen that the equivalent noise temperature of the Schottky diode is

$$T_{sh} = \frac{1}{2} \eta T \quad (19)$$

Note that the noise temperature decreases linearly with decreasing physical temperature. However, the charge transport at room temperature over the Schottky barrier is due to thermionic emission and decreases when the temperature is lowered. Hence for temperatures on the order of 50–100 K and below, temperature-independent tunneling becomes the dominant process for electrons passing the barrier, and the equivalent temperature ηT of Eq. (6) becomes

$$T_{\text{tunnel}} = \frac{qh}{k} \sqrt{\frac{N_d}{4\epsilon m^*}} \quad (20)$$

where N_d is the doping concentration in the epitaxial layer, ϵ the dielectric constant of the semiconductor, and

m^* the effective mass of the electron. In practice, T_{tunnel} is 50 K for $N_d = 3 \times 10^{16}$. This doping concentration is recommended for mixers operated at 15 or 20 K, a typical temperature for commercial cryogenic cooling machines.

3.1.2. 1/f Noise. There is excess noise at low frequencies (of the order 100 kHz and lower for a good diode), which is related to surface phenomena at the metal–semiconductor interface. This noise is normally not important in mixers for millimeter–wave receivers. However, it is an important limiting factor for certain radar and communications systems.

3.1.3. Thermal Noise. The series resistance is essentially an ordinary resistor and consequently causes ordinary thermal (Johnson) noise. The main noise contribution of this type comes from the substrate (corresponding resistance R_{sub}) and is denoted as T_{sub} .

3.1.4. Hot-Electron Noise and Intervalley Scattering Noise. Since the diode area is very small in order to render the capacitance reasonably small, a high current density is required to make $r_j R_s$. This means that electrons may obtain energies larger than the energy related to their thermal movement and *hot-electron noise* is obtained. The increase in energy also means that electrons can be transferred from the main Γ valley in the E - k diagram (for details, see Ref. 3) to the upper L valley, causing fluctuations in the electron velocity and *intervalley scattering noise* is obtained. The hot electron and intervalley scattering noises occur essentially in the undepleted part of the epilayer (resistance R_{epi}) and are denoted as T_{epi} .

3.2. Large-Signal Analysis by Harmonic Balance

When the nonlinear device is pumped by the LO, harmonic currents are created [4–6]. The equivalent circuit of a Schottky diode mixer is shown in Fig. 8. Note that the series resistance is assumed to be linear and will be included in the embedding circuit.

The current $I_e(t)$ contains harmonics of the LO pump frequency, $k\omega_{\text{LO}}$. For a Schottky diode, this current consists of two parts: one that is associated with the nonlinear resistance $i_d(t)$, and one with the parallel nonlinear capacitance $i_c(t)$. We have [using the complex notation; of Eq. (2)]

$$I_e(t) = i_c(t) + i_d(t) = \sum_{k=-\infty}^{k=\infty} I_{ek} e^{jk\omega_{\text{LO}}t} \quad I_{ek} = I_{e-k}^* \quad (21)$$

This current $I_e(t)$ flows through the embedding circuit, creating voltages at harmonic frequencies at $k\omega_{\text{LP}}$:

$$V_j(t) = \sum_{k=-\infty}^{k=\infty} V_k e^{jk\omega_{\text{LO}}t} \quad V_k = V_{-k}^* \quad (22)$$

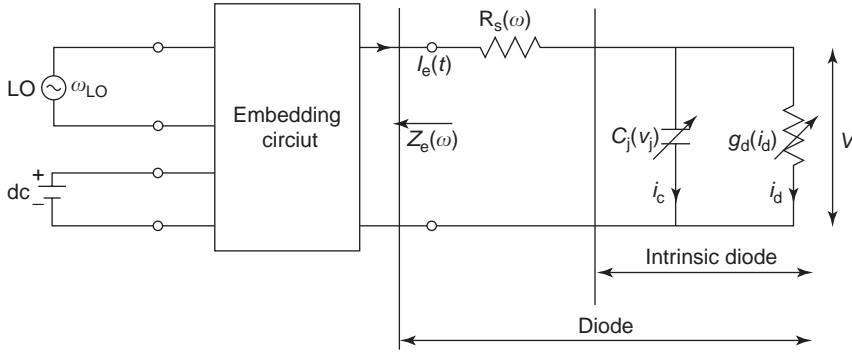

Figure 8. Equivalent circuit of a mixer. For the intrinsic diode, C_j and g_d are nonlinear and are characterized in the time domain, while the diode series resistance R_s and the embedding impedance Z_e are linear and can be described in the frequency domain.

The boundary conditions set by the *embedding circuit* require that

$$V_k = -I_{ek}[Z_{ek}(k\omega_{LO}) + R_s(k\omega_{LO})] \quad (23)$$

$$k = \pm 2, \pm 3, \dots, \pm\infty$$

$$V_{\pm 1} = V_{LO} - I_{e\pm 1}[Z_{e\pm 1}(\pm\omega_{LO}) + R_s(\pm\omega_{LO})] \quad (24)$$

$$V_0 = V_{DC} - I_{e0}[Z_e(0) + R_s(0)] \quad (25)$$

where V_{LO} and V_{DC} are the LO and DC bias voltages, respectively. The frequency dependence of R_s is due to the skin effect. If $V_j(t)$ is known, $i_d(t)$ and $i_c(t)$ (see Fig. 8) can be calculated from Eqs. (15) and (16). We now have a nonlinear problem to solve in order to determine I_{ek} and V_{ek} . Several iteration type methods have been suggested. See Refs. 4 and 5 for more details.

Having determined the components I_k and V_k , we have $V_j(t)$ and $I_e(t)$, and we can determine $i_d(t)$, $i_c(t)$, $g_d(t)$, and $C_j(t)$:

$$g_d(t) = \sum_{k=-\infty}^{k=\infty} G_k e^{jk\omega_{LO}t} \quad G_k = G_{-k}^* \quad (26)$$

$$C_j(t) = \sum_{k=-\infty}^{k=\infty} C_k e^{jk\omega_{LO}t} \quad C_k = C_{-k}^* \quad (27)$$

These equations together with the embedding impedance $Z_e(\omega)$ allow us to determine the small signal properties of the mixer.

3.3. Small-Signal Analyses

The relation between the small-signal current and voltage vectors $\delta\mathbf{I}$ and $\delta\mathbf{V}$ can be expressed in a more general form as

$$\delta\mathbf{I} = \mathbf{Y} \delta\mathbf{V} \quad (28)$$

where

$$Y_{mn} = G_{m-n} + j(\omega_0 + m\omega_{LO})C_{m-n} \quad (29)$$

where for convenience we use ω_0 for ω_{IF} . It is convenient to form an augmented \mathbf{Y} matrix, \mathbf{Y}' , as indicated in Fig. 9. This augmented network contains the whole mixer, including diode and embedding network, but does not contain signal sources associated with these terminations. Since we define the signal sources as current sources, the augmented network in this case is open-circuited. For the augmented network

$$\delta\mathbf{I}' = \mathbf{Y}' \delta\mathbf{V} \quad (30)$$

and

$$\mathbf{Y}' = \mathbf{Y} + \text{diag} \left[\frac{1}{Z_{em} + R_{sm}} \right] \quad (31)$$

Inverting Eq. (23) yields

$$\delta\mathbf{V} = \mathbf{Z}' \delta\mathbf{I}' \quad (32)$$

where

$$\mathbf{Z}' = \frac{1}{\mathbf{Y}'} \equiv \begin{bmatrix} \vdots & \vdots & \vdots & \vdots \\ \dots & Z'_{11} & Z'_{10} & Z'_{1-1} & \dots \\ \dots & Z'_{01} & Z'_{00} & Z'_{0-1} & \dots \\ \dots & Z'_{-11} & Z'_{-10} & Z'_{-1-1} & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots \end{bmatrix} \quad (33)$$

3.4. Mixer Port Impedances

The port impedance Z_{mm} , defined in Fig. 9, can be determined if the corresponding embedding impedance is open-circuited, that is

$$Z_m = Z'_{mm, \infty} \quad (34)$$

where the subscript ∞ means that Z'_{mm} is evaluated for $Z_{em} = \infty$. The IF output impedance becomes

$$Z_{\text{out}} = Z_0 + R_{s0} = Z'_{00, \infty} + R_{s0} \quad (35)$$

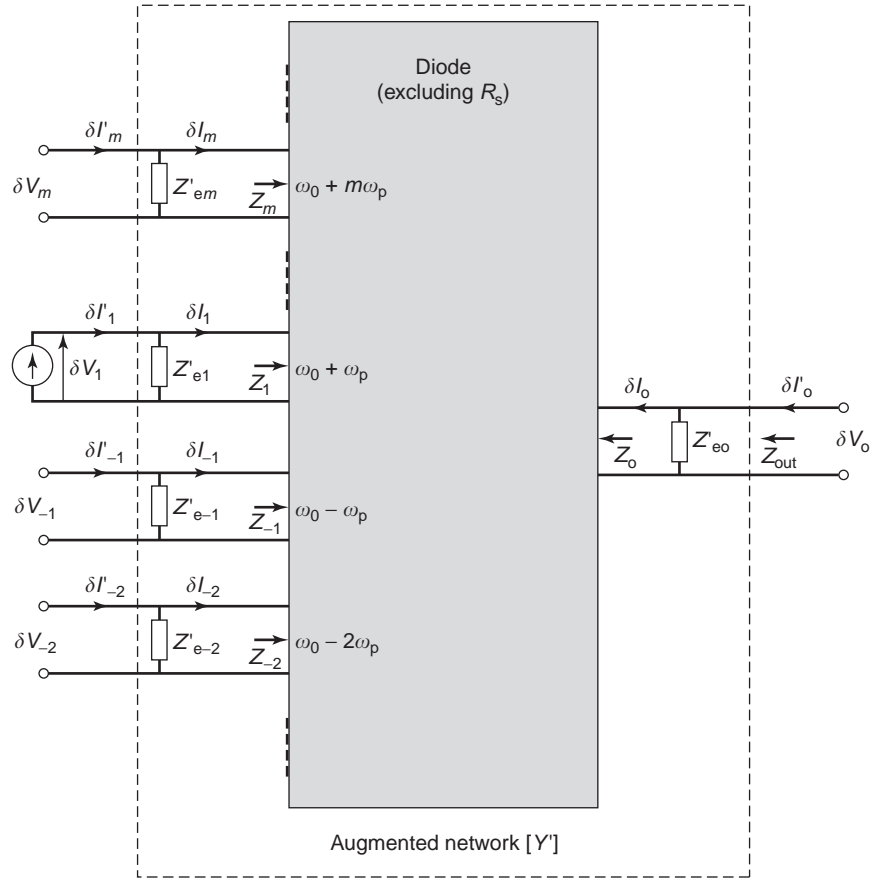

Figure 9. The *small-signal* representation of the mixer as a multifrequency linear multi-port network. Note that R_s is included in $Z' = Z_{ek} + R_s$. In a more exact model, R_s is frequency- and bias-dependent. In this text we use R_{s1} for the series resistance at the input frequency (fundamental mixer) and R_{s0} for the series resistance at the IF. Index 0 indicates parameters at the IF; ω_0 is the IF.

3.5. Conversion Loss

The conversion loss of a mixer is defined as [cf. Eq. (8)]

$$L = \frac{\text{power available from source } Z_{e1}}{\text{power delivered to load } Z_{e0}} \quad (36)$$

yielding the conversion loss

$$L = \frac{1}{4|Z'_{01}|^2} \frac{|Z_{e0} + R_{s0}|^2}{\text{Re}[Z_{e0}]} \frac{|Z_{e1} + R_{s1}|^2}{\text{Re}[Z_{e1}]} \quad (37)$$

where Z_{ek} is defined in Fig. 9 (see figure caption) and Z'_{01} is the 01 diagonal element of Eq. (33). A more general expression for the conversion loss from any sideband j to any other sideband i is

$$L_{ij} = \frac{1}{4|Z'_{ij}|^2} \frac{|Z_{ei} + R_{si}|^2}{\text{Re}[Z_{ei}]} \frac{|Z_{ej} + R_{sj}|^2}{\text{Re}[Z_{ej}]} \quad (38)$$

3.6. Equivalent-Noise Temperature of the Mixer

The equivalent input noise temperature of the mixer T_M is defined as the temperature that the real part of the Z_{e1}

(lower sideband) must have in order to generate the same noise voltage as the diode itself generates during mixer operation. It is

$$T_M = \frac{\langle \delta V_{N0}^2 \rangle}{4k\Delta f} \frac{|Z_{e1} + R_{s1}|^2}{|Z'_{01}|^2 \text{Re}[Z_{e1}]} \quad (39)$$

where $\langle \delta V_{N0}^2 \rangle$ is

$$\langle \delta V_{N0}^2 \rangle = Z'_0 \langle \delta \mathbf{I}'_s \delta \mathbf{I}'_s \dagger \rangle Z_0 \dagger + Z'_0 \langle \delta \mathbf{I}'_T \delta \mathbf{I}'_T \dagger \rangle Z_0 \dagger \quad (40)$$

where

$$\begin{aligned} \langle \delta \mathbf{I}'_{Tm} \delta \mathbf{I}'_{Tm} \dagger \rangle &= \frac{4kT_{eq} R_{sm} \Delta f}{|Z_{em} + R_{sm}|^2} \quad m \neq 0 \\ &= \frac{4kT_{eq} R_{sm} \Delta f}{|Z_0|^2} \quad m = 0 \end{aligned} \quad (41)$$

and

$$\langle \delta \mathbf{I}'_{sm} \delta \mathbf{I}'_{sn} \dagger \rangle = 2eI_{m-n} \Delta f \quad (42)$$

I_{m-n} is the current component at the harmonic $(m-n)$ and Z_0 is the zero row of the matrix Z' , Eq. (33). Z_{e1} is defined in Fig. 9.

The noise temperature as defined in Eq. (42) is the *single-sideband noise temperature* for the lower sideband.

Knowing the diode parameters, we can analyze the Schottky mixer with a high degree of accuracy using commercial software.

4. DIODE MIXER TOPOLOGIES AND MIXER DESIGN

One may consider a number of different approaches in designing mixers. Symmetry properties are one way of defining basic types of mixers:

1. The single-ended mixer with one diode and a common input port for the signal and the LO
2. The single-balanced mixer with two diodes and separate ports for signal and LO
3. The double-balanced mixer with four diodes and separate ports for signal and LO
4. The double-double-balanced mixer with eight diodes and separate ports for signal and LO

For millimeter- and submillimeter-wave applications, types 1 and 2 have been implemented experimentally and are described in the literature, while all four types are common in microwave frequency applications.

The performance of either mixer type depends on the *impedances* seen at the signal, at the IF, and at the harmonic sidebands. The LO should experience a reasonably good match in order to reduce the LO power requirement. In practice, the impedances at the harmonics of the LO and at the harmonic sidebands are very difficult to control. The exception is the impedance at the image frequency, which can often be controlled. The importance is illustrated by referring to properties of a typical broadband mixer (when $L_s = L_i$) used in a single-sideband application. In such a mixer a considerable amount of the signal power ($\approx 25\%$) may end up at the image frequency.

It is also obvious that the *noise* entering the mixer at the image port will be converted with the same efficiency as the signal at the signal port, adding to the system noise.

4.1. Single-Ended Mixer

A single-ended mixer has one input port, used for both the signal and the LO. Hence it is necessary to incorporate a circuit in front of the mixer itself for injecting the LO. This circuit should not significantly attenuate the signal. For example, using a 10-dB directional coupler will attenuate the signal $\sim 10\%$ and add noise (see Fig. 10). A common way of introducing the LO in microwave- and millimeter-wave mixers is to use a narrow band diplexer, for example, a filter structure in the input waveguide or a quasioptical interferometer in the signal path in front of the mixer (e.g., see Ref. 10).

4.2. Single-Balanced Mixers

In single-balanced mixers, the signal and the LO enter the mixer through different ports, isolated from each other. Either 90° or 180° hybrids or baluns are used (Fig. 11a)

Figure 10. Example for a single-ended mixer configuration. Note that the directional coupler used for injecting the LO couples only 10% of the LO power to the mixer diode, and that the coupler consequently attenuates the signal by a factor of 0.9.

(see Ref. 1 for details). Figure 11b shows a low-frequency equivalent circuit of a single-balanced mixer. The paths of the signal current i_s and the LO current i_{LO} indicate that they add in one diode and subtract in the other. This causes an imbalance in A, which will slowly cycle at a frequency equal to the IF. Hence the IF power can be subtracted between A and ground. Note that if the LO is noisy, this will not cause any output noise at the IF port.

The use of two diodes rather than one means that the mixer can handle twice as much power for the same intermodulation as for the single-ended mixer. In summary, for the single-balanced mixer:

- The signal, LO, and IF ports are isolated from each other.
- The LO noise cancels at the IF port.
- The power handling is superior to the single ended mixer.

Figure 11. Basic design of the single-balanced mixer (a) and equivalent circuit of the 180° hybrid mixer, (b).

4.3. Double-Balanced Mixers

Essentially, a double-balanced mixer is constructed from two single-balanced mixers, coupled in parallel and 180° out of phase. The diodes can be arranged in either a star or ring configuration (see Fig. 12). The ring can be arranged very compactly as a monolithic circuit.

If the diodes are perfectly identical, the symmetry ensures perfect isolation between the signal and the LO ports. The topology also yields cancellation at the IF port of the even harmonics of both the signal and the LO frequencies. This also means that intermodulation is reduced as compared to the mixers mentioned above. Hence the advantages of the double-balanced mixer are:

- Excellent isolation between the signal, LO, and IF ports
- LO noise cancellation at the IF port
- Superior power handling compared to the double balanced mixer
- Superior intermodulation properties compared to the double balanced mixer

4.4. Double-Double-Balanced Mixers

Double-double-balanced mixers are constructed using two double-balanced mixers. Eight diodes are used, leading to further power-handling capacity and still better intermodulation properties.

4.5. Image Rejection and Image Enhancement

The system properties of a single-sideband mixer receiver can be improved by introducing a proper circuit at the image frequency. It is of particular importance to reactively terminate the image frequency so that no signal power is lost at the image frequency and no noise (or any other unwanted signal) at the image frequency can be converted to the IF frequency. Furthermore, if the reactance at the image frequency is chosen properly, the “signal will be reflected back into the mixer,” such that the conversion is *enhanced* and/or the noise properties are improved. A stopband filter can be added in the input transmission line to prevent one sideband from reaching the diode. The distance to the diode is chosen to optimize the mixer conversion loss. The conversion loss becomes

Figure 12. A double-balanced mixer configuration: the ring mixer.

several decibels lower than the typical 5 dB for a common broadband microwave mixer.

A most elegant method to realize a single sideband mixer is shown in Fig. 13. By using two balanced mixers and two 90° hybrids, it is possible to arrange that the upper sideband and the lower sideband exit the mixer at different ports (see Ref. 1 or 4 for details).

5. HARMONIC MIXERS

In a harmonic mixer a harmonic of the LO frequency, $n\omega_{LO}$, is used for mixing; that is, the IF is obtained as

$$\omega_{IF} = |n\omega_{LO} - \omega_s| \tag{43}$$

Harmonic mixers are practical when it is difficult to realize LO power at a frequency near the signal frequency. They are particularly useful at millimeter and submillimeter waves.

Large harmonic numbers n are often used when maximum sensitivity is not required. For example, in spectrum analyzers large harmonic numbers may be used.

5.1. Two-Diode Subharmonically Pumped Mixers

If two diodes are used in an antiparallel configuration (see Fig. 14), the small-signal conductance will vary with twice the LO frequency. Hence the mixer will convert signals located near $2f_{LO}$, and no conversion will occur near f_{LO} . The advantage of the two-diode over the single-diode subharmonically pumped mixers is that no conversion can occur at the fundamental frequency. Moreover, the LO noise will contribute less, since the frequency difference between the signal and the LO is of the order f_{LO} . Another advantage is inherent self-protection against large peak reverse voltage burnout.

6. PARAMETRIC FREQUENCY CONVERSION

In a parametric frequency converter, a nonlinear reactance, such as a backward-biased Schottky diode, is used. Common parametric components are frequency downconverters, frequency upconverters, and frequency

Figure 13. A single-sideband mixer using two balanced mixers and two 90° hybrids. Note that at one output port the upper sideband appears, while at the other output port the lower sideband appears.

Figure 14. Subharmonically pumped mixer using antiparallel diodes, showing (a) the mixer circuit, (b) the DC I - V characteristic, and (c) the resulting waveforms for the LO voltage and the time-dependent small signal conductance.

multipliers. In a frequency downconverter, a strong pump signal f_{LO} and signal f_s (strong or weak depending on application) are applied to the device. The output frequency is

$$f_{out} = |f_{LO} - f_s| \text{ frequency downconversion} \quad (44)$$

For a frequency upconversion, we have

$$f_{out} = |f_{LO} + f_s| \text{ frequency upconversion} \quad (45)$$

The signal frequency in this case may be much lower than the LO (or pump) frequency; that is, the output frequency is not far from the LO frequency.

Note that if the device has no resistive parasitics, no power is lost in the device itself, and 100% efficiency is theoretically possible. However, power may go to harmonics or harmonic sidebands and there are always some parasitic resistances present, for example, the series resistance in a Schottky diode.

If we select a large ratio f_{LO}/f_s , the frequency upconverter may have high gain. This is possible since, by appropriate choice of the circuit parameters, parametric amplification is achieved [7]. In the case of gain, one has negative resistance in the circuit and one may face stability problems. However, it is very difficult to make a broadband parametric upconverter, since proper impedances have to be realized at f_s , f_{LO} , and f_{out} . Parametric converters are used much less today than a few decades ago. The reason is that the quality of mixer diodes and FETs has improved significantly and it is much easier to make diode (or FET) mixers very broadband. This is the reason why resistive mixers are preferred in most applications. Note that FET mixers can be designed for a conversion gain greater than one.

A classical reference concerning varactor circuits is the book by Penfield and Rafuse [7]. A parametric downconverter, like the Schottky mixer, can be analyzed using commercial software.

7. NEGATIVE-RESISTANCE DIODE MIXERS

In the current-voltage (I - V) characteristic of, say, the Esaki tunnel diode or the resonant tunneling diode, there is a region that has a differential negative resistance. This means that the mixer can have conversion gain. Tunnel diode mixers have been built and tested. However, a large junction capacitance made the frequency range quite limited, which, together with poor power handling, stability problems, and less favorable noise properties, means that these mixers have very little practical use today.

8. SELF-OSCILLATING MIXERS

The negative resistance devices can as well promote an oscillation. Hence it is possible to design circuits where the LO is delivered by the same device that is performing the mixing. Besides the devices mentioned already, Gunn diodes have also been used in self-oscillating mixers. The sensitivity of such mixers is limited. The advantage may be in applications where the best performance is less important and the lowest price is required, as, for instance, in low-priced Doppler radar applications.

9. BOLOMETER MIXERS

Bolometer mixers have been constructed since the 1950s. Since the electromagnetic absorption in bolometer devices can be essentially frequency-independent, it should be possible to do mixing to several terahertz. In this type of mixer, one is using the fact that when two signals at slightly different frequencies are superimposed the resulting signal can be described as a signal that is amplitude-modulated with the difference frequency. The first useful bolometer mixer was based on InSb devices cooled to temperatures of a few kelvins. When the device absorbs the modulated signal, the electron temperature becomes modulated, leading to a modulation in the device resistance. The theory is described in more detail in Section 10.2 and by Arams et al. [8].

However, the thermal time constant for the InSb device is long, allowing a maximum IF of only about 2 MHz. A more recent bolometer mixer is based on a two-dimensional electron gas in HEMT materials allowing an IF to about 1 GHz [9]. However, the most successful hot-electron bolometer mixer so far is the superconducting hot-electron bolometer mixer.

10. MIXERS BASED ON SUPERCONDUCTING DEVICES

Room-temperature mixers for frequencies from about 100 GHz to a few terahertz THz frequencies use only Schottky diodes. However, if sensitivity is an issue (e.g., as in radioastronomy), there is a better alternative in

Figure 15. Schematic description of typical Dewar setup for a sub-millimeter-wave SIS or HEB mixer. The LO and the signal are entering together through the Dewar window. The radiation is focused on the antenna using a hyperhemispherical lens, downconverted to the IF in the nonlinear device, and finally amplified by the IF amplifier. In this figure the antenna is illustrated as a spiral antenna. There are many other possible planar antenna structures available (see Ref. 9 for details).

mixers based on superconducting devices cooled to a few kelvins. Low-noise superconductor–insulator–superconductor (SIS) mixers have excellent performance up to about 1 THz [10]. Superconductor hot-electron bolometer (HEB) mixers are the best alternative for frequencies above 1 THz.

Figure 15 shows a schematic of a receiver (except for the input quasi-optics) based on superconducting devices.

10.1. The SIS Mixer

The SIS mixer is also called the “quasiparticle mixer.” Because of the extremely strong nonlinearity in the I - V characteristic of the SIS device, quantum effects are important. Indeed, for certain choices of embedding impedance network, this can result in a conversion gain (see Ref. 11 for details).

In a superconductor and at a temperature below the superconducting transition temperature, electrons form

pairs, called *Cooper pairs*. When they do so, the energy of the electrons near the Fermi energy is lowered by a certain amount Δ . Hence, to break up a Cooper pair, an energy of 2Δ is required. This can be described in terms of a bandgap with the energy 2Δ , as shown in Fig. 16.

In the SIS mixer, a tunneling phenomenon is used. In the device, two superconducting films are separated by a thin (~ 20 -Å) layer of insulator. Under bias, Cooper pairs on one side of the insulator break up into two electrons (quasiparticles) that individually tunnel through the insulator and recombine on the other side of the insulator. This is illustrated in Fig. 16. It is interesting to note that the density of states near the band edges becomes “infinite.” This is one important reason why there is such a sharp increase in the current when the device is biased to a voltage $V = 2\Delta/e$ (e is the charge of the electron). The I - V characteristic is shown in Fig. 17. Note that the voltage scale is in millivolts, and that 1 meV corresponds to 240 GHz. The steps in the I - V curve correspond to DC bias voltages, where exactly $eV = 2\Delta - hf$ ($V \approx 1.35$ mV). Since the I - V characteristic is strongly nonlinear within a fraction of a millivolt, the mixer is operating in the quantum regime. See also Fig. 18, where the I - V character of an SIS device is compared with a Schottky diode. The Schottky diode obviously is not very nonlinear within a voltage interval of 1 mV and is therefore operating fully as a classical mixer for frequencies up to several terahertz. It should also be mentioned that the required LO power is very low, on the order nanowatts. This is of great importance for sub-millimeter-wave mixers, where substantial LO power is difficult to obtain.

The best SIS devices are realized in so-called Nb trilayer technology [11]. The device structure is Nb/Al₂O₃/Nb, where the ~ 20 -Å-thick Al₂O₃ serves as the insulator in the SIS device. For frequencies above ~ 700 GHz, one is trying to develop devices based on NbN, which has a higher bandgap (≈ 1.2 THz) than does Nb. So far these attempts have not been very successful.

The basic noise in the SIS mixer is shot noise. Comparing the I - V characteristics of the SIS device and Schottky diode and using the classical theory described in Section 3, one can see that the mixer noise and the conversion loss are essentially lower for the SIS mixer. However, the theory must include quantum effects (see Ref. 11 for more details). This leads to a conversion gain that is possibly larger than one, a fact that has been demonstrated in practice.

Figure 16. The SIS device under bias: (a) no bias; (b) for a voltage bias $V > 2\Delta/e$ electrons will tunnel from right to the left; (c) tunneling is assisted by a photon with energy hf_{LO} for the bias voltage $V = (\Delta - hf_{LO})/e$.

Figure 17. Typical I - V characteristic of a SIS element. The thin line indicates the shape of the pumped I - V characteristic, where $f_{LO} \hbar \approx 1.4$ meV ($f_{LO} = 325$ GHz), while the thick line is for the unpumped device.

10.2. Hot-Electron Bolometer Mixer

A bolometer consists of an absorber that is heated by radiation and a temperature-dependent resistance as a “thermometer.” The bolometer has a thermal time constant τ_0 limiting the maximum detectable modulation frequency of the absorbed power. This means that the maximum feasible IF is $f_{IF} = 1/(2\pi\tau_0)$. When the LO and signal are added together, the instantaneous power variation is described by $[V_{LO} \cos(\omega_{LO}t) + v_s \cos(\omega_s t)]^2 (1/R_{RF})$ (see Fig. 3). If the bolometer can respond to ω_{IF} but not to $(\omega_{LO} + \omega_s)$, $2\omega_{LO}$, and $2\omega_s$, the bolometer temperature and the resistance will be approximately proportional to $P_{LO} + P_s + 2\sqrt{P_{LO}P_s} \cos(\omega_{IF}t)$. Note that the “slow” response of the bolometer device means that there are no harmonics of the LO created and no signal power is transformed to the image frequency, as is the case for both the SIS and Schottky mixers.

Figure 18. Comparing the I - V characteristic of a SIS element with that of a Schottky diode. Note the enormous difference in nonlinearity.

A superconducting hot-electron bolometer (HEB) consists of one or several superconducting thin-film strips in parallel, deposited on a substrate, for example, silicon, single-crystalline quartz, or sapphire. The strips are cooled to the superconducting state and then heated by DC and microwave power to temperatures near the superconducting to normal transition temperature, where the superconductor will gradually become normal (Fig. 19).

The maximum IF is determined by the electron temperature relaxation time τ_0 , that is, $f_{IF} < 1/(2\pi\tau_0)$, and a major issue is to find ways of making the time constant τ_0 short enough. Figure 20 indicates how cooling occurs in the so-called phonon-cooled and the diffusion-cooled bolometer, respectively [10,12].

When operating the mixer, the device is absorbing LO power (P_{LO}) and signal power (P_s) as well as power from the DC bias supply ($P_{DC} = V_0 I_0$). When the power increases, obviously the electron temperature increases and the resistance of the device increases as $\Delta R = (dR_0/dP)\Delta P = C_0 \Delta P$. Figure 21 shows a simple equivalent circuit of the mixer, where the device is biased by a constant DC current. Consequently, the modulation at the IF of the resistance will cause an IF voltage to appear across the device, causing an IF current through the IF load resistance R_L . The IF current ΔI is superimposed on the DC bias current through the mixer device $R_0(P)$ and will cause a “modulation” of the DC power $\Delta P_{DC} \cos(\omega_{IF}t)$. The total power dissipated in the device is then

$$\begin{aligned}
 P(t) &= P_0 + \Delta P(t) \\
 &= P_{DC} + \Delta P_{DC} \cos(\omega_{IF}t) + P_{LO} \\
 &\quad + P_s + 2\sqrt{P_{LO}P_s} \cos(\omega_{IF}t)
 \end{aligned}
 \tag{46}$$

Assuming that DC and RF power affect the resistance by the same amount, the IF modulation of the device resistance becomes $C_0 \Delta P(t)$. There is a resulting bias point of the device $V = V_0$ and $I = I_0$. Defining the device DC resistance R_0 as the time average of $R_0(P)$, that is, $R_0 =$

Figure 19. Current-voltage (I - V) characteristic of a HEB with and without a LO. At the operating point, $V_0/I_0 = R_0$. For large bias voltage the whole strip is normally conducting ($R = R_N$). I_c is the critical current, the maximum current in the completely superconducting state.

Figure 20. Two types of bolometer devices: (a) phonon-cooled; (b) diffusion-cooled.

V_0/I_0 , one obtains (8) the conversion gain

$$G = \frac{P_{IF}}{P_s} = 2C_0^2 \frac{P_{LO}P_{DC}}{(R_L + R_0)^2} \cdot \frac{R_L}{R_0} \left(1 - C_0 \frac{P_{DC}}{R_0} \cdot \frac{R_L - R_0}{R_L + R_0} \right)^{-2} \quad (47)$$

where $C_0 = dR_0/dP$; R_L is the IF load resistance and P_{IF} , P_s , P_{LO} , and P_{DC} are the IF, signal, LO, and DC power, respectively, dissipated in the device.

Figure 21. Equivalent circuit of bolometer with load.

The commonly assumed fundamental limit of -6 dB gain for hot-electron mixers is not valid if a negative differential resistance of the unpumped $I-V$ curve is available (see Ref. 13 for details). The load resistance for maximum gain is equal to the differential resistance of the $I-V$ curve at the bias point of the pumped mixer.

10.3. Experimental Results

In experiments on phonon-cooled NbN HEB mixers, noise temperatures of about 400 K (DSB) have been obtained at 600 GHz, and 1000 K (DSB) at 900 GHz. At 2.5 THz a noise temperature of about 1400 K has been obtained. The conversion loss is typically 10 dB, including losses from the optics in front of the mixer.

The noise of these mixers is caused by thermal fluctuations in the bolometer device (causing resistance fluctuations) and by Nyquist noise. For diffusion-cooled mixers a noise temperature of 650 K DSB at 533 GHz was measured by Skalare et al. [14]. These experiments indicate that an IF bandwidth of at least 3 GHz is achievable. Later experiments show that it should be possible to obtain at least 50% higher IF bandwidths in practical mixers. A crucial number is the maximum IF bandwidth. For a phonon-cooled HEB mixer, a 3.7 GHz IF bandwidth

(−3 dB reduction in conversion gain) has been measured and diffusion-cooled between 2 and 6 GHz. While this bandwidth is defined for a *conversion loss* increase of 3 dB, the bandwidth defined for when the *noise temperature* has increased by 3 dB is about 1.5 times larger (~5.5 GHz for the phonon-cooled one).

The LO power needed is less than 100 nW, which is much lower than that needed for Schottky diode mixers.

FREQUENCY-DIVISION MULTIPLEXERS

RICHARD V. SNYDER
RS Microwave
Butler, New Jersey

1. INTRODUCTION

Frequency multiplexers are networks used to distribute an input spectrum, either through separation into spectral subcomponents or by combination of subcomponents. In the first case, a given input spectrum is separated by fre-

quency-sensitive elements into discrete (but possibly contiguous) segments. In the second case, a multiplicity of discrete (but possibly contiguous) input segments are similarly combined into a composite output spectrum. In most situations, it is required to maintain desirable passband characteristics, such as match to source and load impedances, amplitude flatness, low ripple, and minimum group delay distortion, for all ports of the multiplexer. Certainly the separate spectral portions have to be isolated by maintaining specified stopband slopes for each portion. Because of interactions between the separate portions, these requirements are very difficult to realize. However, there are many techniques that have been developed for frequency multiplexing. Coordination of direct synthesis and mathematical optimization provides the tools necessary to solve the problem.

2. STATEMENT OF THE PROBLEM

It is required to separate a contiguous spectrum into specified portions. In most cases, it is necessary to avoid reflections from the ports associated with the specified portions in order to preserve the total energy contained in the initial contiguous spectrum. The associated problem is combination of specified spectral segments into a contiguous output spectrum, again with the low port reflection criterion pertaining to the combining scheme. These closely related problems are shown in a two-port configuration in Fig. 1. Note that simply minimizing port reflections is normally inadequate, because the intention of the multiplexing schemes is availability of total spectral energy at the respective ports, rather than internal dissipation as an alternative to external reflection. However, examples of important exceptions to this condition will be presented in later sections.

Consideration of Fig. 1 reveals a deceptively simple configuration for the three-port multiplexer, known as a “diplexer.” It consists of two selective filters and an interconnection network. The idealized response is shown in Fig. 2. It is required to determine the criteria for the selective filters and the interconnection network. The filters can employ almost any of the available design approaches, including lumped element, crystal, dielectric resonators, evanescent mode, waveguide, cavity, and SAW. The interconnection network must be physically compatible with the chosen filter approach, but can also consist of a very wide variety of transmission lines, lumped

Figure 1. Three-port multiplexer (a “diplexer”). The common port can be an input or an output, while the isolated ports are, respectively, outputs or inputs.

(−3 dB reduction in conversion gain) has been measured and diffusion-cooled between 2 and 6 GHz. While this bandwidth is defined for a *conversion loss* increase of 3 dB, the bandwidth defined for when the *noise temperature* has increased by 3 dB is about 1.5 times larger (~5.5 GHz for the phonon-cooled one).

The LO power needed is less than 100 nW, which is much lower than that needed for Schottky diode mixers.

FREQUENCY-DIVISION MULTIPLEXERS

RICHARD V. SNYDER
RS Microwave
Butler, New Jersey

1. INTRODUCTION

Frequency multiplexers are networks used to distribute an input spectrum, either through separation into spectral subcomponents or by combination of subcomponents. In the first case, a given input spectrum is separated by fre-

quency-sensitive elements into discrete (but possibly contiguous) segments. In the second case, a multiplicity of discrete (but possibly contiguous) input segments are similarly combined into a composite output spectrum. In most situations, it is required to maintain desirable passband characteristics, such as match to source and load impedances, amplitude flatness, low ripple, and minimum group delay distortion, for all ports of the multiplexer. Certainly the separate spectral portions have to be isolated by maintaining specified stopband slopes for each portion. Because of interactions between the separate portions, these requirements are very difficult to realize. However, there are many techniques that have been developed for frequency multiplexing. Coordination of direct synthesis and mathematical optimization provides the tools necessary to solve the problem.

2. STATEMENT OF THE PROBLEM

It is required to separate a contiguous spectrum into specified portions. In most cases, it is necessary to avoid reflections from the ports associated with the specified portions in order to preserve the total energy contained in the initial contiguous spectrum. The associated problem is combination of specified spectral segments into a contiguous output spectrum, again with the low port reflection criterion pertaining to the combining scheme. These closely related problems are shown in a two-port configuration in Fig. 1. Note that simply minimizing port reflections is normally inadequate, because the intention of the multiplexing schemes is availability of total spectral energy at the respective ports, rather than internal dissipation as an alternative to external reflection. However, examples of important exceptions to this condition will be presented in later sections.

Consideration of Fig. 1 reveals a deceptively simple configuration for the three-port multiplexer, known as a “diplexer.” It consists of two selective filters and an interconnection network. The idealized response is shown in Fig. 2. It is required to determine the criteria for the selective filters and the interconnection network. The filters can employ almost any of the available design approaches, including lumped element, crystal, dielectric resonators, evanescent mode, waveguide, cavity, and SAW. The interconnection network must be physically compatible with the chosen filter approach, but can also consist of a very wide variety of transmission lines, lumped

Figure 1. Three-port multiplexer (a “diplexer”). The common port can be an input or an output, while the isolated ports are, respectively, outputs or inputs.

Figure 2. Diplexer, showing “crossover” region (the frequencies between f2 and f5).

elements, phase shifters, and other components. Interconnection of the various filters and combining networks is an artform, but requires awareness of the parasitic lengths that must be included between the selective filters and necessary reactive elements. These parasitic lengths can cause serious response problems, but the effects can be evaluated during the simulation cycle preceding finalization of any design. A summary of many currently used

multiplexing techniques is presented in Table 1. It is not the purpose of this article to discuss filter implementations, but a summary chart of available approaches will be provided at the conclusion of this article (Fig. 18), following the detailed description and examples of multiplexing.

To maintain match at the common port, the following must be satisfied:

$$Y_{in} = [Y_{ch1}] + [Y_{ch2}] = Y_0 \tag{1}$$

where

- Y_{in} = common port input admittance
- Y_{ch1} = input admittance of the F1–F2 selective filter
- Y_{ch2} = input admittance of the F5–F6 selective filter
- Y_0 = nominal circuit characteristic impedance (e.g., 0.02 mho)

All admittances are generally complex quantities. Satisfaction of this requirement can be accomplished if each of the channel-selective filters is designed so as to present a complementary admittance at the common junction, or if the interconnection network provides the appropriate admittance transformation from the filter to the common junction. If the admittance presented at the common

Table 1. Multiplexer Design Methods

Type	Typical Application	Restrictions or cautions	Comments
Circulator-coupled channel dropping	High-power communication	All circulators must cover the full system bandwidth	Almost plug-and-play (filters can be removed and replaced without retuning), but stopband level limited to intrinsic circulator isolation (see Fig. 6)
Common-connection susceptible cancellation	Electronic warfare: electronic intelligence gathering and radar warning receivers	Difficult and expensive to produce because of element sensitivity and common-junction design; composite performance is quite sensitive to all elements in the structure	Compact, efficient use of available filter topologies (see Figs. 7 and 8)
Directly synthesized singly terminated filters with common-junction connection	Wideband communication and electronic warfare	Composite performance is sensitive to all elements in structure, but less so than in the susceptible cancellation approach	Filters can be essentially designed individually, but filter order is higher than required for doubly terminated designs (see example in Fig. 16)
Separable manifold and filters (channel dropping)	Electronic warfare: electronic intelligence gathering and radar warning receivers	Manifold and filters are separable, designed essentially as independent networks, relatively easy to produce; element sensitivity is acceptable for production	Not as compact as the common-junction approach (see Figs. 9–12 and then Figs. 16 and 17 for special configurations)
Double-diplexing (or double <i>n</i> th-order multiplexing, in general)	Provides multiple passbands for communication applications	Useful when nonmonotonic stopband or guardband between channels is allowed	Limited stopband between filter channels (see Figs. 13–15)
Power-divider-coupled “frequency thinner”	Electronic warfare: electronic intelligence gathering and radar warning receivers	Crossover region not required to display 3 dB dip at common frequency between channels	Flat loss of at least 3 dB (see text and Fig. 4)
Hybrid methods including power dividers and switches	In all systems in which simultaneity of information at all ports is not of primary consideration, i.e., when significant processing of channel information occurs	If it takes longer to process information than to simply acquire information, this approach offers compact designs and ease of production	DC power usually required (see Fig. 5)

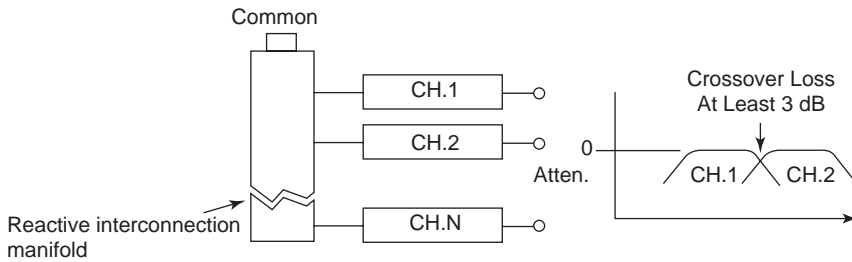

Figure 3. *N*-way reactively connected multiplexer.

junction by one filter is the complex conjugate of that presented by the other filter, Eq. (1) can be satisfied. The imaginary parts of the filter input admittances thus cancel. What is additionally required to ensure compliance with 1.1 is the inclusion of a real transformer, transforming the parallel combination of two real admittances back to Y_0 . These two conditions are summarized in the following equation:

$$\begin{aligned} \text{Re}[Y_{ch1}] + \text{Re}[Y_{ch2}] &= Y_0 = 1 \\ \text{Im}[Y_{ch1}] + \text{Im}[Y_{ch2}] &= 0 \end{aligned} \tag{2}$$

In general, it is not possible to accomplish the requirements of this equation both above and below the passband for each of the two filters, but it is usually sufficient to accomplish the susceptive cancellation in the region closest to the common, or “crossover” region. This region is illustrated in Fig. 2 (between f_2 and f_5 , but of most concern between f_4 and f_7).

An alternative method is presentation of an effective open circuit by each filter to the opposite filter, over a significant part of the frequency range of the opposite filter. To clarify, filter F1–F2 must essentially be open-circuited over the frequency range F5–F6. Filter F5–F6 must essentially be open-circuited over the frequency range F1–F2. Although this is not illustrated, the application of this approach is obvious and will be further clarified in examples to be presented later in this article.

Figure 3 illustrates the *N*-channel extension of the two-channel multiplexer. A three-channel version is known as a *triplexer*; a four-channel version, a *quadruplexer*; a five-channel version, a *quintaplexer*; a six-channel version, a *sextaplexer*, and almost no one is bold enough to attempt higher-order versions but if designed, the Latin-based nomenclature scheme is traditionally extended. Conservation of energy dictates that at the actual frequency common to adjacent channels (the “crossover” frequency), minimum insertion loss is 3 dB because the available energy would be equally shared between the two adjacent channels. The loss might be much higher than 3 dB because the selective filters might be designed with channels more widely separated in frequency than illustrated in Fig. 3. Such separation is known as a “guardband.” If the adjacent passbands of each channel “cross over” at a level of about -3 dB, the device is called a “contiguous” multiplexer. With a guardband (i.e., crossover at levels greater than 3 dB), the device is known as “noncontiguous.”

The -3 dB crossover loss creates a dip at the crossover point, as illustrated in Fig. 3. Although the 3 dB minimum loss cannot be avoided, it is possible to eliminate or drastically reduce the dip with a scheme such as is illustrated in Fig. 4.

The scheme illustrated in Fig. 4 has been termed a “frequency thinner,” and the use of the input isolated power divider allows for common port energy to be distributed equally between the two channels, with non-common-mode reflected energy terminated internally (in the resistor). The circuit thus provides the response with a flat crossover characteristic, as illustrated, at a cost of 3 dB minimum circuit insertion loss (plus the loss associated with each channel filter). The approach can be extended to higher numbers of channels, but if three channels are chosen, for example, the input power divider is three-way, and the minimum insertion loss is thus 4.8 dB. A four channel design would employ a four-way power divider (or an array of two way dividers) with a minimum loss of 6 dB. Although the loss seems high, in many applications in which this scheme is utilized, the loss can be overcome with gain and thus is not a significant problem.

3. FREQUENCY MULTIPLEXING SCHEMES

Let us now explore some of the available techniques (what’s covered and what’s not) for implementing frequency-domain multiplexers. Because many design approaches are considered proprietary by designers and their organizations, this will probably not be a comprehensive coverage, but it will be as comprehensive as the author can provide. Approaches have typically been developed in response to system requirements. Although more than one of the design methodologies can frequently be applied to specific system requirements, some are more appropriate than others. A summary is presented in Table 1. Note that the scope of this article does not include much discussion of time-division multiplexing schemes incorporating switches, but it should be recognized that combinations

Figure 4. Power divider combined diplexer.

Figure 5. Use of time-division multiplexing with switching.

of frequency- and time-domain multiplexing are quite common and efficient. This is indicated in Table 1, with a typical schematic illustrated in Fig. 5.

3.1. Circulator-Coupled Channel Dropping

The first technique to be discussed is illustrated in Fig. 6. Nonreciprocal gyrating devices (“circulators” in the microwave domain but other gyrators such as active filters at lower frequencies) are used to provide unidirectional flow of signal energy while simultaneously achieving port impedance match. This approach can realize isolated passbands and stopbands, good port match conditions, but without a guarantee of stopband levels greater than the intrinsic isolation of the circulators.

Some notes on the circulator-coupled channel dropping method are as follows:

- Relatively lossy due to addition of all circulator losses
- Very flexible (simply replace one filter with another, no retuning)
- Stopband level between channels limited by intrinsic circulator isolation

3.2. Common-Junction Susceptance Annulling Approach

When filters are connected to a common junction as shown in Fig. 7a, one resonator may be “shared” in common, between the filters. Figure 7 illustrates a connection of three combline or perhaps evanescent-mode filters in such a parallel combination. The filters could, however, consist of dielectric resonators, lumped resonators, SAW, superconducting, printed or other form of resonator array, and the same problem would be encountered: the need to satisfy Eq. (2). Note that each filter starts with a shunt tank equivalent circuit, and thus tends toward a short circuit to ground at frequencies outside of the passband. The input susceptance becomes very negative below the passband

Figure 6. Circulator-coupled channel dropping scheme.

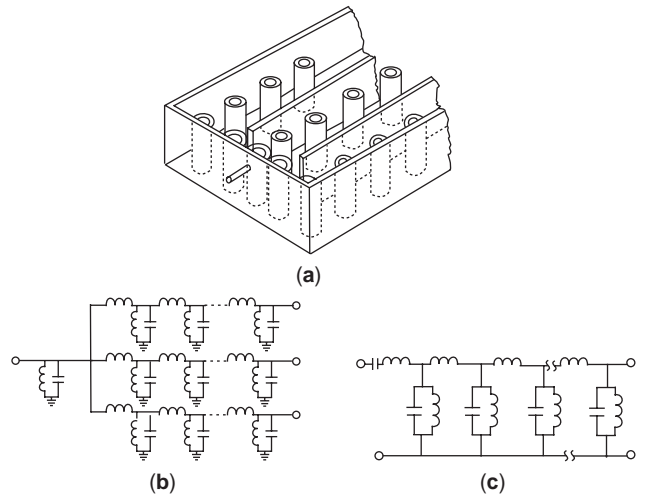

Figure 7. (a) Typical triplexer (three filters connected to common junction); (b) schematic showing common resonator (i.e., shared resonator; can be used for susceptance annulling); (c) schematic showing modification to allow common connection (series-resonant input connection used to assist common connection).

(inductive) and very positive (capacitive) above the passband. This results in very poor input VSWR for the circuit shown in Fig. 7a. If an additional resonator is added, as shown in Fig. 7b, the net susceptance is reduced outside the passband areas. This additional resonator has a resonant frequency well below the operating passband of the bandpass filters. The situation can be further improved if the constituent filters are modified as shown in Fig. 7c, to include a series-resonant input circuit. Without including simulation details, it is sufficient to say that the modification physically takes the form of a high-impedance (large-value) inductor and a small capacitor, inserted between each filter and the additional redundant susceptance annulling resonator, in turn connected to the common junction. The resonator and series circuit result in broadband satisfaction of Eq. (1), for a wide variety of constituent filters. The filters can also be synthesized from singly terminated prototypes, further improving the input VSWR, but at the cost of additional elements in each filter because such prototypes are not as efficient in providing selectivity as doubly terminated prototype designs. Today, it is also possible to implement a variety of cross-coupling schemes between the multiplexer filters, further reducing the problem. An example of such a diplexer is shown in Fig. 8. It is beyond the scope of this article to present

details of the many and varied implementations of this technique, but the Bibliography will provide additional references and examples.

The P/N 80431AD (Fig. 8, top) is a true diplexer. The channel responses are quasielliptic, using crossover coupling to implement real frequency transmission zeros for close-in rejection while still achieving maximum passband width. Specifications are as follows:

- Minimum passband channel 1: 2400–2420 MHz
- Minimum passband channel 2: 2460–2480 MHz
- Maximum loss over either passband as above: 1.5 dB
- Maximum common port return loss over either passband: –16 dB
- Maximum output port return loss over either passband: –14 dB

- Minimum interchannel isolation, common port terminated in 50Ω: 70 dB
- Normal impedance: 50 Ω
- Input power: ≥2 W
- Operating temperature: From –20 to +60°C
- Relative humidity: ≤95%

3.3. Separable Multiplexing

Construction of multiplexers frequently involves many contiguous channels, each with great selectivity. The problem of combining filters of this type at a common junction can be readily approached by separating the filters from the multiplexing network. Slope complementary arrays of lowpass and highpass filters can be used to implement a multiplexing (“combining”) network compatible with sep-

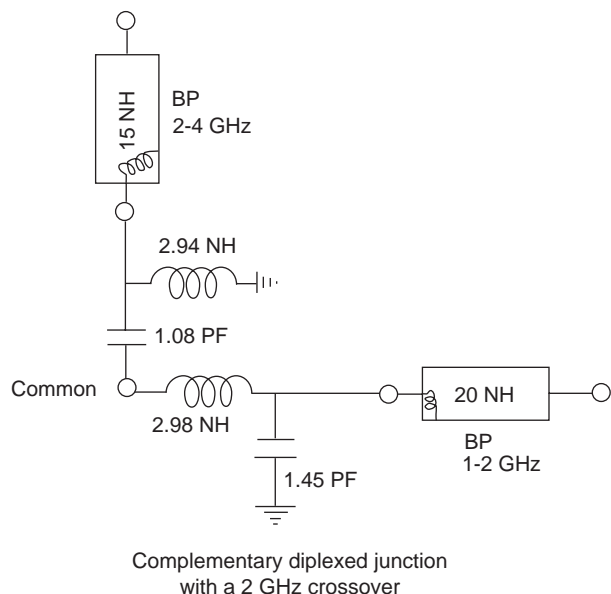

Figure 9. Schematic of second-order complementary low/high-pass combining network (with attached bandpass filters).

arately synthesized and tuned bandpass filters. The bandpass filters are used to provide the required selectivity. The combining network is required only to provide a limited isolation value outside a specified crossover region. Two–five-element lowpass and highpass networks can provide the required isolation. For example, a pair of two-element low/highpass filters will provide 10 dB isolation at a distance (in frequency) of 30% from the crossover of the two. Five-element filters can provide crossover regions with a width of about 5% of the crossover frequency. Isolation of 10 dB is sufficient to provide passband VSWR levels of 1.7–1 over the full range of frequencies covered by the bandpass filters connected to the combining network. The use of these combining networks permits implementation of the bandpass filters as separate networks, with a simple representation of the bandpass filter as a shunt inductor or series capacitor used during modeling and

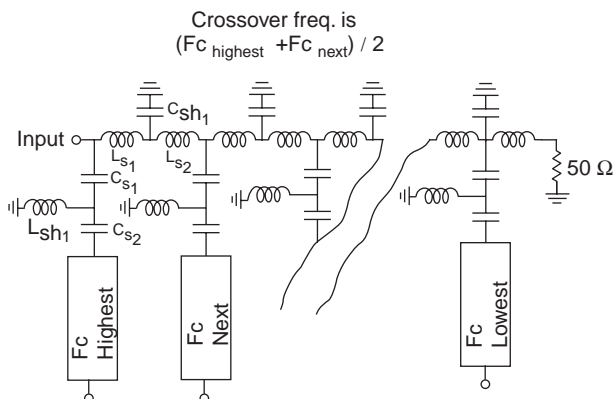

Figure 10. Third-order complementary combining network with bandpass filters; sequential cross over frequencies and channel drop-off.

Figure 11. Quintaplexer using third-order complementary combining network (as depicted schematically in Fig. 10).

tuning of the combining network. A schematic of an example two-element combining network, with crossover frequency of 2 GHz, is shown in Fig. 9; a third-order, *N*-way extension is shown in Fig. 10. Simulation of measurement of the response for this network will show satisfaction of Eq. (1), with matched 50-Ω ports, and at least 10 dB isolation at 1400 and 2600 MHz, or 30 % away from the crossover. This enables immediate connection of almost tuning-free bandpass filters with center frequencies below 1400 or above 2600 MHz. As stated, higher-order combining networks can be used to accommodate bandpass filters with spacing closer to the crossover frequency. An example of a quintaplexer (five-way multiplexer) using third-order complementary combining networks in a channel dropping scheme is pictured in Fig. 11, with typical data for a sixth-degree (sextaplexer) version of the same device shown in Fig. 12.

3.4. Double *N*-Plexing

Filters can be multiplexed by parallel combination at both ends. For example, if two bandpass filters are multiplexed at both input and output, a network results that provides one input and one output, with two passbands, essentially attenuating everything else. Such assemblies are useful in systems such as GPS, which have two or more operating frequencies, with the requirement for isolation between the operating channels and adjacent, cluttered regions of the spectrum. Typically, common-junction multiplexing is employed for this application, but in principle, any of the described combinatorial methods can be used. An example of such an application (double diplexer for combining the L1 and L2 GPS channels) is shown in Fig. 13 (schematic and response). An actual example is shown in Fig. 14. Note the limited stopband between the two bandpass channels as shown in the data. An example illustrating double triplexing is shown in Fig. 15a, with data in Fig. 15b.

Some notes regarding double *N*-plexing are as follows:

- Stopband between filter channels limited by filter order and spacing of channels

Figure 12. Data on six-channel (sex-taplexer) version of quintaplexer pictured in Fig. 11.

- Diplexing methods include nulling, complementary lowpass and highpass
- Very efficient way to meet limited stopband and difficult passbands

P/N 63491A-1 (Fig. 14, top) is a double diplexer, for GPS application. The filter passes only the GPS L1 and L2 channels, rejecting everything else, to at least 10 GHz. An evanescent mode structure, the 63491A-1 is truly GPS “state of the art.” Specifications are as follows:

The fully military-standard, highly ruggedized assembly shown in Fig. 15a is a GPS triple-channel dual triplexer. There are three evanescent-mode bandpass filters connected together at input and output. The bandpass filters tune the L1, L2, and L5 GPS channels. Two of the bandpass filters are provided with internal cross-coupling so as to achieve sharp rejection near their passbands, and thus display at least 20 dB isolation to the adjacent GPS channel. The assembly thus provides passbands for the L1, L2 and L5 GPS frequencies, rejecting all other

4. OTHER SPECIAL CONFIGURATIONS

Some other configuration examples are shown in Fig. 16 (waveguide channel dropping multiplexer for communica-

tion application) and Fig. 17 (low/highpass elliptic complementary filters for ECM application).

5. CONCLUSIONS

The art and science of combining properly designed selective filters to achieve spectrum separation or combining ("multiplexing") is complex, although the requirements for proper combination are easily summarized in a single pair of equations. The intention of this article has been to provide a summary of several available methods for such multiplexing and examples of their use. What has been presented is certainly not all-inclusive, and is based primarily on the experience of this author. Practitioners have tended to treat the subject secretly, with solutions kept as proprietary. With the advent of modern CAD and the ready access to circuit simulation software, the various possible techniques are found to be quite amenable to analysis. Network synthesis now becomes dominant, in the competitive world in which most practitioners function, and the emphasis is on selection of the filter topology and

technology to be employed with cleverly conceived inter-connection schemes. Truly synthesized combinations of lumped, evanescent, and distributed elements, into both filters and connection elements, awaits progress in multivariable synthesis. Real-life combinations of these elements are quite possible and common today, using analysis and optimization. However, much “black art” is still to be found in the multiplexer arena, leaving an

opening for new ideas and concepts and certainly, more participants.

Figure 18 presents a partial summary of filter techniques available for use in multiplexer applications. Many variations are possible, including superconductive implementations, “mixing” techniques (such as combinations of lumped and distributed elements), and nonadjacent element coupled designs. Because of the ever-changing

developments in the filter field, the list is unlikely to ever be complete, but the chart provides an overview applicable in 2004.

More than one technology applies to some of the frequency ranges shown in Fig. 18. New cross-coupling techniques are extending the applicability of many types. Active filters achieve responses similar to those of passive filters but with noise or stability problems.

FREQUENCY-DOMAIN CIRCUIT ANALYSIS

MARIO BIEY
 IVAN A. MAIO
 Politecnico di Torino

When a designer is examining the behavior of an electrical circuit, the first thing to do, as in the case of any other physical system, is to write down a suitable set of equations describing the existing links between the involved physical variables, which are, in this case, voltages and currents. Generally, these equations arise from Kirchhoff's voltage and current laws and from the branch relations that describe circuit components.

If there are *dynamic* components (i.e., described by branch relations where time derivatives of voltages and/or currents are present), then the circuit is governed by a system of mixed algebraic and integrodifferential equations. The solution of such a system may be carried out using time as the independent variable and evaluating the wanted voltages and/or currents by numerical or analytical integration techniques. In this case the analysis is said to be performed in the *time domain*.

A completely different approach may be followed for linear time-invariant circuits. By using suitable transformations—that is, Laplace transform or Fourier transform—the original integrodifferential equations, which are linear with constant coefficients, are reduced to algebraic equations, where the original time functions are substituted by complex-valued functions of a complex variable $s = \sigma + j\omega$ in the case of Laplace transform, or simply $j\omega$ in the case of Fourier transform. Then the system of linear algebraic equations is solved for the new transformed functions. Finally, an inverse transformation recovers the requested voltages or currents as functions of time. When following this procedure, the analysis is said to be performed in the frequency domain or, alternatively, in the s domain when an explicit reference to the Laplace transform is preferred.

The frequency-domain approach offers several advantages over the direct solution of time-domain circuit equations:

1. The solution is reduced to algebra and is greatly simplified by the extensive use of tables.
2. The conditions of energy storage elements within the circuit at the time when the input signal is applied (i.e., the initial conditions) become part of circuit equations and hence are automatically accounted for.
3. There is no need to evaluate initial conditions at $t = 0+$, as in the case of time-domain analysis, when a jump discontinuity occurs at $t = 0$. Only their values immediately before the beginning of the transient (i.e., at $t = 0-$) are required.
4. The sinusoidal steady-state behavior of a linear circuit may be easily analyzed by resorting to network functions defined in terms of Laplace transforms.
5. Frequency-domain analysis provides a deeper insight in the behavior of linear circuits. For example, it is possible to effectively compute sensitivities, to give stability conditions, to establish necessary and sufficient conditions for the realization of one-port and multiport networks, and so on.
6. Many design techniques are based on a description of the circuit behavior in the frequency domain, via network functions. The knowledge of these functions is of paramount importance in designing feedback amplifier, one-ports, multiports, active and passive filters, equalizers, oscillators, and so on.
7. Frequency-domain formulation allows an effective description of transmission lines, which would otherwise require partial differential equation in the time domain.
8. Frequency-domain formulation allows model simplification techniques not possible in the time domain.

1. FREQUENCY-DOMAIN CIRCUIT EQUATIONS

This section introduces the one-sided Laplace transform and a number of its properties, relevant to circuit analysis.

A complete discussion of this topic may be found in Refs. 1 and 2. Successively, we will illustrate the use of Laplace transform to write and solve frequency-domain circuit equations.

1.1. The One-Sided Laplace Transform

Given a function of time $f(t)$ defined for all $t \geq 0$, its one-sided Laplace transform is defined as

$$F(s) = \mathcal{L}[f(t)] = \int_{0-}^{\infty} f(t)e^{-st} dt \tag{1}$$

where $s = \sigma + j\omega$ is a complex variable, called the *complex frequency*. Note that in Eq. (1) the lower limit of integration equals $0-$, to include functions that have a discontinuity or an impulse at $t = 0$.

Equation (1) establishes a correspondence between the time function $f(t)$ defined for all $t \geq 0$ and its Laplace transform $F(s)$. This fact ensures that the solution coming from the frequency-domain approach is identical to the one obtainable by operating in the time domain.

The integral that defines the Laplace transformation exists under mild conditions on the function $f(t)$, generally met for the signals used in engineering. A sufficient condition is that $f(t)$ is exponentially bounded—that is, $|f(t)| \leq Me^{ct}$ —for some constant $M > 0$ and some constant c , for all $t > 0$ (or only for t greater than some t_0).

The greatest lower bound σ_+ of the values of σ for which the Laplace integral (1) exists is called *abscissa of convergence*. It can be shown that the Laplace integral defines an analytic function within the half-plane of convergence $\sigma > \sigma_+$.

Extensive tables of transform pairs have been built (see Refs. 3 and 4) by using the definition given in Eq. (1). Examples of Laplace transforms of elementary functions are reported in Table 1. Some of the main properties of one-sided Laplace transform, relevant in circuit analysis, are shown in Table 2. For proofs and a complete collection of these properties, see Refs. 1 and 2.

The inverse transform, which gives $f(t)$ from its Laplace transform $F(s)$, is denoted by $\mathcal{L}^{-1}[F(s)]$ and is

expressed by

$$\begin{aligned} f(t) &= 0, \quad t < 0 \\ f(t) &= \mathcal{L}^{-1}[F(s)] \\ &= \frac{1}{2\pi j} \int_{\sigma_1 - j\infty}^{\sigma_1 + j\infty} F(s)e^{st} ds, \quad t > 0, \quad \sigma_1 > \sigma_+ \end{aligned} \tag{2}$$

In many practical situations, the inverse transform may be simply obtained by resorting to a partial-fraction expansion of the original function. Then, the inverse transforms of the elementary fractions are found by inspection, resorting to tables of Laplace transforms.

1.2. Tableau Equations

We start by considering the time-domain tableau equations for a linear time-invariant circuit [5,6]. The (node) tableau equations are

$$\mathbf{A}\mathbf{i} = 0 \tag{3}$$

$$\mathbf{v} - \mathbf{A}^T \mathbf{e} = 0 \tag{4}$$

$$(\mathbf{M}_0 \mathbf{D} + \mathbf{M}_1) \mathbf{v} + (\mathbf{N}_0 \mathbf{D} + \mathbf{N}_1) \mathbf{i} = \mathbf{u}_s(t) \tag{5}$$

where \mathbf{i} is the vector of branch currents, \mathbf{v} is the vector of branch voltages, and \mathbf{e} is the vector of node voltages with respect to a datum node. Equations (3) and (4) are the matrix formulation of Kirchhoff's current and voltage laws: \mathbf{A} is the $(n - 1) \times b$ reduced incidence matrix, n being the number of nodes and b the number of branches; the superscript T denotes transposition. The branch equations are given (in matrix form) by Eq. (5): $\mathbf{M}_0, \mathbf{M}_1, \mathbf{N}_0, \mathbf{N}_1$ are $b \times b$ matrices with real constant elements; \mathbf{D} is the differentiation operator d/dt and $\mathbf{u}_s(t)$ is the vector of independent sources.

The application of Laplace transform to both sides of Eqs. (3)–(5), taking into account the properties shown in Table 2, gives the (node) tableau equations in the fre-

Table 1. Elementary One-Sided Laplace Transform Pairs

Time Function $f(t)$	Type	Laplace Transform $F(s) = \mathcal{L}[f(t)]$
$\delta(t)$	Impulse function	1
$u(t)$	Unit step function	$\frac{1}{s}$
t	Ramp	$\frac{1}{s^2}$
e^{-at}	Exponential	$\frac{1}{s+a}$
$e^{-at} \sin \omega_0 t$	Damped sine	$\frac{\omega_0}{(s+a)^2 + \omega_0^2}$
$e^{-at} \cos \omega_0 t$	Damped cosine	$\frac{s+a}{(s+a)^2 + \omega_0^2}$

Table 2. Main Properties of One-Sided Laplace Transform

Property	Transform Pair
Linearity	$\mathcal{L}[a_1 f_1(t) + a_2 f_2(t)] = a_1 F_1(s) + a_2 F_2(s)$
Time differentiation	$\mathcal{L}\left[\frac{df}{dt}\right] = sF(s) - f(0^-)$
Time integration	$\mathcal{L}\left[\int_{0-}^t f(\tau) d\tau\right] = \frac{1}{s} F(s)$
Time shift	$\mathcal{L}[f(t - t_0)u(t - t_0)] = e^{-t_0 s} F(s), \quad t_0 > 0$
Frequency shift	$\mathcal{L}[e^{s_0 t} f(t)] = F(s - s_0)$
Initial-value theorem	$f(0^+) = \lim_{t \rightarrow 0^+} f(t) = \lim_{s \rightarrow \infty} sF(s)$
Final-value theorem	$\lim_{t \rightarrow \infty} f(t) = \lim_{s \rightarrow 0} sF(s), \quad sF(s)$ regular on the $j\omega$ axis and in right half-plane

Table 3. Branch Equations in the Frequency Domain

Component	Parameter(s)	Time Domain	Frequency Domain ^a
Resistor	R	$v(t) = Ri(t)$	$V(s) = RI(s)$
Capacitor	C	$i(t) = C \frac{dv}{dt}$	$I(s) = sCV(s) - CV_0$ or $V(s) = \frac{1}{sC}I(s) + \frac{V_0}{s}$
Inductor	L	$v(t) = L \frac{di}{dt}$	$V(s) = sLI(s) - LI_0$ or $I(s) = \frac{1}{sL}V(s) + \frac{I_0}{s}$
Coupled inductors	M, L_1, L_2	$v_1(t) = L_1 \frac{di_1}{dt} + M \frac{di_2}{dt}$ $v_2(t) = M \frac{di_1}{dt} + L_2 \frac{di_2}{dt}$	$V_1(s) = sL_1I_1(s) + sMI_2(s) - L_1I_{10} - MI_{20}$ $V_2(s) = sMI_1(s) + sL_2I_2(s) - MI_{10} - L_2I_{20}$

^aNote that V_0, I_0, I_{10} and I_{20} are initial values computed at $t = 0^-$.

quency domain

$$\mathbf{A}\mathbf{I}(s) = 0 \tag{6}$$

$$\mathbf{V}(s) - \mathbf{A}^T\mathbf{E}(s) = 0 \tag{7}$$

$$(\mathbf{M}_0s + \mathbf{M}_1)\mathbf{V}(s) + (\mathbf{N}_0s + \mathbf{N}_1)\mathbf{I}(s) = \mathbf{U}_s(s) + \mathbf{U}_0 \tag{8}$$

where $\mathbf{I}(s)$, $\mathbf{V}(s)$, and $\mathbf{E}(s)$, are vectors of transformed branch currents, branch voltages, and node-to-datum voltages, respectively. $\mathbf{U}_s(s)$ is the vector of transformed independent sources and $\mathbf{U}_0 = \mathbf{M}_0\mathbf{v}(0) + \mathbf{N}_0\mathbf{i}(0)$ is the vector of initial conditions. In matrix form we have

$$\mathbf{T}(s)\mathbf{W}(s) \equiv \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{A} \\ -\mathbf{A}^T & \mathbf{1} & \mathbf{0} \\ \mathbf{0} & \mathbf{M}_0s + \mathbf{M}_1 & \mathbf{N}_0s + \mathbf{N}_1 \end{bmatrix} \begin{bmatrix} \mathbf{E}(s) \\ \mathbf{V}(s) \\ \mathbf{I}(s) \end{bmatrix} \tag{9}$$

$$= \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{U}_s(s) + \mathbf{U}_0 \end{bmatrix}$$

where matrix \mathbf{T} is constituted by elements that are either real constants or real polynomials of degree 1 and \mathbf{W} is the vector of output variables.

Other forms of the tableau equations are possible if reference is made to fundamental cutsets or fundamental loops of the connected digraph associated to the considered circuit. These forms of the tableau equations are not considered here, and the interested reader is referred to Ref. 6, pp. 715–717.

As a concluding remark, let us consider tableau equations (6)–(8) in more detail. Equations (6) and (7) may be obtained from Eqs. (3) and (4) by a simple substitution of time functions with their Laplace transforms: They may be viewed as Kirchhoff’s current and voltage laws in the frequency domain. Equation (8) contains the frequency-domain branch equations. They are listed in the fourth column of Table 3, for the components shown in Fig. 1a,

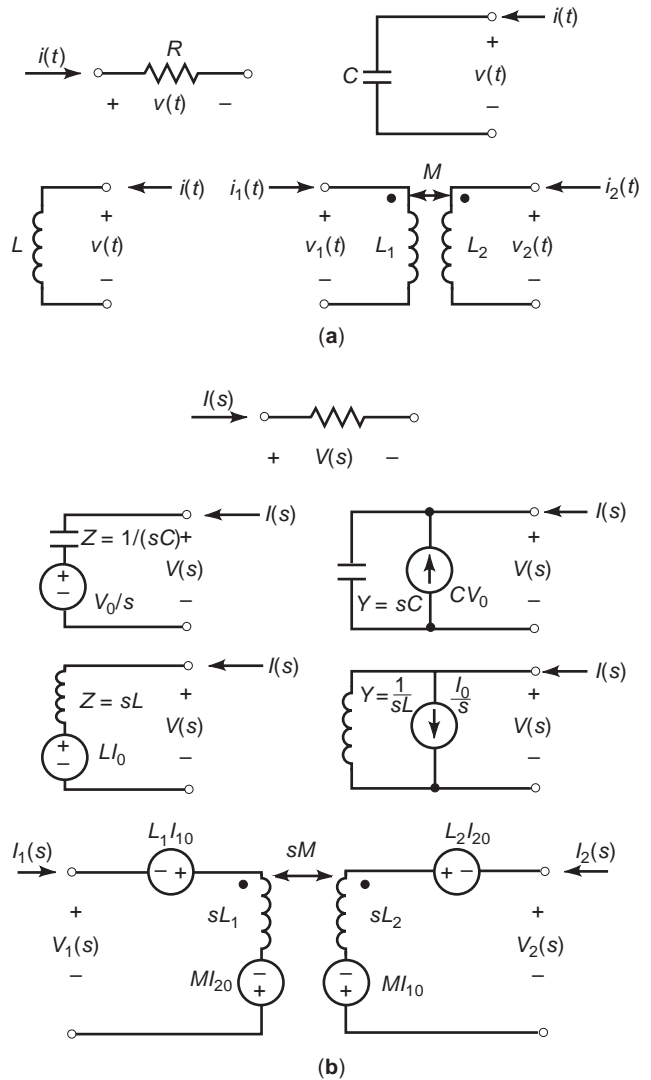

Figure 1. (a) Symbols and associated reference directions for voltages and currents of resistors, capacitors, inductors and coupled inductors; (b) frequency-domain equivalent circuits of resistors, capacitors, inductors, and coupled inductors. For capacitors and inductors both the series and the parallel frequency-domain equivalent circuits are shown. Initial values are denoted by $V_0 = v(0^-)$, $I_0 = i(0^-)$, $I_{10} = i_1(0^-)$ and $I_{20} = i_2(0^-)$.

Table 4. Impedance $Z(s)$ and Admittance $Y(s)$ of Resistors, Capacitors, and Inductors

Component	Parameter	$Z(s)$	$Y(s)$
Resistor	R	R	$G = 1/R$
Capacitor	C	$\frac{1}{sC}$	sC
Inductor	L	sL	$\frac{1}{sL}$

while in the third column the corresponding time-domain equations are shown for comparison.

1.2.1. Impedance and Admittance. Consider a two-terminal element, with zero initial conditions. Let us choose *associated reference directions* for input current and terminal voltage, (e.g., see Fig. 1a) and denote their transforms by $I(s)$ and $V(s)$, respectively. The ratio

$$Z(s) = \frac{V(s)}{I(s)} \tag{10}$$

is called the *impedance* of the two-terminal element. The reciprocal of the impedance

$$Y(s) = \frac{1}{Z(s)} = \frac{I(s)}{V(s)} \tag{11}$$

is referred to as the *admittance* of the two-terminal element. In the frequency domain, impedance and admittance play the same role as resistance and conductance in Ohm's laws, respectively. Table 4 gives impedances and admittances of resistors, capacitors, and inductors.

1.2.2. Writing Circuit Equations by Inspection. Taking into account Eqs. (10) and (11), one can easily verify that the circuits shown in Fig. 1b are governed by the algebraic frequency-domain equations reported in the fourth column of Table 3. These circuits are called the *equivalent circuits* in the frequency domain for resistors, capacitors, inductors, and coupled inductors.

As a consequence, the frequency-domain equations of any circuit may be written directly, avoiding the preliminary step of writing time-domain equations. In fact, it is sufficient to apply the same analysis methods used for resistive circuits (see Ref. 6, Chap. 5; and Ref. 7, Chap. 4) to a frequency-domain equivalent circuit, hereafter called the *transformed circuit*, obtained by replacing each element with its impedance or admittance and adding the appropriate sources to take into account initial conditions.

Furthermore, for this transformed circuit all general theorems, valid for linear time-invariant resistive circuits, (superposition, Thevenin's, Norton's, Tellegen's, etc.), still hold.

Example 1. The results presented above are used to write tableau equations for the very simple circuit of Fig. 2a. The transformed circuit is shown in Fig. 2b, where $v_3(0^-) = V_0$ and $i_4(0^-) = I_0$ are initial values of capacitor voltage and inductor current, respectively. The frequency-domain tableau equations, written in matrix form and partitioned according to Eq. (9), are

$$\begin{bmatrix}
 0 & 0 & \vdots & 0 & 0 & 0 & 0 & \vdots & -1 & 1 & 1 & 0 \\
 0 & 0 & \vdots & 0 & 0 & 0 & 0 & \vdots & 0 & 0 & -1 & 1 \\
 \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\
 1 & 0 & \vdots & 1 & 0 & 0 & 0 & \vdots & 0 & 0 & 0 & 0 \\
 -1 & 0 & \vdots & 0 & 1 & 0 & 0 & \vdots & 0 & 0 & 0 & 0 \\
 -1 & 1 & \vdots & 0 & 0 & 1 & 0 & \vdots & 0 & 0 & 0 & 0 \\
 0 & -1 & \vdots & 0 & 0 & 0 & 1 & \vdots & 0 & 0 & 0 & 0 \\
 \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\
 0 & 0 & \vdots & 0 & 0 & 0 & 0 & \vdots & 1 & 0 & 0 & 0 \\
 0 & 0 & \vdots & 0 & 1 & 0 & 0 & \vdots & 0 & -R_2 & 0 & 0 \\
 0 & 0 & \vdots & 0 & 0 & -sC_3 & 0 & \vdots & 0 & 0 & 1 & 0 \\

 0 \\
 -C_3V_0 \\
 -L_4I_0
 \end{bmatrix} \tag{12}$$

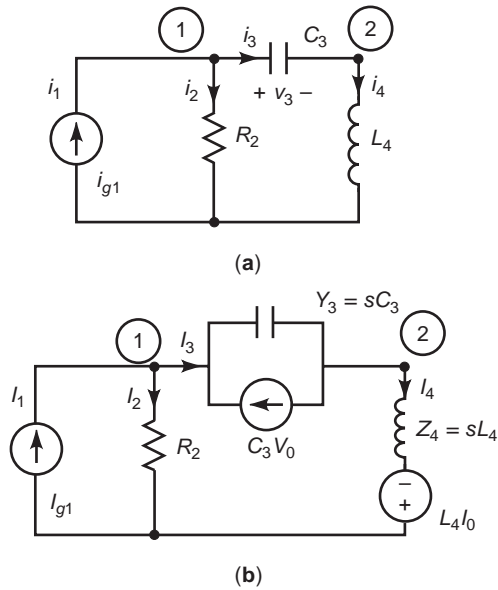

Figure 2. (a) A simple RLC circuit; at $t = 0^-$ the capacitor has an initial voltage $v_3(0^-) = V_0$ and inductor has an initial current $i_4(0^-) = I_0$ (associated reference directions are assumed); (b) the frequency-domain transformed circuit.

1.3. Loop Equations

The set of loop equations may be written directly in the frequency domain by substituting each circuit element with the appropriate series equivalent circuit of Fig. 1b and then applying the standard technique used for resistive circuits. Note that for nonzero initial conditions, supplemental voltage sources of the form LI_0 and/or V_0/s are added to the original circuit.

The final set of loop equations has the form

$$\mathbf{Z}_1(s)\mathbf{I}_1(s) = \mathbf{V}_s(s) + \mathbf{V}_0(s) \tag{13}$$

where $\mathbf{Z}_1(s)$ is called the *loop impedance matrix*, $\mathbf{V}_s(s)$ is the vector of independent voltage sources, and $\mathbf{V}_0(s)$ is the voltage vector due to initial conditions.

The restriction imposed in loop analysis is that all elements must be current-controlled. If this is not the case, one may resort to circuit transformations or to the modified loop analysis (8).

Loop equations may be written by inspection. If the circuit is formed only by resistors, capacitors, and inductors, the rules are particularly simple. The matrix \mathbf{Z}_l is symmetric, the k th diagonal element z_{kk} is the sum of all impedances in loop k , and any off-diagonal element z_{jk} is the sum of all impedances common to loops j and k if the reference directions for the two loops are the same, the negative of the sum otherwise.

Finally, for a circuit with a planar graph, meshes may be used instead of fundamental loops. In this case, mesh equations are obtained in terms of fictitious circulating currents, generally referred to as “mesh currents”.

Example 2. Consider the (planar) circuit of Fig. 3a. The initial values of voltages across capacitors C_p and C are

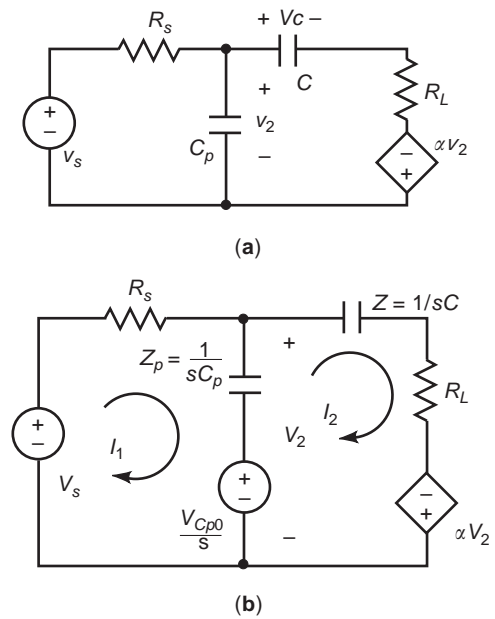

Figure 3. (a) Loop (mesh) analysis—at $t = 0^-$ capacitors C_p and C have initial voltages $v_2(0^-) = V_{C_p,0}$ and $v_c(0^-) = 0$ V, respectively; (b) the frequency-domain transformed circuit.

$v_2(0^-) = V_{C_p,0}$ and $v_c(0^-) = 0$ V, respectively. In this case, meshes can be chosen as fundamental loops. Assuming for the mesh currents I_1 and I_2 the reference directions shown in the transformed circuit of Fig. 3b, we write the following frequency-domain mesh equations:

$$\begin{bmatrix} 1/(sC_p) + R_s & -1/(sC_p) \\ -(1 + \alpha)/(sC_p) & R_L + 1/(sC) + (1 + \alpha)/(sC_p) \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} V_s(s) \\ 0 \end{bmatrix} + \begin{bmatrix} -V_0/s \\ (1 + \alpha)V_0/s \end{bmatrix} \tag{14}$$

1.4. Node Equations

Node equations may be written directly in the frequency domain by substituting each circuit element with the appropriate parallel equivalent circuit of Fig. 1b and then applying the standard technique used for resistive circuits. Note that for nonzero initial conditions, supplemental current sources of the form I_0/s and/or CV_0 are added to the original circuit.

The final form of node equations is

$$\mathbf{Y}_n(s)\mathbf{E}(s) = \mathbf{I}_s(s) + \mathbf{I}_0(s) \tag{15}$$

where $\mathbf{Y}_n(s)$ is called the *node admittance matrix*, $\mathbf{I}_s(s)$ is the vector of independent current sources, and $\mathbf{I}_0(s)$ is the current vector due to initial conditions.

Node equations may be written by inspection. If the circuit is formed only by resistors, capacitors, and inductors, the rules are particularly simple: The matrix \mathbf{Y}_n is symmetric, the k th diagonal element y_{kk} is the sum of all admittances connected to node k , and any off-diagonal

The frequency-domain transformed circuit is shown in Fig. 5b, where V_{20} and V_{30} are initial values of capacitor voltages v_2 and v_3 , respectively. The modified nodal equations are

$$\begin{bmatrix} G_{11} & -G_{11} & 0 & 0 \\ -G_{11} & G_{11} + G_{12} + s(C_2 + C_3) & -sC_3 & -sC_2 \\ 0 & -sC_3 & G_4 + sC_3 & -G_4 \\ 0 & -sC_2 & -G_4 & G_4 + G_6 + sC_2 \\ 0 & 0 & 0 & -G_6 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 \end{bmatrix} \begin{bmatrix} E_1 \\ E_2 \\ E_3 \\ E_4 \\ E_5 \\ I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ V_i(s) \\ 0 \end{bmatrix} + \begin{bmatrix} 0 \\ C_3 V_{30} - C_2 V_{20} \\ -C_3 V_{30} \\ C_2 V_{20} \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad (18)$$

1.6. State Equations

State equations are best suited for time-domain analysis, even if sometimes it may be useful to solve these equations in the frequency domain. Also in this case, all known methods used to write time-domain state equations (inspection, equivalent sources, or network graph theory; see Ref. 11, Chapter 6) may be applied to the transformed circuit obtained by substituting inductors and capacitors with the series and parallel circuits of Fig. 1(b), respectively. In spite of that, state equations are generally written first in the time domain and then transformed to the frequency domain, where they take the following form:

$$s\mathbf{X}(s) = \mathbf{A}\mathbf{X}(s) + \mathbf{B}\mathbf{U}(s) + \mathbf{X}_0 \quad (19)$$

In this equation, $\mathbf{X}(s)$, \mathbf{X}_0 , and $\mathbf{U}(s)$ are the vectors of transformed state variables, of initial conditions, and of transformed independent sources, respectively. \mathbf{A} and \mathbf{B} are matrices of appropriate dimensions (note that \mathbf{A} is not the incidence matrix).

Equation (19) may be rearranged to yield

$$[s\mathbf{1} - \mathbf{A}]\mathbf{X}(s) = \mathbf{B}\mathbf{U}(s) + \mathbf{X}_0 \quad (20)$$

where $\mathbf{1}$ is the identity matrix.

1.7. Natural Frequencies

Let us consider a (linear time-invariant) circuit described by its tableau equations [Eq. (9)]. This system of linear algebraic equations admits a unique solution if and only if matrix $\mathbf{T}(s)$ is invertible; that is, $\det[\mathbf{T}(s)]$ is not identically zero. Furthermore, since all elements of $\mathbf{T}(s)$ are polynomials of degree either 0 or 1 in s , $\det[\mathbf{T}(s)]$ is a polynomial in s too, with real coefficients, called the *characteristic polynomial* of the circuit. The roots λ_i , of

$$\det[\mathbf{T}(s)] = 0 \quad (21)$$

are called the *natural frequencies* of the circuit. They are either real or occur in complex-conjugate pairs.

Note that when working in the time domain, $\mathbf{T}(s)$ becomes $\mathbf{T}(D)$, where D is the differentiation operator d/dt , and hence the definition of natural frequencies presented above coincides with that given in the time domain [12, Chap. 12].

If all independent sources are set to zero (i.e., considering the circuit in the zero-input state), then, applying Kramer's rule, a generic output variable $W_k(s)$ is given by

$$W_k(s) = \frac{\sum_{i=1}^b \Delta_{ik} U_{i0}}{\det[\mathbf{T}(s)]} \quad (22)$$

where Δ_{ik} is the cofactor of the element $(b + n - 1 + i)$, k of $\mathbf{T}(s)$ and U_{i0} denotes the i th source due to initial conditions.

Expanding the right-hand side of Eq. (22) in partial fractions and then taking the inverse Laplace transform of both sides, it turns out that, in general, any zero-input response is a linear combination of exponentials $e^{\lambda_i t}$ (or polynomials in t times $e^{\lambda_i t}$), called *modes*, where each λ_i is a natural frequency of the circuit. For some particular response, some modes may be absent.

If all the natural frequencies of the circuit have a negative real part, then the zero-input response, for any initial state, goes to zero exponentially with increasing time. In this case, the circuit is referred to as *strictly* (or *exponentially*) stable.

Natural frequencies are an intrinsic feature of the circuit: They depend only on the circuit and not on the method used to analyze it. In fact, it can be shown that the nonzero natural frequencies of any linear time-invariant circuit are identical to the nonzero roots of the determinantal polynomial of the matrix of any system of equations describing the circuit, when framed as a set of linear algebraic equations of the form $\mathbf{R}(s)\mathbf{W}(s) = \mathbf{F}(s)$ [13, Chap. 14]. The total number of natural frequencies is not greater than the number of energy-storing elements present in the circuit and it defines the order of complexity of the circuit [14, Chap. 8]. Zero natural frequencies are of

limited physical significance, and in some cases their number may be determined by inspection [12, Chap. 11].

In the case of tableau analysis and MNA, the determinantal polynomials of matrices $\mathbf{T}(s)$ and $\mathbf{P}(s)$ differ from each other only for a multiplicative constant, and hence they give the same set of natural frequencies, including those at $s = 0$ (if any), with the same multiplicities [6, Sect. 10.4.2].

In the case of state equations, let us consider them in the form given by Eq. (20). The natural frequencies are the roots of the determinantal polynomial

$$\det[s\mathbf{1} - \mathbf{A}] = 0 \quad (23)$$

and hence they coincide with the eigenvalues of matrix \mathbf{A} . As in the case of tableau analysis and MNA, Eq. (23) supplies all natural frequencies, including zero natural frequencies, with their own multiplicities.

2. NETWORK FUNCTIONS

Given a linear time-invariant network in the zero state—that is, with zero initial voltages across all capacitors and zero initial current through all inductors—a *network function* $H(s)$ is defined as the ratio of the Laplace transform $W(s)$ of an *output variable* $w(t)$ to the Laplace transform $Q(s)$ of an *input variable* $q(t)$:

$$H(s) = W(s)/Q(s) \quad (24)$$

If the input is an unit impulse, then $Q(s) = 1$ and hence $H(s)$ turns out to be the Laplace transform of the impulse response of the circuit.

If input and output variables are defined at the same terminal pair, the network function is either an impedance or an admittance, as defined in Eqs. (10) and (11), respectively. If input and output are measured at two different terminal pairs, the network function is referred to as a *transfer function*. A transfer function may have the dimension of impedance or admittance or be dimensionless.

In the case of multiple-input multiple-output circuits, a matrix transfer function $\mathbf{H}(s)$ may be defined, whose k, i element is the ratio of the Laplace transform of the k th output variable to the Laplace transform of the i th input variable, when all others input variables are set to zero.

Network functions may be efficiently obtained by resorting to network symbolic analysis programs. In general, these programs are also able to perform mixed numerical-symbolic analysis [15,16] and to evaluate sensitivities [17, Chap. 10; 18, Chap. 8].

2.1. Fundamental Properties

Consider, for simplicity, a single-input single-output circuit. Any network function may be determined starting from any set of circuit equations described in the previous section. Referring again to tableau equations [Eq. (9)] and

using Kramer's rule, we have

$$H_{ki}(s) = \frac{W_k(s)}{Q_i(s)} = \frac{\Delta_{ik}}{\det[\mathbf{T}(s)]} \quad (25)$$

where $W_k(s)$ denotes the k th output variable and Δ_{ik} is the cofactor of the element i, k of $\mathbf{T}(s)$, where i is the position of the independent source $Q_i(s)$ into the right-hand side vector of Eq. (9).

From Eq. (25), it follows that any network function of a linear circuit is a real rational function of s —that is, the ratio of two polynomials with real coefficients. Its finite poles are natural frequencies of the circuit, according to Eq. (21); due to a possible pole-zero cancellation, some natural frequencies may not appear as poles of the network function [6, p. 612].

The transform $W_k(s)$ of the output variable is given by

$$W_k(s) = H_{ki}(s)Q_i(s) = \frac{\Delta_{ik}}{\det[\mathbf{T}(s)]}Q_i(s) \quad (26)$$

Transient response is computed by finding a partial-fraction expansion of the right-hand side of Eq. (26) and then taking the inverse Laplace transform of each term of the expansion. If the network function has no poles inside the right half-plane and if its $j\omega$ -axis poles (if any) are simple, then the (zero-state) impulse response of the circuit remains bounded and the network function is said to be *stable*. If there are no poles on the $j\omega$ axis, then the impulse response decays with time, and moreover, any (zero-state) response remains bounded for any bounded input. In this case the network function is said to be *strictly stable* [e.g., 19, Chap. 9].

When the network functions are impedances or admittances of *RCLM* networks—that is, networks composed of a finite number of resistors, capacitors, inductors, and coupled inductors—they must be positive real functions; other constraints are added for two-element-kind (i.e., *RC*, *RL*, and *LC*) networks (20).

2.2. The Sinusoidal Steady State

The large use of network functions in circuit analysis is only partially due to their utility in evaluating complicated transients. One of the reasons for their acknowledged importance is related to their capability to describe the sinusoidal steady state of stable networks according to the following theorem, usually referred to as the *fundamental theorem of sinusoidal steady state* [19, Sect. 9.4; 6, Sect. 10.5].

Theorem 1. Consider any linear time-invariant circuit, driven by sinusoidal independent sources, all at the same frequency ω . If the circuit is strictly stable (i.e., all the natural frequencies have negative real part), then, for any set of initial conditions, all voltages and currents tend, as time goes to infinity, to a unique sinusoidal steady-state at the same frequency ω .

In the case of a single-input single-output circuit described by Eq. (24), magnitude W_m and phase ϕ_w of

the output waveform are given by [6, Sect. 10.5]

$$W_m = |H(j\omega)|Q_m \quad (27)$$

$$\phi_w = \arg[H(j\omega)] + \phi_q \quad (28)$$

where Q_m and ϕ_q are magnitude and phase of the input signal, respectively.

In terms of phasors [6, Chap. 9] we have

$$\hat{W} = H_\omega \hat{Q} \quad (29)$$

where $\hat{W} = |\hat{W}|e^{j\phi_w}$ and $\hat{Q} = |\hat{Q}|e^{j\phi_q}$ are the phasors of output and input waveforms, respectively, and H_ω is the transfer function defined in terms of the sinusoidal steady state. A comparison of Eq. (29) with Eqs. (27) and (28) shows that any phasor transfer function, defined in the sinusoidal steady state, may be obtained simply by setting $s = j\omega$ in the corresponding transfer function $H(s)$ defined in terms of Laplace transforms.

$H(j\omega)$ is a complex valued function of ω and may be written as

$$H(j\omega) = \mathcal{R}(\omega) + j\mathcal{I}(\omega) = |H(j\omega)|e^{j\phi_h(\omega)} \quad (30)$$

The parts of $H(j\omega)$ —that is, real part $\mathcal{R}(\omega)$, imaginary part $\mathcal{I}(\omega)$, magnitude $|H(j\omega)|$ (or gain $20 \log |H(j\omega)|$), and phase $\phi_h(\omega)$ —are the quantities involved in the steady-state response to sinusoidal excitations. Generally speaking, the overall information contained in any pair of these parts [i.e., magnitude (or gain) and phase, or real and imaginary parts], when considered as a function of frequency $f = \omega/(2\pi)$, is referred to as *frequency response* of the circuit.

It is easily verified that real part $\mathcal{R}(\omega)$ and magnitude-squared function $|H(j\omega)|^2$ are even functions of ω , whereas imaginary part $\mathcal{I}(\omega)$ and $\tan \phi_h(\omega)$ are odd functions of ω .

Transfer functions play an important role in engineering, since they can be easily and accurately measured, resorting to stable sinusoidal oscillators and to precise measurement equipments—for example, to network analyzers. On the other hand, they are the starting point for designing networks with a prescribed frequency behavior, as in the case of electrical filters and equalizers.

When poles and zeros of network functions are known, gain and phase versus frequency curves can be easily plotted, resorting to the so-called Bode plots [21, Sect. 8.2]. On the contrary, if curves of magnitude or phase, or real or imaginary parts, versus frequency are given, methods have been developed to build realizable network functions [20].

It is important to remember that real and imaginary parts of any stable network function are related to each other and, hence, constraints on them cannot be assigned arbitrarily. In fact, for a network function with no poles in the right half-plane and on the $j\omega$ axis (infinity included),

they satisfy the following equations [e.g., 18, Chap. 7]

$$\mathcal{R}(\omega) = \mathcal{R}(\infty) + \frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{\mathcal{I}(x)}{\omega - x} dx \quad (31)$$

$$\mathcal{I}(\omega) = -\frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{\mathcal{R}(x)}{\omega - x} dx \quad (32)$$

where $\mathcal{R}(\infty)$ is the value of the network function at infinity. Equations (31) and (32) state that if the imaginary part is specified over all frequencies, then the real part is determined to within an additive constant and that, if the real part is specified, then the imaginary part is completely determined. Similar results hold also for gain and phase of a network function, provided that it has no zeros in the right half-plane—that is, it is a minimum-phase function [18].

3. TWO-SIDED LAPLACE AND FOURIER TRANSFORMS IN CIRCUIT ANALYSIS

In addition to the one-sided Laplace transform, other frequency representations of time functions are possible and yield circuit equations closely related to the ones introduced in the previous sections. In this section, we discuss the use of two of such representations, the two-sided Laplace transform and the Fourier transform. The two-sided Laplace transform has a marginal role in circuit applications; however, it is considered here because it completes the theoretical framework of frequency-domain analysis. The Fourier transform, instead, adds significant possibilities to the frequency-domain analysis of circuits and, therefore, is discussed for both its theoretical and practical importance. In the following, we briefly review the definition and the properties of the two transforms, along with the frequency-domain circuit equations which arise when such transforms are used.

3.1. Two-Sided Laplace Transform

The two-sided Laplace transform of the function $f(t)$ is

$$\overline{F}(s) = \int_{-\infty}^{+\infty} f(t)e^{-st} dt \quad (33)$$

where $s = \sigma + j\omega$ and lowercase and overlined uppercase letters are used for transform pairs [22].

The following decomposition is useful to compute the two-sided Laplace transform

$$\begin{aligned} \overline{F}(s) &= F_-(s) + F(s) \\ F_-(s) &= \int_{-\infty}^{0-} f(t)e^{-st} dt = \int_{0+}^{+\infty} f(-t)e^{st} dt \end{aligned} \quad (34)$$

where $F(s)$ is the one-sided Laplace transform of $f(t)$ and $F_-(s)$ is the one-sided Laplace transform of $f(-t)$ computed for $t \in [0+, \infty]$ and argument $-s$. The two-sided Laplace transform exists for any s such that both $F_-(s)$ and $F(s)$ exist. If $F_-(s)$ has abscissa of convergence

σ_- (i.e., it exists for $\sigma < \sigma_-$), $F(s)$ has abscissa of convergence σ_+ (i.e., it exists for $\sigma > \sigma_+$), and $\sigma_+ < \sigma_-$, then $\bar{F}(s)$ exists and is an analytic function of s in the strip of convergence $\sigma_+ < \sigma < \sigma_-$. When $\sigma_+ = \sigma_-$, $\bar{F}(s)$ can exist as a distribution, whereas when $\sigma_+ > \sigma_-$, $\bar{F}(s)$ does not exist.

The inversion of the two-sided Laplace transform can be obtained by the line integral

$$f(t) = \frac{1}{2\pi j} \int_{\sigma_0 - j\infty}^{\sigma_0 + j\infty} \bar{F}(s)e^{st} ds \tag{35}$$

where the integration line is in the strip of convergence, or by $F_-(s)$ and $F(s)$ decomposition and tables of one-sided Laplace transform pairs. In the latter case, $F_-(s)$ and $F(s)$ are identified by their poles, since the poles of $F_-(s)$ are on the right of σ_- and those of $F(s)$ are on the left of σ_+ .

3.2. Fourier Transform

The Fourier transform of the function $f(t)$ is

$$\mathcal{F}(\omega) = \int_{-\infty}^{+\infty} f(t)e^{-j\omega t} dt \tag{36}$$

where lowercase and script uppercase letters are used for transform pairs [23]. The inverse transformation is

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \mathcal{F}(\omega)e^{j\omega t} d\omega \tag{37}$$

The term ‘‘spectrum of $f(t)$ ’’ is also used to indicate $\mathcal{F}(\omega)$, or, less often, the magnitude of $\mathcal{F}(\omega)$.

A sufficient condition for the existence of $\mathcal{F}(\omega)$ requires that $f(t)$ has bounded variations (i.e., finite variations for finite time increments) and is absolutely integrable. For time functions with nonvanishing asymptotic values, the Fourier transform may exist as a distribution [23].

3.3. Properties of Two-Sided Laplace Transform and Fourier Transform

Table 5 summarizes two-sided Laplace transform and Fourier transform pairs of common use, with emphasis

Table 5. Elementary Two-Sided Laplace Transform and Fourier Transform Pairs

$w(t)$	$\bar{W}(s)$, s.c. ^a	$\mathcal{W}(\omega)$
1	$2\pi\delta(s)$, $\sigma = 0$	$2\pi\delta(\omega)$
t	$-2\pi\delta'(s)$, $\sigma = 0$	$-2\pi\delta'(\omega)$
t^2	$2\pi\delta''(s)$, $\sigma = 0$	$2\pi\delta''(\omega)$
$\delta(t)$	1, $-\infty < \sigma < \infty$	1
$\exp(s_0 t)$	$2\pi\delta(s - s_0)$, $\sigma = \sigma_0$	$2\pi\delta(\omega + js_0)$
$\cos(\omega_0 t)$	$\pi[\delta(s - j\omega_0) + \delta(s + j\omega_0)]$, $\sigma = 0$	$\pi[\delta(\omega - \omega_0) + \delta(\omega + \omega_0)]$
$\text{sign}(t)$	$2/s$, $\sigma = 0$	$2/j\omega$
$\sum_{n=-\infty}^{\infty} \delta(t - nT)$		$\omega_T \sum_{n=-\infty}^{\infty} \delta(\omega - n\omega_T)$

^aNote that s.c. indicates the strip of convergence of $\bar{W}(s)$; $\delta'(\cdot)$ and $\delta''(\cdot)$ are the first and second derivative of the delta function, respectively; $s_0 = \sigma_0 + j\omega_0$ is a complex constant; and $\omega_T = 2\pi/T$.

on two-sided time functions, as algebraic, rational and harmonic signals [22,23]. Table 6 lists the main properties of the two transformation methods.

Most properties of Table 6 are identical to the corresponding properties of Table 2 for the one-sided Laplace transform, or follow from these by simply replacing s with $j\omega$. A major difference in the properties of the two-sided Laplace transform and of the Fourier transform concerns the derivation formula, where the $f(0-)$ term is dropped. Owing to the latter point, these transforms are not suited for the inclusion of the initial conditions in the solution of circuit equations.

Other properties, involving the parts $\mathcal{F}(\omega)$, are stated for network functions in Section 2.2.

3.4. Relations between Transforms

The different transforms of a waveform can be obtained one from the other via direct relations. Such relations ease the shift between frequency representations, allowing one to exploit their specific properties.

The two Laplace transforms coincide for one-sided functions ($f(t) = 0$ for $t < 0$).

The Fourier transform $\mathcal{F}(\omega)$ exists when $\bar{F}(s)$ exists on the $j\omega$ axis and is given by $\mathcal{F}(\omega) = \bar{F}(j\omega)$ [see Eqs. (33) and (36)]. Graphically, each part of $\mathcal{F}(\omega)$ is the profile of the

Table 6. Main Properties of Two-Sided Laplace Transform and Fourier Transform^a

Property	$w(t)$	$\bar{W}(s)$	$\mathcal{W}(\omega)$
Linearity	$a_1 f_1(t) + a_2 f_2(t)$	$a_1 \bar{F}_1(s) + a_2 \bar{F}_2(s)$	$a_1 \mathcal{F}_1(\omega) + a_2 \mathcal{F}_2(\omega)$
Time differentiation	$\frac{df(t)}{dt}$	$s\bar{F}(s)$	$j\omega\mathcal{F}(\omega)$
Time integration	$\int_{-\infty}^t f(t') dt'$	$\frac{1}{s}\bar{F}(s)$	$\frac{1}{j\omega}\mathcal{F}(\omega) + \pi\mathcal{F}(0)\delta(\omega)$
Time shift	$f(t - t_0)$	$\bar{F}(s)\exp(-st_0)$	$\mathcal{F}(\omega)\exp(-\omega t_0)$
Frequency shift	$f(t)\exp(s_0 t)$	$\bar{F}(s - s_0)$	$\mathcal{F}(\omega + js_0)$
Convolution	$f(t) * g(t)$	$\bar{F}(s)\bar{G}(s)$	$\mathcal{F}(\omega)\mathcal{G}(\omega)$
Moment theorem	$\int_{-\infty}^{\infty} t^n f(t) dt$	$(-1)^n \frac{d^n \bar{F}(s)}{ds^n}$	$j^n \frac{d^n \mathcal{F}(\omega)}{d\omega^n}$

^aNote that * and s_0 indicate convolution and a complex constant, respectively.

corresponding part of $\bar{F}(s)$ along the $j\omega$ axis. If the $j\omega$ axis does not belong to the strip of convergence of $\bar{F}(s)$, $\mathcal{F}(\omega)$ does not exist, whereas if the $j\omega$ axis is a boundary of the strip, $\mathcal{F}(\omega)$ exists as a distribution [e.g., 23, Sect. 9.2].

Finally, $\bar{F}(s)$ can be interpreted as the Fourier transform of the function $f(t)\exp(-\sigma t)$, which is $\mathcal{F}(\omega + \sigma/j) = \mathcal{F}(s/j)$ (see Table 6, frequency shift) for every σ where $f(t)\exp(-\sigma t)$ is Fourier-transformable.

3.5. Circuit Equations and Network Functions

Frequency-domain circuit equations based on the two-sided Laplace transform and on the Fourier transform arise by applying such transformations to the time-domain circuit equations. The equations obtained in this way differ from those based on the one-sided Laplace transform only in the branch relations of dynamic elements. The transformation of linear time-invariant dynamic branch relations via two-sided Laplace transform and Fourier transform replaces the time-derivative operator with s and $j\omega$, respectively, and adds no initial contribution.

For the two-sided Laplace transform, furthermore, the time-integral operator is simply replaced by $1/s$, and, hence, the equivalent circuits of basic elements follow from those of Fig. 1b by simply dropping the initial condition sources. Accordingly, the one-sided Laplace equations written in Section 1 become two-sided Laplace equations by setting initial conditions to zero and representing variables by two-sided Laplace transform [i.e., $F(s) \rightarrow \bar{F}(s)$].

For the Fourier transform, instead, some additional care is required. In order to avoid frequency-domain equations containing $\delta(\omega)$ terms, it is expedient to avoid the Fourier transformation of time-domain equations involving the time-integral operator (e.g., see row 3 of Table 6). Every one-sided Laplace equation written in Section 1 that does not contain the factor $1/s$ can be turned into an equation based on the Fourier transform by replacing s with $j\omega$, setting initial conditions to zero and representing variables by a Fourier transform. As an example, the tableau equations in the Fourier domain are

$$\mathbf{T}(j\omega) \begin{bmatrix} \mathcal{E}(\omega) \\ \mathcal{V}(\omega) \\ \mathcal{I}(\omega) \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathcal{U}_s(\omega) \end{bmatrix} \quad (38)$$

Similarly, in Section 2 we define network functions in terms of two-sided Laplace and Fourier transforms by

$$\bar{H}(s) = \frac{\bar{W}(s)}{\bar{Q}(s)}, \quad \mathcal{H}(\omega) = \frac{\mathcal{W}(\omega)}{\mathcal{Q}(\omega)} \quad (39)$$

The network functions H , \bar{H} , and \mathcal{H} are the different transforms of the same impulse response $h(t)$. Since $h(t)$ is supposed to be causal (i.e., one-sided) function, $\bar{H}(s) = H(s)$ and, provided $H(s)$ is strictly stable (i.e., the $j\omega$ axis belongs to its strip of convergence), $\mathcal{H}(\omega) = \bar{H}(j\omega) = H(j\omega)$ (see Section 3.4). The latter relation also highlights that $\mathcal{H}(\omega)$ yields the steady-state response to a harmonic input

signal (see Section 2.2). In the following, network functions are indicated only by $H(s)$ and $H(j\omega)$.

3.6. Additional Fourier Transform Properties

Additional properties of the Fourier transform relevant to circuit analysis are briefly reviewed.

3.6.1. Physical Meaning of the Fourier Representation. The Fourier representation describes signals in terms of harmonic components and the behavior of linear time-invariant systems in terms of transformation of harmonic components. This interpretation arises from Eqs. (37) and (39)

$$\begin{aligned} w(t) &= \frac{1}{2\pi} \int_{-\infty}^{+\infty} \mathcal{W}(\omega) e^{j\omega t} d\omega \\ &= \frac{1}{2\pi} \int_{-\infty}^{+\infty} H(j\omega) \mathcal{Q}(\omega) e^{j\omega t} d\omega \end{aligned} \quad (40)$$

where $q(t)$ and $w(t)$ are the input and output signals of a circuit with network function $H(s)$, respectively, and \mathcal{W} and \mathcal{Q} are their Fourier transforms. In the above equation, $[1/2\pi \mathcal{W}(\omega) d\omega] e^{j\omega t}$ are the complex harmonic signals composing $w(t)$, each of which comes from the corresponding component of the input signal $[1/2\pi \mathcal{Q}(\omega) d\omega] e^{j\omega t}$ modified by $H(j\omega)$. Such an equation formalizes the operation of linear frequency selective circuits and is the basis for the physical interpretation of frequency responses.

3.6.2. Energy and Power Spectra. The Fourier transform allows also a frequency representation of the energy content of signals [24]. The energy of $q(t)$ can be expressed by the sum of the energies of its harmonic components

$$\mathcal{E} \stackrel{\text{def}}{=} \int_{-\infty}^{+\infty} q(t) q^*(t) dt = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \mathcal{Q}(\omega) \mathcal{Q}^*(\omega) d\omega \quad (41)$$

where $*$ denotes complex conjugation. This equation stems from the orthogonality of harmonic components and is known as the Parseval's formula for finite-energy signals. This relation leads to the definition of the energy spectrum $G_q(\omega) \stackrel{\text{def}}{=} \mathcal{Q}(\omega) \mathcal{Q}^*(\omega) / 2\pi$ [i.e., the energy density of $q(t)$ within $[\omega, \omega + d\omega]$] and of the autocorrelation function $R_q(\tau)$ as the inverse Fourier transform of $G_q(\omega)$.

The autocorrelation and energy spectrum concepts can be extended to signals with finite average power and to stationary stochastic processes, thereby providing a frequency representation also for these important class of signals [24]. In this case, the energy spectrum is renamed power spectrum and the frequency-domain analysis results extend to these signals by the transfer relation

$$G_w(\omega) = |\bar{H}(j\omega)|^2 G_q(\omega) \quad (42)$$

where $G_q(\omega)$ and $G_w(\omega)$ are the power spectra of the input and output related by the network function $H(j\omega)$, respectively.

4. APPLICATIONS OF FREQUENCY-DOMAIN ANALYSIS

The procedure for the frequency-domain analysis of circuits is almost independent of the transformation method used. This latter decides only which waveforms can be represented, how they are represented, and which elements of the circuit behavior are highlighted. Apparently, Laplace transform seems able to handle a more general class of functions and, therefore, seems preferable. This point, however, is controversial [e.g., 23] and the transformation method, instead, should be chosen according to applications.

Roughly speaking, network functions in the s domain offer zero-pole portraits of the circuit behavior and provide the most reliable information on system dynamics and stability. Furthermore, the one-sided Laplace transform takes into account the initial conditions of energy-storing elements and is the preferred transformation method for the frequency-domain solution of transient problems.

When network functions are computed on the $j\omega$ axis (i.e., the Fourier representation is used), they offer a frequency-by-frequency portrait of the circuit behavior, describing how the harmonic components of the input signals are changed. This is useful both in obtaining and in specifying the circuit frequency responses, helps the physical interpretation of frequency-domain results, and allows the frequency characterization of circuits by measurements. For its properties, the Fourier approach is common in problems involving steady-state analysis, signal propagation, and stochastic signals.

In this section we show examples of frequency-domain circuit analysis, which illustrate typical applications and remark the features of the different transformation methods.

4.1. Transient and Frequency Responses

In order to illustrate the evaluation of transient and frequency responses, we consider the circuit of Fig. 4a. For such a circuit, we compute the zero-state response of voltage $v_0(t)$ across resistor R_L to a rectangular input pulse of duration T and height E_0 ; that is, $v_s(t) = E_0[u(t) - u(t - T)]$. Besides, we also compute the frequency response of v_0 to the input v_s . The components have the following (normalized) values: $R_s = R_L = 1 \Omega$, $C_1 = C_2 = 1 \text{ F}$, $L = 2 \text{ H}$, $E_0 = 2 \text{ V}$, and $T = 1 \text{ s}$.

To solve this problem, we first compute the voltage transfer function $H(s) = V_0(s)/V_s(s)$, by using Eq. (16) and setting to zero the sources related to initial conditions

$$H(s) = \frac{V_0(s)}{V_s(s)} = \frac{\Delta_{12}}{\Delta} = \frac{0.5}{s^3 + 2s^2 + 2s + 1} \quad (43)$$

where Δ is the determinant of the node admittance matrix Y_n and Δ_{12} is the cofactor of element 1,2 of Y_n .

From Tables 1 and 2, the Laplace transform of the input waveform turns out to be $V_s(s) = E_0(1 - e^{-Ts})/s = 2(1 - e^{-s})/s$. As a consequence, the transform of output

voltage is

$$V_0(s) = H(s)V_s(s) = \frac{1}{s(s^3 + 2s^2 + 2s + 1)}(1 - e^{-s}) \quad (44)$$

By expanding in partial fractions, we obtain

$$V_0(s) = \left[\frac{1}{s} - \frac{1}{s + 1} - \frac{1}{(s + 0.5)^2 + (\sqrt{3}/2)^2} \right] (1 - e^{-s}) \quad (45)$$

Taking the inverse Laplace transform of each term of the above equation and resorting again to Tables 1 and 2, we have

$$v_0(t) = \left[1 - e^{-t} - \frac{2}{\sqrt{3}} e^{-0.5t} \sin \frac{\sqrt{3}}{2} t \right] u(t) - \left[1 - e^{-t+1} - \frac{2}{\sqrt{3}} e^{-0.5t+0.5} \sin \left(\frac{\sqrt{3}}{2} (t - 1) \right) \right] \times u(t - 1) \quad (46)$$

where v_0 is expressed in volts and t in seconds.

To obtain the frequency response, we set $s = j\omega$ in Eq. (43):

$$H(j\omega) = \frac{0.5}{(1 - 2\omega^2) + j\omega(2 - \omega^2)} \quad (47)$$

The parts of $H(j\omega)$ are easily computed from the above equation. Figure 6 shows the curves of gain $g_H = 20 \log |H(j\omega)|$ and phase $\phi_H = \arg[H(j\omega)]$ for $0 \leq \omega \leq 4 \text{ rad/s}$.

4.2. Asymptotic Responses of Circuits

The response of (strictly) stable circuits can be intuitively divided into a *transient part* and an *asymptotic part* (see Ref. 25 for a complete discussion). The two parts can be visualized and computed by a partial-fraction expansion of the circuit response. Fractions from the poles of the circuit

Figure 6. Frequency response for the circuit of Fig. 4.

transfer function $H(s)$ represent decreasing time functions and form the transient part, whereas the other terms form the asymptotic part. The asymptotic part can also be computed directly by the two-sided Laplace transform [e.g., 26, Chap. 9].

The evaluation of the asymptotic part is particularly important for periodic input signals. In this case, the asymptotic response is usually named *steady-state response*. Here, we illustrate two typical approaches to the evaluation of such a response. For this, we write a periodic input signal of period T as

$$q(t) = \sum_{n=-\infty}^{\infty} q_T(t - nT) = q_T(t) * \sum_{n=-\infty}^{\infty} \delta(t - nT) \quad (48)$$

where $q_T(t)$ is the *cycle function*, which coincides with $q(t)$ in $[0, T]$ and is null elsewhere, and $*$ denotes convolution.

5. ONE-SIDED APPROACH

The steady-state response $w_a(t)$ is a periodic function of period T . The one-sided approach consists in applying the periodic input from $t=0$ and leads to the cycle function $w_{aT}(t)$ of $w_a(t)$.

With this approach, the transform $W(s)$ of the complete response $w(t)$ is given by

$$W(s) = H(s)Q(s) = H(s) \frac{Q_T(s)}{1 - e^{-sT}} = W_t(s) + W_a(s) \quad (49)$$

where W_t and $W_a = W_{aT}(s)/(1 - e^{-sT})$ collect the poles of $H(s)$ and $1/(1 - \exp(-sT))$, respectively ($Q_T(s)$ is analytic everywhere but at infinity). In Eq. (49), $W_t(s)$ can be explicitly computed from the partial fraction terms of $W(s)$ involving the poles of $H(s)$. Once $W_t(s)$ is computed, $W_{aT}(s)$ is obtained as

$$W_{aT}(s) = H(s)Q_T(s) - W_t(s)(1 - e^{-sT}) \quad (50)$$

The interested reader is referred to Ref. 27 for a detailed discussion and illustrative examples.

6. FOURIER APPROACH

In this approach $w_a(t)$ is obtained as a Fourier series via $H(j\omega)$ and the Fourier transform of the periodic input.

The Fourier transform of the periodic input is a *line spectrum* composed of equispaced ideal pulses [see Eq. (48) and Table 5] and $\mathcal{W}_a(\omega)$ is composed of the same input lines modified by $H(j\omega)$

$$\begin{aligned} \mathcal{Q}(\omega) &= \mathcal{Q}_T(\omega) \sum_{n=-\infty}^{\infty} \omega_T \delta(\omega - n\omega_T), \quad \omega_T = 2\pi/T \\ \mathcal{W}_a(\omega) &= H(j\omega) \mathcal{Q}(\omega) \\ &= H(j\omega) \mathcal{Q}_T(\omega) \sum_{n=-\infty}^{\infty} \omega_T \delta(\omega - n\omega_T) \end{aligned} \quad (51)$$

from which the Fourier series of $w_a(t)$ follows

$$w_a(t) = \sum_{n=-\infty}^{\infty} \frac{1}{T} H(jn\omega_T) \mathcal{Q}(jn\omega_T) e^{jn\omega_T t} \quad (52)$$

Although the computation of $w_a(t)$ via its Fourier series is simple, it is practically useful only when the number of significant harmonic component is small. On the other hand, this representation can be exploited also for the asymptotic responses of weakly nonlinear circuits driven by periodic sources. For such an analysis, each nonlinear circuit element is characterized by generalized network functions describing how the element combines its input spectral lines into output ones [28].

6.1. Noise Sources

In this section we illustrate the frequency-domain analysis of circuits containing stochastic sources characterized by their power spectra [24, Chap. 10].

We consider the very simple example of Fig. 7a. Noise sources $e_1(t)$ and $e_2(t)$ model the thermal noise generated by the two resistors. A typical problem in noisy two-port elements is the evaluation of the source terms of their chain matrix constitutive relations—that is, the equivalent sources v_{01} and i_{01} shown in Fig. 7b.

In order to obtain the equivalent sources for this example, we replace $e_1(t)$ and $e_2(t)$ with deterministic signals with spectra $\mathcal{E}_1(\omega)$ and $\mathcal{E}_2(\omega)$ and generate the transformed circuit of the problem. $\mathcal{V}_{01}(\omega)$ and $\mathcal{I}_{01}(\omega)$ be computed as the voltage and current at port 1, ensuring null voltage and current at port 2. This analysis yields the

Figure 7. Evaluation of equivalent noise sources for a two-port element with noisy resistors: (a) original problem; (b) transformed circuit with equivalent sources $\mathcal{V}_{01}(\omega)$ and $\mathcal{I}_{01}(\omega)$.

following transfer relations:

$$\begin{aligned}\mathcal{V}_{01}(\omega) &= \mathcal{E}_1(\omega) + (R_1/R_2)\mathcal{E}_2(\omega) \\ \mathcal{I}_{01}(\omega) &= j\omega C\mathcal{E}_1(\omega) + [j\omega C(R_1/R_2) - 1/R_2]\mathcal{E}_2(\omega)\end{aligned}\quad (53)$$

When noise sources are described by their power spectra $G_{e1}(\omega)$ and $G_{e2}(\omega)$, the power spectra of the equivalent sources are obtained by using the statistical independence of e_1 and e_2 , so that Eq. (42) yields

$$\begin{aligned}G_{v01}(\omega) &= G_{e1}(\omega) + (R_1/R_2)^2 G_{e2}(\omega) \\ G_{i01}(\omega) &= (\omega C)^2 G_{e1}(\omega) + [(\omega C(R_1/R_2))^2 + 1/R_2^2] G_{e2}(\omega)\end{aligned}\quad (54)$$

6.2. Frequency-Domain Analysis of Large Circuits

The evaluation of network functions and of frequency responses amounts to the symbolic or numerical solution of frequency-domain equations. For large networks, with hundreds or thousands of dynamic elements, both tasks can be prohibitively expensive. In these cases, approximate frequency solutions are sought, which reproduce the exact solution in a limited frequency range. The approximate solutions are defined by a reduced number of poles, which approximate some of the poles of the exact solution.

The most used approach to generate reduced order approximations of network functions relies on Padé approximants [29]. A rational approximation $\hat{H}(s)$ of order p to $H(s)$

$$\hat{H}(s) = \sum_{j=1}^p \frac{\hat{k}_j}{s - \hat{s}_j} \quad (55)$$

can be sought by expanding the Maclaurin series of $\hat{H}(s)$ and $H(s)$, up to order $n = 2p - 1$:

$$\sum_{n=0}^{2p-1} s^n \left[-\sum_{j=1}^p \frac{\hat{k}_j}{\hat{s}_j^{n+1}} \right] = \sum_{n=0}^{2p-1} s^n \left[\frac{H^{(n)}(0)}{n!} \right] \quad (56)$$

This equation requires

$$-\sum_{j=1}^p \frac{\hat{k}_j}{\hat{s}_j^{n+1}} = \frac{H^{(n)}(0)}{n!}, \quad n = 0, 1, \dots, 2p - 1 \quad (57)$$

which yield the unknown parameters \hat{k}_j and \hat{s}_j as functions of the coefficients $H^{(n)}(0) = [d^n H(s)/ds^n]_{s=0}$. Such coefficients are shortly named moments of $H(s)$ (see Table 6), and are much easier to compute than $H(s)$ itself. In this basic version, $\hat{H}(s)$ approximates $H(s)$ for small s values (i.e., in the low-frequency range), however, different series expansion and coefficient identities have been devised to cope with different frequency ranges (the interested reader may refer to Ref. 30 for a detailed discussion).

The moments of network functions can be easily obtained by MNA. It is expedient to compute simultaneously the moments of all network functions relating a source $q(t)$ with the unknowns of the MNA equations. Such network functions are the responses of the transformed circuit when q is the only active source and $Q(s) = 1$. They can be collected in a vector $\mathbf{H}(s)$, which is the solution of $(s\mathbf{P}_1 + \mathbf{P}_0)\mathbf{H}(s) = \mathbf{E}$, where $(s\mathbf{P}_1 + \mathbf{P}_0)$ is the MNA matrix (\mathbf{P}_0 and \mathbf{P}_1 being constant matrices) and \mathbf{E} is the source vector, containing only the source $Q(s) = 1$. When $\mathbf{H}(s)$ is represented by its moments, the following equations arise [30]:

$$(s\mathbf{P}_1 + \mathbf{P}_0)(\mathbf{H}(0) + s\mathbf{H}^{(1)}(0) + (s^2/2)\mathbf{H}^{(2)}(0) + \dots) = \mathbf{E} \quad (58)$$

$$\mathbf{P}_0\mathbf{H}(0) = \mathbf{E} \quad (59)$$

$$\mathbf{P}_0\mathbf{H}^{(n)}(0) = -\mathbf{P}_1\mathbf{H}^{(n-1)}(0), \quad n > 0$$

From these equations, the zeroth-order moments $\mathbf{H}(0)$ are obtained as $\mathbf{H}(0) = \mathbf{P}_0^{-1}\mathbf{E}$ (which requires one matrix inversion), and the higher-order moments are obtained as $\mathbf{H}^{(n)}(0) = -\mathbf{P}_0^{-1}\mathbf{P}_1\mathbf{H}^{(n-1)}(0)$ (which requires one matrix multiplication for every vector of moments). This procedure is nearly equivalent to a DC solution of the network.

6.3. Transmission-Line Frequency-Domain Analysis

Transmission lines (TLs) are important circuit elements, because of their many applications (e.g., the modeling of electrically long interconnects). As linear time-invariant elements, TLs are effectively treated by the frequency-domain approach. Both one-sided Laplace transform (transient problems) and Fourier transform (steady-state problems and physical interpretation) are used for TL analysis.

The Fourier transform of voltages and currents along a two-conductor uniform TL supporting a quasi-TEM field are related by the telegrapher equations [31]:

$$\frac{d\mathcal{V}(\omega, z)}{dz} = -\tilde{\mathbf{Z}}(j\omega)\mathcal{I}(\omega, z) \quad (60)$$

$$\frac{d\mathcal{I}(\omega, z)}{dz} = -\tilde{\mathbf{Y}}(j\omega)\mathcal{V}(\omega, z)$$

In these equations, z is the longitudinal coordinate (see Fig. 8), and $\tilde{\mathbf{Z}}(j\omega)$ and $\tilde{\mathbf{Y}}(j\omega)$ are the TL per unit length impedance and admittance, respectively [31].

The solution of Eqs. (60) is

$$\mathcal{V}(\omega, z) = \mathcal{V}^+(\omega)e^{-Kz} + \mathcal{V}^-(\omega)e^{Kz} \quad (61)$$

$$\mathcal{I}(\omega, z) = (\mathcal{V}^+(\omega)e^{-Kz} + \mathcal{V}^-(\omega)e^{Kz})Y(j\omega)$$

where $\mathcal{V}^+(\omega)$ and $\mathcal{V}^-(\omega)$ are arbitrary functions and K and Y are the TL complex propagation constant and

Figure 8. A two-conductor transmission line and the quantities relevant to its analysis.

characteristic admittance, respectively:

$$K(j\omega) = \alpha(\omega) + j\beta(\omega) = \sqrt{\tilde{\mathbf{Z}}(j\omega)\tilde{\mathbf{Y}}(j\omega)} \quad (62)$$

$$Y(j\omega) = \sqrt{\tilde{\mathbf{Y}}(j\omega)/\tilde{\mathbf{Z}}(j\omega)}$$

The waveform described by $\mathcal{V}^+(\omega) \exp(-Kz)$ has harmonic components $\mathcal{V}^+(\omega) \exp[-\alpha(\omega)z - j\beta(\omega)z + j\omega t] d\omega/2\pi$. Each of such components is a harmonic function $\mathcal{V}^+(\omega) \exp(j\omega t)$ traveling toward increasing z with phase velocity $v_\phi = \omega/\beta(\omega)$ and attenuating according to $\exp(-\alpha(\omega)z)$. It describes a transverse electromagnetic field concentrated on the line cross section and propagating along $+z$ as a plane wave.

The frequency-domain analysis of a circuit containing the TL can be carried out by relating voltages and currents at the line ends through the TL solution [Eq. (61)]. The relations are (see Fig. 8)

$$\begin{aligned} \mathcal{V}_1(\omega) &= \mathcal{V}^+ + \mathcal{V}^- \\ \mathcal{V}_2(\omega) &= \mathcal{V}^+ \exp(-\Theta) + \mathcal{V}^- \exp(+\Theta) \\ \mathcal{I}_1(\omega) &= Y(\mathcal{V}^+ - \mathcal{V}^-) \\ \mathcal{I}_2(\omega) &= -Y\mathcal{V}^+ \exp(-\Theta) + Y\mathcal{V}^- \exp(+\Theta) \end{aligned} \quad (63)$$

with $\Theta = K(j\omega)\ell$, where ℓ is the linelength. The arbitrary functions $\mathcal{V}^+(\omega)$ and $\mathcal{V}^-(\omega)$ are determined by the preceding relations and the constitutive relations of the circuit connected at the TL ends. Alternatively, the TL can be characterized as a two-port circuit by a set of network parameters. The network parameters can be obtained by expressing two of the TL end variables as a function of the other two through Eqs. (63). As an example, the chain matrix of the TL is obtained by computing $\mathcal{V}^+(\omega)$ and $\mathcal{V}^-(\omega)$ via the second and fourth lines of Eqs. (63) and by using the first and third lines of Eqs. (63) to obtain $\mathcal{V}_1(\omega)$ and $\mathcal{I}_1(\omega)$. The chain relations

are

$$\mathcal{V}_1(\omega) = \cosh(\Theta)\mathcal{V}_2(\omega) + [\sinh(\Theta)/Y][-\mathcal{I}_2(\omega)] \quad (64)$$

$$\mathcal{I}_1(\omega) = Y \sinh(\Theta)\mathcal{V}_2(\omega) + \cosh(\Theta)[-\mathcal{I}_2(\omega)] \quad (65)$$

Chain parameters can be interpreted as transfer functions in the s domain by replacing $j\omega$ with s in $\Theta = K(j\omega)\ell$ and $Y(j\omega)$. The network functions of distributed circuits, however, are not rational functions of s , because they have infinitely many poles. For small $\Theta(s)$ values (i.e., electrically short lines), the lumped parameter formulation can be recovered by approximating the TL transfer functions with rational functions.

Multiconductor TLs can be treated similarly, by replacing scalar relations for voltages and currents along the line with vector relations for voltages and currents on the different conductors [31]. The formulation becomes considerably complicated, yet it maintains the same properties of the two-conductor case.

FREQUENCY-INDEPENDENT ANTENNAS

DEJAN S. FILIPOVIC
University of Colorado
Boulder, Colorado

THOMAS P. CENCICH
Lockheed Martin
Denver, Colorado

MICHAEL W. NURNBERGER

1. INTRODUCTION

Frequency-independent (FI) antennas are characterized by virtually invariant impedance and pattern performance over wide bandwidths or over multiple logarithmically periodic bands. A true FI antenna must have an infinitely large aperture (no low-frequency limit) and an infinitely fine and small central/feeding region

(no high-frequency limit). Its geometry must be described by angles, and no single structural characteristic should depend on length. To eliminate contaminating radiation from various regions on the FI structure, the nonradiated (often referred to as *residual*) currents must decay to zero after passing an appropriate active region and before entering the next radiating region. The most desirable way to attenuate excited currents on an FI antenna is through radiation, but complete radiation from a single active region (constructive radiation) is not possible. Ideal FI antennas must use a frequency-independent feed to realize their full bandwidth.

Certainly, no practically realizable antenna can fulfill these requirements, and thus a more lenient definition of a FI antenna (from the beginning of the text) is generally accepted. After half of century of development, consistent impedance and pattern characteristics over 100:1 bandwidths can be achieved today with a single antenna. Even in the early days (mid-1950s), the bandwidth of the first FI antennas was larger than the bandwidth of the supporting electronics, so once the range of 20:1 was demonstrated, antenna researchers attempted to gain a theoretical understanding of FI antenna performance. The list of individuals and respective electromagnetics groups with significant contributions in FI research is rather large, but a special place belongs to the early work of Prof. Victor H. Rumsey and his colleagues and their students at the Antenna Laboratories at the University of Illinois at Urbana and Champaign (UIUC) and at the University of California at Berkeley (UCB). In addition to the FI concept, quite a few pioneering antenna designs, including spirals, log-periodic antennas, and FI arrays, to mention only a few, emerged from these two laboratories.

In this article, Rumsey's theory of FI antennas [1,2] is reviewed and some historical highlights of the most important contributions in this area are outlined. A mathematical derivation for a general FI structure is provided, and some special cases are considered both theoretically and practically. The underlying theory of operation for several FI antenna types, including equiangular spirals, sinuous antennas, and log-periodic slot arrays, is also described.

2. HISTORICAL OVERVIEW

Professor Victor Rumsey first proposed the FI concept in the mid-1950s. He initiated the research while he was with the Ohio State University, but the major contributions to the definition and analytical treatment of FI antennas came during his stay with UIUC, where he and other researchers, such as Raymond DuHamel and Dwight Isbell (log-periodic antenna concept, etc.), John Dyson (experimental work on spiral antennas, etc.), Paul Mayes (multiarm spirals, backward-traveling waves in periodic structures, etc.), Georges Deschamps (theoretical concepts on impedance, etc.), and their students were instrumental in both theoretical and experimental verification of this revolutionary concept in

antenna theory. The list of individuals and their inventions is extensive, and since a comprehensive overview of historical developments can be found in Ref. 3, here we outline only a few contributions available in the open literature (it is important to note that the work of many researchers was shielded from the public eye for decades; thus some concepts might have been proposed earlier than the cited publications):

- 1943: Schelkunoff [4] developed a transmission-line model of a biconical antenna—the first antenna specified by angles. However, the currents do not decay faster than the far field of the antenna and the truncation principle is not satisfied. Thus, while the bicone is not an FI antenna, it was nevertheless instrumental in future developments.
- 1957: Rumsey [1] derived an analytical formulation of FI principles; specifically, a mathematical derivation of the generic angle-specified geometries.
- 1957: DuHamel and Isbell [5] proposed an analytical formulation of log-periodic principles: mathematical derivation of log-periodic geometry, planar sheet design, and experimental verification of log-periodic FI performance over 10:1 bandwidth.
- 1958: DuHamel and Ore [6], while designing wire log-periodic antennas, noticed that the current is concentrated at the edges of a planar sheet; thus they removed metal in between and obtained a lightweight structure. Their work included some circularly polarized designs, as well as unidirectional folded structure (origin of this concept is traced to D. Isbell's work published in a UIUC report).
- 1959: Deschamps [7], investigated the modal impedances of multiarm self-complementary structures, extending the concept suggested by Mushiake in 1949 (published in Japanese) to multiarm structures and derived the formula for arm impedances.
- 1959: Dyson [8,9] experimentally verified the FI performance of the spiral antenna and designed planar and conical slot spirals operating over bandwidths in excess of 10:1 and infinite (Dyson) balun feed with practically unrestricted bandwidth (for other contributions in spiral antennas, see article SPIRAL ANTENNAS).
- 1961: Carrel [10] established design guidelines for the log-periodic dipole antenna, with transposed feeder design.
- 1961: Berry and Ore [11] designed a log-periodic $\lambda/4$ monopole array over a finite-size ground plane, with reactive feeder design.
- 1961: Mayes et al. [12] investigated the excitation of backward-traveling waves on log-periodic structure.
- 1961: Cheo et al. [13] proposed an analytical treatment of the orthogonal radiation modes on an infinitely large spiral antenna with an infinite number of arms.
- 1965: Mei et al. [14] proposed the concept of highly directive FI array topology.
- 1968: Yeh and Mei [15] developed a method-of-moment characterization of spirals.
- 1968: Ingerson and Mayes [16] used an impedance-modulated feedline to prevent occurrence of bandstop behavior and also proposed a novel log-periodic cavity backing concept to support efficient flush mounting.
- 1987: DuHamel [17] designed the sinuous antenna: an omnipolarized, planar, single aperture, log-periodic antenna.

3. BASIC THEORETICAL PRINCIPLES

For the design and realization of FI antennas, the following principles play an important role and thus must be understood:

- Geometry/performance scaling
- Angular description of the geometry
- Termination of residual nonradiated currents
- Self-complementary geometry

The FI idea started with the notion that for a nondispersive medium, the current distribution on an antenna as a function of frequency remains fixed only if the dimensions of both the antenna and the operating wavelength are changed by the same fraction; that is, only if the electrical dimensions of the antenna remain invariant to changes in operating frequency. From another perspective, in order to maintain a constant (unaltered) current distribution on an antenna as a function of frequency, the antenna structure must scale with wavelength. Then, since the current distribution does not change with normalized frequency, neither will the impedance at the antenna terminals or the fields radiated from the antenna, and the antenna performance will be invariant with frequency. This concept can be extended to include an inhomogeneous structure (any combination of metals, dielectrics) provided all dimensions of the structure are scaled in proportion to the wavelength (inversely to frequency).

Rumsey [1] recognized that to obtain a continuous scaling of antenna performance with frequency, that is, with virtually unchanged characteristics, an antenna should have no lineal dependence. More specifically, if the antenna geometry is specified only by angles, then the frequency scaling, which for antennas with lineal structural form is manifested by the scaling of resonances, will correspond to rotation and translation of the basic structure. On the basis of this observation, and with some minor restrictions, he was able to derive a mathematical formula for a frequency independent radiator in both planar and nonplanar forms (see next section).

Ultimately, while yielding an infinitely broadband antenna, any structure defined purely by angles must also both be infinitely large and have infinitely fine center details. Therefore, in order to be practically useful, the antenna structure must be of finite size and should satisfy the truncation principle; that is, the currents on the

antenna must decay to zero after they radiate from the lowest-order active region. Any residual currents must be prevented from radiating from the higher-order active regions, as this ultimately will contaminate the far-field pattern of the antenna. If the currents indeed reduce to zero after passing this dominant active region, the antenna aperture can be terminated at a finite distance and the reflection from structural ends will be nonexistent. Another way of saying this is that the radiation pattern of the finite, truncated structure must approach a limiting form—generally, the pattern of the infinite structure—as the frequency is increased.

The truncation principle establishes the lower frequency limit of the FI behavior of the antenna. As the frequency decreases, a point will be reached when the currents on the antenna begin to encounter its end before decaying to zero. Below this frequency the antenna will still radiate, but its current distribution will be disturbed by the above-mentioned encounter. As a consequence, antenna gain, pattern, and input impedance will be inconsistent with frequency. A lossy termination is often integrated with the end of the radiator to mitigate end effects as well as to extend the low-frequency performance of the antenna (provided that lower efficiency is acceptable). The upper frequency limit of an FI antenna is based on the finesse, detail, and precision with which the balun and feed region can be fabricated.

Self-complementary geometry is not a necessary condition for FI performance, but certainly is one that helps to obtain consistent broadband behavior. Applied only to planar structures, this principle states that if the interchange between metallic and nonmetallic (or slot) parts on a planar antenna embedded in a homogeneous medium leaves the geometry unchanged except for a rotation equal to half of the angular periodicity, then the respective impedances of two complementary antennas are related by

$$Z_{\text{metal}}Z_{\text{slot}} = \left(\frac{\eta}{2}\right)^2 \quad (1)$$

where η is the plane-wave impedance for the homogeneous medium (for an antenna in air $\eta = 120\pi \Omega$, and the impedance is $Z_{\text{metal}} = Z_{\text{slot}} = 188.5 \Omega$). As noted by Mushiake in 1949, formula [1] is based on Booker's extension of Babinet's principle (see any antenna textbook, e.g., Ref. 18) can be utilized for designing antennas with broadband impedance matching. Several examples of planar self-complementary structures are shown in Fig. 1.

Finally, FI performance can also be claimed if minimal variation in the measurable parameters of the antenna—typically its gain, pattern, and input impedance—occurs within a certain frequency range and is repeated for several consecutive (logarithmic) periods. In the ideal case, an infinite number of these periods would exist, and the resulting infinitely large and detailed structure would have unlimited bandwidth. The connection between these two seemingly different approaches is mathematically supported through the logarithmic dependence of the structural features of a planar projection of a 3D truly FI antenna structure, known as a *conical screw*, as shown in the next section. This principle is a rule more for eval-

Figure 1. Several examples of self-complementary planar structures.

uation rather than the design, and implies that a properly designed FI antenna should have identical performance at frequencies related by the (logarithmic) periodicity of the antenna with as little variation as possible in the performance within each period.

A generic log-periodic structure is depicted in Fig. 2. The geometric ratio, or growth rate, is denoted by τ and is the ratio of frequencies between which “small” variations in antenna performance occur. The growth rate is also equal to the ratio of the lower (smaller) and the next-higher (larger) repeatable structural dimension, $\tau = f_n / f_{n+1} = r_{n+1} / r_n$. Achievement of a pattern null (zeroing) in the plane of the antenna is needed for reasons of truncation. If the zeroing of the pattern is not produced in the truncated direction, the currents will also exist to infinity and the end effect will be pronounced. As discussed earlier, this would violate the truncation principle and antenna would cease to produce FI behavior.

4. MATHEMATICAL DERIVATION OF FREQUENCY INDEPENDENCE

The analytical treatment of a generic FI structure given in this section follows the original derivation by Rumsey [1], with generalizations provided by Elliott [19] and certain specifics for log-periodic structures given by DuHamel and Isbell [5]. Thorough theoretical background can be found in Ref. 2. Assume the following:

- An antenna is fed through infinitesimally close ports symmetrically displaced around the origin of the spherical coordinate system.

Figure 2. Schematic of a planar log-periodic geometry.

- An axis of symmetry coincides with the z axis.
- The antenna extends to infinity.
- The antenna arms are made of a perfect electrical conductor.
- The antenna is embedded in a homogeneous, isotropic, unbounded medium.
- The outline of the arms of the antenna can be described using the generic formula $R = R(\phi, \theta)$, where R, ϕ, θ are spherical coordinates and $R(\phi, \theta)$ denotes a mathematical dependence of the radial distance from the origin to any point on the antenna structure.

If we want to have the same performance of the original structure at K times lower frequency (K times larger wavelength), we must preserve the electrical dimensions of the original. In other words, every defining dimension or point of the antenna must be multiplied with K , and the new antenna can now be described by

$$R' = KR(\phi, \theta) \quad (2)$$

Examples of original and scaled geometry with the scale factor $K=2$ are shown in Fig. 3. The solid circle in the

middle denotes the infinite precision of the feeding region (remember that the geometry has infinite extension). As shown in the figure, the scaling discussed above produced merely the rotation of the geometry by the angle ϕ' around the fixed antenna terminals, and can be expressed as follows:

$$R' = KR(\phi, \theta) = R(\phi + \phi', \theta) \quad (3)$$

This equation, along with the discussion leading to its derivation, clearly shows that the two antennas will have the same performance at two frequencies related by the scale factor K , except for the associated azimuth rotation ϕ' . Additionally, the scaling factor K and associated azimuth rotation ϕ' are mutually dependent and invariant with any other parameter of the antenna. As a result, we can take partial derivatives of both sides of (3) with respect to ϕ and ϕ' and obtain Eqs. (4) and (5), respectively:

$$\begin{aligned} K \frac{\partial R(\phi, \theta)}{\partial \phi} &= \frac{\partial R(\phi + \phi')}{\partial \phi} \\ &= \frac{\partial R(\phi + \phi')}{\partial(\phi + \phi')} \frac{\partial(\phi + \phi')}{\partial \phi} \\ &= \frac{\partial R(\phi + \phi')}{\partial(\phi + \phi')} \end{aligned} \quad (4)$$

$$\begin{aligned} R(\phi, \theta) \frac{dK}{d\phi'} &= \frac{\partial R(\phi + \phi')}{\partial \phi'} \\ &= \frac{\partial R(\phi + \phi')}{\partial(\phi + \phi')} \frac{\partial(\phi + \phi')}{\partial \phi'} \\ &= \frac{\partial R(\phi + \phi')}{\partial(\phi + \phi')} \end{aligned} \quad (5)$$

Since the right-hand sides of (4) and (5) are the same, we can write

$$\frac{1}{R(\phi, \theta)} \partial R(\phi, \theta) = \left(\frac{1}{K} \frac{dK}{d\phi'} \right) \partial \phi = a \partial \phi \quad (6)$$

where $a = K^{-1} dK/d\phi'$ does not depend on any spherical coordinate (it is a constant). The solution of (6) is

$$R = R(\phi, \theta) = f(\theta) \exp(a\phi) \quad (7)$$

where $f(\theta)$ is an arbitrary function describing the dependence of the antenna structure on elevation angle θ . A generic antenna whose shape can be described using Eq. (7) will be frequency-independent. For the example shown in Fig. 3, the infinitely large structures represented by solid and dotted lines follow the same growth rate a and dependence on elevation angle $f(\theta) = \text{const}$. When the scaling factor is $K=2$, the original equiangular spiral (solid line) “rotates” in azimuth by $\phi' = \log 2/a$ to conform to the dotted spiral structure. Thus, the antenna scaling is equivalent to a rotation and the performance at any two frequencies f_1 and Kf_1 must be the same except for the rotation ϕ' in azimuth.

Figure 3. Notion of scaling through rotation of an infinite FI geometry. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Special cases derived from Eq. (7) are [19]

- *Planar equiangular spiral*, for which $f(\theta) = A\delta(\pi/2 - \theta)$, where A is constant and $\delta(\pi/2 - \theta)$ is the Dirac delta function describing the planar nature of this structure. The governing equation which defines the planar equiangular spiral is then

$$R = A \exp(a\phi) \tag{8}$$

- *Conical equiangular spiral*, obtained if $f(\theta) = A\delta(\beta - \theta)$, where β is the apex angle of the cone and the spiral is projected to its surface. Note that the planar equiangular spiral is a special case of the conical spiral when $\beta = \pi/2$.
- *Conical screw*, obtained when an equiangular spiral is projected to the volume between two cones with the same axis and orientation but different apex angles. Multiple screws can be arranged within periodic azimuth angles ϕ .
- *Log-periodic planar sheet*, obtained using a $\phi = \text{const}$ cut through a conical screw with axis on the θ axis. A drawing of the first log-periodic antenna [5], whose 3D equivalent is a biconical screw, is shown in Fig. 4. A log-periodic structure can also be obtained by utilizing a projection between two spaces, $z(x,y)$ and

$w(\rho,\phi)$, connected using transformation $z = \ln(w)$. For example, the projections of the constant and variable growth planar sinusoidal antennas produce sinu-

Figure 4. Drawing of the first planar sheet log-periodic antenna.

soidal lines with constant and varying periods, as will be shown in the next section.

5. TYPICAL FI ANTENNAS

5.1. Equiangular Spiral

The equiangular spiral (also known as a *logarithmic spiral*, or *log-spiral*) is a planar embodiment of an FI antenna, with a structure described by Eq. (8). For a constant growth rate a , an angle (α) subtended between the radius vector of an arbitrary point on the edge of the spiral arm and tangent to the arm through the same point is constant throughout the spiral structure. This angle and spiral growth rate are related as $a = 1/\tan \alpha$. Equiangular spirals are discussed in more detail in the SPIRAL ANTENNAS article, so only a few features unique to the FI performance of this antenna will be discussed here. More specifically, the spectral content of the higher-order modes excited on and supported by the spiral, including their radiated power densities (and associated gains) relative to that of a dominant mode, can be utilized for determining the high end of FI performance. Typically, this frequency is determined by the size and finesse of the feeding region, but if the attenuation of the traveling wave through the active region is insufficient, strong undulations in the antenna radiation pattern can occur [20,21], thus reducing the highest frequency of operation.

Figure 5 shows the relative gains of the higher-order modes M3 and M5 (compared to the gain of mode M1) excited on two (2A)-, four (4A)-, and eight (8A)-arm free-standing 5-cm-diameter equiangular wire spirals. The first higher-order mode on an 8A spiral, M9, is also shown. Two sets of antennas, shown in Fig. 6, are used for this demonstration: equiangular spirals with the same growth rate in Fig. 6a and spirals with equidistant arm-to-arm spacing measured at the same radii in Fig. 6b. Note that the 2A spiral is the base geometry. These results are obtained by applying modal decomposition to the radiated fields computed using a method-of-moments code (NEC). Although the gains of the dominant mode (M1) are virtually the same for all antennas, the higher-order mode gains are significantly different for the three antennas and the bandwidth with respect to the uncontaminated M1 radiation differs as well. As can be seen, the higher-order modes M3 and M5 for the 2A spiral are well above computational noise and could be seen in the patterns. The first higher-order mode for the 4A spiral, M5, turns on later (at higher frequency) than does the M3 of a 2A spiral, and its relative gain is higher than the gain of M5-2A (i.e., mode 5 for the two-arm spiral). Note that in the 2A case, modes M1 and M3 have already radiated from the 1 and 3 wavelengths rings; thus lower residual energy remains on the arms, giving rise to the reduced M5 efficiency. The first higher-order mode for the 8A spiral is M9, which turns on at much higher frequency than do the corresponding first higher-order modes for A2 and A4 spirals. Modes M3 and M5 of the 8A spiral are very inefficient, and the gains of M3-4A and M3-8A are too low to be seen in the figure. A cross-modal discrimination of 30–40 dB provides little, if any, visible effects in the radiation pattern, so, clearly an

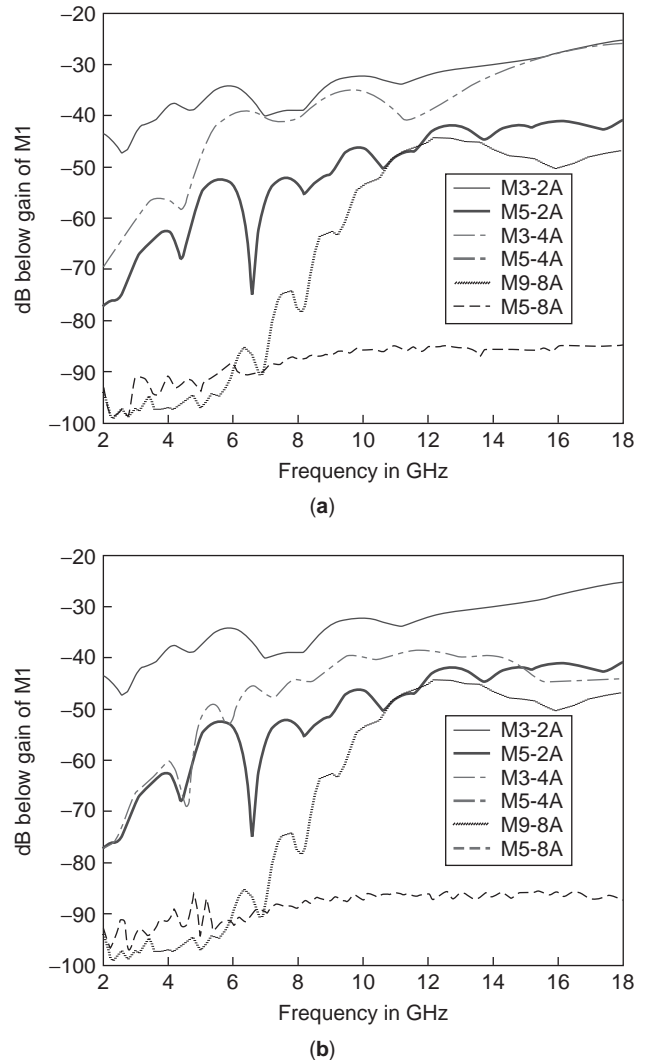

Figure 5. Modal decomposition of two-, four-, and eight-arm self-complementary equiangular spirals with same growth rate (a) and equal separation between arms measured at the same radii (b). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

eight-arm spiral has the largest FI bandwidth. The radiation from the higher-order mode regions contributes to the attenuated traveling wave in the outer region of the antenna, and care must be exercised when the truncation principle is applied. Also, note that the smaller growth rate [case (a)] for the 4A spiral amounts to more radiation in the M1 active region and thus lower gain in the higher-order mode M5.

Excellent discussions of planar and conical equiangular spirals, including some practical aspects of feeding, and multiarm designs, as well as FI-related differences with Archimedean spirals, can be found in the literature [8,9,21–23].

5.2. Log-periodic Antennas

DuHamel and Isbell [5] defined the log-periodic antenna as a structure whose electrical properties vary periodically

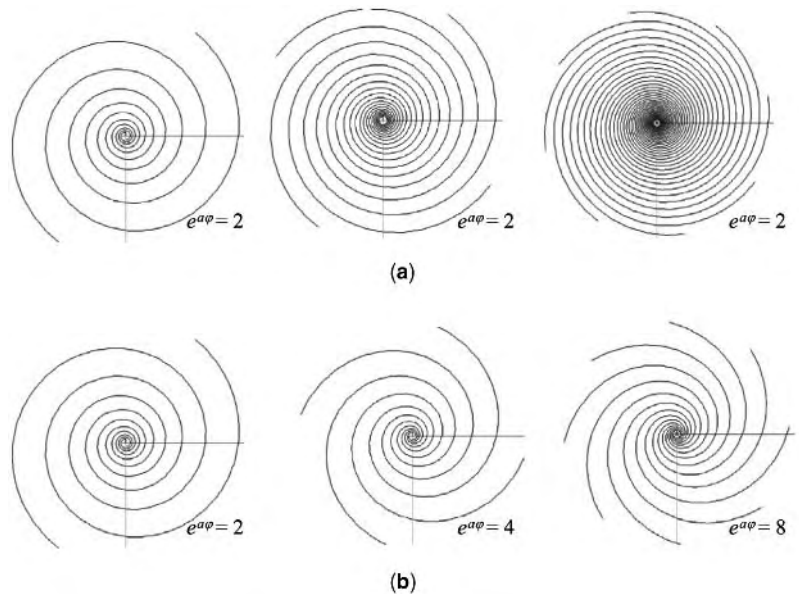

Figure 6. Two-, four-, and eight-arm spirals with the same growth rate (a) and equal separation between arms measured at the same radii (b). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

with the logarithm of frequency. If an antenna is realized such that within each period its performance changes within bandwidth-defined conditions (e.g., the real part of the input impedance = $70 \pm 20 \Omega$, or the gain = 5 ± 1 dBi), then multidecade operation can be achieved. As stated earlier, a log-periodic structure can be obtained by taking an appropriate 2D cut of a 3D FI antenna known as a *conical screw*. The first log-periodic designs (the very first one is shown in Fig. 4) were obtained that way. The list of contributions and different designs embracing the same principles is very long [3,24], so only a few will be reviewed here. A more in-depth discussion of log-periodic antennas can be found in Ref. 20.

5.2.1. Log-periodic Tooth Structure. Experimental verification of a decade-bandwidth log-periodic FI design was first demonstrated in 1957 [5]. The planar freestanding element, shown in Fig. 4, is a linearly polarized bidirectional radiator. Very efficient attenuation through the active region composed of several teeth in the neighborhood of a half-wavelength-long pair results in little (if any) observable end effect. The teeth can be of circular or straight/trapezoidal shape with respective antennas showing little difference in performance. For bidirectional operation, the feedline is planar and is realized using a coaxial cable (coax) soldered to the metal portion between the teeth (equivalent to the Dyson balun [8]). The coax transitions to the slot in the geometric center of antenna aperture. When unidirectional operation of a planar structure backed by a cavity is sought, a vertical balun feed is typically utilized (it also serves as an impedance transformer). The typical impedance at the balanced ports of an antenna with self-complementary geometry is $\sim 160 \Omega$. This is slightly lower than the theoretical value of 188.5Ω because of the nonzero metallization thickness, finite features of the feed region, dielectric support (if used), and so on. Lowering the impedance by increasing the

capacitance, namely, the metal-to-slot ratio (deviation from the self-complementary structure), have proved to be very challenging since impedance and pattern variations within both the period and the bandwidth are typically significant.

Efficient unidirectional operation can be achieved by folding the planar arms, that is, by reducing the angle between the axes of the arms (in planar configuration this angle is 180°). Folding eliminates the need for lossless reflective (bandlimited) and/or lossy absorptive (broadband) cavities and typically yields a 2–2.5 dB increase in forward gain when compared to the freestanding (or absorptive cavity-backed) antenna. To reduce the antenna weight and windload, the solid metallic arms can be replaced by a thin metallic wire or strip that outlines the previously solid structure [6]. Changes in impedance and pattern are minimal since the current is concentrated along the edges of the original geometry. By utilizing a simple $\pm 90^\circ$ hybrid or other more complicated beamformers, multipolarized operation can be obtained when two pairs of arms are placed in mutually orthogonal planes with their teeth interleaved. The first publications by the inventors of log-periodic antennas, conveying their enduring conclusions and vision, are not only a testament of the excellence coming from the UIUC but also a cornerstone and guideline for the future research and application of frequency-independent principles.

5.2.2. Log-periodic Dipole Arrays. The log-periodic dipole array antenna was the first FI antenna that immediately after being conceived truly made a huge impact on both commercial and military applications throughout the world. Although Carrel's studies have provided theoretical and experimental foundation of log-periodic dipole antennas [10], the concept was first proposed by Isbell [25], who made the following modifications to the structure he previously conceived with DuHamel (see Fig. 4):

- Arms of the tooth structure are folded and their axes are made parallel. This corresponds to the limiting case of the angle $\psi \sim 0^\circ$.
- The width of the teeth $r_n - r'_n$ is kept constant throughout the antenna structure.
- Planar circular teeth are replaced by straight wires with uniform cross section.
- The apex angle of an embedded cone (in the basic conical screw geometry, which, as discussed earlier, is the foundation for the planar sheet) approaches 0° in the limit. In other words, the supporting booms are straight rods typically with rectangular cross section.

As a result of these modifications, a log-periodic wire dipole antenna emerged, most frequently used worldwide as a receiving antenna for terrestrial VHF/UHF radio and television. As such, its structure, theory of operation, design guidelines, and performance are well documented in classical antenna textbooks and practitioner handbooks, and will not be discussed further in this article. Comprehensive discussion of the performance of this antenna can be found in a classic paper by Carrel [10].

5.2.3. Log-periodic Folded Slot Antenna. Figure 7 shows a 16-element log-periodic folded slot antenna with basic parameters and equations describing its structure depicted in the same drawing. The shading represents slots etched in a (typically) copper metallization of a thin low-dielectric constant, low-loss substrate. Between the folded slots are “phasing slots” needed to provide the proper phase delay necessary for endfire radiation. As with other log-periodic antennas, $\tau = L_{i+1}/L_i$ is the growth rate, which determines the period of logarithmic repetition in electrical performance. The parameter $\sigma = d_i/(2L_i)$ is the relative electrical distance between the active (half-wavelength) dipole and its neighbor, while 2α represents the angular opening of the structure. As seen from the figure, to uniquely specify the antenna geometry, we need to define the growth rate τ and either of the remaining two parameters. log-periodic folded slot antennas designed for the same frequency range but with three different growth rates and numbers of arms are shown in Fig. 8. The pa-

Figure 7. log-periodic folded slot antenna with corrective phasing slots and equations that fully describe its structure.

rameters for these antennas are determined for performance over a 4:1 range, so that the number of arms is $N = 9, 12, 17$ for $\tau = 0.8, 0.85, 0.9$, respectively. As stated earlier, the presence of the phasing slot is critical for endfire performance of this antenna. If the phasing slot is not used, the growth rate has to be very high (close to 1) in order to reduce (but ultimately not prevent) the gain dropouts and other anomalies in the radiation pattern. Maximum gain for two different lengths of the phasing slot is computed and compared with the case without it (see Fig. 9). Three-dimensional radiation patterns for the cases with and without the phasing slot are shown in Fig. 10. As seen, the narrowband gain dropouts, as well as deteriorated front-back ratio, multilobes, and other characteristics, are present when the phasing slot is not used. With the

phasing slot, the near- and far-field characteristics of the antenna improve vastly. The simulations have shown that the slot lengths around α produce the best antenna performance.

5.2.4. Sinuous Antenna. The traditional sinuous antenna is a broadband, log-periodic structure with $N \geq 4$ arms composed of arcs and bends, and whose low- and high-frequency operation limits are determined by the outer and inner diameter of the antenna, respectively. As shown in Fig. 11, the sinuous configuration is fully depicted by the angles α —angular span of defining sinuous curve—and δ —rotation angle needed to outline the sinuous arms—as well as the log-periodic growth rate— τ . If any of these three defining parameters is varied from cell to cell, a quasi log-periodic sinuous structure is obtained. Layouts of the constant-growth-rate (log-periodic) and variable-growth-rate (quasi log-periodic) four-arm sinuous antennas are shown in Fig. 12. Also depicted are their projections in the z plane, which clearly indicate not only the (quasi)log-periodic behavior of the essential sinuous curves but also the self-complementary feature of these planar shapes. Detailed description of a sinuous structure with various modifications, as well as its operation principles, practical aspects such as feeding, parameters, and modeforming, can be found in Ref. 17.

Most sinuous antenna research has been devoted to the planar four-arm printed/wire geometries. Since a free-standing antenna radiates bidirectionally, an absorptive

Figure 11. Sinuous antenna geometry and relevant parameters.

cavity or conical projection of the sinuous structure (as with spirals) are required for unidirectional operation. Although lossy cavity backing reduces the antenna efficiency, it is the preferred approach for conformal and

Figure 12. A layout of the constant-growth sinuous and its transform (a) and variable-growth sinuous and its transform (b).

flush-mounted applications. Reflective metal backing (empty cavity or cavity with vertical wall absorber liners) causes strong coupling into the sinuous feeds and severe mismatch as well as contaminated far-field radiation patterns [gain dropouts, increased axial ratio, and WoW (Wobble on Wave)]. Several sinuous antennas including an interferometer configuration manufactured by L-3 Communication Randtron Antenna Systems, are shown in Fig. 13.

A special case of a sinuous antenna is the folded spiral, constructed as a spiral that is “folded” back on itself. The angular arm expansion of the folded spiral is the same as that of a sinuous antenna, and the main difference is in the shape or curvature of the arm bends. More specifically, the bends of a sinuous structure are rounded as opposed to the sharp tips of a folded spiral. The performance of the two antennas is virtually the same, and often the folded spirals are referred to as “sinuous” antennas. Thus any reference to one can be equally applied to the other antenna. Looking at a single arm composed of several cells of arcs and bends, we can see that the folded spiral is a combination of both clockwise (CW) and counterclockwise (CCW) wound spiral segments. Thus, the band theory used for describing spiral operation can be utilized for understanding the performance of sinuous antennas. A tightly coupled sinuous antenna, where arms have significant interlacing ($\tau > 0.8$), has approximately the same frequency limits as a spiral; that is, the sinuous antenna should be N wavelengths in circumference to support efficient mode N radiation. In practice, for a given low-frequency limit, the circumference of the sinuous antenna should be increased by a certain value (typically $\lambda/2$) to account for the finite width of the radiation region. Excitation of the sinuous antenna, when operated in a single circularly polar-

ized mode, is also identical to the feeding of a spiral antenna. One exception to the similarity is that the sinuous is dual-polarized and has additional capabilities, and unfortunately additional restrictions. Because of the alternating CW and CCW wrapping senses in each arm and inability of the aperture to perform polarization filtering, the sinuous antenna with N arms can support $(N - 1)/2$ broadband modes. Although the overall number of modes on an N -arm sinuous antenna is one-half the number of modes on a comparable N -arm spiral, their radiation patterns are very similar. Only mode 1 has a broadside radiating component, and all other modes have a null on boresight, with each higher-order mode peaking further from the null. Note that each mode on a sinuous antenna can be obtained in either left- or right-handed circular polarization (RCP, LCP). If we need M modes of operation with the same polarization, an $N = (2M + 1)$ -arm sinuous antenna is needed. These modes will be excited if equal amplitudes and phase progressions of $-360^\circ nm/N$ are provided at the arm feeds (taken in the CW direction). Here, n is the arm number ($n = 1, 2, \dots, N$), m is the mode number ($m = 1, 2, \dots, \lfloor (N - 1)/2 \rfloor$), and N is the total number of arms. If the highest-order mode that can be supported by an arbitrary N -arm sinuous antenna is m ($m > 0$), the following modes can coexist: $-m, -m + 1, \dots, -1, 1, \dots, m - 1, m$, with positive modes denoting the RCP and negative modes LCP, respectively. Therefore, at least $N = 5$ arms are needed to obtain dual-mode operation, which is important for monopulse direction finding.

To further understand the relation between the number of sinuous arms and the modal spectrum supported by its structure, we will examine in more detail an arbitrary ($N = 4$)-arm sinuous geometry. A corresponding four-arm CCW wound spiral antenna will support broadband RCP

(a)

(b)

Figure 13. Photographs of several sinuous antennas (a) and a high-pressure interferometer (b). (Courtesy of L-3 Communications Randtron Antenna Systems.)

modes M1 $\{0^\circ, 90^\circ, 180^\circ, 270^\circ\}$, M2 $\{0^\circ, 180^\circ, 360^\circ, 540^\circ\} \equiv \{0^\circ, 180^\circ, 0^\circ, 180^\circ\}$, and M3 $\{0^\circ, 270^\circ, 540^\circ, 810^\circ\} \equiv \{0^\circ, -90^\circ, 180^\circ, 90^\circ\}$ with the phase progression (in CW sense) denoted in brackets $\{ \}$. A four-arm sinuous antenna has spiral segments capable of radiating both senses of circular polarization; thus when the mode 2 phase progression is provided at the arm ports $\{0^\circ, -180^\circ, -360^\circ, -540^\circ\} \equiv \{0^\circ, 180^\circ, 0^\circ, 180^\circ\}$, the aperture cannot differentiate between it and the mode -2 phase progression $\{0^\circ, 180^\circ, 360^\circ, 540^\circ\} \equiv \{0^\circ, 180^\circ, 0^\circ, 180^\circ\}$, so the radiating region radiates the mixture of modes 2 and -2 . The mode 3 phase progression is $\{0^\circ, -270^\circ, -540^\circ, -810^\circ\}$, and the RCP four-arm spiral supports its efficient and broadband radiation (provided the circumference is larger than three wavelengths). If the same phase progression is provided to the sinuous antenna, we notice that it is equal to the progression of $\{0^\circ, 90^\circ, 180^\circ, 270^\circ\}$, which is identical to that of mode -1 . This mode will be excited first (it radiates from the area the traveling wave encounters before arriving at the mode 3 radiating region) and little energy will be left for mode 3. Thus, as stated above, for dual-mode operation a sinuous antenna must have at least five arms, with unique and unambiguous phase progressions for mode 2 $\{0^\circ, -144^\circ, 72^\circ, -72^\circ, 144^\circ\}$ and mode -2 $\{0^\circ, 144^\circ, -72^\circ, 72^\circ, -144^\circ\}$. Six or eight arms are generally used because of beamformer limitations. An eight-arm sinuous antenna has the additional benefit of supporting a third mode, or modes ± 3 . Radiation patterns for the three modes radiated from an eight-arm sinuous antenna are shown in Fig. 14. As seen, the previously discussed characteristics of modes 2 and 3 as well as a very good cross-polarization at beam peak angles are obtained with this structure.

With good-quality sinuous designs, currents decay rapidly past the radiation region and the radiated power of higher-order modes ($m+N, m+2N, \dots$ and $m-N, m-2N, \dots$) is low. Thus, the azimuth pattern symmetry is usually excellent. As with equiangular spirals, the modal decomposition of the radiated far-field pattern can show the level of modal isolation for each sinuous mode. For example, the radiation pattern of mode 1 of an eight-arm sinuous antenna (see Fig. 15a) is decomposed into the higher-order (contaminating) modes, and the cross-modal difference (with respect to the dominant mode 1) of the most significant modes is shown in Fig. 15b. As can be seen, the cross-modal difference is better than 30 dB for both higher-order modes supported by this antenna (modes -7 and 9), while mode 5 is (virtually) not excited. Since radiation from the dominant mode region is very efficient, end terminations are rarely needed, as opposed to spirals where some form of lossy arm termination is normally used. Also, for similarly sized and designed feed regions, the high-frequency radiation of a sinuous antenna is usually superior to that of a spiral.

The nominal modal impedance of a freestanding, self-complementary, N -arm printed sinuous antenna can be computed using the Deschamps formula [7]

$$Z_m = \frac{\eta_0/4}{\sin\left(\frac{|m|\cdot\pi}{N}\right)} \quad (9)$$

Figure 14. Radiation patterns for the M1 (a), M2, and M3 (b) of an eight-arm sinuous antenna. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

where $\eta_0 = 120\pi\Omega$ is the free-space impedance and m is the sinuous mode. Impedance variations from these nominal values can be significant, typically exceeding 2:1 for the mode ± 1 operation. Higher-order modes usually have smaller impedance variations, but these deviations are still larger than their spiral counterparts. If necessary, a spiral can be used in the sinuous interior as a tapered matching section.

Most commercial sinuous antennas are four-arm structures, and are designed to operate over different bands. The most common realization is a 5-cm-diameter 2–18-GHz antenna operating in a dual-circular mode 1, or dual-linear mode. The dual circularly polarized sinuous has already been discussed. A linearly polarized version has properties similar to those of a planar log-periodic antenna. As with good log-periodic design having a typical growth rate of $\tau > 0.8$, there are several arc sections in the active region. Opposite arms are fed antiphase $(0, 180^\circ)$, and the two orthogonal arm pairs of a four-arm sinuous

Figure 15. Higher-order mode gains relative to the gain of M1 (a) for an eight-arm sinuous antenna (b). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

antenna form two linearly polarized radiators. A small shift in the polarization vector with changing frequency is present as a consequence of the oscillating sinuous form of the structure. The polarization swings back and forth about the arms' central axis. When operating in circular polarization (with addition of a 90° QJ;hybrid), this polarization oscillation or wobble does not degrade the polarization purity since all arms have identical rotations.

When the arms of a sinuous antenna are fed with ambiguous phasing, very interesting performance is obtained. For instance, two unconventional four- and two-arm sinuous designs [26,27] are shown in Fig. 16. Also given are drawings of their lossless reflective cavity backings used to enhance the quality of circularly polarized radiation. The four-arm slot sinuous antenna, shown in Fig. 16a, is fed using a nonradiating coplanar waveguide mode with resulting phase progression of {0°, 180°, 0°, 180°}. This phase progression is equivalent to the second mode excitation of a related four-arm spiral antenna and, as discussed above, is ambiguous for a broadband operation of a sinuous structure. Since the CW and CCW segments of the sinuous antenna allow it to support

both polarizations, a mixture of modes 2 and -2 is excited and unique multiband multipolarized performance is obtained. The polarization signature of this antenna, shown in Fig. 17a, illustrates that the bands of LCP and RCP are alternating, with the periodicity related to the growth rate of the structure (in this case it was variable growth rate). Since a simple, single-port feed is used for the excitation of this modal mixture, an efficient, small, flush-mounted antenna with simultaneous RCP and LCP operation is obtained without the need for a complex hybrid network. The same principle is applied to a two-arm folded spiral, shown in Fig. 16b, for which the balanced excitation of {0, 180°} cannot distinguish between the two polarization senses, and broadband operation is not possible. However, a multiband, multipolarized performance with maximum gain at broadside is demonstrated. The associated polarization signature depicted in Fig. 17b clearly shows the alternating handedness of the polarization over a relatively large bandwidth.

To summarize, the sinuous antenna is a very broadband radiator and can be classified as an FI antenna. It has many characteristics similar to those of a spiral,

(a)

(b)

Figure 16. Photographs of unconventional four-arm (a) and two-arm (b) sinuous antennas with sketched lossless cavity backing. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

which is also an FI antenna, but has the additional capability of broadband dual polarization. It should be noted that another spiral antenna, the modulated-armwidth (MAW) spiral, is also capable of dual-polarized FI operation and is discussed in the *SPIRAL ANTENNAS* article.

5.3. Cavity Backing

The projections of a planar spiral [9,22] or sinuous [17] FI structure onto a cone as well as folding a planar sheet antenna [6] produce efficient unidirectional radiation. However, for mounting an antenna in a flush or conformal manner, this approach is typically inadequate and some form of cavity backing is necessary. An absorbing (lossy) cavity must be used for sinuous antennas,

and is preferred as well for the multioctave bandwidth operation of spiral antennas. Of course, reduced radiation efficiency is the price to be paid, but consistent pattern and smooth impedance curves are usually more important.

Ingerson and Mayes [16] suggested a log-periodic cavity arrangement for backing an array of log-periodic slot antennas; specifically, they applied the same principles used for the design of a radiator to the design of its backing. As a result, a log-periodic array of rectangular lossless cavities with slanted metallic bottoms was developed as an embodiment of the log-periodic approach for the design of flush-mounted antenna backing. The growth rates of the slots and the cavities were the same, and a modulated impedance feeder was introduced to provide not only proper phasing for the endfire radiation but also to

Figure 17. Polarization signature of unconventional four-arm (a) and two-arm (b) sinuous antennas.

eliminate the stopbands. Consistent radiation patterns and well-behaved VSWR performance were obtained.

An interesting approach for the design of a broadband cavity backing was explored by Nurnberger [28]. After investigating the excitation of various cavity modes, their effects on the radiation pattern of a slot spiral, and various

loading techniques for mitigating these, Nurnberger suggested that the same theoretical guidelines for achieving FI performance should be applied to the cavity backing. More specifically, the cavity must be entirely defined by angles, the currents should decay outside the “hot” active region, and periodicity in performance has to be attained.

The evolution of the FI cavity idea is depicted in Fig. 18, while the photograph of the developed conical cavity is shown in Fig. 19. Although the prototype from Fig. 19 does not obey all the abovementioned principles (similar to the bicone antenna, the conical inset does not satisfy the truncation principle for currents), the addition of radial and vertical absorber liners significantly reduced the negative effects of the enclosing cavity wall. Overall antenna gain was 2–2.5 dB higher than the gain of typical wire spiral antennas backed by a regular lossy cavity, while the radiation pattern and VSWR demonstrated very consistent behavior across an 8:1 bandwidth.

6. SUMMARY

The operation of frequency-independent antennas, including the underlying theory and mathematical foundation,

are reviewed in this article. Several FI antennas, including equiangular spirals, log-periodic planar sheets, and dipole and folded slot arrays, as well as sinuous antennas, are described and their performance is utilized for a practical demonstration of FI principles. Although FI antennas have been researched for a half-century, there are plenty of challenges still to be investigated. Some are classical/fundamental issues such as miniaturization versus bandwidth, the associated efficiency tradeoff (more efficiency since FI bandwidth can be well controlled), and broadband arraying, to mention just a few. More recent developments in artificial materials and the possibility of realizing antennas on substrates with any values of dielectric and magnetic constants are also of interest. Further investigation and developments of FI cavities, terminations, and feeds, as well as unconventional designs of basic radiating elements, will also play important role.

FREQUENCY MODULATION

L. B. FERTIG
J. H. MCCLELLAN
Georgia Institute of Technology

Frequency-modulated waveforms are commonly utilized for information transmission in radiocommunications, as well as for environmental sensing in radar, sonar, and bioengineering. In many of these situations, the desired information is extracted from the received signal by monitoring one or more dominant frequencies in the signal and examining their variation as a function of time. The process by which a local approximation to a signal's frequency is obtained is known as *instantaneous frequency estimation* (IFE).

In this article, concepts relating to instantaneous frequency, along with algorithms for its computation, are reviewed. First, several means by which instantaneous frequency is commonly defined are discussed, and the relationships between instantaneous frequency and time-frequency distributions are explored. Next, several measures of performance commonly used to evaluate instantaneous frequency algorithms, such as the Cramer-Rao lower bound, are examined. Finally, a number of algorithms that have been suggested for IFE are summarized. Despite the relative maturity of frequency modulation in the field of radiocommunications, the field of IFE is a growing one, and one in which research is still quite active.

1. INSTANTANEOUS FREQUENCY ESTIMATION: BACKGROUND AND DEFINITIONS

The instantaneous frequency of a signal can be defined in several different ways. Two of the most popular definitions relate the instantaneous frequency to time-frequency distributions and to the analytic signal. Either of these definitions can satisfy intuition in certain situations, but yield puzzling results in others. Nevertheless, useful estimates of the instantaneous frequency can usually be obtained for narrowband signals, and to a lesser degree for certain wideband signals. In this section, relationships between instantaneous frequency, time-frequency distributions, and the analytic signal are discussed.

1.1. Time-Frequency Distributions

The concept of frequency has long played a major role in the analysis of signals. Through the Fourier transform, a signal may be decomposed into a continuum of complex exponentials. In fact, the basis functions of the Fourier transform are pure tones of *infinite* time extent. However, when the spectral composition of a signal varies as a function of time, the Fourier transform no longer provides a simple spectral description of the signal. Instead, a *time-frequency distribution* yields more insight into the signal's behavior. The most common example of time-frequency analysis—the printed musical score—has existed for

hundreds of years. With a musical score, it is possible to denote the tones that are present in an arrangement at discrete intervals in time. In the following paragraphs, a short discussion of the key developments in time-frequency analysis that have been obtained since 1949 is provided. Among the topics explored are Gabor's time-frequency distribution, the short-time Fourier transform, perfect reconstruction filterbanks, the wavelet transform, and Cohen's class of time-frequency distributions. The relationship between instantaneous frequency and time-frequency distributions is then discussed.

The development of the first algorithm for time-frequency analysis of an arbitrary signal is generally credited to Gabor [1]. His work was motivated by a desire to define the information content of signals. He considered the time-frequency representation of a signal as a "diagram of information," where areas in the two-dimensional representation were proportional to the amount of data that they could convey. Gabor suggested that the time and frequency characteristics of a signal $x(t)$ be simultaneously observed with the expansion

$$x(t) = \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} g_{mn} \psi_{mn}(t)$$

where $\psi_{mn}(t)$ is expressed in terms of an elementary signal $\psi(t)$ with

$$\psi_{mn}(t) = \psi(t - mT) \exp(jn\Omega t)$$

The time and frequency lattice intervals are defined by T and Ω , respectively. Gabor also proposed that the signal with minimum area on the time-frequency plane be used to generate the basis functions for his time-frequency decomposition. Furthermore, he demonstrated that the signal with minimum area, as defined by the product of the signal's root-mean-square (RMS) width in time and frequency, was given by the Gaussian-modulated sinusoid. The concept that the time and frequency widths of a signal cannot be made arbitrarily small simultaneously is a well-known property of Fourier analysis called the *uncertainty principle* (a term that originated in the physics community). These ideas form the cornerstones of time-frequency analysis.

The growing interest in time-frequency analysis accelerated in the 1970s due to research regarding the short-time Fourier transform (STFT) [2,3]. These efforts were motivated by a desire to analyze the time-varying spectral content of speech signals. The STFT is created by inserting a window function $h(n)$ into the computation of the Fourier transform, as expressed by

$$X(n, \omega) = \sum_{m=-\infty}^{\infty} x(m) h(n - m) \exp(-j\omega m)$$

The discrete index n varies from $-\infty$ to $+\infty$, while the continuous parameter ω varies from 0 to 2π . For a fixed analysis time n , the window function selects a portion of the original signal for spectral analysis, thereby allowing nonstationary behavior to be observed in a manner

impossible with the traditional Fourier transform. At each time instant, the signal segment selected for analysis is formed by the product of the timeshifted window function with the original signal. It is recognized that the result of this operation in the frequency domain is the convolution of the spectral representation of the two functions. Thus, the shape of the window function is fundamental to the STFT results. The rectangular window yields the minimum mainlobe spectral width (and therefore the best frequency resolution) at the cost of large sidelobes (the peak of the largest sidelobe has a magnitude only 13 dB less than the peak of the mainlobe). Other window functions, such as the Hamming window, generate lower sidelobes, at the price of a wider mainlobe. The length of the window function also affects the results produced by the STFT. The longer the timelength of the window, the greater the frequency resolution of the time–frequency representation, but the poorer the time resolution.

A second interpretation of the STFT is obtained by examining the structure of the discrete short-time Fourier transform (DSTFT), which is written as

$$X(n, k) = \sum_{m=-\infty}^{\infty} x(m)h(n - m) \exp\left(\frac{-j2\pi km}{N}\right)$$

The discrete index n varies from $-\infty$ to $+\infty$, while the discrete index k varies from 0 to $N - 1$. For a fixed frequency index k , it is seen that the signal of interest is modulated by $\exp(-j2\pi km/N)$ and then convolved with the window function (which typically has a lowpass frequency response). The series combination of the modulator and the window function results in a bandpass filter. The DSTFT can therefore be thought of as being generated by passing a signal through a set of bandpass filters. Furthermore, if the discrete signal is processed with an ideal bandpass filter with a passband equal to π/N , then the output of the filter can be *decimated* by a factor of N (all signal samples are discarded except those corresponding to indices of $N, 2N, 3N$, etc.) with no loss of information. The incorporation of this philosophy with the bandpass filter view of the STFT yields the analysis portion of the *filterbank* structure shown in Fig. 1. The rationale for decimating the output of each of the bandpass filters is to reduce the storage requirements of the filterbank. In a similar fashion, a signal approximately equal to the input

signal can be produced with the synthesis structure also shown in Fig. 1. Note that the synthesis network contains *interpolators* (which insert N zeros between each input sample) and window functions known as *synthesis filters*. In general, the synthesis filters are similar, but not identical, to the analysis filters. In a typical data compression application of a filterbank, the outputs of the analysis section are encoded, transmitted over a channel, and then reconstructed with the synthesis section. Equality between the input and output of the filterbank subject to a finite delay, called *perfect reconstruction*, is achieved only for specific combinations of analysis filters and synthesis filters.

It is evident that filterbanks are a natural extension of the STFT. As is the case for the STFT, filterbanks may be utilized for instantaneous frequency estimation. Properly implemented, they permit a compact representation of the time–frequency properties of a signal with no loss of information. The characteristics of analysis and synthesis filters that eliminate aliasing, along with the requirements for perfect reconstruction, are thus of interest.

In an actual implementation of a filterbank, the digital analysis filters are of finite length, and thus they cannot form an ideal bandpass filter with unity gain in the passband and zero gain in the stopband. Therefore, some degree of aliasing will occur when the output of each of the analysis filters is decimated as in Fig. 1. If the analysis filters are not correctly designed, the aliased signals propagate through the filterbank and severely limit the quality of the filterbank’s output. Croisier et al. [4] examined this problem for the two-channel filterbank shown in Fig. 2, and they derived conditions on the analysis and synthesis filters such that these aliased terms are completely canceled. Filters designed with this approach are called *quadrature mirror filters*, since the analysis filters of a two-channel network are mirrors of one another about $\pi/2$. It is important to note that while the output of a filterbank employing quadrature mirror filters does not contain aliased terms, other magnitude and phase distortions typically exist.

The necessary and sufficient conditions for the design of a perfect reconstruction filter bank were derived by Smith and Barnwell [5]. They also proposed an algorithm to construct analysis and synthesis filters that satisfied these conditions, using well-known filter design techniques [6]. Although they termed these filters *conjugate quadrature*

Figure 1. Structure for N -channel filterbank. This tool is frequently employed for time–frequency analysis.

Figure 2. Structure for two-channel filterbank. This simple configuration can be used to construct more complicated structures.

filters, many researchers consider them to be a class of quadrature mirror filters. The power of Smith and Barnwell’s algorithm is demonstrated by the fact that it is applicable to the two-channel structure shown in Fig. 2, the N -channel structure shown in Fig. 1, and the tree-structured analysis section shown in Fig. 3, as well as to filterbanks employing nonuniform decimation and interpolation rates. Additional results regarding the implementation of perfect reconstruction filterbanks are included in Refs. 7 and 8.

A topic closely related to time–frequency analysis is *timescale* analysis, which is provided by the *wavelet transform*. Because of the similarity of the discrete wavelet transform with perfect reconstruction filterbanks, as well as the immense number of applications of the wavelet transform that have been investigated since 1989, a brief discussion of its development is included in the following.

In the late 1970s, the French geophysical engineer Morlet derived an alternative to the STFT for time–frequency analysis. The seismic signals of interest to Morlet contained high-frequency components with shorter time-spans than did the low-frequency components. With the STFT, it was impossible to simultaneously obtain good time resolution for the high-frequency components and good frequency resolution for the low-frequency

components. Morlet recognized that his goal could be obtained by decomposing the seismic signals not with *translated* and *modulated* versions of an elementary signal (as was done in Gabor’s work and the STFT), but with the *translated* and *scaled* versions of an elementary signal. This concept yielded basis functions that contained a constant number of cycles. Morlet chose to call his functions “wavelets of constant shape” [9]. Although the term “wavelet” had been used in the seismic field for a number of years before Morlet’s work, it had been used to denote seismic pulses, not a time–frequency tool.

Morlet later collaborated with Grossman to place the wavelet transform on a firm mathematical foundation [10]. They defined the continuous wavelet transform as

$$W_x(\tau, a) = \frac{1}{\sqrt{|a|}} \int_{-\infty}^{\infty} x(t) m^* \left(\frac{t - \tau}{a} \right) dt$$

where a is a scale factor and the “mother wavelet” $m(t)$ serves as a window function. The inverse wavelet transform is given by

$$x(t) = c \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{1}{a^2} W_x(\tau, a) m \left(\frac{t - \tau}{a} \right) da d\tau$$

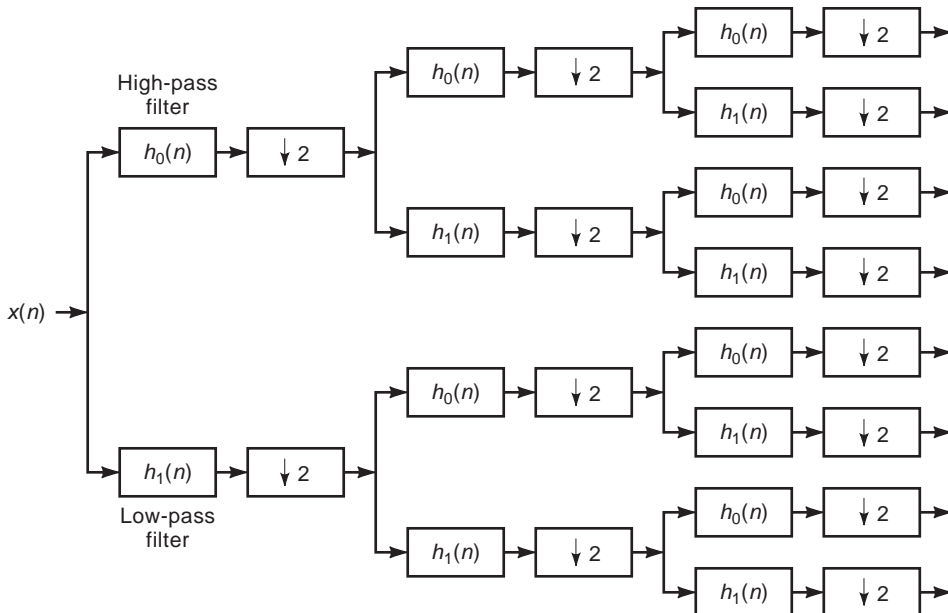

Figure 3. Analysis portion of tree-structured filterbank formed by the sequential application of two-channel filterbanks.

Morlet and Grossman used a nonorthogonal basis for the transform consisting of functions very similar to Gabor’s Gaussian-modulated sinusoids. An orthogonal basis was developed in 1985 by Meyer.

Structures for the discrete wavelet transform and its inverse were developed by Daubechies [11]. The form of the forward structure is shown in Fig. 4 and is seen to be very similar to a pruned version of the tree-structured filterbank shown in Fig. 3. At each level of the discrete wavelet transform, the input signal is passed through a lowpass filter and a highpass filter. The outputs of the filters are decimated by a factor of 2, and the decimated lowpass filter output is again passed to a lowpass/highpass filter pair. Daubechies derived conditions for the filters such that the structure yields perfect reconstruction, and she used these conditions to generate a set of viable filters frequently referred to as “Daubechies wavelets.” Of special interest to Daubechies was the relatively long impulse response of the filter produced by a series of short filters alternated with decimators. She termed the combined impulse response of the lowpass filters alternated with decimators the *scaling function* and the impulse response of the lowpass filters alternated with decimators and followed by a highpass filter, the *wavelet function*. She showed that as the number of levels in the transform grows large, the scaling function and the wavelet function converge to smooth waveforms, provided that the component filters have sufficient “regularity.” In digital signal processing terms, the regularity of a filter corresponds to the number of zeros at $z = -1$ ($\omega = \pi$) in the filter transfer function. Soon after Daubechies’ work was published, Mallat extended her results to two dimensions and applied them to image processing [12]. It has since been recognized that Daubechies’ conditions for perfect reconstruction are identical to those published by Smith and Barnwell. It has also been recognized that the structure corresponding to the discrete wavelet transform is equivalent to an octave-channel filterbank, a form of which had been investigated earlier for speech coding [3]. Nevertheless, the attention focused on filterbanks and time–frequency analysis due to the introduction of the wavelet transform has resulted in an explosion of new developments in these fields that has continued today.

In addition to the time–frequency distributions described above, many others have been developed since the late 1940s. A significant number of continuous time–frequency distributions can be characterized by what is

known as *Cohen’s class* of distributions [13], which is defined by

$$C_x(t, \omega) = \frac{1}{4\pi^2} \iiint x^*(u - \frac{1}{2}\tau)x(u + \frac{1}{2}\tau)\phi(\theta, \tau) \exp(-j\theta t - j\tau\omega + j\theta u) du d\tau d\theta$$

where $\phi(\theta, \tau)$ is a two-dimensional function known as the “kernel” and $x(t)$ is the signal under consideration. A particular member in Cohen’s class is identified by its kernel. For example, the *spectrogram*, which is defined as the magnitude squared of the STFT, is a recognized member of Cohen’s class of distributions, with a kernel given by

$$\phi(\theta, \tau) = \int h^*(u - \frac{1}{2}\tau)\exp(-j\theta u)h(u + \frac{1}{2}\tau) du$$

where $h(t)$ is the window function defined previously. A discrete form of Cohen’s class of time–frequency distributions is examined in Ref. 14.

With respect to a time–frequency distribution, there are two possible means of defining the instantaneous frequency of a signal at a point in time. The instantaneous frequency may be associated with either (1) the peak value of the signal’s distribution at that time or (2) the average of the frequencies present in the signal at that time. These approaches are appealing because they permit the introduction of the *instantaneous bandwidth* concept in a natural manner as the spectral spread of energy in the time–frequency plane about the instantaneous frequency. In the following section, it is shown that the instantaneous frequency estimate derived from certain time–frequency distributions is equivalent to the corresponding quantity derived from the analytic signal.

A major benefit obtained by employing a time–frequency distribution for instantaneous frequency estimation is the capability of the distribution to aid in determination of whether the signal under examination is monocomponent or multicomponent. Monocomponent signals are those that can be shown to possess energy in a contiguous portion of the time–frequency plane. At any point in time, this type of signal exhibits a narrowband characteristic. An example of this type of signal is a sinusoid with a continuous time-varying frequency. Conversely, multicomponent signals are those that can be shown to possess energy in multiple, well-isolated frequency bands at the same instant in time. Speech frequently displays this behavior. It

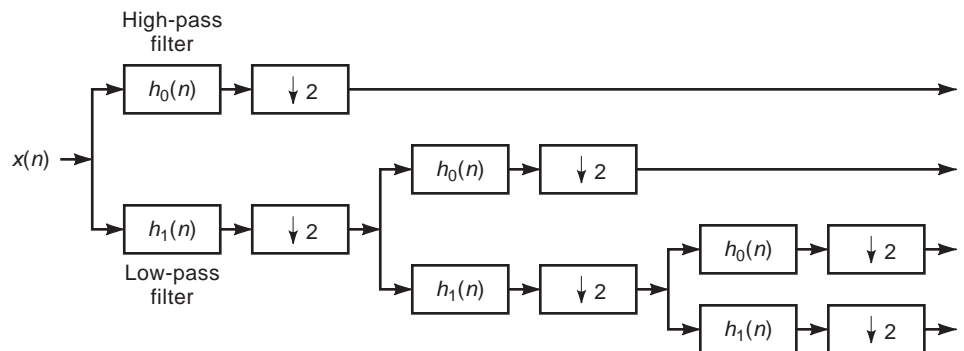

Figure 4. Structure for discrete wavelet transform. Note the similarity of this configuration to the structure shown in Fig. 3.

is noted that the preceding definition of monocomponent excludes signals such as an impulse, which could also be argued to be monocomponent because of its ridgeline time–frequency distribution. Obviously, the identification of a signal as monocomponent or multicomponent is not precise [15], but it is important, as the instantaneous frequency of a multicomponent signal may have no physical meaning [16].

A significant disadvantage of employing time–frequency distributions for IFE is that the construction of the distribution is a computationally complex procedure, even when filterbank structures are utilized. Fortunately, there is an alternative approach for IFE. In many situations, a reasonable estimate of the instantaneous frequency of a signal can instead be obtained from computationally simple operations on its analytic signal. Background for this philosophy is given in the following section. A summary of algorithms that have been suggested for implementation of this approach are provided in Section 3.

1.2. Analytic Signals

In this section, the relationships between the instantaneous frequency of a signal and its analytic signal are examined. First, a brief review of the analytic signal is provided. The definition of the instantaneous frequency in terms of the analytic signal is then discussed. Practical issues regarding the computation of the analytic signal are also presented. Finally, the situations for which the estimate of instantaneous frequency obtained via the analytic signal agrees with the estimate obtained from certain time–frequency distributions are examined.

Interestingly, as was the case with time–frequency analysis, the original work done in the area of analytic signals was conducted by Gabor [1]. He defined the complex analytic signal $z(t)$ corresponding to a real signal $x(t)$ to be the sum of the signal with a second signal generated via the Hilbert transform

$$\begin{aligned} z(t) &= x(t) + j\mathbf{H}\{x(t)\} \\ &= x(t) + jy(t) \end{aligned}$$

The continuous Hilbert transform is defined as

$$\mathbf{H}\{x(t)\} = \text{PV} \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{x(\tau)}{t - \tau} d\tau$$

where PV indicates the Cauchy principal value of the integral. The signal $z(t)$ is similar to $x(t)$, in that for positive frequencies, $Z(f) = 2X(f)$. However, the spectrum of $z(t)$ contains no energy at negative frequencies. Indeed, one technique for deriving the analytic signal of a real signal is to compute its Fourier transform, ignore the spectral components corresponding to negative frequencies, apply the appropriate scaling factor, and then compute the inverse Fourier transform of the modified signal. Gabor developed the analytic signal concept to aid in derivation of the signal with minimum time–frequency extent. However, the most extensive application of analytic signals has been in the communications field.

The importance of the analytic signal to the definition of instantaneous frequency can be seen by considering a simple example. Suppose that a continuous real signal $x(t)$ is given by

$$x(t) = a(t) \cos(\phi(t))$$

where $a(t)$ represents a time-varying amplitude and $\phi(t)$ represents a time-varying phase. Since the “frequency” of a sinusoid is defined as the derivative of its phase, the instantaneous frequency of a signal $x(t)$ could be computed with the derivative of $\phi(t)$. This definition appears to agree with intuition. However, when the magnitude of $a(t)$ is bounded by b , the signal $x(t)$ can also be expressed as

$$x(t) = b \cos(\tilde{\phi}(t))$$

where $\tilde{\phi}(t) \neq \phi(t)$. Therefore, the postulated definition does not yield a unique instantaneous frequency for the signal $x(t)$. By defining the instantaneous frequency of $x(t)$ to be the derivative of the phase of the corresponding unique analytic signal $z(t)$, this ambiguity can be eliminated [17]. Since the analytic signal is complex, it can always be expressed uniquely as

$$z(t) = m(t) \exp(j\theta(t))$$

The instantaneous frequency can thus be uniquely defined as $d\theta(t)/dt$. However, it is not claimed that this definition provides satisfactory results in every scenario.

In practice, discrete sequences $x(n)$ corresponding to samples of the continuous signal $x(t)$ at time instants $t = nT$ are available, and it is desired to form the discrete analytic signal $z(n)$ where

$$z(n) = x(n) + jy(n)$$

The analytic signal $z(n)$ can be obtained in a number of ways, each with its own advantages and disadvantages. The sequence $y(n)$ can be generated by the brute-force approach of zeroing the spectral components of $x(n)$ corresponding to negative frequencies. This technique works well for finite datasets, but can be difficult to implement in real-time applications. The sequence $y(n)$ can also be generated by processing the sequence $x(n)$ with a digital filter designed to approximate the Hilbert transform [6]. However, the group delay introduced to $y(n)$ by the digital filter must also be introduced to $x(n)$, which can be difficult for noninteger delays. A third approach is to compute the complex sequence $z(n)$ directly, by processing the sequence $x(n)$ with a complex filter constructed by modulating a real lowpass filter by a complex exponential [18].

It is interesting to note the relationship between (1) the instantaneous frequency estimate obtained from a time–frequency distribution and (2) the instantaneous frequency estimate obtained from the derivative of the analytic signal’s phase. For continuous signals, it can be shown that the first moment of a time–frequency distribution of Cohen’s class is equivalent to the derivative of the analytic

signal's phase if the kernel $\phi(\theta, \tau)$ is selected such that

$$\left. \frac{\partial \phi(\theta, \tau)}{\partial \tau} \right|_{\tau=0} = 0$$

Furthermore, for signals with quadratic phase functions, the peak of the time–frequency distribution known as the *Wigner–Ville distribution* corresponds to the instantaneous frequency [19]. Results for the discrete signal case have appeared in Refs. 14 and 20.

2. MEASURES OF PERFORMANCE FOR INSTANTANEOUS FREQUENCY ESTIMATION ALGORITHMS

To evaluate various IFE algorithms, there must be a means of comparing the performance and implementation of a specific algorithm to an alternate approach. In this section, the measures of performance typically used to compare IFE algorithms to one another are discussed. The measures of performance that are considered include both statistical and computational issues. At the conclusion of this section, these criteria are demonstrated by utilizing them to evaluate the performance of the classical periodogram approach to estimating the frequency of a sinusoid embedded in white Gaussian noise.

Since the problem of interest concerns the estimation of an unknown quantity in the presence of noise, it is useful to introduce several statistical concepts from estimation theory. Typically, it is desired to estimate the value of an unknown parameter θ from N noisy measurements of a quantity related to θ . An estimator is considered *unbiased* when the expected value of the estimate $\hat{\theta}$ equals the true value of the parameter:

$$E\{\hat{\theta}\} = \theta$$

If this condition does not hold, the estimator is termed *biased*. An estimator is considered *consistent* if it yields an estimate that asymptotically converges in probability to the true value. For a consistent estimator, we obtain

$$\lim_{N \rightarrow \infty} \Pr\{|\hat{\theta} - \theta| > \varepsilon\} = 0$$

where \Pr denotes probability and ε is an arbitrary small positive number. Both of these characteristics are generally thought to be desirable but, depending on the problem of interest, may or may not be required.

The benchmark by which the variance of a particular unbiased estimator can be evaluated is given by the Cramer–Rao lower bound (CRLB). As its name implies, the CRLB provides a lower bound on the variance of any linear or nonlinear unbiased estimator. Thus, given the variance of a particular unbiased estimator, the CRLB may be used to determine if other unbiased estimators might exist that exhibit smaller variance. Although other bounds on estimator variance exist, it is generally agreed that the CRLB is the easiest to compute, and hence finds extensive use [21]. The CRLB for the scalar parameter θ is expressed

in terms of the measurement vector \mathbf{x} with

$$\text{var}(\hat{\theta}) \geq \frac{1}{-E\left\{\frac{\partial^2 \ln p(\mathbf{x}; \theta)}{\partial \theta^2}\right\}}$$

where $p(\mathbf{x}; \theta)$ is the probability density function (pdf) of \mathbf{x} given the parameter θ [22]. The expectation is taken with respect to $p(\mathbf{x}; \theta)$, which results in a function of θ . When the pdf is considered to be a function of the unknown parameter θ (with a fixed measurement vector \mathbf{x}), it is called the “likelihood function.”

Although the CRLB may be computed for a specific estimation problem, there is no guarantee that an unbiased estimator exists that will equal the bound for all values of the unknown parameter. If such an estimator does exist, it is said to be *efficient*. An estimator is considered *asymptotically efficient* if its variance converges to the CRLB as the number of observations becomes large. *Maximum-likelihood* (ML) estimators are known to be asymptotically efficient, and they can be constructed by computing the value of θ that maximizes the likelihood function. The performance of ML algorithms for large data records, along with the existence of an analytical approach to their derivation, makes ML algorithms very appealing. In practice, these algorithms can be computationally complex, such that other approaches may be preferred.

At high signal-to-noise ratio (SNR), the variance of ML estimators is typically very close to the CRLB. As the SNR is decreased, the CRLB and the estimator variance increase at the same rate. For nonlinear estimators, this behavior continues until a *threshold* is reached. Below this value of SNR, the variance of the estimator increases at a much faster rate than does the CRLB. In a plot of the variance as a function of SNR, a knee will be seen at the threshold. Thus, the estimator threshold is frequently used as a metric to compare several estimators that have similar high-SNR characteristics. For maximum-likelihood estimators, the threshold typically decreases as the size of the data window increases.

In addition to the factors described above, various algorithms for the estimation of a particular parameter may also be compared to one another with respect to computational considerations. Computational issues include the algorithm's complexity as measured by the number of arithmetic operations (such as multiplications or arctan function calls) required for its implementation, the storage requirements of the algorithm, and the data window size required for satisfactory performance.

As a demonstration of the concepts described in this section, the classical approach to the estimation of the frequency of a single complex sinusoid with unknown amplitude and phase in the presence of white Gaussian noise is considered. The CRLB for the frequency estimate is given by

$$\text{CRLB} = \frac{12}{T^2 N(N^2 - 1)} \left(\frac{\sigma^2}{A^2} \right)$$

where A is the amplitude of the complex sinusoid, σ^2 is the power of the complex white Gaussian noise, T is the

sampling period, N is the number of available data samples, and A^2/σ^2 is the SNR. To derive a ML estimator for this problem, the likelihood function L is computed in terms of the unknown frequency, amplitude, and phase. It has been shown that the likelihood function is given by

$$L(\omega, A, \theta) = 2A \operatorname{Re}[\exp(-j\theta) \exp(-j\omega t_0) X(\omega)]$$

where θ is the unknown phase, t_0 is the time corresponding to the first data sample, and $X(\omega)$ represents the discrete-time Fourier transform of the data sequence $x(nT)$ [23]. The ML estimate of the sinusoid's frequency is the maximum of $L(\omega, A, \theta)$ with respect to ω over all values of A and θ , and it can be shown to correspond to the frequency that maximizes the periodogram $|X(\omega)|^2$. To implement this approach, it has been suggested that a coarse frequency estimate be obtained from the peak magnitude of the discrete Fourier transform (DFT) and that a more accurate result be obtained via an interpolation algorithm. The performance of the overall algorithm is significantly improved if the length of the original data sequence is increased by a factor of 2 or 4 by zero padding, before the coarse DFT is computed. An accurate means of implementing the interpolation procedure with only three DFT points is presented in Ref. 24.

The ML algorithm for estimating the frequency of a single sinusoid in noise is conceptually simple but computationally intensive. This is especially the case when the algorithm must be implemented under a real-time schedule in order to track a time-varying frequency. In the following section, additional approaches to the implementation problem are examined.

3. ALGORITHMS FOR INSTANTANEOUS FREQUENCY ESTIMATION

In this section, a selection of algorithms that have been suggested for IFE are summarized. This selection is not all-inclusive, and it is in fact concentrated in two areas. The first set of algorithms employ *weighted phase averaging* techniques, and the second set of algorithms are designed to function with extremely short data windows in high-SNR environments. Both sets of algorithms are designed for monocomponent signals. References to other approaches for estimating the instantaneous frequency of monocomponent signals, along with approaches for multicomponent signals, are provided.

3.1. Algorithms Employing Weighted Phase Averaging

One way to represent a constant-amplitude, complex signal with time-varying frequency is to model the signal as a complex exponential with polynomial phase. From the Weierstass theorem, it is known that all continuous phase functions can be approximated to any desired accuracy by a polynomial. The polynomial phase model is thus very general, in addition to being easily analyzed. When P coefficients are considered in the polynomial, the signal

model is expressed by

$$z(n) = A \exp\left(j \sum_{p=0}^P c_p n^p\right) + \varepsilon(n)$$

where A is the constant signal amplitude, n is the sampling index, c_p is the polynomial coefficient, and $\varepsilon(n)$ is complex zero-mean white Gaussian noise. In the following discussion, algorithms that employ weighted phase averaging to estimate the coefficients of the polynomial phase model are examined. Before examining algorithms capable of estimating all P coefficients, less complex approaches corresponding to linear and quadratic phase models are summarized. The less sophisticated approaches are of interest because of their relatively undemanding computational requirements. In fact, it has been suggested that time-varying frequencies be tracked with sliding-window implementations of these simpler algorithms.

A sinusoid with constant frequency can be represented by the polynomial phase model with a constant plus linear phase term. As discussed in the previous section, the ML estimate of the frequency of a single sinusoid embedded in white Gaussian noise is given by the peak of the periodogram. Unfortunately, the construction of the periodogram is computationally intensive, and other less complex approaches are desired. One such approach was suggested by Tretter [25]. He considered the input data sequence to be modeled by

$$z(n) = A \exp(j(\theta + \omega n)) + \varepsilon(n)$$

where θ is a constant phase and ω is the signal's angular frequency. The angular frequency is assumed to be bounded by $-\pi < \omega \leq \pi$. The noise power is given by σ^2 , and the SNR is thus expressed as

$$\operatorname{SNR} = \frac{A^2}{\sigma^2}$$

Tretter showed that for $\operatorname{SNR} \gg 1$, the data sequence can be approximated as

$$\begin{aligned} z(n) &\approx A \exp(j(\theta + \omega n + v(n))) \\ &\approx A \exp(j\phi(n)) \end{aligned}$$

where $v(n)$ is a real Gaussian white noise sequence with variance equal to $1/(2\operatorname{SNR})$. The impact of this approximation is that all the information required to estimate the frequency ω is contained in the signal phase $\phi(n)$. Tretter suggested that the phase be estimated by unwrapping the sequence obtained from computing the arctan of $z(n)$. The frequency is then estimated via least-squares of linear regression. For high SNR, this estimation scheme achieves the CRLB.

An alternate viewpoint to this problem was provided by Kay [26]. He suggested that phase differences, rather than the phases themselves, be employed. The phase difference $\Delta(n)$ can be written as

$$\begin{aligned} \Delta(n) &= \phi(n+1) - \phi(n) \\ &= \omega + v(n+1) - v(n) \end{aligned}$$

The frequency estimation problem can then be expressed as the estimation of the mean of a colored Gaussian noise process. Kay showed that the ML frequency estimate for this problem is given by

$$\hat{\omega}_K = \sum_{n=0}^{N-2} \omega(n) \Delta(n)$$

where the total number of data samples available for processing is denoted by N , and $w(n)$ represents a parabolic weighting function given by

$$\omega(n) = \frac{1.5N}{N^2 - 1} \left[1 - \left(\frac{n - (0.5N - 1)}{0.5N} \right)^2 \right]$$

Kay noted that if a uniform weighting is applied, the phase differences are merely averaged, and the variance of the estimate is increased by a factor equal to $N/6$ at high SNR. It was later shown that Kay's algorithm can be derived from Tretter's algorithm using "summation by parts" [27].

As is typical with nonlinear estimation methods, the variance of Kay's algorithm departs from the CRLB when the SNR is reduced below a threshold value. Kim noted that the threshold of Kay's algorithm occurs when the SNR drops below a value for which the phase noise approximation is valid. He suggested that the SNR of the signal be increased before the phase of the data samples is computed, by averaging K adjacent data samples. In this manner, the threshold is decreased at the cost of a small loss in estimation performance and a decreased estimation range [28]. For example, for datalengths greater than 24 and $K=4$, Kim determined that his algorithm departs from the CRLB at high SNR by less than 0.2 dB. The threshold is reduced by a factor of $20 \log(K)$ dB, and the estimation range is reduced by a factor of K .

In the frequency estimation work conducted by Rife and Boorstyn [23], it was noted that the angular frequency estimate of their algorithm (described in the previous section of this article) was biased whenever the angular frequency was close to zero or the sampling frequency. Similarly, the variance of Kay's estimator also significantly degrades when the angular frequency is close to these values. A means of overcoming this problem was proposed by Lovell and Williamson [29]. They noted that the performance degradation is avoided if the weighting function is applied to the phase differences in a circular, rather than linear, fashion. For example, to compute the mean of a group of phases, they suggested that the phases first be expressed as unit magnitude phasors and that the argument of the sum of phasors then be computed. By incorporating these concepts into Kay's estimators, the sensitivity of the estimator variance with respect to angular frequency was significantly reduced.

The second coefficient relating to frequency in a polynomial phase model corresponds to frequency rate. Including this parameter μ , the signal model is written as

$$z(n) = A \exp(j(\theta + \omega n + \frac{1}{2} \mu n^2)) + \varepsilon(n)$$

The frequency rate is assumed to be bounded by $-\pi < \mu \leq \pi$. This type of modulation is termed *linear frequency mod-*

ulation (LFM), and the corresponding signal is termed a *chirp* signal. Despite its simple form, this signal is utilized in many fields and is thus of significant interest.

A procedure to jointly estimate θ , ω , and μ for a chirp signal was suggested by Djuric and Kay [30]. In this approach, the additive complex noise is modeled as real phase noise, as was the case in Refs. 25 and 26. However, a different technique is utilized to estimate the unambiguous phase sequence. First, two phase difference operations are implemented on the original data sequence, and the phases of the resulting data samples are computed with the arctan function. The sequence $d(n)$ is thus generated, where

$$d(n) = \mu + \Delta^2 \omega(n)$$

and $\Delta^2 \omega(n)$ denotes a colored-noise sequence. An estimate $\hat{\phi}(n)$ of the unambiguous phase sequence $\phi(n)$ corresponding to the original data sequence is then obtained by twice integrating $d(n)$. The estimates of θ , ω , and μ are then jointly obtained from $\hat{\phi}(n)$. If only the frequency rate is desired, μ may be estimated directly from $d(n)$ in a similar fashion as ω was estimated in Ref. 26.

One shortcoming of the algorithm suggested by Djuric and Kay is its performance for large values of μ . When the magnitude of this parameter is close to its upper bound, errors occur in the phase unwrapping algorithm, and the performance of the estimator degrades. To overcome this effect, they suggested that a third phase difference operation be employed. However, this approach increases the probability of an outlier occurring due to differentiation of the phase noise, thereby degrading the unwrapping process and hence the estimation performance. An alternative solution to this problem was proposed by Slocumb and Kitchen [31]. In their work, an iterative procedure is suggested in which the phase unwrapping and parameter estimation is conducted concurrently. A recursive least-squares (RLS) algorithm [32] is employed to improve the phase unwrapping process, thereby removing the sensitivity of the threshold to the value of μ . For large values of μ , the threshold corresponding to Slocumb and Kitchen's approach is as much as 12 dB lower than the threshold of Djuric and Kay's algorithm.

The approaches presented above for chirp signals can be extended to estimate an arbitrary number of coefficients of the polynomial phase model. To prevent aliasing in a critically sampled signal, the polynomial coefficients must be bounded by

$$|c_p| < \frac{\pi}{p!}$$

For the algorithm presented in Ref. 30, increasing the number of parameters to be estimated also increases the threshold of the algorithm.

3.2. Algorithms Employing Short Data Windows

In certain situations, it is reasonable to assume a very high SNR, even as high as 40 dB. It is then possible to obtain estimates of the instantaneous frequency of a monocomponent signal with only a few data samples. In this section, two computationally efficient algorithms are described that obtain accurate estimates of the

instantaneous frequency with only four or five data samples. This feature is very desirable, because the instantaneous frequency estimate is thus highly localized in time.

Teager's energy operator was originally proposed as a means of quantifying the "energy" present in a harmonic oscillation [33]. It has since been utilized to derive algorithms for instantaneous frequency estimation that are highly time-localized. The discrete form of this operator is given by

$$\Psi[x(n)] = x^2(n) - x(n+1)x(n-1)$$

where it is assumed that the sampling period is unity. Utilizing this operator, three different algorithms have been derived to estimate the instantaneous frequency and amplitude of a monocomponent AM-FM signal [34]. The three algorithms are denoted DESA-1a, DESA-1, and DESA-2, and the associated instantaneous frequency estimation algorithms are expressed as

$$\begin{aligned}\omega_{1a}(n) &= \arccos\left(1 - \frac{\Psi[x(n)] - x(n-1)}{2\Psi[x(n)]}\right) \\ \omega_1(n) &= \arccos\left(1 - \frac{\Psi[x(n)] - x(n-1) + \Psi[x(n+1)] - x(n)}{4\Psi[x(n)]}\right) \\ \omega_2(n) &= \frac{1}{2} \arccos\left(1 - \frac{\Psi[x(n+1)] - x(n-1)}{2\Psi[x(n)]}\right)\end{aligned}$$

The first algorithm requires four data points for its operation, and the remaining two algorithms require five data points. All three algorithms may be implemented with only a few multiplications per timestep.

A second means of constructing highly time-localized instantaneous frequency estimators is by symbolically expressing the roots of the predictor filter corresponding to a sinusoidal signal model in terms of the input data samples [35]. Two forms of linear prediction have been examined for this application: the covariance method and the modified covariance method. For the modified covariance method, two estimators were derived in Ref. 35. The first estimator requires four data samples for its operation, and the second requires five data samples. The estimators are expressed in terms of the input data samples via

$$\begin{aligned}\omega_{MC4}(n) \\ = \arccos\left(\frac{x(n-2)x(n-1) + 2x(n-1)x(n) + x(n)x(n+1)}{2(x^2(n-1) + x^2(n))}\right)\end{aligned}$$

and

$$\begin{aligned}\omega_{MC5}(n) \\ = \arccos\left(\frac{x(n-2)x(n-1) + 2x(n-1)x(n) + 2x(n)x(n+1) + x(n+1)x(n+2)}{2(x^2(n-1) + x^2(n) + x^2(n+1))}\right)\end{aligned}$$

Utilizing the covariance method, a single estimator was derived that required five data samples for its operation:

$$\omega_{C5}(n) = \arccos\left(\frac{x(n-1)x(n) - x(n-2)x(n+1)}{x^2(n) - x(n-1)x(n+1) + x^2(n-1)}\right)$$

These algorithms have been shown to require fewer computational operations per timestep than the DESAs. The linear predictive algorithms also yield smaller mean and RMS errors than the DESAs when simulated with signals having various amounts of amplitude and frequency modulation. The performance of linear predictive techniques with respect to the CRLB was investigated in Ref. 36.

3.3. Other Algorithms

The algorithms for IFE that were summarized in this section were concentrated in two general areas. Many other approaches for estimating the instantaneous frequency of monocomponent signals exist, such as the extended Kalman filter [37], the cross-power spectrum [38], and the discrete polynomial transform [39]. Still other techniques are described in Ref. 19. For multicomponent signals, proposed approaches include adaptive notch filters [40], recursive least squares [41], cross-coupled digital phase-locked loops [42], and the periodic algebraic separation energy demodulation algorithm [43]. Additional techniques are discussed in Ref. 43.

4. CONCLUSION

In this article, the connection between instantaneous frequency and time-frequency analysis were explored. Definitions for instantaneous frequency with respect to time-frequency distributions and to the analytic signal were provided. Measures of performance for estimators of instantaneous frequency were illustrated, such as the Cramer-Rao lower bound. Finally, a selection of algorithms that have been recently proposed for instantaneous frequency estimation were summarized.

FREQUENCY SELECTIVE SURFACES

TE-KAO WU
Northrop-Grumman
Redondo Beach, California

1. INTRODUCTION

A frequency-selective surface (FSS) is a structure consisting most typically of two-dimensional periodic elements, as depicted in Fig. 1, which exhibits frequency filtering

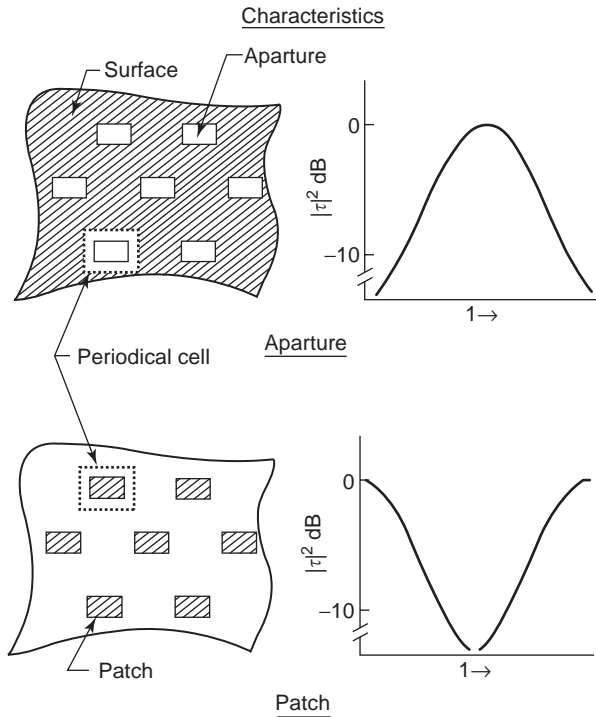

Figure 1. Typical frequency filtering characteristics of aperture and patch element FSS.

properties similar to those of frequency filters in traditional radiofrequency (RF) circuits. Here the periodic array of slots (or apertures) in a perfect conducting sheet act as a *bandpass* filter, namely, *passing* waves at the resonant frequency of the slots but rejecting them at higher and lower frequencies. On the contrary, the array of conducting patches act as a *bandstop* filter, namely, *rejecting* waves at the patches resonant frequency but passing them at higher and lower frequencies. In the case of freestanding and thin grids without dielectrics, the filtering performances of the patch element FSS and aperture FSS are exactly complementary to each other. Because of this filtering property, there are two major applications of FSS. One is in reflector antenna systems, where FSS reflectors are used to separate feeds of different bands. The other

application is to use FSS as antenna radomes for better control of the transmitted and reflected electromagnetic waves [1–3].

FSS may also be categorized as thick- or thin-screen FSS, depending on the thickness of the element. The term *thin-screen FSS* usually refers to a screen with printed-circuit-type elements, specifically, patch or aperture elements with thickness less than 0.001 wavelength of the screen’s resonant frequency. In general, the thin-screen FSS is light in weight, low-volume, and inexpensive, capable of being fabricated with conventional printed-circuit technology. On the other hand, a thick-screen FSS, used mostly for bandpass applications (aperture type), is a periodic array of elements with electrically large thickness. It is heavy, and the fabrication requires precise and expensive machining of a thick metal block. Waveguide stacks [4,5] have been a popular thick-screen FSS. The advantage of thick-screen FSS is that the transmission and reflection frequency ratio (f_t/f_r) or the band separation can be reduced to as low as 1.15 (= 14.0/12.2 GHz), which is required for the advanced multifrequency communication satellite antennas [5]. When filled with a dielectric such as paraffin wax, the waveguide’s cutoff frequency is reduced. This results in a smaller waveguide size; hence a closely packed array is achieved without any grating lobe occurring in the operation bands. It has also been found that increasing the angle of incidence increases the cross-polarization level and also causes ellipticity in circularly polarized waves. One way to overcome this is to make the holes slightly oval, instead of circular, as indicated in Ref. 6.

There are a variety of FSS element shapes (Fig. 2 illustrates some of the most common shapes), including square patch, dipole, circular patch, cross-dipole, Jerusalem cross, square loop, ring (or circular loop), square aperture, etc. The resonant frequency of a freestanding dipole array has the worst stability with incident angle variations. The reason for this can be explained as follows. When a vertically polarized incoming wave hits a half-wave vertical dipole, the dipole will resonate no matter what the incident angle is. However, if the incident direction is oblique to the broadside of the dipole, the dipole will not resonate effectively, depending on the incident angles. This is because the projected length of the dipole in the

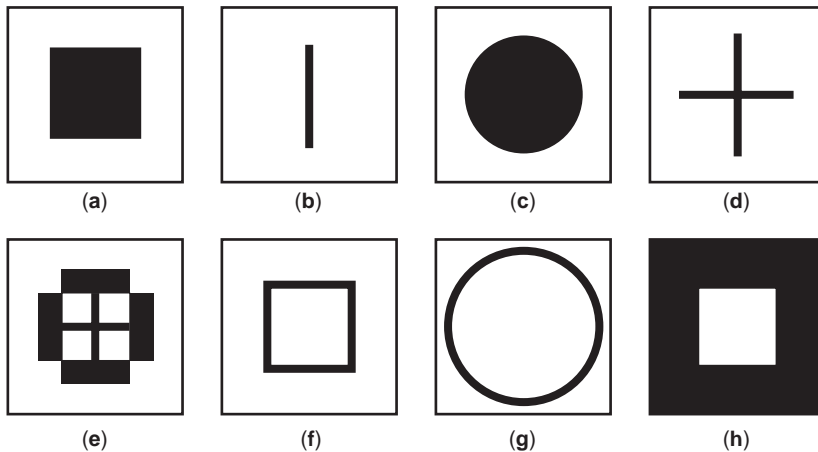

Figure 2. Some typical FSS element shapes.

incident direction is now less than a half-wavelength. This is why the resonant frequency of the dipole or the crossed-dipole element FSS shifts drastically, when the incoming waves have large incident angles.

For the square-loop and the circular-loop (ring) elements shown in Fig. 2, resonance occurs when the length of each half-loop is a multiple of one half-wavelength. In other words, each half-loop is acting as a dipole element. The length of the whole loop needs, therefore, to be a multiple of one full wavelength. To avoid a null in the scattered pattern, the length of the loop must be one wavelength instead of a multiple wavelength. This is because a one wavelength-long dipole will have a null in its broadside, a 1.5-wavelength long dipole will form two nulls in the off-broadside directions, and so on. Similarly, a multiwavelength loop is expected to have the undesirable nulls formed in its scattered pattern. To summarize, the mean circumference of a printed circular ring element for the FSS application must be one wavelength long. For a ring element printed on a dielectric substrate, the electrical length of the circumference must be one effective wavelength, and the physical circumference will therefore be less than one free-space wavelength; this requirement is the result of the dielectric loading effect.

2. FSS ANALYSIS TECHNIQUES AND TOOLS

Numerous methods have been employed in analyzing FSS. One of the simplest methods is the equivalent-circuit model [7,8]. In this analysis the various strip segments that form a freestanding patch element in a periodic array are modeled as inductive and capacitive components on a transmission line. The reflection and transmission coefficients of the FSS screen are found from the solution of this circuit. Since this approach uses the quasistatic approximation for the calculation of the circuit components, it is accurate only up to the resonant frequency of the screen. In addition, it will not model the dielectric loading effects accurately. Another method used successfully is the mutual impedance method [3]. This method uses antenna array theory and requires some knowledge of the mutual impedance between apertures.

The modal (or integral equation) method [1–3] has been the most successful in predicting the performance of the periodic structure, particularly in its ability to handle arbitrary incidence angles. The method involves first derivation of the integral equation by matching the Floquet modes in space and the aperture or current modes on the periodic surface. The integral equation may be formulated using the spatial or the spectral domain approach [1]. With the spectral domain approach the complicated integral equation is reduced to a simple algebraic multiplication of simple functions (trigonometric functions and integrals involve with them). Next, the method of moments or conjugate gradient technique is employed to solve the integral equation.

For a solution of the integral equation, the infinite number of equations with an infinite number of unknowns must be truncated to a finite number of equations with the same number of unknowns. This must be done in accor-

dance with the relative convergence criteria as indicated by Lee [9]. Another successful FSS analysis is the finite-difference time-domain (FDTD) approach [10].

Many analytical tools are available for analyzing and designing FSS [2,3]. Among them, the most popular one is the PMM (Periodic Moment Method) code [11], which implements the versatile method of moments to the solutions of arbitrarily shaped FSS elements. Ansoft Corporation also provides commercially available Designer (which integrates the PMM code with other system design codes) and HFSS (high-frequency structure simulator) tools [12].

3. DIELECTRIC LOADING EFFECTS

Dielectrics are often used for stabilizing the drift of FSS resonant frequency with the steering of incident angle or for structural support. A number of dielectric loading effects have been published in the literature [1–3,13]. Figure 3 shows that the resonant frequencies decrease

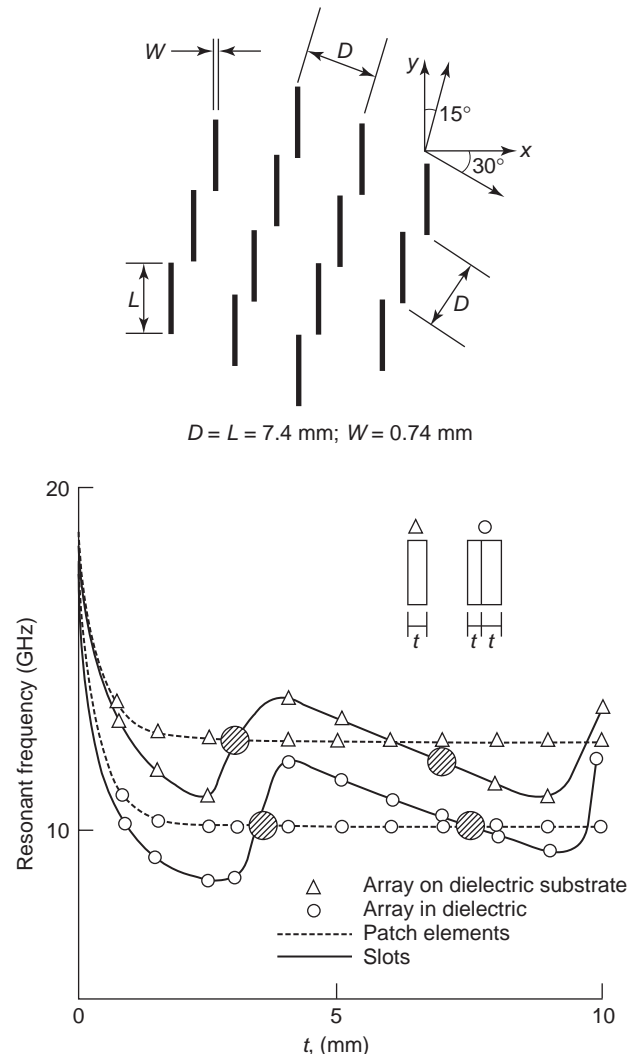

Figure 3. Variation of resonant frequency with the dielectric thickness for normal incidence.

as the dielectric thickness increases [13]. Note that two basic dielectric configurations are shown: (1) the grids are bonded on one side and (2) the grids are embedded centrally in the dielectrics. For a normally incident thin grid (with a 0.02-mm-thick dielectric with dielectric constant or $DK = 3$) the resonant frequency is at 20 GHz. As can be seen, the resonant frequency of the *patch* array embedded in the dielectrics (with $DK = 4$) approaches 10 GHz ($= 20/\text{square root of } DK = 4$) as the dielectric thickness is increased beyond 5 mm. The passband frequency of the *slot* (aperture element) array in the dielectrics also tends to this value, but it exhibits an oscillatory behavior about 10 GHz. For a patch or slot array bonded on one side of the dielectric (with $DK = 4$), the resonant frequency approaches 12.5 GHz (or $20/\text{square root of } DK = 2.5$, which is the average of 4 and 1).

The dielectric loading effect of a slot array is also dependent on the incident angle and the wave polarizations. For TE incidence, the resonance decreases as the dielectric thickness increases (similar to the case of normal incidence). For TM incidence, a significant reduction in the dielectric loading effect is noticed as the Brewster angle (63°) is approached. At this angle the air/dielectric interface does not reflect incident waves, and the resonant frequency behaves similarly to that of the patch array (i.e., it remain constant at 10 GHz). In fact, the angular stability of the slot arrays is lost for dielectric thickness greater than 1 mm. However, if the dielectric is a multiple quarter-wavelength thick (i.e., $t = 4$ and 7.5 mm) the resonant frequency becomes 10 GHz as shown by the hatched circles in Fig. 3.

Note that there is a mismatch loss for a slot array with dielectric on one side, unless it is a multiple half-wavelength thick. For example, the mismatch loss is 2 dB at normal incidence with a $DK = 4$ dielectric substrate. However, with an equal thickness of dielectric on both sides of the grid, the reflections at the two air/dielectric interfaces are tuned out at the resonant frequency; consequently there is no passband mismatch loss whatever the dielectric thickness.

One of the most important applications of dielectric loading is the multiband FSS design. For a multiband FSS application, the highest frequency generally determines the element spacing or lattice size. For the triband FSS [14] illustrated in Fig. 4, the element spacing is 0.39 free-space wavelengths at Ku band (13.8 GHz). This element spacing is too small to accommodate the circumference of the ring element, which has to be one electrical wavelength long at X band for reflection to occur. One method to achieve both criteria of one electrical wavelength circumference at X band and less than half free-space wavelength spacing at Ku band is to reduce the ring's physical size by the dielectric loading effect. Calculation shows that a triangular lattice can be used with a material of relative dielectric constant of 8.0. However, such material is not commercially available. Hence a material with a relative dielectric constant of 3.5 (Kevlar epoxy) and thickness of 0.064 cm is used as the substrate on both sides of the ring elements. In this design, the square lattice is adequate to avoid grating lobes. Although this Kevlar epoxy material

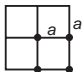

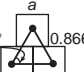

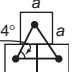

Figure 4. Transmission performance of a ring element FSS with dielectrics on both sides.

has a relatively higher loss tangent, it does not introduce significant insertion loss for the FSS. This is true because the RF energy travels only perpendicularly through the very thin substrate instead of parallel along the substrate, as in the case of a microstrip or stripline transmission line. Therefore, for the FSS application, the high-dielectric-constant substrate should be kept thin enough to prevent the generation of surface waves, especially at large incident angles. It should be noted that the surface wave (or Wood's anomaly; see Section 5) of an FSS grid embedded in dielectrics will not be eliminated, but only pushed higher in frequency, if the dielectric is thin. Furthermore, the occurrence of grating lobes is dependent on the physical size of the lattice and *not* the presence of the dielectrics [15].

4. GRATING LOBE PHENOMENON

Grating or Bragg lobes are undesired secondary mainbeams occurring at angles with higher-order constructive interference when the lattice size becomes electrically large. Since the periodic array elements behave similarly to the conventional array, the largest lattice size to avoid grating lobes should obey the same rule that governs a conventional array antenna. A general rule to avoid grating lobes is that the lattice size should be less than one wavelength for the normal incident case (0° incident angle). For large incident angles, the spacing should be kept below half free-space wavelength. Table 1 lists three different lattice types, such as square, triangular, and the brick lattices. It also shows the

Table 1. FSS Lattice Types and Grating Lobe Criteria

Lattice Type	Maximum Spacing	$\theta_0 = 0^\circ$	$\theta_0 = 45^\circ$
 Square spacing	$\frac{a}{\lambda_0} < \frac{1}{1 + \sin \theta_0}$	$\frac{a}{\lambda_0} < 1$	$\frac{a}{\lambda_0} < 0.59$
 Triangular spacing	$\frac{a}{\lambda_0} < \frac{1.15}{1 + \sin \theta_0}$	$\frac{a}{\lambda_0} < 1.15$	$\frac{a}{\lambda_0} < 0.67$
 Brick spacing	$\frac{a}{\lambda_0} < \frac{1.12}{1 + \sin \theta_0}$	$\frac{a}{\lambda_0} < 1.12$	$\frac{a}{\lambda_0} < 0.65$

Source: Ref. 2.

maximum lattice size to avoid grating lobes. As can be seen, the square lattice has the most closely packed elements, while the triangular lattice has the largest element spacing. The spacing requirements given in this table prevent the peak of the grating lobe from entering real space. To avoid wasted energy, not even the shoulder region of the grating lobe should enter real space; therefore, the lattice size should be approximately two-thirds or less of that given in Table 1.

5. WOOD'S ANOMALY PHENOMENON

Wood's anomalies were first observed in the diffraction spectrum of optical gratings in 1902 [2]. They exhibit themselves as rapid variations in the intensity of the various diffracted spectral orders in certain narrow frequency bands, which could not be explained by the grating theory at that time. These anomalies usually occur at frequencies near or higher than the resonant frequency of any periodic structure. Thus they have significant impacts on the design of periodic structures used in solar filters and FSS radomes [15]. Figure 5 shows the manifestation of these anomalies as the nulls in the transmission characteristics of a slot array. It also shows that the frequency of Wood's anomaly or the transmission null is decreased with an increase in the dielectric thickness. Further, for a slot array in free space, the Wood's anomaly will occur just below the frequency at which the grating lobe starts to propagate in real space, which for normal incidence on a rectangular grid array will first occur when the lattice size is one wavelength. It has been shown that these nulls are associated with a surface wave propagating along the surface of the array [15].

6. APPLICATIONS

FSS has a myriad of commercial and military applications. A good commercial application is the screen door of a microwave oven in a typical kitchen. It is a screen consisting

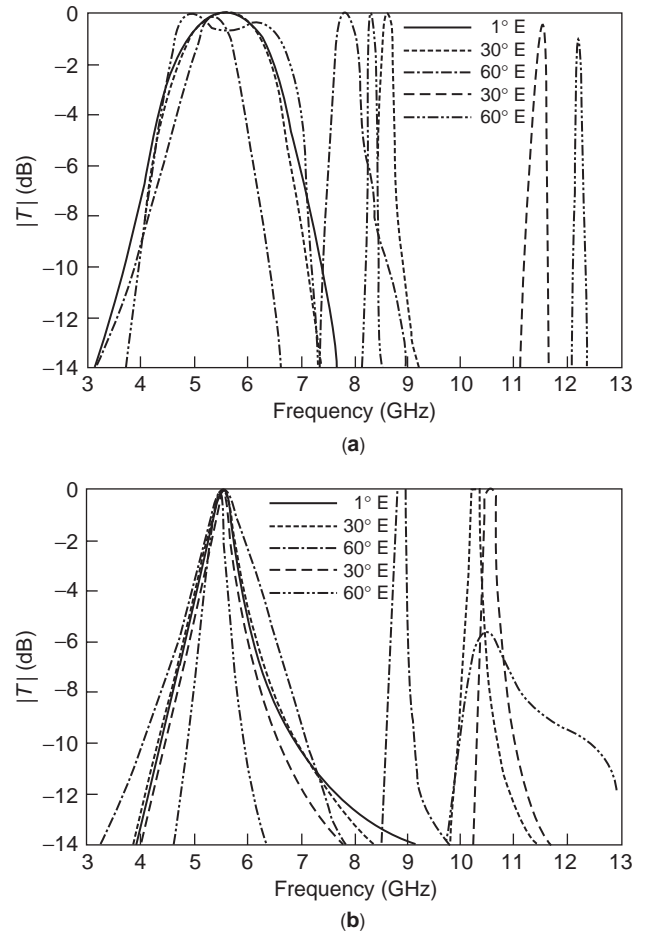

Figure 5. Transmission performance of a thin-slot FSS (square lattice, period = 1.78 cm, slot length = 1.32 cm, width = 0.128 cm) with dielectrics $DK = 4$, thickness = 0.7 and 0.35 cm for cases (a) and (b), respectively, on both sides.

of a periodic array of metallic holes designed for reflecting microwave energies at 2.45 GHz while passing through the light, allowing the user to see the food being cooked inside the oven.

In a dual-reflector antenna system, an FSS can be employed for the subreflector. Different frequency feeds are optimized independently and placed at the real and virtual foci of the subreflector. Hence, only a single main reflector is required for multifrequency operation. For example, the FSS on the high-gain antenna (HGA) of the Voyager spacecraft, as illustrated in Fig. 6, was designed to diplex S and X bands [2]. In that application the S-band feed is placed at the prime focus of the main reflector, and the X-band feed is placed at the Cassegrain focal point. Note that only one main reflector is required for this two-band operation. Thus, tremendous reductions in mass, volume and, most importantly, the cost of the antenna system are achieved with this two-band FSS subreflector. For a multiband and multifunction reflector antenna, a four-band (or S-, X-, Ku-, and Ka-band) double square-loop FSS, as shown in Fig. 7, was developed for the Cassini HGA [2].

Figure 6. Voyager HGA with a two-frequency (S/X-band) subreflector.

FSS radomes [3] with aperture-type element can be tuned to provide bandpass characteristics and to reduce the radar cross section (RCS) of the antenna system enclosed inside a surface or airborne vehicle. In other words, at the operating (in-band) frequency of the antenna, the signal will pass through the radome with minimum insertion loss, while at the out-of-band frequencies, the signal will be reflected

exactly as from a conducting surface or the metallic outer skin of the vehicle. Usually the radome can be designed to blend with the outer curvature and skin of the vehicle to minimize backscattering or to achieve low RCS.

Another useful FSS application is the circuit analog absorber consisting of resistive cross-dipole array backed by a ground plane, which provides absorbing capability superior to that of the Salisbury and Jaumann absorbers [3]. Here the lossy dipole element exhibits circuit-type characteristics, namely, a capacitance and inductance in series as well as a series resistance. Circuit analog absorbers with more than 25 dB attenuation over a 10–1 bandwidth has been achieved by cascading several cross-dipole sheets.

A thick rectangular or circular aperture element FSS has been designed for collecting solar energy [16]. This type FSS is a bandpass screen; specifically, it is essentially transparent in the frequency band where the solar cells are most efficient, but is reflecting at frequencies outside this band. In the far-infrared region, passive quasioptical grids are used as beamsplitters and mirrors [17] for improving the pumping efficiency in molecular lasers. Typically, a laser cavity mirror is a rectangular mesh grid designed to totally reflect at the wavelength of the energy used to pump the cavity while partially transmit (0–40%) at the lasing wavelength. Since no energy used in the laser pumping is lost at the mirror, the efficiency of the system is optimized. Another interesting quasioptical application is the use of a sunshield as a thermal control cover of spacecraft antennas. The sunshield consists of a square lattice array of vacuum-deposited aluminum square patches on a thin Kapton film. This grid not only provides for sunlight blockage but also allows for RF signal transmission.

FREQUENCY STABILITY

DAVID A. HOWE
 National Institute of Standards
 and Technology (NIST)
 Boulder, Colorado

1. THE SINE WAVE AND STABILITY

A sine-wave signal generator produces a voltage that changes in time in a sinusoidal manner as shown in Fig. 1. The signal is an *oscillating signal* because the

Figure 1. A repeating sine function is the basis of an oscillating signal.

sine wave repeats itself. A cycle (2π radians of phase) of the oscillation is produced in one period T .

It is convenient for us to express angles in radian units rather than in units of degrees, and positive zero crossings of the voltage will occur every 2π radians. The *frequency* ν is the number of cycles in one second (Hz), which is the reciprocal of period (seconds per cycle). The expression describing the voltage V produced by a sine-wave signal generator is given by

$$V(t) = V_0[1 + a(t)] \sin[\Phi(t)]$$

where V_0 is the peak voltage amplitude, $a(t)$ is amplitude noise, and $\Phi(t)$ is the total accumulated phase. Equivalent expressions are

$$V(t) = V_0[1 + a(t)] \sin\left(2\pi \frac{t}{T}\right)$$

and

$$V(t) = V_0[1 + a(t)] \sin(2\pi\nu t)$$

For the following discussion, we will assume the amplitude noise $a(t)$ is zero. Consider Fig. 2. Let's assume that the maximum value of V equals 1, hence $V_0 = 1$. We say that the voltage $V(t)$ is normalized to unity.

If we are given the frequency of the sine wave, then no matter how big or small Δt may be, we can determine ΔV . Let us look at this from another point of view. Suppose that we can measure ΔV and Δt . From this, there is a sine wave at a unique minimum frequency corresponding to the given ΔV and Δt . For infinitesimally small Δt , this frequency is called the *instantaneous frequency* at this t . The smaller the interval Δt , the better the approximation of

Figure 2. For a given phase, ΔV vs. Δt of the sine-wave signal corresponds to a unique minimum frequency called the instantaneous frequency if Δt is diminishingly small.

instantaneous frequency at t . In practice, because of finite bandwidths, we cannot measure the instantaneous frequency.

When we speak of oscillators and the signals they produce, we recognize that an oscillator has some nominal frequency at which it operates. The “frequency stability” of an oscillator is a term used to characterize how small the frequency fluctuations of the oscillator signal are. We usually refer to frequency stability when comparing one oscillator with another. As we shall see later, we can define particular aspects of an oscillator’s output, then draw conclusions about its relative frequency stability. People often speak of “frequency stability” when they actually mean “frequency instability.” Frequency stability is the degree to which an oscillating signal produces the same value of frequency for any interval Δt throughout a specified period of time. An internationally recommended definition of “frequency instability” is: “The spontaneous and/or environmentally caused frequency change within a given time interval.”¹

Let’s examine the two waveforms shown in Fig. 3. Frequency stability depends on the amount of time involved in its measurement. Of the two oscillating signals, it is evident that “2” is more stable than “1” from time t_1 to t_3 assuming that the horizontal scales are linear in time. From time t_1 to time t_2 , there may be some question as to which of the two signals is more stable, but it’s clear that from time t_2 to time t_3 , signal “1” is at a frequency different from that in interval t_1 to t_2 .

If we want an oscillator to produce a particular frequency ν_0 , then we’re correct in stating that if the oscillator signal frequency deviates from ν_0 over any interval, this is a result of something that is undesirable. In the design of an oscillator, it is important to consider the sources of mechanisms that degrade the oscillator’s frequency stability. These undesirable mechanisms cause random (noise) or systematic processes to exist on top of the sine-wave signal of the oscillator. To account for the noise components at the output of a sine-wave signal generator, we can express the output as

$$V(t) = V_0[1 + a(t)] \sin[2\pi\nu_0 t + \phi(t)] \quad (1)$$

where

V_0 = nominal peak voltage amplitude
 $a(t)$ = deviation of amplitude from nominal (i.e., $\delta V/V_0$)
 ν_0 = nominal fundamental frequency
 $\phi(t)$ = deviation of phase from nominal

Ideally a and ϕ should equal zero for all time. However, in the real world there are no perfect oscillators. To determine the extent of the noise components a and ϕ , we turn our attention to measurement techniques.

¹The present IEEE standard for the measure of frequency stability is the one-sided spectral density $S_y(f)$ in the frequency domain or the two-sample or Allan variance $\sigma_y(\tau)$ in the time domain. These are explained later.

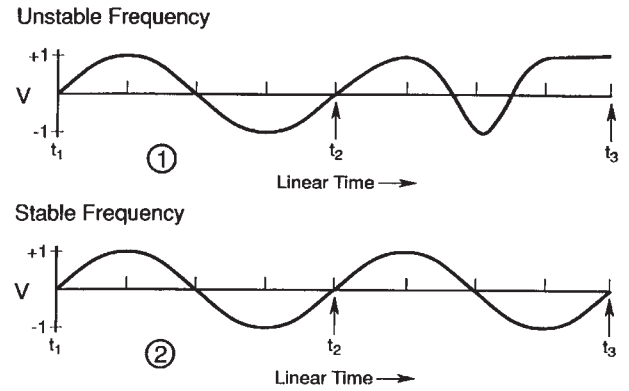

Figure 3. Top (1): Instantaneous frequency is inconsistent and less stable from t_2 to t_3 . Bottom (2): Instantaneous frequency is consistent and more stable throughout.

The typical precision oscillator, of course, has a presumably stable sinusoidal voltage output with a frequency ν and a period of oscillation T (which is the reciprocal of the frequency: $\nu = 1/T$). One goal is to measure the frequency and/or the frequency stability of the sinusoid. Instability is actually what is measured, but with little confusion it is usually called “stability” in the literature. Naturally, fluctuations in frequency correspond to fluctuations in the period. Almost all frequency measurements, with very few exceptions, are measurements not of frequency but of the phase or of the period fluctuations in an oscillator, even though the frequency may be the readout. As an example, most frequency counters sense the zero (or near-zero) crossing of the sinusoidal voltage, which is the point at which the voltage is the most sensitive to phase fluctuations.

We must also realize that any frequency measurement involves two oscillators. In some instances, one oscillator is in the counter. It is impossible to purely measure only one oscillator. In some instances one oscillator may sufficiently outperform the other, and the fluctuations measured may be considered essentially those of the latter. However, in general because frequency measurements are always dual, it is useful to define

$$y(t) = \frac{\nu_1 - \nu_0}{\nu_0} \quad (2)$$

as the fractional frequency difference or offset of oscillator one ν_1 with respect to a reference oscillator ν_0 divided by the nominal frequency ν_0 . Conceptually, we can also think of Eq. (2) as the free-running frequency of an individual oscillator ν_1 , differentiated with respect to its own nominal value ν_0 . Now, $y(t)$ is a dimensionless quantity and useful in describing oscillator and clock performance; that is, the time fluctuation or difference $x(t)$ of an oscillator over a period of time t is given simply by

$$x(t) = \int_0^t y(t') dt' = \frac{\phi(t)}{2\pi\nu_0} \quad (3)$$

We see that the time deviations and the phase deviations are related by a constant, $1/2\pi\nu_0$. Since it is impossible to

measure instantaneous frequency, any frequency or fractional frequency measurement always involves some sample time, Δt or τ —some time window through which the oscillators are observed; whether it’s a picosecond, a second, or a day, there must always be some sample time. So, when determining a fractional frequency $y(t)$, what is in fact happening is that the time difference is being measured starting at, say, some time t and again at a later time, $t + \tau$. The difference between these two time differences, divided by τ , gives the average fractional frequency over that period τ :

$$\bar{y}(t) = \frac{x(t + \tau) - x(t)}{\tau} \tag{4}$$

Tau (τ) may be called the sample time or averaging time; it may be determined, for example, by the gate time of an electronic counter.

What happens in many cases is that we sample a number of cycles of an oscillation during the preset gate time of a counter; after the gate time has elapsed, the counter latches the value of the accumulated count of cycles so that it can be read out, printed, or stored in some other way. Then there is a delay time for such processing of the data before the counter arms or initializes and resumes on the next cycle of the oscillation. During the delay time (or process time), information is lost. This is called “dead-time”, and in some instances it becomes a problem. Unfortunately for data processing in typical oscillators the effects of deadtime often hurt most when it is the hardest to avoid. In other words, for times that are short compared to a second, when it is very difficult to avoid deadtime, this is usually where deadtime can make a significant difference in the data analysis. Typically, for many oscillators, if the sample time is long compared to a second, the deadtime makes little difference in the data analysis, unless it is excessive [1]. New equipment or techniques are now available that contribute zero or negligible deadtime [2].

In reality, of course, the sinusoidal output of an oscillator is not pure; it contains noise (frequency) fluctuations as well. We will describe three different methods of measuring the frequency fluctuations in precision oscillators other than measuring the frequency directly with a frequency counter, listed as a fourth method. The direct frequency counter technique is often very limiting because the number of resolvable digits on the counter are often inadequate for precision oscillators, and counter input noise masks oscillator noise for short sample times. In all the methods one also needs to properly match the impedances of different connected electronic instruments, use short connecting cable lengths, and use high-quality, stable connectors.

1.1. Common Methods of Measuring Frequency Stability

1.1.1. Beat-Frequency Method. The first technique is called a heterodyne frequency-measuring method or beat-frequency method. The signals from two independent oscillators are fed into the two ports of a double balanced mixer, as illustrated in Fig. 4. The device labeled “Amp” is an amplifier.

Figure 4. Measurement of the frequency difference (“beat note”) between oscillators can increase measurement precision. State-of-the-art oscillators can readily be measured by this method.

The difference frequency, or the beat frequency v_b , is obtained as the output of a lowpass filter (to suppress carrier frequency harmonics) that follows the mixer. This beat frequency is then amplified and fed to a frequency counter and printer or other recording device. The fractional frequency is obtained by dividing v_b by the nominal carrier frequency v_0 . This system has excellent precision; one can measure essentially all state-of-the-art oscillators.

1.1.2. Dual-Mixer Time-Difference (DMTD) System. This technique uses two heterodyne measurements operating simultaneously. The time difference of the zero crossings of each beat frequency is measured and yields an excellent precision, 10^{-13} seconds. A block diagram is shown in Fig. 5. It should be mentioned that if time or time fluctuations can be measured directly, an advantage is obtained over just measuring frequency. The reason is that we can readily calculate the frequency from the time, only if there is no deadtime. In the past, frequency was not inferred from the time (for sample times of the order of several

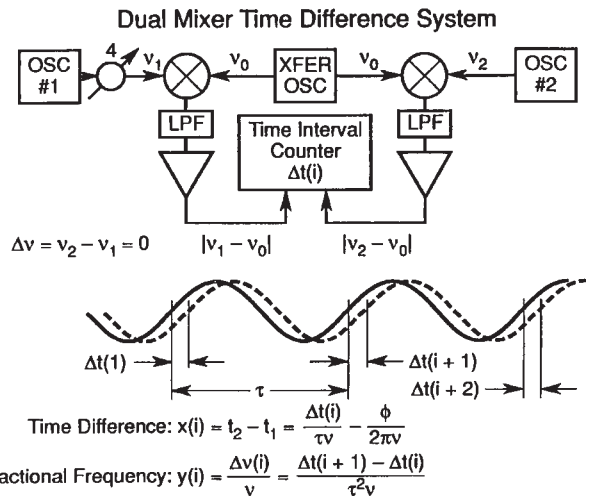

Figure 5. Measurement of the time difference between two beat notes from two oscillators with a common transfer oscillation can further increase measurement precision. Instability of transfer oscillator cancels to first order.

seconds and less) because the time difference between a pair of oscillators operating as clocks could not be measured with sufficient precision. However, now the precision of DMTD opens the door to measuring time fluctuations as well as frequency fluctuations for sample times as short as a few milliseconds, all without deadtime.

In Fig. 5, oscillator 1 could be considered to be under test and oscillator 2 could be considered to be the reference oscillator. Their outputs go to the ports of a pair of double-balanced mixers. Another oscillator with separate symmetric buffered outputs is fed to the other two ports of the pair of double-balanced mixers. This common oscillator's frequency is offset by a desired amount from those of the other two oscillators. Then two different beat frequencies are produced by the two mixers as shown. These two beat frequencies will be out of phase by an amount proportional to the time difference between oscillators 1 and 2—excluding the differential phase shift that may be inserted (component “4” is a phase shifter). Further, the beat frequencies differ in frequency by an amount equal to the frequency difference between oscillators 1 and 2.

This measurement technique is very useful where oscillators 1 and 2 outputs are at very nearly the same frequency. This is typical for atomic standards (cesium, rubidium, and hydrogen frequency standards).

Illustrated at the bottom of Fig. 5 is what might represent the beat frequencies from the two mixers. A phase shifter may be inserted as component “4” to adjust the phase so that the two beat rates are nominally in phase; this adjustment sets up the nice condition that the noise of the common oscillator tends to cancel (for certain types of noise) when the time difference is determined. After these beat signals are amplified, the start port of a time interval counter is triggered with the positive zero crossing of the other beat. Taking the time difference between the zero crossings of these beat frequencies, we measure the time difference between zero crossings of oscillators 1 and 2, but with a precision that has been amplified by the ratio of the carrier frequency to the beat frequency (over that normally achievable with this same time interval counter). The time difference $x(i)$ for the i th measurement between oscillators 1 and 2 is given by

$$x(i) = \frac{\Delta t(i)}{\tau_b \nu_0} - \frac{\phi}{2\pi \nu_0} \frac{k}{\nu_0} \quad (5)$$

where $\Delta t(i)$ is the i th time difference as read on the counter, τ_b is the beat period, ν_0 is the nominal carrier frequency, ϕ is the phase delay in radians added to the signal of oscillator 1, and k is an integer number of cycles of ν_0 to be determined in order to remove the cycle ambiguity. It is important to know k only if the absolute time difference is desired; for measurements of frequency and of time fluctuations, k may be assumed zero unless we go through a cycle during a data run. The fractional frequency $y(i, \tau)$ between oscillators 1 and 2 can be derived in the normal

way from the time fluctuations:

$$y_{1,2}(i, \tau) = \begin{cases} \frac{\nu_1(i, \tau) - \nu_2(i, \tau)}{\nu_0} \\ \frac{x(i+1) - x(i)}{\tau} \\ \frac{\Delta t(i+1) - \Delta t(i)}{\tau_b^2 \nu_0} \end{cases} \quad (6)$$

In Eqs (5) and (6), it is assumed that the transfer (or common) oscillator is set at a frequency lower than those of oscillators 1 and 2, and that the voltage zero crossing of the beat frequency $\nu_1 - \nu_c$ starts—and that $\nu_2 - \nu_c$ stops—the time interval counter. The fractional frequency difference may be averaged over any integer multiple of τ_b

$$y_{1,2}(i, m\tau_b) = \frac{x(i+m) - x(i)}{m\tau_b} \quad (7)$$

where m is any positive integer. If needed, τ_b can be made to be very small by having very high beat frequencies. The transfer (or common) oscillator may be replaced with a low phase noise frequency synthesizer, which derives its basic reference frequency from oscillator 2. In this setup the nominal beat frequencies are given simply by the amount by which the output frequency of the synthesizer is offset from ν_2 . Sample times as short as a few milliseconds with subpicosecond (< 1 ps) resolution are obtained. Note that logging the data at such a rate usually requires special equipment. The National Institute of Standards and Technology (NIST) timescale measurement system is based on the DMTD.

1.1.3. Loose Phase-Locked Loop Method. This type of method is illustrated in Fig. 6. The signal from an oscillator under test is fed into one port of a mixer. The signal from a reference oscillator is fed into the other port of this mixer. The signals are in quadrature; that is, they are 90° out of phase, so that the average voltage out of the new mixer is nominally zero, and the instantaneous voltage fluctuations correspond to phase fluctuations rather than to amplitude fluctuations between the two signals. The mixer is a key element in the system. The advent of the Schottky barrier diode was a significant breakthrough in

Figure 6. Direct measurement of the phase difference between two oscillators yields excellent precision. The technique requires electronic frequency control of a clean reference oscillator to maintain a loose phase lock, hence a zero beat.

making low-noise precision stability measurements. The output of this mixer is fed through a lowpass filter and then amplified in a feedback loop, causing the voltage-controlled oscillator (reference) to be phase-locked to the test oscillator. The response time of the loop is adjusted such that a very loose phase-lock (long-time-constant) condition exists.

The response (or attack) time is the time it takes the servo system to make 70% of its ultimate correction after being slightly disturbed. The response time is equal to $1/\pi w_h$, where w_h is the servo bandwidth. If the response time of the loop is about a second, then the voltage fluctuations will be proportional to the phase fluctuations for sample times shorter than one second. Depending on the coefficient of the tuning capacitor and the quality of the oscillators involved, the amplification used may vary significantly, but may typically range from 40 to 80 dB via a good low-noise amplifier. In turn this signal can be fed to a spectrum analyzer to measure the Fourier components of the phase fluctuations. It is of particular use for sample times shorter than one second (for Fourier frequencies greater than 1 Hz) in analyzing the characteristics of an oscillator. It is particularly useful if one has discrete sidebands such as 60 Hz, or detailed structure in the spectrum.

One may also take the output voltage from the above-mentioned amplifier and feed it to an analog-to-digital (A/D) converter. This digital output becomes an extremely sensitive measure of the short-term time or phase fluctuations between the two oscillators. Resolutions of the order of a picosecond (ps) are easily achievable.

1.1.4. Time-Difference Method Using a Counter. The last measurement method we will illustrate is very commonly used, but typically does not have the measurement precision that is more readily available in the first three methods illustrated above. This method, called the *time-difference method*, is shown in Fig. 7. Because of the wide bandwidth needed to measure fast-risetime pulses, this method is limited in signal-to-noise ratio. However, some commercially available counters allow us to do sig-

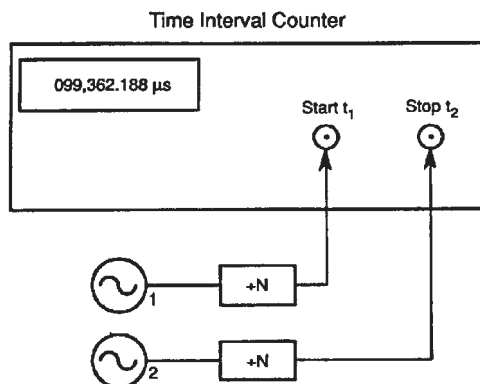

Figure 7. Measurement of the time difference between two oscillators, usually after division by N to obtain 1 pulse-per-second, yields only moderate measurement performance compared to previous methods. The technique is dependent on several properties of the counter and its trigger circuits.

nal averaging or precision risetime comparisons (precision of time-difference measurements in the range of 10 ns–10 ps are now available). Such a method yields a direct measurement of $x(t)$ without any translation, conversion, or multiplication factors. However, even if adequate measurement resolution is available, caution should be exercised in using this technique because it is not uncommon to have significant instabilities in the frequency dividers shown in Fig. 7—of the order of 100 ps. The technique is therefore suitable for long, not short, averaging times.

A trick to bypass divider problems is to feed the oscillator signals directly into the time interval counter and observe the zero-voltage crossing. The divided signal can be used to resolve cycle ambiguity of the carrier; otherwise the carrier phase at zero volts may be used as the time reference. The slope of the signal at zero volts is $2\pi V_0/\tau_1$, where $\tau_1 = 1/\nu_1$ (period of oscillation). For $V_0 = 1$ V and a 5-MHz signal, this slope is 3 mV/ns, which is a good sensitivity. (*Caution:* A correct impedance match of less than 1.5 VSWR is critical for this setup to be stable.)

2. CHARACTERIZATION

Given a set of data for the fractional frequency or time fluctuations between a pair of oscillators, it is useful to characterize these fluctuations with reasonable and tractable models of performance. In so doing for many kinds of oscillators, it is useful to consider the fluctuations as random (may be predicted only statistically) or nonrandom (i.e., systematic—environmentally induced or that have a causal effect that can be determined and in many cases be predicted).

2.1. Nonrandom Fluctuations

Nonrandom fluctuations are usually the main cause of departure from “true” time or “true” frequency in the long term.

If, for example, we have values of the frequency over a period of time, and a frequency offset from nominal is observed, one may calculate directly that the phase error will accumulate as a ramp. If, on the other hand, the frequency values drift linearly, then the time fluctuations will behave quadratically. In almost all oscillators, these “systematics,” as they are sometimes called, are the primary cause of time and/or frequency departure. A useful approach for determining the value of the frequency offset is to calculate the simple mean of the set, or for determining the value of the frequency drift by calculating a linear least-squares fit to the frequency. A least-squares quadratic fit to the phase or to the time deviations is rarely as efficient an estimator of the frequency drift for most oscillators. Precision frequency standards are affected by their environment. These environmental perturbations often cause long-term departures of frequency and time, which in a data run can look like drift, but are not.

2.2. Random Fluctuations

After the systematic or nonrandom effects of a dataset have been calculated or estimated, they may be subtracted

from the data, leaving the residual random fluctuations. They can usually be best characterized statistically using $\sigma_y(\tau)$, the Allan deviation, for short τ (values) and “Theo1” for long τ , the agreed-on standards (IEEE) in the time domain, to be explained in the next section. It is often the case for precision oscillators that these random fluctuations may be effectively modeled with power-law spectral densities. This topic and measurements of spectrum are discussed later. We have

$$S_y(f) = h_x f^\alpha \tag{8}$$

where $S_y(f)$ is the one-sided spectral density of the fractional frequency fluctuations, f is the Fourier frequency at which the density is taken, h_x is the coefficient indicating the level of that type of noise, and α is a number modeling the most appropriate type of power law for the data. If we observe from a $\log \sigma_y^2(\tau)/\log \tau$ diagram a particular slope (call it μ) over certain regions of sample time, τ , this slope has a correspondence to a power-law spectral density or a set of the same with some amplitude coefficient h_x . In particular, $\mu = -(\alpha + 1)$ for $-3 < \alpha < 1$ and $\mu \cong -2$ for $\alpha \geq 1$. Further, a correspondence exists between h_x and the coefficient for $\sigma_y(\tau)$ [1]. The transformations for some of the more common power-law spectral densities have been tabulated, making it quite easy to transform the frequency stability modeled in the time domain over to the frequency domain and vice versa. Examples of some power-law spectra and other types of noise that have been simulated by computer are shown in Fig. 8. The root Allan variance (an RMS or deviation called “Adev”) and Theo1-deviation are constructed to extract frequency instability and not measurement system noise. Synchronization and measurement system noise is phase or time instability characterized by other statistics such as time deviation (TDEV) and maximum time interval error (MTIE) [3].

Once the noise characteristics have been determined, one is often able to deduce whether the oscillators are performing properly, and whether they are meeting either the design specifications or the manufacturer’s specifications. For example, a cesium beam frequency standard or a rubidium gas cell frequency standard, when working

Figure 8. “Adev” (root Allan variance estimate) showing power-law noise as straight lines in addition to other errors. Our goal is to properly interpret this kind of plot of frequency stability.

properly, should exhibit white frequency noise (slope of $-\frac{1}{2}$) for values of τ of the order of a few seconds to several thousand seconds.

3. ANALYSIS OF TIME DOMAIN DATA

Suppose now that we are given the time or frequency fluctuations between a pair of precision oscillators measured, for example, by one of the techniques outlined in Section 1, and a stability analysis is desired. Let this comparison be depicted by Fig. 9. The minimum sample time is determined by the measurement system. If the time difference or time fluctuations are available, then the frequency or the fractional frequency fluctuations may be calculated from one period of sampling to the next. Suppose further there are M values of the fractional frequency y_i . Now there are many ways to analyze these data. Historically, people have typically used the standard deviation equation shown in Fig. 9, $\sigma_{\text{std.dev.}}(\tau)$, where y_i is the average fractional frequency over the dataset, and is subtracted from each value of y_i before squaring, summing, and dividing by the number of values minus one ($M - 1$), and taking the square root to get the standard deviation. We have studied what happens to the standard deviation when the dataset may be characterized by power-law spectra that are more dispersive than classical white-noise frequency fluctuations. In other words, if the fluctuations are characterized by flicker noise or any other non-white-noise frequency deviations, what happens to the standard deviation for that dataset? We can show that the standard deviation is a function of the number of data points in the set (discussed next), and it is also a function of the dead-time and of the measurement system bandwidth. For example, using flicker-noise frequency modulation as a model, as the number of data points increases, the standard deviation increases monotonically without limit. Some statistical measures have been developed that do not depend on the datalength and that are readily usable for characterizing the random fluctuations in precision oscillators. The IEEE has adopted a standard measure

Figure 9. A simulated plot of the time fluctuations $x(t)$ between a pair of oscillators and of the corresponding fractional frequencies calculated from the time fluctuations each averaged over a sample time τ . At the bottom are the equations for the standard deviation (left) and for the time-domain measure of frequency stability as recommended by the IEEE (right).

known as the “Allan variance” taken from the set of useful variances developed, and an experimental estimation of the square root of the Allan variance is shown as the bottom right equation in Fig. 9 [2,4]. This equation is very easy to implement experimentally, as we need to simply add up the squares of the differences between adjacent values of y_i , divide by the number of them and by 2, and take the square root. We then have the quantity that the IEEE subcommittee has recommended for specification of stability in the time domain, denoted by $\sigma_y(\tau)$

$$\sigma_y(\tau) = \left\langle \frac{1}{2} (\bar{y}(t+\tau) - \bar{y}(t))^2 \right\rangle^{1/2} \tag{9}$$

where the brackets “ $\langle \rangle$ ” denote infinite time average. In practice this is easily estimated from a finite dataset as follows:

$$\sigma_y(\tau) = \left[\frac{1}{2(M-1)} \sum_{i=1}^{M-1} (y_{i+1} - y_i)^2 \right]^{1/2} \tag{10}$$

where the y_i are the discrete frequency averages as illustrated in Fig. 9.

We would like to know how $\sigma_y(\tau)$ varies with the sample time τ . A simple and very useful trick that we can use if there is no deadtime is to average the values for y_1 and y_2 and call that a new y_1 averaged over 2τ ; similarly average the values for y_3 and y_4 and call that a new y_2 averaged over 2τ , and so on, and finally apply the same equation as before to get $\sigma_y(2\tau)$. One can repeat this process for other desired integer multiples m of τ , and from the same dataset generate values for $\sigma_y(m\tau)$ as a function of $m\tau$, from which one may be able to infer a model for the process that is characteristic of this pair of oscillators. If we have deadtime in the measurements, adjacent pairs cannot be averaged in an unambiguous way to simply increase the sample time. We have to retake the data for each new sample time—often a very time-consuming task. This is another instance where deadtime can be a problem.

The classical variance (standard deviation squared) is the wrong statistic for measurements of frequency stability, because in most cases it depends on the number of data samples. Fig. 10 plots the ratio of the standard deviation squared for N samples to the standard deviation squared for two samples, $\langle \sigma^2(2, \tau) \rangle$, which is the same as the Allan variance, $\sigma_y^2(\tau)$. We can see the dependence of this standard deviation on the number of samples for various kinds of power-law spectral densities commonly encountered as reasonable models for many important precision oscillators. Note that $\sigma_y^2(\tau)$ has the same value as the classical variance for the classical noise case (white-noise FM). Figure 10 shows that with the increasing length of data the standard deviation of the common classical variance is not well behaved.

We may combine Eqs. (4) and (9) to obtain an equation for $\sigma_y(\tau)$ in terms of the time-difference or time-deviation measurements:

$$\sigma_y(\tau) = \left\langle \frac{1}{2\tau^2} (-x(t+2\tau) + 2x(t+\tau) - x(t))^2 \right\rangle^{1/2} \tag{11}$$

Figure 10. The ratio of the time average of the standard deviation squared for N samples over the time average of a two-sample standard deviation squared as a function of the number of samples N . The ratio is plotted for various power-law spectral densities that commonly occur in precision oscillators. This figure illustrates one reason why the standard deviation is not a suitable measure of frequency stability [4].

which for N discrete time readings, also called N_x , may be estimated as

$$\sigma_y(\tau) \cong \left[\frac{1}{2(N-2)\tau^2} \sum_{i=1}^{N-2} (-x_{i+2} + 2x_{i+1} - x_i)^2 \right]^{1/2} \tag{12}$$

where the i integer denotes the number of the reading in the set of N and the nominal spacing between readings is τ . If there is no deadtime in the data and the original data were taken with a sample time τ_0 , a set of x_i values can be obtained by integrating the y_i values:

$$x_{i+1} = x_i + \tau_0 \sum_{j=1}^i y_j \tag{13}$$

Once we have the x_i values, we can pick τ in Eq (13) to be any integer multiple m of τ_0 , specifically $\tau = m\tau_0$:

$$\sigma_y(m\tau_0) \cong \left[\frac{1}{2(N-2m)m^2\tau_0^2} \sum_{i=1}^{N-2m} (-x_{i+2m} + 2x_{i+m} - x_i)^2 \right]^{1/2} \tag{14}$$

Equation (14), called the “max-overlap estimator,” is regarded as the best estimator of $\sigma_y(m\tau_0)$.

Example 1. Find the two-sample (Allan) variance, $\sigma_y^2(\tau)$, of the following sequence of fractional frequency fluctuation

values y_k , each value averaged over one second:

$$\begin{aligned} y_1 &= 4.36 \times 10^{-5} & y_5 &= 4.47 \times 10^{-5} \\ y_2 &= 4.61 \times 10^{-5} & y_6 &= 3.96 \times 10^{-5} \\ y_3 &= 3.19 \times 10^{-5} & y_7 &= 4.10 \times 10^{-5} \\ y_4 &= 4.21 \times 10^{-5} & y_8 &= 3.08 \times 10^{-5} \end{aligned}$$

(assume no deadtime in measurement of averages).

Since each average of the fractional frequency fluctuation values is for one second, then the first variance calculation will be at $\tau=1$ s. We are given $M=8$ (eight values); therefore, the number of pairs in sequence is $M-1=7$. We have

Data Values y_k ($\times 10^{-5}$)	First Differences ($y_{k+1} - y_k$) ($\times 10^{-5}$)	First Difference Squared ($y_{k+1} - y_k$) ² ($\times 10^{-10}$)
4.36	—	—
4.61	0.25	0.06
3.19	-1.42	2.02
4.21	1.02	1.04
4.47	0.26	0.07
3.96	-0.51	0.26
4.10	0.14	0.02
3.08	-1.02	1.04
		Sum = 4.51

$$\sum_{k=1}^{M-1} (y_{k+1} - y_k)^2 = 4.51 \times 10^{-10}$$

Therefore the Allan variance is

$$\sigma_y^2(1 \text{ s}) = \frac{4.51 \times 10^{-10}}{2(7)} = 3.2 \times 10^{-11}$$

and the Allan deviation is

$$\sigma_y(1 \text{ s}) = [\sigma_y^2(1 \text{ s})]^{1/2} = [3.2 \times 10^{-11}]^{1/2} = 5.6 \times 10^{-6}$$

Using the same data, we can calculate the Allan variance for $\tau=2$ s by averaging pairs of adjacent values and using these new averages as data values for the same procedure as above. For three second averages ($\tau=3$ s), take adjacent threesomes and find their averages and proceed in a similar manner. More data must be acquired for use of longer averaging times.

The confidence of the estimate on $\sigma_y(\tau)$ improves nominally as the square root of the number of data values used. In this example $M=8$, and the confidence can be expressed as being no better than $1/\sqrt{8} \times 100\% = 35\%$. This is a one-sigma (1σ) uncertainty (68% confidence interval) in the estimate for the $\tau=1$ s average. We can dramatically improve confidence using a combination of signal processing, as discussed next.

For the particularly difficult measurement problem of determining the frequency stability of frequency

standards and oscillators for long averaging times, we can use the special-purpose statistic, the estimator of a theoretical variance 1 (“Theo1”), given in native form by [5]

$$\begin{aligned} \widehat{\text{Theo1}}(m, \tau_0, N_x) &= \frac{1}{0.75(N_x - m)(m\tau_0)^2} \\ &\times \sum_{i=1}^{N_x - m} \sum_{\delta=0}^{(m/2) - 1} \frac{1}{\left(\frac{m}{2} - \delta\right)} [(x_{i-x_i-\delta+\frac{m}{2}}) + (x_{i+m-x_i+\delta+\frac{m}{2}})]^2 \end{aligned} \tag{15}$$

for m even, $10 \leq m \leq N_x - 1$, and $\tau = 0.75 m \tau_0$. It has statistical properties like those of the Allan variance, with the significant enhancement that it can evaluate frequency stability at longer averaging times than by using the Allan definition. We can remove bias relative to “Avar” by a composite statistic given by

$$\begin{aligned} \text{TheoH}(m, \tau_0, N_x) &= \begin{cases} \text{Avar}(m, \tau_0, N_x) & \text{for } 1 \leq m < \frac{k}{\tau_0} \\ \text{TheoBR}(m, \tau_0, N_x) & \text{for } \frac{k}{0.75\tau_0} \leq m \leq N_x - 1, m \text{ even} \end{cases} \end{aligned} \tag{16}$$

where k is the largest $\tau \leq T/10$ where $\text{Avar}(m, \tau_0, N_x)$ has sufficient confidence. In this equation TheoBR is defined

$$\begin{aligned} \text{TheoBR}(m, \tau_0, N_x) &= \left[\frac{1}{n+1} \sum_{i=0}^n \frac{\text{Avar}(m = 9 + 3i, \tau_0, N_x)}{\widehat{\text{Theo1}}(m = 12 + 4i, \tau_0, N_x)} \right] \widehat{\text{Theo1}}(m, \tau_0, N_x), \end{aligned} \tag{17}$$

where

$$n = \left\lfloor \frac{0.1N_x}{3} - 3 \right\rfloor$$

(where $\lfloor \cdot \rfloor$ means the integer part). Equation (16) computes a function that is Avar in short term and Theo1 in long term.

4. SPECTRUM ANALYSIS

Another method of characterizing the noise in a signal source is by means of spectrum analysis [6–8]. To understand this approach, let’s examine the waveform shown in Fig. 11.

Here we have a sine wave that for short instances is perturbed by noise. Some workers loosely refer to these types of noises as “glitches.” The waveform has a nominal frequency over one cycle that we’ll call ν_0 ($\nu_0 = 1/T_0$). At times, noise causes the instantaneous frequency to differ markedly from the nominal frequency. If a pure sine-wave signal of frequency ν_0 is subtracted from this waveform,

Figure 11. Sine wave that is perturbed by periodic glitches.

the remainder is the sum of the noise components. These components are of various frequencies and the sum of their amplitudes is nearly zero except for the intervals during each glitch, when their amplitudes momentarily reinforce each other. This is shown graphically in Fig. 12.

We can construct a graph plotting RMS power against frequency for a given signal into a given load. This kind of plot is called the *power spectrum*. For the waveform of Fig. 11, the power spectrum will have a high value at ν_0 and lower values for the signals produced by the glitches. Closer analysis reveals that there is a recognizable, somewhat constant, repetition rate associated with the glitches.

In fact, we can deduce that there is a significant amount of power in another signal whose period is the period of the glitches as shown in Fig. 12. Let's call the frequency of the glitches ν_s . Since this is the case, we will observe a noticeable amount of power in the spectrum at ν_s with an amplitude that is related to the characteristics of the glitches. The power spectrum shown in Fig. 13 has this feature. A predominant ν_s component has been depicted, but other harmonics also exist.

Some noise will cause the instantaneous frequency to "jitter" around ν_0 , with a distribution that is higher and lower than ν_0 . We thus usually find a "pedestal" associated with ν_0 as shown in Fig. 14.

The process of breaking a signal down into all of its various components of frequency is called *Fourier expansion*. In other words, the addition of all the frequency components, called *Fourier frequency components*, produces the original signal. The value of a Fourier frequency is the difference between the frequency component and the fundamental frequency. The power spectrum can be normalized to unity such that the total area under the curve equals one. The power spectrum normalized in this way is the *power spectral density*.

The power spectrum of $V(t)$, often called the *RF spectrum*, is very useful in many applications. Unfortunately, if we are given the RF spectrum, it is impossible to determine whether the power at different Fourier frequencies is a result of amplitude fluctuations " $a(t)$ " or phase fluctua-

Figure 12. Periodic glitches are undesirable and can be separated from the desired sine wave and characterized in the frequency domain.

Figure 13. A plot of power (into a load) vs. frequency is a *power spectrum*.

tions " $\phi(t)$." The RF spectrum can be separated into two independent spectra, one of which is the *spectral density* of $\phi(t)$.

For the purpose here, the phase fluctuation components are the ones of interest. The spectral density of phase fluctuations is denoted by $S_\phi(f)$, where f is Fourier frequency. For the frequently encountered case where the AM power spectral density is negligibly small and the total modulation of the phase fluctuations is small (mean-square value is much less than 1 rad^2), the RF spectrum has approximately the same shape as the phase spectral density.

However, a main difference in the representation is that the RF spectrum includes the fundamental signal (carrier), and the phase spectral density does not. Another major difference is that the RF spectrum is a *power* spectral density and is measured in units of watts/hertz. The phase spectral density involves no "power" measurement of the electrical signal. The units are radians²/hertz. It is tempting to think of $S_\phi(f)$ as a "power" spectral density because in practice it is measured by passing $V(t)$ through a phase detector and measuring the detector's output power spectrum. The measurement technique makes use of the relation that for small deviations ($\delta\phi \leq 1$ radian)

$$S_\phi(f) = \left[\frac{V_{\text{RMS}}(f)}{V_s(f)} \right]^2 \tag{18}$$

where $V_{\text{RMS}}(f)$ is the root-mean-square noise voltage in a 1 Hz bandwidth (i.e., per $\sqrt{\text{Hz}}$) at a Fourier frequency f , and $V_s(f)$ is the sensitivity (volts per radian) at the phase quadrature output of a phase detector that is comparing the two oscillators. In the next section, we will look at a scheme for directly measuring $S_\phi(f)$ by determining $V_s(f)$.

SPECTRAL DENSITY

Figure 14. The power spectrum of an oscillator includes its "noise pedestal."

One question we might ask is “How do frequency changes relate to phase fluctuations?” After all, it’s the frequency stability of an oscillator that is a major consideration in many applications. The frequency is equal to a rate of change in the phase of a sine wave. This tells us that fluctuations in an oscillator’s output frequency are related to phase fluctuations since we must change the rate of $\phi(t)$ to accomplish a shift in $\nu(t)$, the frequency at time t . A rate of change of total $\phi_T(t)$ is denoted by $\dot{\phi}_T(t)$. We then have

$$2\pi\nu(t) = \dot{\phi}_T(t) \quad (19)$$

The dot denotes the mathematical operation of *differentiation* on the function ϕ_T with respect to its independent variable t .² From Eqs. (19) and (1) we get

$$2\pi\nu(t) = \dot{\phi}_T(t) = 2\pi\nu_0 + \dot{\phi}(t)$$

Rearranging, we have

$$2\pi\nu(t) - 2\pi\nu_0 = \dot{\phi}(t)$$

or

$$\nu(t) - \nu_0 = \frac{\dot{\phi}(t)}{2\pi} \quad (20)$$

The quantity $\nu(t) - \nu_0$ can be more conveniently denoted as $\delta\nu(t)$, a change in frequency at time t . Equation (20) tells us that if we differentiate the phase fluctuations $\phi(t)$ and divide by 2π , we will have calculated the frequency fluctuation $\delta\nu(t)$. Rather than specifying a frequency fluctuation in terms of shift in frequency, it is useful to denote $\delta\nu(t)$ with respect to the nominal frequency ν_0 . The quantity $\delta\nu(t)/\nu_0$ is called the *fractional frequency fluctuation*³ at time t and is signified by the variable $y(t)$. We then have

$$y(t) = \frac{\delta\nu(t)}{\nu_0} = \frac{\dot{\phi}(t)}{2\pi\nu_0} \quad (21)$$

The fractional frequency fluctuation $y(t)$ is a dimensionless quantity. When talking about frequency stability, its appropriateness becomes clearer if we consider the following example. Suppose that in two oscillators $\delta\nu(t)$ is consistently equal to +1 Hz and we have sampled this value for many times t . Are the two oscillators equal in their ability to produce their desired output frequencies? Not if one oscillator is operating at 10 Hz and the other at 10 MHz. In one case, the average value of the fractional frequency fluctuation is 1 in 10, and in the second is 1 in 10,000,000 or 1×10^{-7} . The 10 MHz oscillator is then more accurate. If frequencies are multiplied or divided using ideal electronics, the fractional stability is not changed.

In the frequency domain, we can measure the spectrum of frequency fluctuations $y(t)$. The spectral density of fre-

quency fluctuations is denoted by $S_y(f)$ and is obtained by passing the signal from an oscillator through an ideal FM detector and performing spectral analysis on the resultant output voltage. $S_y(f)$ has dimensions of (fractional frequency)²/Hz or Hz^{-1} . Differentiation of $\phi(t)$ corresponds to multiplication by f/ν_0 in terms of spectral densities. With further calculation, one can deduce that

$$S_y(f) = \left(\frac{f}{\nu_0}\right)^2 S_\phi(f) \quad (22)$$

We will address primarily $S_\phi(f)$, that is, the spectral density of phase fluctuations. For the purpose of noise measurements, $S_\phi(f)$ can be measured with a straightforward, easily duplicated equipment setup. Whether one measures phase or frequency spectral densities is of minor importance since they bear a direct relationship. It is important, however, to make the distinction and to use Eq. (22) when necessary.

4.1. The Loose Phase-Locked Loop

In Section 1.1.3 we described a method of measuring phase fluctuations between two phase-locked oscillators. Now we will review a common procedure for measuring $S_\phi(f)$.

Suppose that we have a noisy oscillator. We wish to measure the oscillator’s phase fluctuations relative to nominal phase. One can do this by phase-locking another oscillator (called the *reference oscillator*) to the test oscillator, and mixing the two oscillator signals 90° out of phase (phase quadrature). This is shown schematically in Fig. 15. The two oscillators are at the same frequency in the long term, as guaranteed by the phase-locked loop (PLL). A lowpass filter (to filter the RF sum component) is used after the mixer since the difference (baseband) signal is the one of interest. By holding the two signals at a relative phase difference of 90°, short-term phase fluctuations between the test and reference oscillators will appear as voltage fluctuations from the mixer.

With a PLL, if we can make the servo time constant very long, then the PLL bandwidth as a filter will be small. This may be done by lowering the gain A_v of the loop amplifier. We want to translate the phase modulation

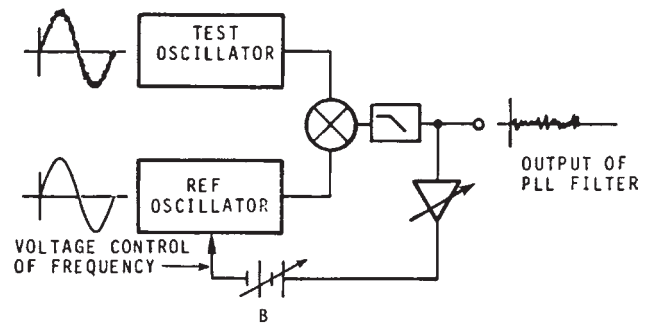

Figure 15. The *phase noise* of a test oscillator is usually measured by a loose phase-locked loop. The test and reference oscillators will naturally lock so that their signals have a phase difference of 90 deg. and the PLL output voltage fluctuations correspond to phase fluctuations between the oscillators.

²As an analogy, the same operation relates the velocity of an object to its acceleration.

³Some international recommendations replace “fractional” by “normalized.”

spectrum to baseband spectrum so that it is easily measured on a low-frequency spectrum analyzer. With a PLL filter, we must keep in mind that the reference oscillator should be as good as or better than the test oscillator. This is because the output of the PLL represents the noise from both oscillators, and if not properly chosen, the reference can have noise masking the noise from the test oscillator. Often, the reference and test oscillators are of the same type and have, therefore, approximately the same noise levels. We can acquire a meaningful measurement by noting that the noise we measure is from two oscillators. Many times a good approximation is to assume that the measured noise power is twice that associated with either single oscillator. $S_{\phi}(f)$ is general notation depicting spectral density on a reciprocal hertz (Hz^{-1}) basis. The output from PLL filter necessarily yields noise from two oscillators.

The output of the PLL filter at Fourier frequencies above the loop bandwidth is a voltage representing phase fluctuations between reference and test oscillator. It is necessary to make the time constant of the loop long compared to the inverse of the lowest Fourier frequency that we wish to measure, that is, $\tau_c > [1/2\pi f(\text{lowest})]$. This means that if we want to measure $S_{\phi}(f)$ down to 1 Hz, the loop time constant must be greater than $1/2\pi$ seconds. We can measure the time constant by perturbing the loop (momentarily disconnecting the battery is convenient) and noting the time it takes for the control voltage to reach 70% of its final value. The signal from the mixer can then be inserted into a spectrum analyzer. A preamplifier may be necessary in the signal path into the spectrum analyzer.

The analyzer determines the mean-square voltage that passes through the analyzer's bandwidth centered around a prechosen Fourier frequency f . It is desirable to normalize results to a 1 Hz bandwidth. Assuming white phase noise (white PM), this can be done by dividing the mean-square voltage by the analyzer bandwidth in hertz. We may have to approximate for other noise processes. [The phase noise sideband levels will usually be indicated in RMS volts per root hertz ($\text{V}/\sqrt{\text{Hz}}$) on most analyzers.]

4.2. Equipment for Frequency-Domain Stability Measurements

4.2.1. Low-Noise Mixer. This should be a high quality, double-balanced type as shown in Fig. 16 but single-ended types may be used. The oscillators should have well-buffered outputs to be able to isolate the coupling between the two input RF ports of the mixer. Results that are too good

Figure 16. A low noise mixer is a key component for precise phase-noise measurements.

may be obtained if the two oscillators couple tightly via signal injection through the input ports. We want the PLL to control locking. One should read the specifications in order to prevent exceeding the maximum allowable input power to the mixer. However, it is best to operate near the maximum for best signal-to-noise ratio out of the IF port of the mixer, and, in some cases, it is possible to drive the mixer into saturation without burning out the device.

4.2.2. Low-Noise DC Amplifier. The amount of gain A_v needed in the loop amplifier will depend on the amplitude of the mixer output and the degree of varactor control in the reference oscillator. We may need only a small amount of gain to acquire lock. On the other hand, it may be necessary to add as much as 80 dB of gain. Good low-noise DC amplifiers are available from a number of sources, and with cascading stages of amplification, each contributing noise, it will be the noise of the first stage that will add most significantly to the noise being measured. Amplifiers with very low equivalent input noise performance are available from many manufacturers. The response of the amplifier should be flat from DC to the highest Fourier frequency one wishes to measure. The loop time constant is inversely related to the gain A_v , and A_v is best determined experimentally by sweeping the system with known modulation applied at the output of one oscillator [9].

4.2.3. Voltage-Controlled Reference Quartz Oscillator. This oscillator should be a good one with specifications available on its frequency-domain stability. The reference must be no worse than the test oscillator in the frequency domain. The varactor control should be sufficient to maintain phase lock of the reference. In general, test oscillators of moderate quality may have varactor control of as much as 1×10^{-6} fractional frequency change per volt. Some provision should be available on the reference oscillator for tuning the mean frequency over a frequency range that will enable phase lock. Many factors enter into the choice of the reference oscillator, and often it is convenient to simply use two test oscillators phase-locked together. In this way, we can assume that the noise out of the PLL filter is no worse than 3 dB greater than the noise from each oscillator. If it is uncertain whether both oscillators contribute approximately equal noise, then we should perform measurements on three oscillators, taking two at a time. The noisier-than-average oscillator will reveal itself.

4.2.4. Spectrum Analyzer. The signal analyzer should typically be capable of measuring the noise in RMS volts in a narrow bandwidth from near 1 Hz to the highest Fourier frequency of interest. This may be 50 kHz for carrier frequencies of 10 MHz or lower and several megahertz for microwave carrier frequencies. For voltage measuring analyzers, it is typical to use units of "volts per $\sqrt{\text{Hz}}$ ". The spectrum analyzer and any associated input amplifier will exhibit high-frequency rolloff. The Fourier frequency at which the voltage has dropped by 3 dB is the measurement system bandwidth f_h , or $\omega_h = 2\pi f_h$. This can be measured directly with a variable signal generator.

A frequency-domain measurement setup is shown schematically in Fig. 17. The component values for the lowpass filter out of the mixer are suitable for oscillators operating at around 5 MHz.

The active gain element (A_v) of the loop is a DC amplifier, hopefully with flat frequency response, or, if not, a known frequency response. One may replace this element by an integrator to achieve high gain near DC and hence, maintain better lock of the reference oscillator in long term. Otherwise long-term drift between the reference and test oscillators might require manual re-adjustment of the frequency of either oscillator [1,6].

Rather than measure the spectral density of phase fluctuations between two oscillators, it is possible to measure the phase fluctuations introduced by a device such as an active filter or amplifier. Only a slight modification of the existing PLL filter equipment setup is needed. The required scheme is shown in Fig. 18.

Figure 18 is a *differential phase noise measurement* setup. The output of the reference oscillator is split so that part of the signal passes through the device under test. We want the two signals going to the mixer to be 90° out of phase; thus, phase fluctuations between the two input ports cause voltage fluctuations at the output. The voltage fluctuations then can be measured at various Fourier frequencies on a spectrum analyzer.

To estimate the noise inherent in the test setup, one can in principle bypass the device under test and compensate for any change in amplitude and phase at the mixer. In order to measure inherent test equipment noise, the PLL filter technique must be converted to a differential phase noise technique. It is good practice to measure the system noise before proceeding to measurement of device noise.

4.3. Procedure and Example

For all of these setups, at the input to the spectrum analyzer, the voltage varies as the phase fluctuations in short term. The conversion to spectral density is

$$S_\phi(f) = \left(\frac{V_{RMS}(f)}{V_s(f)} \right)^2,$$

$$\text{and } \mathcal{L}(f) = \frac{1}{2} S_\phi(f)$$

Figure 17. Typical hookup for a phase-noise measurement using a loose PLL.

where V_s is the phase sensitivity of the mixer in volts per radian at offset frequency f . Using the setup described previously, V_s can be measured by disconnecting the feedback loop to the varactor of the reference oscillator. The peak voltage swing is equal to V_s in units of V/rad (volts per radian) if the resultant beat note is a sine wave at frequency f . This may not be the case for state-of-the-art $S_\phi(f)$ measurements, where one must drive the mixer very hard to achieve low mixer noise levels. Hence the output will not be a sine wave, and the V/rad sensitivity must be estimated by the slew rate (through zero volts) of the resultant square wave from the mixer/amplifier.

The value for the measured $S_\phi(f)$ in decibels is given by

$$S_\phi(f) = 20 \log \frac{V_{RMS}(f)}{V_s \text{ full-scale } \phi - \text{detector voltage at } f}$$

Example 2. Given a PLL with two oscillators such that at the mixer output: $V_s = 1 \text{ V/rad}$ with a beat frequency $f = 45 \text{ Hz}$, $V_{RMS}(45 \text{ Hz}) = 100 \text{ nV}$ per root hertz. Solve for $S_\phi(45 \text{ Hz})$:

$$S_\phi(45 \text{ Hz}) = \left(\frac{100 \text{ nV/Hz}^{-1/2}}{1 \text{ V/rad}} \right)^2 = \left(\frac{10^{-7}}{1} \right)^2 \text{ rad}^2/\text{Hz}$$

$$= 10^{-14} \frac{\text{rad}^2}{\text{Hz}}$$

$$\mathcal{L}(45 \text{ Hz}) = 5 \times 10^{-15} \frac{\text{rad}^2}{\text{Hz}}$$

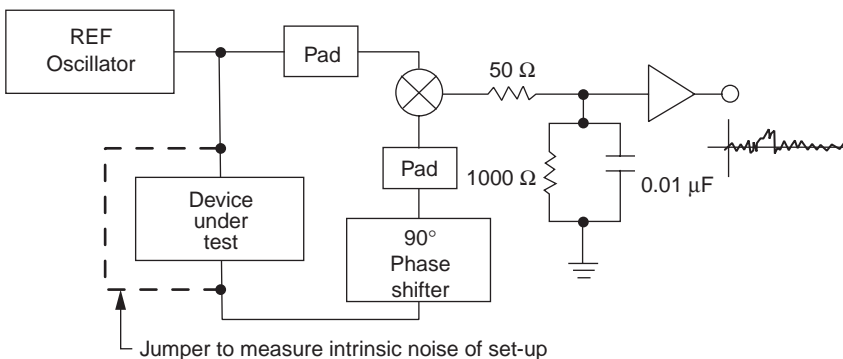

Figure 18. A differential measurement and measurement of the noise floor (by replacing the device under test with a through-cable) requires a 90 deg. phase shift at one of the mixer inputs.

In decibels

$$S_{\phi}(45 \text{ Hz}) = 20 \log \frac{100 \text{ nV}}{1 \text{ V}} = 20 \log \frac{10^{-7}}{10^0}$$

$$= 20(-7) = -140 \text{ dB at } 45 \text{ Hz,}$$

$$\mathcal{L}(45 \text{ Hz}) = -143 \text{ dB at } 45 \text{ Hz}$$

In the example, note that the mean frequency of the oscillators in the PLL was not essential to computing $S_{\phi}(f)$. However, in the application of $S_{\phi}(f)$, the mean frequency ν_0 is necessary information. Along with $S_{\phi}(f)$, one should always refer to ν_0 . In the example above, where $\nu_0 = 5 \text{ MHz}$, we have

$$S_{\phi}(45 \text{ Hz}) = 10^{-14} \frac{\text{rad}^2}{\text{Hz}}, \nu_0 = 5 \text{ MHz}$$

From Eq. (22), $S_y(f)$ can be computed as

$$S_y(45 \text{ Hz}) = \left(\frac{45}{5 \times 10^6} \right)^2 10^{-14} \frac{\text{rad}^2}{\text{Hz}}$$

$$= 5.1 \times 10^{-25} \text{ Hz}^{-1}, \nu_0 = 5 \text{ MHz.}$$

5. POWER-LAW NOISE PROCESSES

Power-law noise processes are models of precision oscillator noise that produce a particular *slope* on a spectral density plot. We often classify these noise processes into one of five categories. For plots of $S_{\phi}(f)$, they are

1. Random-walk FM (random walk of frequency), S_{ϕ} plot goes down as $1/f^4$.
2. Flicker FM (flicker of frequency), S_{ϕ} plot goes down as $1/f^3$.
3. White FM (white of frequency), S_{ϕ} plot goes down as $1/f^2$.
4. Flicker PM (flicker of phase), S_{ϕ} plot goes down as $1/f$.
5. White PM (white of phase), S_{ϕ} plot is flat.

Power-law noise processes are characterized by their functional dependence on Fourier frequency. Equation (22) relates $S_{\phi}(f)$ to $S_y(f)$, the spectral density of frequency fluctuations.

The spectral density plot of a typical oscillator’s output is usually a combination of different power-law noise processes. It is very useful and meaningful to categorize the noise processes. The first job in evaluating a spectral density plot is to determine which type of noise exists for a particular range of Fourier frequencies. It is possible to have all five noise processes generated from a single oscillator, but in general only two or three noise processes are dominant. Figure 19 is a graph of $S_{\phi}(f)$ showing the five noise processes on a log–log scale. Figure 20 shows the

Figure 19. Power-law noise is indicated by a particular slope in the phase-noise measurement.

spectral density of phase fluctuations for a typical 5-MHz quartz oscillator.

6. CAUSES OF NOISE TYPES IN A SIGNAL SOURCE

6.1. Power-Law Noise Processes

Section 5 pointed out the five commonly used power-law models of noise. With respect to $S_{\phi}(f)$, one can estimate a straight-line slope (on a log–log scale) that corresponds to a particular noise type. This is shown in Fig. 19.

We can make the following general remarks about power-law noise processes:

1. Random-walk FM ($1/f^4$) noise is difficult to measure since it is usually very close to the carrier. “Random-walk FM” usually relates to the oscillator’s physical environment. If random walk FM is a predominant feature of the spectral density plot, then mechanical shock, vibration, temperature, or other environmental effects may be causing “random” shifts in the carrier frequency.
2. Flicker FM ($1/f^3$) is a noise whose physical cause is seldom fully understood but may typically be related

Figure 20. Different power-law noises have different causes in an oscillator’s output signal.

Figure 21. 60 Hz and harmonics are easily distinguished in a phase-noise measurement.

to the physical resonance mechanism of an active oscillator, or the design or choice of parts used for the electronics, or environmental properties. Flicker FM is common in high-quality oscillators, but may be masked by white FM ($1/f^2$) or flicker PM ($1/f$) in lower-quality oscillators.

3. White FM ($1/f^2$) noise is a common type found in passive-resonator frequency standards. These contain a slave oscillator, often quartz crystal, which is locked to a resonance feature of another device that behaves much like a high- Q filter. Cesium and rubidium standards have white FM noise characteristics.
4. Flicker PM ($1/f$) noise may relate to a physical resonance mechanism in an oscillator, but it usually is added by noisy electronics. This type of noise is common even in oscillators of the highest quality because in order to bring the signal amplitude up to a usable level, amplifiers are used after the signal source. Flicker PM noise may be introduced in these stages. It may also be introduced in a frequency multiplier. Flicker PM can be reduced with good low-noise amplifier design (i.e., using RF negative feedback) and hand-selecting transistors and other electronic components.
5. White PM (f^0) noise is broadband phase noise and has little to do with the resonance mechanism. It is probably produced by phenomena similar to that of flicker PM ($1/f$) noise. Stages of amplification are usually responsible for white PM noise. This noise can be kept at a very low value with good amplifier design, hand-selected components, the addition of narrowband filtering at the output, or, if feasible, increasing the power of the primary frequency source.

6.2. Other Types of Noise

A commonly encountered type of noise from a signal source or measurement apparatus is the presence of

60-Hz AC line noise. Shown in Fig. 21 is a constant white PM noise source with 60-, 120- and 180-Hz components added. This kind of noise is usually caused by AC power getting into the measurement system or the source under test. In the plot of $S_\phi(f)$, we observe discrete line spectra. Although $S_\phi(f)$ is a measure of spectral density, we can interpret the line spectra with no loss of generality, although one seldom refers to spectral densities when characterizing discrete lines. Figure 22 is the time-domain representation of the same white phase modulation level with 60-Hz noise. Note that the amplitude of $\sigma_y(\tau)$ varies up and down depending on sampling time. This is because in the time domain the sensitivity to a periodic wave varies directly as the sampling interval. This effect (which is an aliasing effect) can be used as a tool for filtering out a periodic wave imposed on a signal source. By sampling in the time domain at integer periods, we can be virtually insensitive to the periodic (discrete line) term, which is a useful strategy for removing the effect of the periodic wave.

Figure 22. It is not easy to interpret an Allan deviation plot when 60 Hz noise is present on an oscillating signal.

Figure 23. An oscillator under vibration causes sideband modulation that is apparent in a phase-noise measurement.

Figure 24. The Allan deviation of an oscillator under vibration causes a general increase in the level of frequency instability.

For example, diurnal variations in data due to day-to-day temperature, pressure, and other environmental effects can be eliminated by sampling the data once per day. This approach is useful for data with only one periodic term.

Figure 23 shows the kind of plot one might see of $S_{\phi}(f)$ with vibration and acoustic sensitivity in the signal source with the device under vibration. Figure 24 shows the translation of this effect to the time domain. Also noted in Fig. 23 is a (typical) flicker FM behavior in the low-frequency region. In the translation to time domain (Fig. 24), the flicker FM behavior masks the white PM (with the superimposed vibration characteristic) for long averaging times.

FREQUENCY STANDARDS, CHARACTERIZATION

EVA S. FERRE-PIKAL
 University of Wyoming
 Laramie, Wyoming
 FRED L. WALLS
 Total Frequency
 Boulder, Colorado

In this article we describe the characterization of frequency standards following the general definitions accepted by the IEEE, the International Telecommunication Union—Radiocommunications (ITU-R), and International Radio

Consultative Committee (CCIR) [1–3]. In using the term “frequency standard”, we imply that changes in the frequency $\Delta\nu$ of the device are small compared to its nominal frequency ν_0 and that therefore the frequency would be about the same if we were to remeasure it. This permits us to treat the variations in fractional frequency $\Delta\nu/\nu_0$ as small compared to 1, and this greatly simplifies the mathematics of the characterization. We describe what is meant by accuracy and frequency stability of a frequency standard. The variations in frequency (which define the frequency stability) can be classified into two basic types: random and systematic. To characterize the random variations in frequency, the systematic effects must be removed from the data. Special statistical techniques other than the standard variance must then be used to quantify the random variations in frequency because some of the noise processes are not stationary. By this we mean that the mean of the frequency noise changes slowly with time. As part of the statistical treatment, we describe how to determine the confidence intervals for the estimates of the various types of random frequency noise.

1. ACCURACY

Frequency standards generate a periodic voltage signal, whose ideal frequency is defined as a specific number of oscillations per second. The second is the agreed unit of time, based on the energy difference between two energy levels of the unperturbed cesium atom [4], and it is this definition that allows the specification of accuracy of a frequency standard. Generally there will be offsets or biases in the actual frequency of a standard when compared to the ideal or defined value (according to the definition of the second) due to systematic and random effects [5–7]. The *accuracy* of a frequency standard, more recently described as an uncertainty, is a measure of the confidence relative to a physical model of the standard and the evaluation process. To evaluate the accuracy of a frequency standard, all the known sources of frequency offsets are listed, and the offset or bias due to each source and its uncertainty are carefully measured or computed. The uncertainty is a proper summation of the estimates of various systematic offsets and random noise [8]. For example, a frequency standard with an output frequency of 10 MHz and an uncertainty of 10^{-8} has a frequency error of $\leq \pm 0.1$ Hz.

2. STABILITY

Figure 1 shows the output voltage signal of an ideal *frequency standard* as a function of time. The maximum value V_0 is the nominal amplitude of the signal. The time required for the signal to repeat itself is the period T of the signal. The nominal frequency ν_0 of the signal is the reciprocal of the period, $1/T$. This voltage signal can be represented mathematically by a sine function

$$v(t) = V_0 \sin \theta = V_0 \sin(2\pi\nu_0 t) \tag{1}$$

Figure 1. Ideal output voltage of a frequency standard.

where the argument $\theta = 2\pi\nu_0 t$ of the sine function is the nominal phase of the signal. The time derivative of the phase θ is $2\pi\nu_0$ and is called the *nominal angular frequency* ω_0 . In the frequency domain, this ideal signal is represented by a delta function located at the frequency of oscillation. Since this signal is ideal, there are no known sources that cause frequency shifts, and thus its frequency is *totally accurate* and its uncertainty is 0. Furthermore, its frequency, phase, and amplitude are constant; therefore the signal is also stable in frequency, phase, and amplitude.

In real situations, the output signal of an oscillator (source) or frequency standard has noise. Such a *noisy signal* is illustrated in Fig. 2. In this example we have depicted a case where the noise power is much less than the signal power. Frequency instability is the result of fluctuations in the period of the signal. Amplitude instability is the result of fluctuations in the peak values of the voltage. Phase instability is the result of fluctuations in the zero crossings. Since the period (and thus the frequency) of the signal is related to its phase, frequency instability and phase instability are directly related.

Figure 3 shows the *power spectrum of a noisy signal* (power as a function of frequency) as measured by a spectrum analyzer. Although the maximum power occurs at the frequency of oscillation, other peaks are observed at frequencies of $2\nu_0, 3\nu_0, \dots, n\nu_0$, where n is a positive integer. These frequencies are called *harmonics* of the fundamental frequency ν_0 ; $2\nu_0$ is the second harmonic, $3\nu_0$ is the third harmonic, and so on. The power at these harmonic frequencies will depend on the design of the source. The spectrum around the fundamental frequency displays power sidebands at frequencies above the carrier (upper

Figure 2. Output voltage of a noisy signal.

Figure 3. Power spectrum of a noisy signal.

sideband) and at frequencies below the carrier (lower sideband). These power sidebands are the result of phase fluctuations and amplitude fluctuations in the signal. While the power spectrum gives an idea of the total noise of a signal, it does not give information about the relative magnitude of its phase instabilities and amplitude instabilities. Furthermore, at frequencies close to v_0 it is difficult to separate the noise power from the power of the fundamental frequency. Therefore, special measurement techniques are needed to measure phase instabilities and amplitude instabilities in sources.

A noisy signal can be mathematically represented by

$$v(t) = [V_0 + \varepsilon(t)] \sin[2\pi v_0 t + \phi(t)] \quad (2)$$

where $\varepsilon(t)$ represents amplitude fluctuations (amplitude deviation from the nominal amplitude V_0) and $\phi(t)$ represents phase fluctuations (phase deviation from the nominal phase $2\pi v_0 t$) [1]. The instantaneous frequency of this signal is defined as

$$v(t) = \frac{1}{2\pi} \frac{d}{dt}(\text{phase}) = v_0 + \frac{1}{2\pi} \frac{d}{dt} \phi(t) \quad (3)$$

Frequency fluctuations refer to the deviation $v(t) - v_0$ of the instantaneous frequency from the nominal frequency. Fractional frequency fluctuations, denoted as $y(t)$, refer to frequency fluctuations normalized to v_0 :

$$y(t) = \frac{v(t) - v_0}{v_0} = \frac{1}{2\pi v_0} \frac{d}{dt} \phi(t) \quad (4)$$

Equation (4) indicates that there is a direct relation between phase fluctuations and fractional frequency fluctuations. Therefore, if a signal exhibits a certain amount of phase fluctuation, it also exhibits frequency fluctuation given by Eq. (4). The time deviation $x(t)$ of a signal is the integral of $y(t)$ from 0 to t . Thus one can write

$$y(t) = \frac{d}{dt} x(t) \quad (5)$$

The frequency stability of a frequency standard is affected by random-noise processes and by systematic, deterministic changes. Systematic effects often dominate the frequency stability in nonlaboratory environments. The sensitivity of the standard to temperature, humidity, atmospheric pressure, magnetic field, and radiation may play a role [9–11]. Generally, frequency (and thus phase) stability is divided into three regions: short-term, medium-term, and long-term stability. (Although the term *frequency stability* is used throughout most of the literature, the term actually refers to instabilities in the frequency.)

Short-term frequency stability refers to the random, nonsystematic fluctuations that are related to the signal-to-noise ratio (SNR) of the device. In quartz crystal resonators this refers to the region dominated by white phase noise, where the time between observed frequencies (sample time) is less than a second. In atomic frequency standards the short-term stability also includes white frequency noise and extends to sampling times of several minutes.

Medium-term frequency stability refers to the region where flicker noise dominates. The sampling time characteristic of this region is a function of the type of frequency standard. Short-term and medium-term frequency stability can be characterized in either the frequency domain or the time domain, after known systematic effects have been removed. Frequency-domain characterization and measurements are generally used when the sample time of interest is less than a second. For sampling times longer than a second, time-domain measurements are used to characterize frequency stability.

Long-term frequency stability includes random-walk frequency-noise processes in addition to systematic, deterministic changes in frequency observed when the sampling time is long. The long-term, systematic frequency change is called *frequency drift* [2,12]. Drift includes frequency changes due to changes in the components of the source in addition to those due to external parameters such as temperature, humidity, pressure, magnetic field, and radiation [9–11]. Frequency *aging*, on the other hand, refers to the long-term systematic frequency change due to changes in the components of the source, independent of parameters external to the source [2,12].

2.1. Frequency-Domain Characterization

Phase fluctuations in the frequency domain, or *phase modulation (PM) noise*, are characterized by the power spectral density (PSD) of the phase fluctuations, given by [13]

$$S_\phi(f) = \mathcal{F}[\mathcal{R}_\phi(\tau)] = \int_{-\infty}^{\infty} \mathcal{R}_\phi(\tau) e^{-j\omega\tau} d\tau \quad (6)$$

where $\mathcal{F}[\]$ is the Fourier transformation and $\mathcal{R}_\phi(\tau)$ is the autocorrelation function of the phase fluctuations given by

$$\mathcal{R}_\phi(\tau) = \langle \phi(\tau)\phi(t - \tau) \rangle \quad (7)$$

A more practical definition of PSD [$\phi(t)$] is

$$S_\phi(f) = \text{PSD}[\phi(t)] = [\phi(f)]^2 \frac{1}{\text{BW}} \quad (8)$$

where $[\phi(f)]^2$ is the mean-squared phase deviation at an offset frequency f from the frequency ν_0 (called the “carrier” in this context), and BW is the bandwidth of the measurement system [1,13–15]. The offset frequency f is also called the *Fourier frequency*. The units for $S_\phi(f)$ are rad^2/Hz . Equation (8) is defined for $0 < f < \infty$; nevertheless, it includes fluctuations from the upper and lower sidebands and thus is a double-sideband measure.

The PM noise measure recommended by the IEEE [1,14,15] is $\mathcal{L}(f)$, defined as

$$\mathcal{L}(f) \equiv \frac{S_\phi(f)}{2} \quad (9)$$

At Fourier frequencies far from the carrier frequency, where the integrated PM noise from ∞ to f (the Fourier frequency) is less than 0.1 rad^2 , $\mathcal{L}(f)$ is equal to the single-sideband phase noise. The units for $\mathcal{L}(f)$ are decibels below the carrier in a 1-Hz bandwidth (dBc/Hz).

Frequency fluctuations in the frequency domain, or *frequency modulation (FM) noise*, are characterized by the power spectral density of the fractional frequency fluctuations, given by

$$S_y(f) = \text{PSD}[y(t)] = [y(f)]^2 \frac{1}{\text{BW}} \quad (10)$$

where $y(f)^2$ represents the mean-squared fractional frequency deviation at an offset (Fourier) frequency f from the carrier [1,13–15]. $S_y(f)$ is defined for Fourier frequencies $0 < f < \infty$, and its units are inverse hertz.

The conversion between $S_y(f)$ and $S_\phi(f)$ can be obtained from Eq. (4). Applying the Fourier transformation to both sides of Eq. (4), squaring, and dividing by the measurement bandwidth results in

$$S_y(f) = \left(\frac{1}{2\pi\nu_0} \right)^2 (2\pi f)^2 S_\phi(f) = \left(\frac{f}{\nu_0} \right)^2 S_\phi(f) \quad (11)$$

Amplitude fluctuations in the frequency domain, or *amplitude modulation (AM) noise*, are characterized by the power spectral density of the fractional amplitude fluctuations, given by

$$S_a(f) = \text{PSD} \left[\frac{\varepsilon(t)}{V_0} \right] = \left[\frac{\varepsilon(f)}{V_0} \right]^2 \frac{1}{\text{BW}} \quad (12)$$

where $\varepsilon(f)^2$ represents the mean squared amplitude deviation at an offset frequency f from the carrier [1]. $S_a(f)$ is defined for Fourier frequencies $0 < f < \infty$, and its units are inverse hertz.

In free-running sources, the FM noise is usually modeled by the sum of five different power laws or noise types as

$$S_y(f) = \sum_{\alpha=-2}^2 h_\alpha f^\alpha = h_{-2}f^{-2} + h_{-1}f^{-1} + h_0f^0 + h_1f^1 + h_2f^2 \quad (13)$$

where $h_{-2}f^{-2}$ represents random-walk frequency noise, $h_{-1}f^{-1}$ represents flicker frequency noise, h_0f^0 represents white frequency noise, h_1f^1 represents flicker phase noise, and h_2f^2 represents white phase noise. Similarly, the PM noise can be modeled by

$$S_\phi(f) = \sum_{\beta=-4}^0 k_\beta f^\beta = k_{-4}f^{-4} + k_{-3}f^{-3} + k_{-2}f^{-2} + k_{-1}f^{-1} + k_0f^0 \quad (14)$$

where $k_{-4}f^{-4}$ represents the random-walk frequency noise, $k_{-3}f^{-3}$ represents flicker frequency noise, $k_{-2}f^{-2}$ represents white frequency noise, $k_{-1}f^{-1}$ represents flicker phase noise, and k_0f^0 represents white phase noise. Notice that $S_\phi(f)$ and $S_y(f)$ have different slopes for a specific type of noise, as implied by Eq. (11). Equation (11) can be used to obtain the conversion between the $S_\phi(f)$ and $S_y(f)$ coefficients, yielding

$$k_\beta = \nu_0^2 h_\alpha \quad \text{for } \beta = \alpha - 2 \quad (15)$$

Figure 4 shows the common noise types characteristic of the PM noise and the FM noise of a source [1,14–17]. Usually a source exhibits two or three of the noise types shown in the plots [17].

The AM noise of a source can typically be modeled by the sum of three different power laws of noise types:

$$S_a(f) = \sum_{\alpha=-2}^0 h_\alpha f^\alpha = h_{-2}f^{-2} + h_{-1}f^{-1} + h_0f^0 \quad (16)$$

where $h_{-2}f^{-2}$ represents random-walk amplitude noise, $h_{-1}f^{-1}$ represents flicker noise, and h_0f^0 represents white amplitude noise [18]. Figure 5 shows the common noise types characteristic of the AM noise of a source.

Upper and lower PM sidebands are always equal and 100% correlated. Likewise, the upper and lower AM sidebands are always equal and 100% correlated. This is true even when the RF spectrum is not symmetric about the carrier [19]. The phase between AM and PM noise varies randomly with time for broadband additive noise [19].

2.2. Time-Domain Characterization

In the time domain, the *fractional frequency stability* of a signal is usually characterized by the Allan variance, a type of two-sample frequency variance given by [1,13–15]

$$\sigma_y^2(\tau) = \frac{1}{2} \langle (\bar{y}_{i+1} - \bar{y}_i) \rangle \quad (17)$$

where \bar{y}_i is the average fractional frequency of interval i given by

$$\bar{y}_i = \frac{1}{\tau} \int_{t_i}^{t_i + \tau} y(t) dt = \frac{1}{\tau} [x(t_i + \tau) - x(t_i)] = \frac{1}{\tau} (x_{i+1} - x_i) \quad (18)$$

In practical situations only a finite number of fractional frequency samples are available, and the Allan variance is

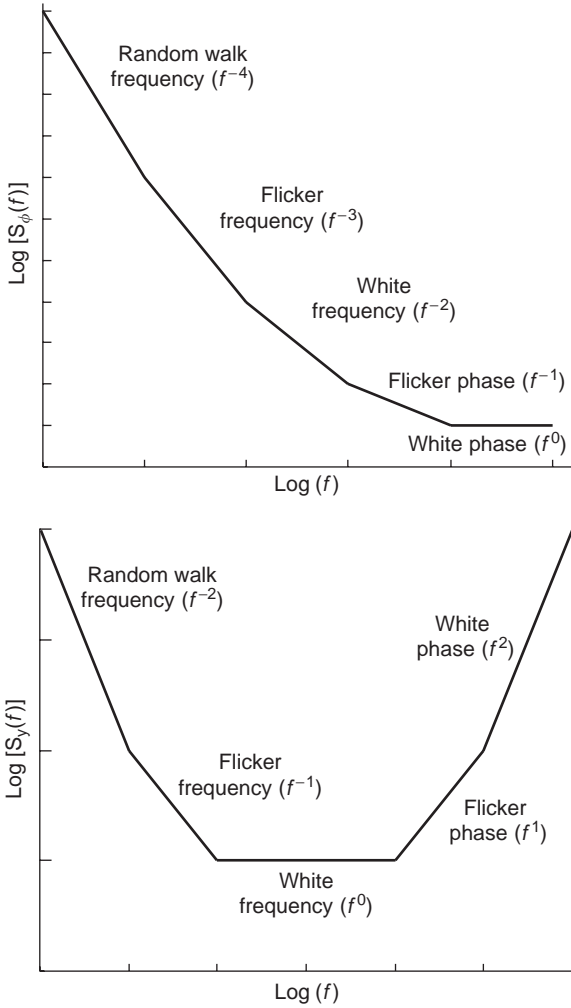

Figure 4. PM and FM noise characteristics of a source.

approximated by

$$\sigma_y^2(\tau) \approx \frac{1}{2(M-1)} \sum_{i=1}^{M-1} (\bar{y}_{i+1} - \bar{y}_i)^2 \quad (19)$$

where $M = N - 1$ is the number of frequency samples (N is the number of time samples) [1,14,15]. The Allan variance

Figure 5. AM noise characteristics of a source.

can also be expressed in terms of time samples using $\bar{y}_i = (x_{i+1} - x_i)/\tau$:

$$\sigma_y^2(\tau) \approx \frac{1}{2(N-2)\tau^2} \sum_{i=1}^{N-2} (x_{i+2} - 2x_{i+1} + x_i)^2 \quad (20)$$

The square root of the Allan variance is called the *Allan deviation*, $\sigma_y(\tau)$.

When time samples are taken every τ_0 seconds, the Allan variance can be computed for several sampling times $\tau = n\tau_0$ where $n > 0$. For $n > 1$, overlapped samples can be used to compute σ_y^2 as shown in Fig. 6, providing better confidence intervals [1,20]. An expression for the fully overlapped Allan variance can be derived using Fig. 6 and Eq. (19). For $\tau = n\tau_0$, Eq. (19) becomes

$$\sigma_y^2(\tau) \approx \frac{1}{2(M-2n)} \sum_{i=1}^{M-2n} (\bar{y}_{i+n} - \bar{y}_i)^2 \quad (21)$$

which can also be expressed in terms of time-domain data by substituting \bar{y}_i for $(x_{i+n} - x_i)/n\tau_0$:

$$\sigma_y^2(\tau) \approx \frac{1}{2(N-2n)\tau^2} \sum_{i=1}^{N-2n} (x_{i+2n} - 2x_{i+n} + x_i)^2 \quad (22)$$

Figure 7a shows a log-log plot of the Allan variance as a function of the sampling time τ for a source that exhibits all five common noise types. The slopes of the white PM noise and the flicker PM noise are the same; therefore, these two noise types cannot be separated using this plot. The Allan variance can often be modeled by the sum of four different power laws

$$\sigma_y^2(\tau) = \sum_{\mu=-2}^1 p_\mu \tau^\mu = p_{-2}\tau^{-2} + p_{-1}\tau^{-1} + p_0\tau^0 + p_1\tau^1 \quad (23)$$

where $p_{-2}\tau^{-2}$ represents white phase and flicker phase noise, $p_{-1}\tau^{-1}$ represents white frequency noise, $p_0\tau^0$ represents flicker frequency noise, and $p_1\tau^1$ represents random-walk frequency noise.

When the dominant noise type in the short term is flicker PM or white PM, the modified Allan variance can be used to improve the estimate of the underlying frequency stability of the sources [1,14,21]. Here a new series $\{\bar{x}_i\}$ is created by averaging n adjacent phase (time) measurements of duration τ_0 . The average fractional frequencies are computed from the $\{\bar{x}_i\}$, as illustrated in Fig. 8. For

Figure 6. Computation of $\{\bar{y}_i\}$ for the overlapped Allan variance and $n = 2$.

Figure 7. $\sigma_y^2(\tau)$ and $\text{Mod } \sigma_y^2(\tau)$ for the five noise types.

N time samples and $\tau = n\tau_0$, the resulting modified Allan variance is

$$\text{Mod } \sigma_y^2(\tau) \approx \frac{1}{2(N-3n+1)} \sum_{i=1}^{N-3n+1} (\bar{y}'_{i+n} - \bar{y}'_i)^2 \quad (24)$$

Equation (24) can also be expressed in terms of the initial time-domain data $\{x_k\}$:

$$\text{Mod } \sigma_y^2(\tau) \approx \frac{1}{2\tau^2 n^2 (N-3n+1)} \times \sum_{j=1}^{N-3n+1} \left[\sum_{i=j}^{n+j-1} (x_{i+2n} - 2x_{i+n} + x_i) \right]^2 \quad (25)$$

Figure 8. Computation of $\{\bar{x}_i\}$ and $\{\bar{y}'_i\}$ for the modified Allan variance and $n=3$.

where

$$\bar{y}'_i = \frac{\bar{x}_{i+n} - \bar{x}_i}{\tau} \quad (26)$$

$$\bar{x}_i = \frac{\sum_{k=0}^{n-1} x_{i+k}}{n} \quad (27)$$

Here \bar{x}_i is the phase (time) averaged over n adjacent measurements of duration τ_0 . Thus $\text{Mod } \sigma_y(\tau)$ is proportional to the second difference of the phase averaged over a time $n\tau_0$. Viewed from the frequency domain, $\text{Mod } \sigma_y(\tau)$ is proportional to the first difference of the frequency averaged over n adjacent samples. The square root of the modified Allan variance is called the *modified Allan deviation* $\text{Mod } \sigma_y(\tau)$.

Figure 9 shows the ratio $R(n) = [\text{Mod } \sigma_y^2(\tau)] / \sigma_y^2(\tau)$ as a function of n for all five types of noise processes [15]. For random-walk FM, flicker FM, and white FM the ratio is constant for $n \geq 5$. Therefore, $\text{Mod } \sigma_y^2(\tau)$ and $\sigma_y^2(\tau)$ have the same slope for these noise types. For white PM noise ($\alpha=2$), the slope is $-1/n$; therefore, the slope of $\text{Mod } \sigma_y^2(\tau)$ is equal to the slope of $\sigma_y^2(\tau)$ divided by τ . Finally, for flicker PM noise the ratio asymptotically reaches $3.37/(1.04 + 3 \ln \omega_h \tau)$. In this case and for $n > 10$, the slope of $\text{Mod } \sigma_y^2(\tau)$ is approximately τ^{-1} . Figure 9 also shows that $\text{Mod } \sigma_y^2(\tau)$ is considerably smaller than $\sigma_y^2(\tau)$ for white PM and flicker PM noise. Not only does $\text{Mod } \sigma_y^2(\tau)$ provide a different slope for white PM noise and flicker PM noise, allowing the separation of the two noise processes (see Fig. 7b); it can also speed the stability measurements. If a system is limited by white and flicker PM noise at short average times, using $\text{Mod } \sigma_y^2(\tau)$ reduces the measurement time required to observe white FM, flicker FM, and random-walk FM at longer averaging times, in comparison with that required when using $\sigma_y^2(\tau)$ [15].

At long averaging times when the ratio $N\tau_0/(2n\tau_0)$ is close to 1, the Allan variance has a bias related to its insensitivity to odd noise processes in the phase (time) fluctuations (odd with respect to the midpoint). In these situations an extension of the Allan variance that removes this bias can be used to characterize the frequency stability of a source. This variance, $\sigma_{y,\text{TOTAL}}^2(\tau)$, is obtained by extending the $\{x_i\}$ in both directions and then computing the Allan variance from the new $\{x'_i\}$ sequence [22–24]. Figure 10 illustrates this extension of $\{x_i\}$: on the left side the extension is the inverted mirror image of $\{x_i\}$ with

Figure 9. Ratio of the modified Allan variance to the Allan variance, $R(n) = [\text{Mod } \sigma_y^2(\tau)] / \sigma_y^2(\tau)$, as a function of n [15]; $\tau = n\tau_0$.

respect to x_N . How far this extension depends on the maximum value of n_m of n . For N time data points, n_m is the integer part of $(N - 1)/2$. The far-left data point is $x'_{2-n_m} = 2x_1 - x_{n_m}$; the far-right data point is $x'_{N+n_m-1} = 2x_N - x_{N-n_m+1}$. Thus $\sigma_{y,\text{TOTAL}}^2(\tau)$ is given by

$$\hat{\sigma}_{y,\text{TOTAL}}^2(\tau) = \frac{1}{2(N-2)} \sum_{i=2}^{N-1} (\bar{y}'_i - \bar{y}'_{i-n})^2 \quad (28)$$

Equation (28) can be expressed in terms of $\{x'_i\}$ using $\bar{y}'_i = (x'_{i+n} - x'_i) / \tau$ as

$$\hat{\sigma}_{y,\text{TOTAL}}^2(\tau) = \frac{1}{2\tau^2(N-2)} \sum_{i=2}^{N-1} (x'_{i-n} - 2x'_i + x'_{i+n})^2 \quad (29)$$

For a detailed description of $\sigma_{y,\text{TOTAL}}^2(\tau)$, see Refs. 22–24.

Figure 10. Extension of $\{x_i\}$ for $\sigma_y^2(\tau)$.

3. CONVERSION BETWEEN TIME-DOMAIN MEASURES AND FREQUENCY-DOMAIN MEASURES

Frequency-domain data $S_\phi(f)$ can be converted to time-domain data $\sigma_y^2(\tau)$ using the relation [1,25]

$$\sigma_y^2(\tau) = \frac{2}{(\pi\nu_0\tau)^2} \int_0^{f_h} S_\phi(f) \sin^4(\pi f\tau) df \quad (30)$$

Equation (30) is derived by expressing both $S_\phi(f)$ and $\sigma_y^2(\tau)$ in terms of the autocorrelation function $\mathcal{R}_\phi(\tau)$ of the random process $\phi(t)$ and then combining the two expressions to cancel $\mathcal{R}_\phi(\tau)$ [13]. Similarly

$$\sigma_y^2(\tau) = \frac{2}{(\pi\tau)^2} \int_0^{f_h} S_y(f) \frac{\sin^4(\pi f\tau)}{f^2} df \quad (31)$$

Expressions for $\text{Mod } \sigma_y^2(\tau)$ (15,24), obtained using a similar procedure are

$$\text{Mod } \sigma_y^2(\tau) = \frac{2}{n^4(\pi\nu_0\tau_0)^2} \int_0^{f_h} \frac{S_\phi(f) \sin^6(\pi\tau f)}{\sin^2(\pi\tau_0 f)} df \quad (32)$$

$$\text{Mod } \sigma_y^2(\tau) = \frac{2}{n^4(\pi\tau_0)^2} \int_0^{f_h} \frac{S_y(f) \sin^6(\pi\tau f)}{f^2 \sin^2(\pi\tau_0 f)} df \quad (33)$$

The inclusion of f_h as the upper limit of the integral assumes that the term inside the integral is multiplied or “filtered” by an infinitely sharp lowpass filter with cutoff frequency f_h . Table 1 shows the results of Eqs. (31) and (33) for the five types of noise for $2\pi f_h \tau \gg 1$ [1,14–16,25]. The results will depend on the type of filter assumed. While an infinitely sharp filter was assumed in Eqs. (30)–(33), actual measurement systems have different filter responses.

Table 1. Conversion Factors for $\sigma_y^2(\tau)$ and Mod $\sigma_y^2(\tau)$ [1,14–16,25]

Noise Type	$S_y(f)$	$\sigma_y^2(\tau)$	Mod $\sigma_y^2(\tau)$
Random-walk frequency	$h_{-2}f^{-2}$	$(2\pi^2\tau/3)h_{-2}$	$5.42h_{-2}\tau$
Flicker frequency	$h_{-1}f^{-1}$	$(2\ln 2)h_{-1}$	$0.936h_{-1}$
White frequency	h_0f^{08}	$h_0/2\tau$	$h_0/4\tau$
Flicker phase	h_1f^1	$\frac{1.038 + 3 \ln(\omega_h\tau)}{4\pi^2}h_1\frac{1}{\tau^2}$	$\frac{3.37}{4\pi^2}h_1\frac{1}{\tau^2}$
White phase	h_2f^2	$\frac{3f_h}{4\pi^2}h_2\frac{1}{\tau^2}$	$\frac{3f_h}{4\pi^2}h_2\frac{1}{n\tau^2}$

Expressions have also been derived for a single-pole filter [15,26,27]. These expressions, along with those in Table 1, constitute the boundaries for $\sigma_y^2(\tau)$ and Mod $\sigma_y^2(\tau)$, given a specific PSD of phase fluctuations [15]. For this reason it is important to specify the filter frequency response, including the high cutoff frequency, when specifying the Allan and modified Allan variances of a source.

Generally, conversion from $\sigma_y^2(\tau)$ or Mod $\sigma_y^2(\tau)$ to the frequency domain is not possible, unless specific information about the noise characteristics is known. Greenhall demonstrated that several different spectral densities of random processes can have the same Allan variance [28]. However, in the case where the spectral density follows the noise model in Eqs. (13) and (14), a one-to-one correspondence between $S_\phi(f)$ and $\sigma_y^2(\tau)$ and Mod $\sigma_y^2(\tau)$ is found, except that for white PM and flicker PM noise $\sigma_y^2(\tau)$ exhibits the same slope, corresponding to τ^{-2} . Often, uniqueness fails more generally. Some sources have internal phase-locked loops, and their noise spectra deviates from the model in Eqs. (13) and (14), [29]; others exhibit 60-Hz and other peaks that will affect $\sigma_y^2(\tau)$ [16,30]. Generally, multivariate analysis should be used to obtain frequency-domain coefficients for each type of noise from time-domain data [31].

4. CONFIDENCE INTERVALS FOR $\sigma_y^2(\tau)$ AND MOD $\sigma_y^2(\tau)$

The Allan variance is defined as the first difference of average fractional frequencies, averaged over an infinite time. Since only a finite number M of frequency samples can be taken, we can only estimate the Allan variance and deviation, and the confidence of this estimate depends on the number of samples.

A simple method to obtain confidence intervals is to use the chi-squared distribution function. The Allan variance has a chi-squared distribution function given by

$$\chi^2 = \text{df} \frac{\hat{\sigma}_y^2(\tau)}{\sigma_y^2(\tau)} \quad (34)$$

where df is the number of degrees of freedom [16]. The Allan variance is the sum of the squares of the first differences of adjacent fractional frequency values. If all the

first-difference values were independent, then the number of degrees of freedom would be equal to the number of first-difference values. This is not the case, and thus other procedures have been used to compute the number of degrees of freedom for $\sigma_y^2(\tau)$ [16]. Table 2 shows analytical (empirical) equations that approximate the number of degrees of freedom for the fully overlapped Allan variance [16]. The equation depends on the noise type. For nonoverlapped estimates, n in Table 2 is equal to 1, N refers to the equivalent number of time samples for $\tau = n\tau_0$ given by $\text{Int}((N-1)/n) + 1$, and $\text{Int}(\)$ refers to the integer part.

Usually a $(p \times 100)\%$ confidence interval is computed, where p is the probability that the true Allan variance or Allan deviation is within the computed confidence interval. The $(p \times 100)\%$ confidence interval for the overlapped Allan variance is given by

$$\chi^2\left(\frac{1-p}{2}\right) < \text{df} \frac{\hat{\sigma}_y^2(\tau)}{\sigma_y^2(\tau)} < \chi^2\left(p + \frac{1-p}{2}\right) \quad (35)$$

$$\frac{\text{df}}{\chi^2\left(p + \frac{1-p}{2}\right)} \hat{\sigma}_y^2(\tau) < \sigma_y^2(\tau) < \frac{\text{df}}{\chi^2\left(\frac{1-p}{2}\right)} \hat{\sigma}_y^2(\tau) \quad (36)$$

where the chi-squared value $\chi^2(C)$ for $(p \times 100)\%$ confidence can be obtained from chi-squared distribution tables or from several computer programs. The $(p \times 100)\%$ confidence interval for the Allan deviation is

$$\sqrt{\frac{\text{df}}{\chi^2\left(p + \frac{1-p}{2}\right)}} \hat{\sigma}_y(\tau) < \sigma_y(\tau) < \sqrt{\frac{\text{df}}{\chi^2\left(\frac{1-p}{2}\right)}} \hat{\sigma}_y(\tau) \quad (37)$$

The chi-squared distribution can also be used to find the confidence intervals for Mod $\sigma_y^2(\tau)$.

Table 2. Empirical Equations for the Number of Degrees of Freedom When Computing Confidence Intervals for the Overlapped Allan Variance [16]

Noise Type	α	Degrees of Freedom df
White phase	-2	$\frac{(N+1)(N-2n)}{2(N-n)}$
Flicker phase	-1	$\exp\left[\ln\left(\frac{N-1}{2n}\right) \ln\left(\frac{(2n+1)(N-1)}{4}\right)\right]^{1/2}$
White frequency	0	$\left(\frac{3(N-1)}{2n} - \frac{2(N-2)}{N}\right) \frac{4n^2}{4n^2+5}$
Flicker frequency	+1	$\frac{2(N-2)^2}{2.3N-4.9}$ for $n=1$ $\frac{5N^2}{4n(N+3n)}$ for $n \geq 2$
Random-walk frequency	+2	$\frac{N-2}{n} \frac{(N-1)^2 - 3n(N-1) + 4n^2}{(N-3)^2}$

Table 3. Confidence Intervals for the Nonoverlapped and Fully Overlapped $\sigma_y(\tau)$ [16] and for the Fully Overlapped Mod $\sigma_y(\tau)$ [32–34]^a

n	Noise Type	Confidence Interval (%)					
		Nonoverlapped $\sigma_y(\tau)$		Fullyoverlapped $\sigma_y(\tau)$		Fully overlapped Mod $\sigma_y(\tau)$	
		–	+	–	+	–	+
2	White PM	4.1	4.8	2.9	3.2	3.1	3.4
8		7.7	10.1	2.9	3.2	5.2	6.1
32		13.6	23.1	3.0	3.4	9.7	14
2	Flicker PM	3.7	4.3	2.9	3.1	3.0	3.3
8		7.1	9.0	3.6	4.0	5.7	6.8
32		12.7	20.7	5.2	6.1	11	16
2	White FM	3.6	4.0	2.8	3.0	3.0	3.2
8		6.8	8.6	4.8	5.6	5.8	7.0
32		12.5	20.1	8.8	12	11	16
2	Flicker FM	3.2	3.5	2.6	3.0	2.9	3.2
8		6.1	7.4	5.1	6.0	5.8	7.1
32		11.1	16.8	9.9	14	11	16
2	Random-walk FM	3.0	3.3	3.0	3.3	3.2	3.5
8		5.7	6.8	5.7	7.0	6.4	8.0
32		10.4	15.2	11	16	12	19

^aConfidence intervals for the nonoverlapped $\sigma_y(\tau)$ were obtained using the df in Table 2 [16]. The degrees of freedom used for the fully overlapped $\sigma_y(\tau)$ were computed using numerical methods and are approximately equal to those obtained using Table 2 [16,20]. Confidence intervals for the fully overlapped Mod $\sigma_y(\tau)$ were obtained from Ref. 34 ; $N = 1025$.

Walter [32] and Greenhall [33] have derived expressions for the number of degrees of freedom of Mod $\sigma_y^2(\tau)$ using different procedures. These expressions are complicated and will not be presented here. The two methods yield similar results (33). Table 3 shows the confidence intervals for $\sigma_y(\tau)$ with no overlap and full overlap (16), (19), and for Mod $\sigma_y(\tau)$ [32–34] for the five noise types. In general, the confidence intervals for the fully overlapped $\sigma_y(\tau)$ are smaller than those for the non-overlapped $\sigma_y(\tau)$. For random-walk FM noise, the confidence intervals for the nonoverlapped and the fully overlapped $\sigma_y(\tau)$ are approximately the same, although Table 3 shows a small degradation when using fully overlapped estimates. This degradation is due to the approximations used in the analytical expressions. Table 3 also shows that the confidence intervals for the fully overlapped Allan deviation are smaller than the ones for the fully overlapped modified Allan deviation. Nevertheless, the modified deviation is generally smaller than the Allan deviation, and thus the absolute confidence intervals for the two are similar.

FREQUENCY SYNTHESIZERS

BAR-GIORA GOLDBERG
Sciteq Electronics, Inc.

Frequency synthesis is the engineering discipline dealing with generation of a single or of multiple tones, all derived from a common timebase, always a crystal oscillator.

Traditionally, frequency synthesis (FS) generated a single tone with variable frequency or amplitude. There are new applications, especially for testing and simulation, that require multitone generation and even arbitrary wave generation, which relate to digital frequency synthesis. Since the late 1970s, FS has evolved from mainly analog to a mix of analog, radiofrequency (RF), digital, and digital signal processing (DSP) technologies.

There are three major FS techniques:

1. *Phase-Locked Loop*. Also known as *indirect synthesis*, this is the most popular FS technique, based on a feedback mechanism that enables simplicity and economics via digital division and analog processing.
2. *Direct Analog*. An analog technique using multiplication, division, and mix filtering, this offers excellent signal quality and speed.
3. *Direct Digital*. This DSP method generates and manipulates the signal in the numbers (digital) domain and eventually converts to its analog form via a digital-to-analog converter.

Frequency synthesis is a mature technology yet is evolving rapidly. The traditional analog designs are supplemented with ever-increasing digital and DSP methods and technologies. These allow a high level of integration, lower power, manufacturing uniformity (and thus yield uniformity), and low cost. Although a novel technology in 1979, FS and especially the phase-locked loop (PLL) are very popular, accessible, and economical. Traditionally, FS started to enter the field of electronics as quite bulky and expensive instruments, using multiple crystals and complex analog processing functions such as mixing, filtering, and division. Better architectures and simpler designs have replaced these. Accelerating integrated circuit (IC) technology and high-level integration silicon now offer complete synthesizers, especially PLL and direct digital synthesizers (DDSs) on a single chip and sometimes more than one on a single die (Tables 1 and 2).

Table 1. Integrated Circuits Used in Phase-Locked Loops

Fujitsu Semiconductors: MB15xx
National Semiconductors: 23xx
Philips: SA7025, SA8025, UMA1014
Motorola: MC145xxx
Plessey: SP55xx, SP56xx, SP88xx
Texas Instruments: TRF2020, 2050, 2052

In the engineering realm, all signals generated are *amplified and filtered noise*. There are no deterministic signals in nature. The cardinal issue for FS is therefore how clean these signals are and how close they come to a theoretical $\sin(\omega t)$. Such a theoretical signal will have all of its energy in a single spectral line. In reality, signal spectra have a noise distribution caused by amplitude modulation (AM) noise and phase perturbation, also known in FS as *phase noise*. Phase noise can be described by its spectral properties, usually its noise distribution designated in dBc/Hz, or its time equivalent, also known as “jitter”. Spectral distribution $L(fm)$ details the exact spectral shape of the signal’s noise and is defined by the single-sideband energy level of the signal at a specific offset from the carrier relative to the signal’s total energy. This detailed technique has become the de facto method used to describe and characterize phase noise (see Fig. 1).

For example, a 1000-MHz signal with a spectral noise characteristic of -70 dBc/Hz (dB is used almost exclusively because of the large ratios involved) at an offset of 1 kHz from the carrier means that at 1 kHz from the carrier (either 1000.001 or 999.999 MHz), the single-sideband noise power contained in 1 Hz bandwidth is 10^{-7} compared with the signal’s total power. The function $L(fm)$ that defines the noise distribution spectrum is always measured in decibels of the noise level. Note that the noise is part of the signal and that the integral energy under the $L(fm)$ curve is the signal total power (Fig. 1).

1. SYNTHESIZER PARAMETERS

1.1. Stepsize

This is also known as *resolution*, and it measures the smallest frequency increment the synthesizer can generate. As an example, an FS used in a North American cellular phone (AMPS—American Mobile Phone Service—standard), or time-division multiple access (TDMA), has 30 kHz resolution. In frequency modulation (FM) broadcasting radio, the step is usually 100 kHz.

Table 2. Integrated Circuits Used in Direct Digital Synthesis

Analog Devices: AD7008, AD9830/9831, AD9720/9721
Sciteq Communications: SEI-432, SEI-631, DCP-1

**Figure 1.** Phase noise of a typical synthesizer.

1.2. Phase Noise

This parameter was already mentioned before. The issue of signal integrity, or otherwise the issue of the signal’s “cleanliness,” is the major challenge for FS designers. Long-term noise deals mainly with the accuracy, drift, and aging of the crystal, and short-term noise deals with rapid phase fluctuations.

1.3. Spurious Responses

These define the level of the discrete interferences, noise sources that are periodic and therefore exhibit spectral lines rather than a spectrum. These noise sources emerge from radiation—for example, line spurious responses at 60 Hz (US)—or from its multiples that always exist in the air and power supplies, as well as from other radiated energy that exists because of the enormous wireless traffic that is emerging and growing. Other sources are mixing products in the radio or synthesizer, nonlinearities, and ground currents.

1.4. Switching Speed

This defines the amount of time it takes the synthesizer to hop from a frequency F_1 to another F_2 . This parameter is usually measured in two ways: by checking when the new frequency settles to within a frequency tolerance (say, within 5 kHz), or (a more strict requirement) by checking the time it takes to settle to within a phase tolerance, in most cases to within 0.1 rad. The phase settling requirement can be as much as 3–5 times longer than the frequency settling.

1.5. Phase Transient

This defines the way the signal’s phase behaves in transition from frequency F_1 to frequency F_2 . There are three main ways to switch:

1. It might be a random parameter, so the phase is unknown after switching.

2. The phase can switch continuously, meaning that when switching from F_1 to F_2 , there will be no disturbance in the phase. Such switching requirements are necessary when generating linear FM signals or minimum shift keying (MSK) modulation, or other phase modulation waveforms.
3. In the case of phase memory, if switched from F_1 to F_2 and then back to F_1 , the signal's phase will be as if the switching did not occur. This is useful in coherent detection radars and frequency-hop communications.

1.6. Frequency Range

This defines the frequency band the FS covers.

1.7. Other Parameters

Other parameters are not unique to FS; these include output impedance, power flatness, size, power consumption, and the environment.

The main tools used in FS are as follows: multiplication by comb generation, addition and subtraction by mix and filtering, and division (digital) and feedback for PLL. Another cardinal principle in FS is as follows—multiplication by N corrupts phase noise and spurious by N^2 or $20 \log(N)$ dB; division improves by the same ratio.

2. SYNTHESIS TECHNIQUES

2.1. Direct Analog Synthesis

This method, the first to be used in FS, derives the signals directly from the reference—as compared to PLL, which it does indirectly. Direct analog uses building blocks such as comb generators, mix and filter, and dividers as the main tools. Many direct analog synthesizers use similar repeating blocks for resolution. These blocks usually generate a 10 MHz band in the ultra-high-frequency (UHF) range, in 1 MHz steps, and after division (mostly by 10) they are used as an input to the next similar stage. Every stage divides by 10, thereby increasing the resolution arbitrarily by as many stages as the designer chooses to use. Most direct analog synthesizers are instruments and traditionally use binary-coded decimal (BCD) for control. This is losing importance because a computer controls all modern applications.

Signals are therefore very clean because they are derived directly from the crystal; however, complexity is high and resolution comes at a high price. Direct analog synthesizers also achieve fast switching speed, limited mainly by filters propagation delay. Speed ranges from <1 to $50 \mu\text{s}$. Because there are no mechanisms to clean the signals at high offset frequencies from the carrier, their noise floor—where the phase noise levels—is comparatively (to PLL) high.

Direct analog synthesizers are available from DC to 26 GHz, are usually quite bulky and expensive, exhibit excellent phase noise and switching speed, and find applications in communications, radar, imaging, magnetic

resonance imaging, simulators, and automatic test equipment (ATE).

2.2. Direct Digital Synthesis (DDS)

DDS is a DSP technology based on the sampling theorem. The principle of its operation is based on storing the digital values of sine-wave amplitude in memory, then flushing these samples out by addressing the memory with an indexer. The indexer is always a digital accumulator, allowing the phase ramp (memory address) to change its slope to any value (compared with a counter that can index the RAM or ROM memory only by increments of 1).

As a consequence, the accumulator output can be interpreted as a signal phase, ωt (actually ωnT , where T is clock time, since it is sample data), with a variable slope given by the accumulator control. For example, if a 32 bit binary accumulator, which performs the function

$$S_n = S_{n-1} + W \quad (S_n \text{ is the output of sample } n, W \text{ is the input}) \tag{1}$$

is addressed with $W=0$, the output will not change, signifying direct current (dc) signal. However, if $W=1$, the accumulator will take 2^{32} clock ticks to come back to its original state. So a complete cycle of the phase from $\phi=0$ (accumulator is 0) to 2π (accumulator is full) takes 2^{32} ticks. Generally, a DDS output frequency is given by

$$F_o = F_{ck} W / \text{ACM} \tag{2}$$

where F_{ck} is the clock frequency, W is the input control, ACM is the accumulator size, and $W < \text{ACM}/2$.

For $\text{ACM} = 2^{32}$, $F_{ck} = 20 \text{ MHz}$, and $W = 1$, output frequency is given by $0.00465 \dots \text{ Hz}$, which is also the synthesizer resolution, its smallest step.

The read-only memory (ROM) output is connected to a digital-to-analog converter (DAC), which generates the analog signal smoothed by the output filter (see Fig. 2). According to the sampling theorem, the maximum output frequency is $F_{ck}/2$, also known as Nyquist frequency.

The various waveforms and modulation points are shown. Because the accumulator output is the signal phase, phase modulation can be applied; amplitude modulation can be applied at the output of the ROM, the amplitude point.

DDS is thus a numbers technology, related to frequency only by the clock. The artifacts caused by sampling generate many (mirror) frequencies as shown in the sampling theorem; these are usually referred to as aliasing frequencies.

DDS offers simplicity, economy, integration, and very fast switching speed. The digital nature of the technology offers design flexibility and simplicity, low-cost manufacturing, and very high density (small die).

As sampled data, DDS suffers the common problems of quantization. The level of accuracy determines the dynamic range of the design, in most cases 10–12 bits. The most significant weakness of DDS are limited bandwidth (clock frequencies are in the vicinity of 400 MHz

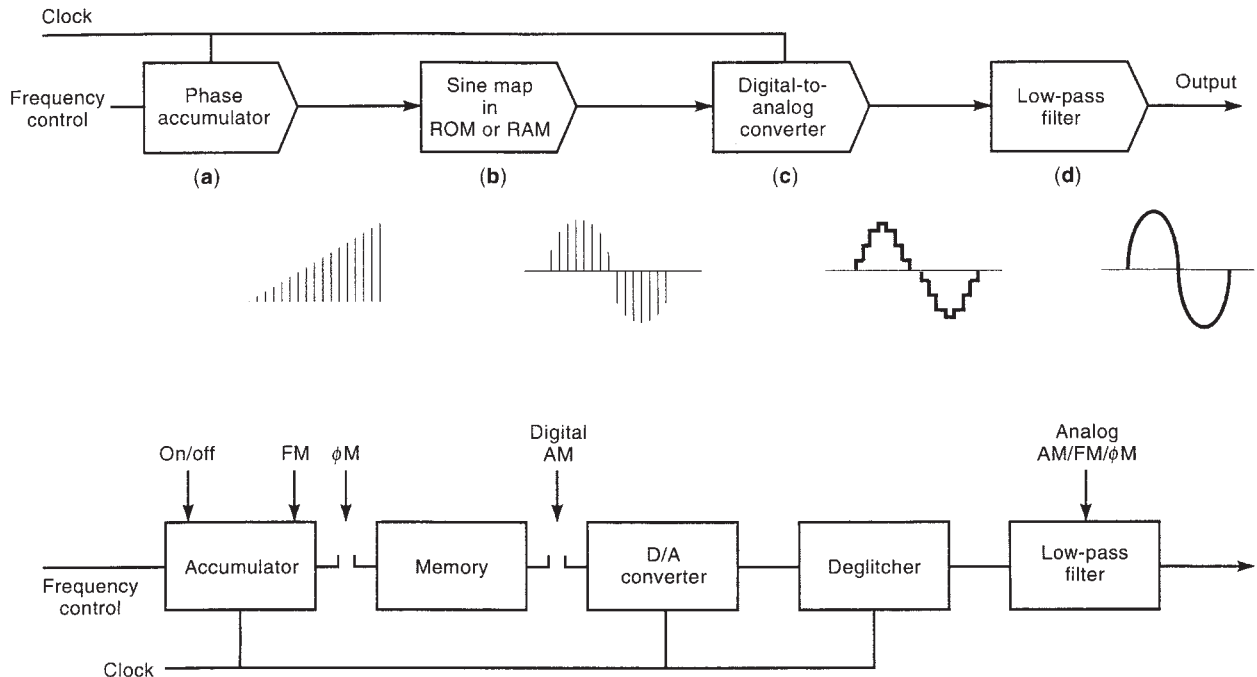

Figure 2. Direct digital synthesizer block diagram and functionality.

for CMOS devices and 1500 MHz for GaAs) and spurious response. Spurious responses are generally limited to $-6D$, where D is the number of bits used in the DAC. Thus a 10-bit DDS (using a 10 bit DAC) usually be limited to -60 dBC spurious responses. These spurious responses are either periodicities generated in the quantization process or intermodulation products generated by the DAC, the only analog part. As a rule of thumb, spurious performance deteriorates with increased output frequency or otherwise with decrease in samples per cycle. Arbitrary waveform generators (AWGs) are a superset of DDS. These enable the memory to be loaded with arbitrary wave samples, and then they sequentially flush the wave samples out. AWGs found use in simulation and testing.

2.3. Phase-Locked Loop

PLL is the technology of choice for generating radiofrequencies and microwave frequencies for radio applications. PLL, also known as *indirect synthesis*, is a negative-feedback loop structure that locks the phase of the output signal after division to the reference. Synthesis is simple because the variable counter (divider) N allows the generation of many frequencies F_o

$$F_o = NF_r \quad (F_o = \text{output frequency,} \\ F_r = \text{reference}) \quad (3)$$

by changing the division ratio N . Changing N is made easy by the use of dual modulus devices, capable of dividing by two (and sometimes more) ratios. For example, 64/65 or 128/129 are very common.

PLL chips are available in a great variety, in low power and at very low cost, and include all the functionality necessary with the exception of an external crystal, voltage-controlled oscillator (VCO) and loop filter (mainly resistors and capacitors). Convenience, economy, simplicity, and ease of use made PLL a household name used in television, radio, consumer electronics, cellular phones, and sat-com terminals, practically in almost any conceivable electronics radio (see Fig. 3).

When locked, PLL can be assumed to be a linear system, and classical feedback theory can be applied for analysis. The most common PLL structure is of second order, and there are two poles in the transfer function denominator: one from the VCO, with a Laplace domain transfer function given by K_v/s (K_v is the VCO constant, phase is the integral of frequency) and one from the loop filter having a memory device (capacitor). The loop transfer function is given by

$$\phi_o/\phi_i(s) = \frac{2\xi\omega_n s + \omega_n^2}{s^2 + 2\xi\omega_n s + \omega_n^2} \quad (4)$$

ω_n is the natural frequency and ξ is the damping, both borrowed from classical control theory. ω_n and ξ are given by (for the active loop structure shown in Fig. 4)

$$\omega_n = (K/T_1 N)^{0.5} \quad \text{and} \quad \xi = \omega_n T_2/2 \quad (5)$$

$T_1 = R_1 C$, $T_2 = R_2 C$, $K = K_v K_p/N$, K_v (Hz/V), and K_p (V/radian) are VCO and phase detector constants.

Overall performance is controlled by noise sources from phase detector, divider, and other active components within the loop bandwidth and by the VCO outside. Within the

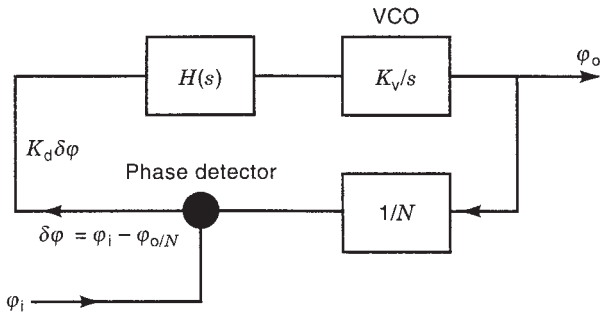

Figure 3. Phase lock loop block diagram.

loop bandwidth, VCO noise is suppressed by the loop. PLL noise sources within the loop are multiplied by $20 \log(N)$, which can be very significant when N is large. Typical phase detector noise is in the -150 dBc/Hz range for well-designed circuits. An advanced PLL technology known as fractional- n allows lowering N and generating step size smaller than F_r (hence fractional), thereby gaining phase noise performance. The fractional principle requires dynamic changes in division ratio N , thereby causing spurious signals, which are compensated by either extra filtering, analog feed forward correction (open loop), or digital waveshaping techniques.

FRIIS FREE-SPACE TRANSMISSION FORMULA

CURT A. LEVIS
 The Ohio State University
 Columbus, Ohio

1. STATEMENT OF THE FORMULA

For a free-space transmission path, the power P_r available at the receiving antenna terminals is related to the power input P_t at the transmitting antenna terminals by the ratio

$$\frac{P_r}{P_t} = \frac{A_t A_r}{\lambda^2 R^2} \tag{1}$$

In this expression A_r denotes the effective area of the receiving antenna in the direction of the transmitter, A_t is the effective area of the transmitting antenna in the direction of the receiver, λ is the wavelength, and R is the distance separating the transmitting and receiving antennas, all measured in compatible units (e.g., both powers in watts, both areas in square meters, λ and R in meters). An alternative form is

$$\frac{P_r}{P_t} = \frac{G_t G_r \lambda^2}{(4\pi)^2 R^2} \tag{2}$$

where G_t and G_r denote, respectively, the gain of the transmitting antenna in the direction of the receiver and the gain of the receiving antenna in the direction of the transmitter, and λ and R must be given in the same units. For convenience, a decibel formulation is sometimes used. Such formulations are obtained from Eq. (2) by setting $\lambda = c/f$, where c is the free-space velocity of light and f the frequency, converting quantities to the desired units (e.g., R from meters to kilometers), taking the common logarithm of both sides of the resulting equation, and multiplying by 10. Algebraic and arithmetic manipulation then yield expressions such as

$$P_{r,\text{dBW}} = P_{t,\text{dBW}} + G_{t,\text{dB}} + G_{r,\text{dB}} - 20 \log_{10} R_{\text{km}} - 20 \log_{10} f_{\text{MHz}} - 32.4 \tag{3}$$

In this example of the decibel (dB) form of the formula, the power at the transmitting antenna terminals, and the power available at the receiving antenna terminals are expressed in dBW (i.e., the power relative to one watt expressed in decibels), the distance is given in kilometers, and the frequency is given in megahertz. Other units might have been used. The value of the constant (here -32.4)

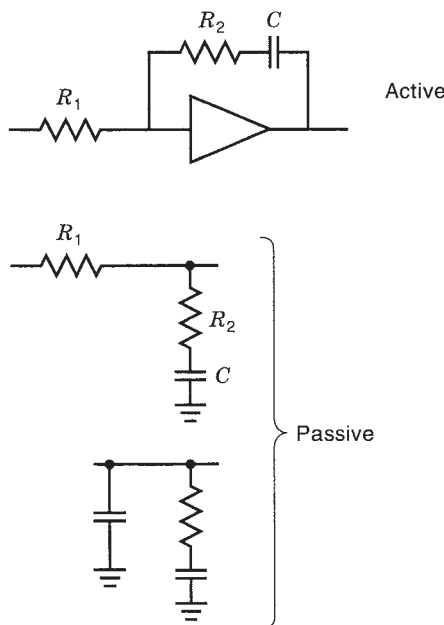

Figure 4. Second-order loop circuits.

depends on the units used. In the decibel form of the formula, the antenna gains are always specified in decibels.

2. ASSUMPTIONS

2.1. Free Space

The term “free space” implies that environmental effects, such as the effects of the ground and of the atmosphere, are negligible. This is sometimes a very good approximation. For example, in the case of a transmission from the Earth surface to a satellite appearing not too near the horizon in the frequency range 500 MHz–10 GHz, the antenna will usually be sufficiently directive to prevent substantial power from impinging on the ground. Also, in this frequency range atmospheric effects are small. Thus the Friis formulation is directly applicable. In other situations the free-space equation may be the starting formulation to which corrections for other effects (e.g., atmospheric attenuation, attenuation due to refraction by the ground) can be added. In fact, attenuation over a path is often specified as the attenuation relative to that for the same system in free space; the latter would be calculated by the Friis transmission formula [1].

2.2. Far Field

The antennas must be in the far field (Fraunhofer region) with respect to one another. This means that the distance must be sufficient so that the transmitted field at the receiving antenna is a spherical wave that may be approximated as a plane wave over the receiving antenna aperture. A frequently used criterion is that the longest and shortest paths between the two antenna apertures should not differ by more than $\frac{1}{16}$ wavelength.

2.3. Polarization

In this formulation it has been assumed that the polarization of the wave at the receiving antenna is optimal for that antenna; otherwise a polarization mismatch factor (in the decibel formula, a polarization mismatch term) must be included.

3. DERIVATION

Equations (1) and (2) can be derived easily from basic physical principles. For a lossless, isotropic transmitting

antenna the power applied to the input terminals would be spread uniformly over a sphere at radius R , giving a flux density

$$S_i = \frac{P_t}{4\pi R^2} \quad (4)$$

For an actual antenna, by the definition of antenna gain, the field in the receiver direction is obtained by

$$S = S_i G_t = \frac{P_t G_t}{4\pi R^2} \quad (5)$$

By definition of the effective area, the power available at the receiving antenna terminals for optimum polarization is given by

$$P_r = S A_r = \frac{P_t G_t A_r}{4\pi R^2} \quad (6)$$

Use of the relationship between gain and effective area

$$G = \frac{4\pi A}{\lambda^2} \quad (7)$$

then leads to either Equation (1) or (2).

4. HISTORICAL NOTE

The formulas (1) and (2) are named after Harald Trap Friis, who published Eq. (1) in 1946 while a research engineer at Bell Telephone Laboratories, Inc. [2] Mr. Friis later became Director of Research in High Frequency and Electronics at Bell Telephone Laboratories and was honored with numerous medals and awards for his technical work and his leadership.

GALERKIN METHOD (RAYLEIGH–RITZ METHOD)

DANIEL S. WEILE
 RAYMOND A. WILDMAN
 GREESHMA PISHARODY
 ANURAAG MOHAN
 University of Delaware
 Newark, Delaware

1. INTRODUCTION

Galerkin’s method and the Rayleigh–Ritz method are perhaps the primary techniques used in the computational solution of boundary value problems and eigenvalue problems involving linear ordinary and partial-differential equations. Galerkin’s method is also used for the discretization of integral equations. In modern computational electromagnetics (CEM), these methods form the basis for the now ubiquitous method of moments (MoM) and finite-element method (FEM) [1–6]. While the Rayleigh–Ritz and Galerkin methods are in principle very different, they often lead to the same set of discretized equations, are closely related, and are often discussed as if they were identical.

Both methods assume that the unknown function in the problem at hand can be well approximated by a series of *basis* or *coordinate* functions with unknown coefficients, and both methods create a system of equations to solve for these unknown coefficients. Because both methods use basis functions, we will generically refer to Galerkin’s method and the Rayleigh–Ritz method collectively as *basis function approaches*.

In the Rayleigh–Ritz approach, the original problem is reformulated as a *variational problem*. More specifically, a *functional* (i.e., a function that maps functions to real numbers) is created that has a stationary point (most often a minimum) at the solution of the differential equation. The basis function series is then substituted into this functional, transforming the functional into a simple function of the unknown coefficients. Minimizing this function with respect to the unknown coefficients gives rise to a set of linear algebraic equations to be solved for the unknowns.

In the Galerkin approach, the basis function series is substituted directly into the equation at hand. This equation is then projected onto each of the basis functions in turn (in a manner to be explained in more detail below), again giving rise to a set of linear algebraic equations to be solved for the unknown coefficients.

Before discussing Galerkin’s method and the Rayleigh–Ritz method in more detail, we note that these methods are not the only methods used for the discretization of differential and integral equations. Alternative methods are used quite often in the CEM community, and a brief discussion of these approaches serves to define the Galer-

kin and Rayleigh–Ritz methods by contrast. In the differential equations realm, the primary competitors to basis function approaches are finite-difference methods [7–9]. Instead of approximating the unknown function as a series of basis functions, finite-difference methods seek to find the value of the unknown function on a (usually very regular) grid of points. The derivatives in the differential equations are then approximated by finite differences, leading to a set of linear algebraic equations to be solved for the values of the unknown function at the grid points.

The primary competitor to basis function approaches in the field of integral equations is the Nyström method [10,11]. In the Nyström method, the integral in the integral equation is approximated using a numerical quadrature rule, and the resulting equation is enforced at the quadrature points. This leads to a set of linear algebraic equations for the value of the unknown function at the quadrature points. Note that the primary difference between these techniques and the basis function approaches discussed here is that the former methods do not use basis functions at all, but instead seek to find the value of the unknown function at a set of points. Thus, the nomenclature “basis function approaches” serves to distinguish the methods described here from these other *point-based approaches*. [Actually, even the point-based approaches may be interpreted as basis function approaches with the proper choice of basis and testing functions. Nonetheless, as discussed above, the motivation for the point-based methods is completely different from that of the basis function approaches. Most importantly, their governing equations can be (and usually are) derived without reference to basis function approaches at all.]

In the remainder of this article we discuss the two basis function approaches in detail. Section 2 relates a brief history of the two basis function approaches. Section 3 discusses the Rayleigh–Ritz method and provides examples of its application. The same is done for the Galerkin approach in Section 4. Finally, Section 5 briefly discusses the MoM and FEM, and gives a few examples of their applications.

2. A BRIEF HISTORY OF BASIS FUNCTION APPROACHES

The history of basis function approaches begins with the prolific third Lord Rayleigh (John William Strutt). Rayleigh was one of the most accomplished physicists of the late nineteenth and early twentieth centuries; his accomplishments include the first correct explanation of the blueness of the sky, and the discovery of the inert gas argon for which he received the Nobel prize in 1904 [12]. (Indeed, Rayleigh was so famous even in his own time that he succeeded no less a physicist than James Clerk Maxwell to become the second Cavendish professor of experimental physics at Cambridge University [12].) In his book *The Theory of Sound* [13], Rayleigh describes a method for the approximate determination of the lowest frequency of vibration of an acoustical system. To verify the method, he

first applies it to the problem of determining the lowest frequency of vibration of a stretched string. His argument and conclusions are presented here in a modernized notation.

Consider a string length l with a constant mass density ρ and tension τ . The string is supposed to exist along the line segment $-l/2 \leq x \leq l/2$, and its height at position x and time t will be denoted by $y(x,t)$. Now, a natural mode of the string occurs when $y(x,t)$ is nonzero in the absence of an external driving force. Since the natural modes of lossless linear systems are always sinusoidal, the displacement of the string may be taken to be

$$y(x,t) = v(x) \cos \omega t \tag{1}$$

The total kinetic energy of the string can be expressed as

$$T(t) = \frac{1}{2} \int_{-l/2}^{l/2} \rho \left(\frac{\partial y}{\partial t} \right)^2 dx = \omega^2 \sin^2 \omega t [\tilde{T}(v)] \tag{2}$$

where

$$\tilde{T}(f) = \frac{1}{2} \int_{-l/2}^{l/2} \rho [v(x)]^2 dx \tag{3}$$

Similarly, the total potential energy of the string may be written as

$$V(t) = \frac{1}{2} \int_{-l/2}^{l/2} \tau \left(\frac{\partial y}{\partial x} \right)^2 dx = \cos^2 \omega t [\tilde{V}(v)] \tag{4}$$

where

$$\tilde{V}(f) = \frac{1}{2} \int_{-l/2}^{l/2} \tau [v'(x)]^2 dx \tag{5}$$

and the prime denotes differentiation.

The requirement that the energy of the system remain constant implies that

$$\frac{d}{dt} [T(t) + V(t)] = 0 \tag{6}$$

So long as $\omega \neq 0$ (which indicates a trivial solution anyway), the value of ω corresponding to a given $v(x)$ that solves the appropriate wave equation is given by

$$\omega^2 = \frac{\tilde{V}(v)}{\tilde{T}(v)} \tag{7}$$

In the paragraph preceding his derivation of this result (which was slightly different than that presented here), Rayleigh made a heuristic argument for discrete problems that demonstrates that the minimum positive value of ω delivered by this expression (over all admissible functions v) is in fact the minimum frequency of free vibration of the system. He then suggested that formulas of the form of Eq. (7) might be useful for computing the minimum free vibration frequency of systems. Specifically, if a function

$v(x)$ is a good approximation to the true solution, in error by a linear quantity Δv , then the approximation of ω^2 will be in error only by a quantity of order $(\Delta v)^2$. Moreover, if a set of functions $\tilde{u}_n(x)$ is substituted into Eq. (7), the best estimate of ω^2 is necessarily the smallest.

For the problem given above, the true solution is found when

$$v(x) = u(x) = \cos\left(\frac{\pi x}{l}\right) \tag{8}$$

for which

$$\omega^2 = \frac{\pi^2 \tau}{\rho l^2} \tag{9}$$

(We will always use the variable v to indicate arbitrary functions, and the variable u to indicate true solutions. Trial solutions are indicated by \tilde{u}_n , where the subscript indicates some parameter defining the trial.) Rayleigh suggested testing the method with the set of functions

$$\tilde{u}_n(x) = 1 - \left(\frac{2|x|}{l}\right)^n \tag{10}$$

for $n \geq 1$, for which

$$\tilde{T}(\tilde{u}_n) = \frac{\rho l n^2}{(n+1)(2n+1)} \tag{11}$$

and

$$\tilde{V}(\tilde{u}_n) = \frac{2\tau n^2}{(2n-1)l} \tag{12}$$

These expressions lead to an approximation of the form

$$\omega_n^2 = \frac{2(n+1)(2n+1)}{2n-1} \frac{\tau}{\rho l^2} = \lambda_n^2 \frac{\tau}{\rho l^2} \tag{13}$$

From this expression, $\lambda_1 = \sqrt{12}$, off from the true value of π by a little more than 10%. Similarly, $\lambda_2 = \sqrt{10}$, a value in error by 0.65%. The best possible value of n is the one that minimizes Eq. (13); this value is $n_{\text{opt}} = \frac{1}{2}(1 + \sqrt{6}) \approx 1.72474$. Using this value in Eq. (13) gives rise to the value $\lambda_{n_{\text{opt}}} = 3.1463$ and a scant error of 0.149%.

Throughout the rest of *The Theory of Sound*, Rayleigh continues to apply this method to problems that cannot be solved analytically, especially problems involving inhomogeneous material parameters. While Rayleigh’s method as presented above has been superceded by the Ritz (i.e., Rayleigh–Ritz) method described below, Rayleigh quotients similar to Eq. (7) are still used today in numerical linear algebra in the eigenvalue computation technique known as *Rayleigh quotient iteration* [14].

Rayleigh’s method was generalized by the Swiss physicist Walther Ritz shortly before he died of tuberculosis in 1909 [15]. Specifically, Ritz proposed a method for the solution of physical problems expressed variationally;

that is, as the minimization of some functional. Suppose that a given physical problem involves the minimization of a functional $F(v)$, where v is an arbitrary admissible function. (Both eigenvalue problems and boundary value problems can be expressed in this way.) Ritz suggested that the solution u be approximated as a series of the form

$$u \approx \tilde{u}_N = \sum_{i=1}^N x_i u_i \tag{14}$$

where the x_i are unknown coefficients and the u_i are what Ritz called “coordinate functions” [16,17]. (In modern parlance, these would be deemed *basis functions*.) These basis functions are known functions that can well approximate the unknown function u . (Notationally, they are differentiated from the true solution by the existence of the subscript.) Substituting Eq. (14) into the functional yields a function of the x_i :

$$G(x_1, \dots, x_N) = F\left(\sum_{i=1}^N x_i u_i\right) \tag{15}$$

The difficult problem of minimizing the functional is now reduced to the simpler problem of minimizing G . Thus, the original problem can be approximately be solved by enforcing the equations

$$\frac{\partial G}{\partial x_i} = 0 \tag{16}$$

for $i = 1, \dots, N$. Ritz also showed that under certain conditions, if the basis function set u_i is complete as $N \rightarrow \infty$, then the solutions obtained will converge to the true solution [18]. (In addition, he asserted that it not possible, in general, to say the same about the convergence of the derivatives.) Ritz applied his method to find the deflection of a fixed plate under a normal load, to solve Dirichlet’s problem for the Laplace equation, to the computation of the natural oscillation frequencies of a string, and to many other more complex problems [16,17].

After Ritz, the story continues in Russia in 1913 where a naval architect named Ivan Grigorievich Bubnov was reviewing a paper on the stability of plates and beams written by Stephen Prokofyevich Timoshenko. Timoshenko was applying the Ritz method to the problem, and Bubnov noted that the same results could be achieved without resorting to variational expressions [18]. Specifically, Bubnov noted that the same equations generated by the Ritz method could be more easily derived by simply substituting the approximation of Eq. (14) into the original differential equation, and then multiplying the result by each basis function in turn and integrating over the domain. Bubnov apparently believed, however, that the basis functions needed to be orthogonal for the procedure to be applicable. Nonetheless, because of this contribution, the Galerkin method described below is often called the *Bubnov–Galerkin method*, especially in the Russian literature.

In 1915, Boris Grigorievich Galerkin published a paper entitled “Rods and plates. Series occurring in various

questions concerning the elastic equilibrium of rods and plates,” in which he introduced the method that now bears his name [19]. Formally identical to the method suggested by Bubnov, Galerkin’s method drops the condition that the basis functions be orthogonal. Furthermore, Galerkin makes no mention of the Rayleigh–Ritz method, quite possibly cementing his name in history.

Both the Rayleigh–Ritz method and the Galerkin method are used today in the numerical solution of partial-differential equations, and the Galerkin method is used in the solution of integral equations as well. Specifically, the Ritz method is used as the basis of the variational FEM with very little change. Many authors trace the development of the FEM to a 1943 paper by Richard Courant [15], who suggests that the Ritz method be used together with piecewise linear basis functions situated on a triangular mesh. Modern variationally based FEM algorithms differ little from this suggestion, and indeed the variational FEM can be accurately characterized as the Ritz method applied to finite basis functions.

Modern MoM and Galerkin-based FEM algorithms also differ little from Galerkin’s original outline. Some approaches derive the set of equations to be solved by multiplying the equation with a set of functions other than the original basis functions; this *weighted-residual method* is a straightforward generalization of the original Galerkin idea. (The functions iteratively multiplied by the equation before integration are called *weighting* or *testing functions*. Indeed, many MoM papers refer to the use of the basis functions for testing as Galerkin testing. This serves to differentiate Galerkin’s specific choice from the more general approach discussed in Section 4.)

Since the history of basis function methods begins with Rayleigh and Ritz, our discussion of the methods begins with the method that today bears their names.

3. THE RAYLEIGH–RITZ METHOD

In this section, the Rayleigh–Ritz method is described in detail. Because variational approaches are not familiar to many readers, Section 3.1 describes the calculus of variations. Section 3.2 then discusses variational principles important in mathematical physics. The Rayleigh–Ritz method is finally described and applied to boundary value problems in Section 3.3. Finally, Section 3.4 describes the application of the Rayleigh–Ritz method to eigenvalue problems.

3.1. The Calculus of Variations

As mentioned in Section 2, a functional is a mapping from some space of functions to some field (usually complex or real numbers). In the context of the Rayleigh–Ritz method, the stationary point of such a functional corresponds to the solution of some differential equation under study. Thus, before proceeding to describe the Rayleigh–Ritz method in more detail, a bit of the variational calculus will be reviewed here. For simplicity, the discussion in this section is restricted to one dimension.

Consider the functional described by the integral

$$I(v) = \int_a^b F(x, v, v') dx \tag{17}$$

where v is a function of x and v' denotes the derivative of v . The central problem in the calculus of variations is the determination of the function v that gives a minimum or maximum value to this integral, subject to the restrictions

$$\begin{aligned} v(a) &= v_a \\ v(b) &= v_b \end{aligned} \tag{18}$$

Suppose that the minimum of Eq. (17) is achieved for some function $v(x) = u(x)$. We wish to determine the differential equation satisfied by u . Any other function that satisfies the boundary conditions [Eq. (18)] can be written as

$$v(x) = u(x) + \varepsilon h(x) \tag{19}$$

if $h(a) = h(b) = 0$. Moreover, in most variational approaches, the function h is assumed independent of ε . (This restriction is called the case of *weak variations* in the literature [20].) If the function F possesses continuous partial derivatives, an application of Taylor’s theorem gives

$$\begin{aligned} F(x, u + \varepsilon h, u' + \varepsilon h') \\ = F(x, u, u') + \varepsilon \left[h \frac{\partial F(x, u, u')}{\partial u} + h' \frac{\partial F(x, u, u')}{\partial u'} \right] + O(\varepsilon^2) \end{aligned} \tag{20}$$

The first variation of I is denoted by δI , and can be defined by the equation

$$\delta I = \lim_{\varepsilon \rightarrow 0} \frac{I(u + \varepsilon h) - I(u)}{\varepsilon} \tag{21}$$

From Eqs. (17), (20), and (21), the first variation of I is given by

$$\delta I = \int_a^b \left[h \frac{\partial F(x, u, u')}{\partial u} + h' \frac{\partial F(x, u, u')}{\partial u'} \right] dx \tag{22}$$

This “first variation” plays roughly the same role in the calculus of variations that the derivative plays in the standard calculus.

The form of Eq. (22) can be further simplified by applying integration by parts to the second term, and recalling that $h(a) = h(b) = 0$. This procedure gives a final form for δI :

$$\delta I = \int_a^b h \left\{ \frac{\partial F(x, u, u')}{\partial u} - \frac{d}{dx} \left[\frac{\partial F(x, u, u')}{\partial u'} \right] \right\} dx \tag{23}$$

Since the value of I depends linearly on ε , a minimum or maximum of I can be achieved only if $\delta I = 0$ independent of the choice of h . This observation leads directly to a differ-

ential equation first derived by Euler in 1744 [20], now known as the *Euler differential equation*:

$$\frac{\partial F(x, u, u')}{\partial u} - \frac{d}{dx} \left[\frac{\partial F(x, u, u')}{\partial u'} \right] = 0 \tag{24}$$

Much of physics can be formulated variationally, that is, as the minimization of an appropriate functional. The history of modern variational approaches to physics begins roughly with the work of Pierre de Fermat, and major contributions were made by a host of eminent physicists and mathematicians including Isaac Newton, Gottfried Wilhelm von Leibnitz, Johann and Jacob Bernoulli, Jean Le Rond d’Alembert, Joseph-Louis Lagrange, and William Rowan Hamilton [21].

The particular genius of Rayleigh and Ritz was not in this use of the calculus of variations to derive differential equations or formulate physical problems, but to convert it into a practical method for solving differential equations. Specifically, if the solution to a differential equation can be shown to minimize some functional, the Rayleigh–Ritz method approximates the solution through an appeal to the variational principle that describes it. (More generally, the solution of the differential equation may make the functional *stationary*, i.e., make its first variation vanish.) Since the Rayleigh–Ritz approach hinges on the creation of a variational principle, before discussing the method itself, we describe a variational principle useful in the solution of electromagnetic problems.

3.2. Variational Principles for the Scalar Helmholtz Equation

Consider the scalar Helmholtz equation

$$\mathcal{L}u = f \tag{25}$$

where \mathcal{L} is the linear Helmholtz operator

$$\mathcal{L}v = \nabla \cdot (p \nabla v) + k^2 qv \tag{26}$$

u is an unknown function defined on some closed domain Ω , k^2 is a constant, and p , q , and f are known real functions over the domain Ω . (For now, we assume that Ω is three-dimensional, but the derivation presented here can easily be specialized to fewer dimensions.) To completely characterize u , boundary conditions must also be specified on S , the boundary of Ω . To this end, assume that S is split into two nonoverlapping parts S_E and S_N . On S_E , the value of the function is specified; i.e.,

$$u = U \tag{27}$$

on S_E , where U is a given function. On S_N , the boundary condition is assumed to be

$$\frac{\partial u}{\partial n} + au = U' \tag{28}$$

where a and U are given functions, and $\partial u / \partial n$ denotes the outward normal derivative. (Of course, any of the given data, a , U , or U' , can be taken to be zero.)

We now show that the solution to this boundary value problem is the function that satisfies Eq. (27) and makes the functional

$$I(v) = \frac{1}{2} \iiint_{\Omega} [p \nabla v \cdot \nabla v - k^2 q v^2 + 2fv] d\Omega + \frac{1}{2} \iint_{S_N} p v [a v - 2U'] dS \tag{29}$$

stationary. Because the boundary condition of Eq. (28) is contained in the variational principle, it is said to be a *natural boundary condition*. Equation (27), on the other hand, is satisfied only by an explicit restriction of the domain of the functional, and is thus termed an *essential boundary condition*.

Using Eqs. (19) and (21), the first variation of I is given by

$$\delta I = \iint_{\Omega} [p \nabla u \cdot \nabla h - k^2 q u h + f h] d\Omega + \iint_{S_N} h p [a u - U'] dS \tag{30}$$

Now, simple differential identities allow the first term in δI to be simplified, since

$$p \nabla u \cdot \nabla h = \nabla \cdot [h p \nabla u] - h \nabla \cdot [p \nabla u] \tag{31}$$

Substituting this expression into Eq. (30) and applying the divergence theorem allows it to be written as

$$\delta I = - \iiint_{\Omega} h [\nabla \cdot (p \nabla u) + k^2 q u - f] d\Omega + \iint_{S_N} h \left[p \frac{\partial u}{\partial n} + a u - U' \right] dS \tag{32}$$

Because the function h is arbitrary, enforcing $\delta I = 0$ implies that each integral in Eq. (32) vanishes, which in turn implies Eqs. (25) and (28) as was asserted. Note that the application of the essential boundary condition is indeed essential; Eq. (32) implies that if nothing is done on S_E , the variational principle will enforce the condition

$$\frac{\partial u}{\partial n} = 0 \tag{33}$$

Similar variational principles may be derived for the vector Helmholtz equation, and may be found in Refs. 1 and 3.

3.3. Examples of the Rayleigh-Ritz Method for Boundary Value Problems

Now that variational principles have been described, the description of the Rayleigh-Ritz method itself is relatively simple. Suppose that a variational expression $I(v)$ for some differential equation is available. The unknown u is

approximated by a series \tilde{u} of the form

$$u \approx \tilde{u}_N = u_0 + \sum_{i=1}^N x_i u_i \tag{34}$$

where the u_i , $i = 0, \dots, N$, are known functions and the x_i , $i = 1, \dots, N$, are unknown coefficients. If there are essential boundary conditions of the form of Eq. (27), the function u_0 is assumed to satisfy them; if there are no such conditions, u_0 can be dropped. The remaining functions u_i , $i = 1, \dots, N$, satisfy the homogeneous form of Eq. (27), thus ensuring that the approximation of Eq. (34) satisfies the essential boundary conditions. As described in Section 2, substituting Eq. (34) into the functional gives rise to a function of the variables x_i . Stationary points of this functional satisfy the N equations

$$\frac{\partial I(\tilde{u}_N)}{\partial x_i} = 0 \tag{35}$$

which may then be solved to yield the x_i .

As a first simple example of the Rayleigh-Ritz method, consider finding the solution of the differential equation

$$\frac{\partial^2 u}{\partial t^2} = 36t^2 + 12t - 4 \tag{36}$$

subject to the boundary conditions

$$u(1) = u(-1) = 0 \tag{37}$$

The true solution to this problem, as is easily verified, is

$$u(t) = 3t^4 + 2t^3 - 2t^2 - 2t - 1 \tag{38}$$

According to the recipe above, the functional for this problem is given by

$$I(v) = \int_{-1}^1 \left[\frac{1}{2} \left(\frac{dv}{dt} \right)^2 + (36t^2 + 12t - 4)v \right] dx \tag{39}$$

Now, consider trial solutions of the form

$$\tilde{u}_N = \sum_{i=0}^{N-1} x_{i+1} t^i (t^2 - 1) \tag{40}$$

Note that each term in this series satisfies the homogeneous essential boundary conditions of Eq. (37). We examine the solutions given by the approximations \tilde{u}_1, \tilde{u}_2 , and \tilde{u}_3 .

For \tilde{u}_1 , the functional becomes

$$I(\tilde{u}_1) = \frac{4}{3} x_1^2 - \frac{64}{15} x_1 \tag{41}$$

Enforcing the condition of Eq. (35) gives the equation

$$\frac{8}{3} x_1 = \frac{64}{15} \tag{42}$$

Thus, $x_1 = \frac{8}{5}$, and the approximate solution is given by

$$\tilde{u}_1 = \frac{8}{5}t^2 - \frac{8}{5} \tag{43}$$

Using trial function \tilde{u}_2 gives rise to the function

$$I(\tilde{u}_2) = \frac{4}{3}x_1^2 + \frac{4}{5}x_2^2 - \frac{64}{15}x_1 - \frac{16}{5}x_2 \tag{44}$$

The gradient of this function vanishes when

$$\begin{bmatrix} \frac{8}{3} & 0 \\ 0 & \frac{8}{5} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} \frac{64}{15} \\ \frac{16}{5} \end{bmatrix} \tag{45}$$

giving rise to $x_1 = \frac{8}{5}$, $x_2 = 2$, and the approximate solution

$$\tilde{u}_2 = 2t^3 + \frac{8}{5}t^2 - 2t - \frac{8}{5} \tag{46}$$

Finally, using trial function \tilde{u}_3 , the functional becomes the function

$$I(\tilde{u}_3) = \frac{4}{3}x_1^2 + \frac{4}{5}x_2^2 + \frac{4}{105}x_3^2 + \frac{8}{15}x_1x_3 - \frac{64}{15}x_1 - \frac{16}{5}x_2 - \frac{64}{21}x_2 \tag{47}$$

The stationary point of this function occurs at the solution of the equations

$$\begin{bmatrix} \frac{8}{3} & 0 & \frac{8}{15} \\ 0 & \frac{8}{5} & 0 \\ \frac{8}{15} & 0 & \frac{8}{105} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} \frac{64}{15} \\ \frac{16}{5} \\ \frac{64}{21} \end{bmatrix} \tag{48}$$

which is at the point $x_1 = 1$, $x_2 = 2$, $x_3 = 3$. In particular, $\tilde{u}_3 = u$, the exact solution. The exact solution and the two other trial solutions are plotted in Fig. 1.

A few comments about these results are in order. The error in each result can be computed in the relative L_2 norm; that is, the error in an approximate solution \tilde{u} relative to the true solution can be written as

$$\text{Error} = \frac{\int_{-1}^1 (u - \tilde{u})^2 dt}{\int_{-1}^1 u^2 dt} \tag{49}$$

Using this error criterion, the error in \tilde{u}_1 is about 29.3%, and that in \tilde{u}_2 is 9.6%. Of course, \tilde{u}_3 is exact.

The large error in the first two approximations can be traced to the fact that they simply cannot curve enough to capture the true behavior of the solution. On the other hand, the third approximation is exact because the true solution lies in the space spanned by the basis functions

Figure 1. Approximate solutions of the boundary value problem of Eqs. (36) and (37) using the Rayleigh–Ritz method. The dotted line is \tilde{u}_1 , the dashed line is \tilde{u}_2 , and the solid line is $\tilde{u}_3 = u$.

used to construct it; that is, since the exact solution can be represented by \tilde{u}_3 with a proper choice of coefficients, the Rayleigh–Ritz method returns the exact solution. This highlights (in a fairly trivial way) the importance of basis function selection in the Rayleigh–Ritz method; a judicious choice of basis leads to good results fast, while a poor choice of basis may result in a poor approximation. Nonetheless, if a given set of basis functions is complete (i.e., can represent any function as the number of bases becomes large), the result will eventually converge.

The inclusion of inhomogeneous essential conditions creates no major problems. Consider, for instance, the problem of solving Eq. (36), subject to the boundary conditions

$$u(1) = -u(-1) = 1 \tag{50}$$

The inclusion of these boundary conditions necessitates adding a nonzero u_0 function to the trial function of Eq. (40) that satisfies the boundary conditions. The simplest way to satisfy this criterion is to make the new trial function

$$\tilde{u}_N = t + \sum_{i=0}^{N-1} x_{i+1} t^i (t^2 - 1) \tag{51}$$

and repeat the process. Substituting this function into the functional does not alter it in any way except by adding a meaningless value of 2 to the function $I(\tilde{u}_N)$. (The added value is meaningless in that it is annihilated by differentiation in the minimization of the function.) The reason for the simple result is clear; the exact solution to the new boundary value problem is just

$$u(t) = 3t^4 + 2t^3 - 2t^2 - t - 1 \tag{52}$$

which is just the old solution, plus the new term t . Choosing a different function to satisfy Eq. (50) would lead to different results in general, but exact results will always be obtained once the true solution can be expressed exactly in terms of the basis functions. (In particular, if u_0 is chosen to be t^3 instead of t , the solutions \tilde{u}_1 and \tilde{u}_2 will change, but \tilde{u}_3 will still be exact. If instead $u_0 = t^5$, the exact solution will not be obtained until $N = 4$.) In short, inhomogeneous essential boundary conditions do not alter the procedure significantly.

We now examine Eq. (36) under natural boundary conditions. To begin, note that in general Eq. (36) is incompatible with the simplest natural boundary condition, the homogeneous Neumann condition $u'(1) = u'(-1) = 0$. This is because integrating Eq. (36) between -1 and 1 gives

$$u'(1) - u'(-1) = 32 \tag{53}$$

where the homogeneous Neumann boundary condition requires this difference to vanish. The Rayleigh-Ritz method cannot save us from an improperly formulated problem!

Thus, consider Eq. (36) subject to the boundary conditions

$$\begin{aligned} -u'(-1) + u(-1) &= 1 \\ u'(1) - 4u(1) &= 2 \end{aligned} \tag{54}$$

The exact solution to this problem is given by

$$u(t) = 3t^4 + 2t^3 - 2t^2 \tag{55}$$

The functional for this problem can be constructed with reference to Eqs. (25)–(29), but only with some care. For instance, the surface integral in Eq. (29) must be interpreted as merely the value of the integrand at the endpoints. Similarly, the normal derivative in Eq. (28) should be interpreted as the usual derivative of the function at the right endpoint of the interval, and minus the usual derivative at the left endpoint of the interval. [The first boundary condition in Eq. (54) is written in a form that makes this explicit.] With these caveats in mind, the functional to be minimized for this problem is

$$\begin{aligned} I(v) = \int_{-1}^1 \left[\frac{1}{2} \left(\frac{dv}{dt} \right)^2 + (36t^2 + 12t - 4)v \right] dx \\ + \frac{1}{2}v^2(-1) - 2v^2(1) - v(-1) - 2v(1) \end{aligned} \tag{56}$$

For this case, the trial function series will be constructed as

$$\tilde{u}_N = \sum_{i=0}^{N-1} x_{i+1} t^i \tag{57}$$

Substituting this trial function into the functional yields a function of the form

$$I(\tilde{u}_N) = \frac{1}{2} \mathbf{x}^T \mathbf{A} \mathbf{x} - \mathbf{b}^T \mathbf{x} \tag{58}$$

where \mathbf{b} and \mathbf{x} are column vectors of N elements and \mathbf{A} is an $N \times N$ matrix. Specifically, the i th element of \mathbf{x} is x_i , and the i th element of \mathbf{b} is given by the formula

$$[\mathbf{b}]_i = \begin{cases} \frac{i-23}{i+1} & i \text{ even} \\ \frac{3i^2 - 58i + 16}{i^2 + 2i} & i \text{ odd} \end{cases} \tag{59}$$

and the elements of \mathbf{A} are given by

$$[\mathbf{A}]_{ij} = \begin{cases} \frac{2ij - 5i - 5j + 4}{i+j-1} & i+j \text{ even} \\ -5 & i+j \text{ odd} \end{cases} \tag{60}$$

The stationary point of this function occurs when $\mathbf{A}\mathbf{x} = \mathbf{b}$. Solving the set of equations for $N = 2, \dots, 5$ gives the solutions

$$\begin{aligned} \tilde{u}_2 &= 1 + 2t \\ \tilde{u}_3 &= -\frac{3}{5} + 2t + \frac{8}{5}t^2 \\ \tilde{u}_4 &= -\frac{3}{5} + \frac{8}{5}t^2 + 2t^3 \\ \tilde{u}_5 &= u = -2t^2 + 2t^3 + 3t^4 \end{aligned} \tag{61}$$

These solutions are plotted in Fig. 2. As expected, \tilde{u}_5 is exact, but the next best estimate, \tilde{u}_4 , is about 22% in error.

This example further clarifies issues involved both the Rayleigh-Ritz and Galerkin methods. First, problems

Figure 2. Approximate solutions of the boundary value problem of Eqs. (36) and (54) using the Rayleigh-Ritz method. The dashed-dotted line is \tilde{u}_2 , the dashed line is \tilde{u}_3 , the dotted line is \tilde{u}_4 , and the solid line is $\tilde{u}_5 = u$.

involving natural boundary conditions generally involve more unknowns than do those involving essential boundary conditions. In the cases presented here, it is clear that the exact solution to the differential equation is a fourth-order polynomial. In the case of natural boundary conditions, this implies that the solution has 5 degrees of freedom. (Here we chose the coefficient of each monomial term, but that specific choice is not necessary.) On the other hand, essential boundary conditions limit the choice of acceptable functions by forcing the functions with unknown coefficients to have a value of zero at both ends of the interval. In effect, for a one-dimensional problem, this reduces the number of degrees of freedom by 2. (In this case, the 2 degrees of freedom removed were the purely constant and linear terms, since neither of these terms can satisfy this condition.) In greater numbers of dimensions, the savings can be even more profound.

The second observation that can be made here concerns the choice of basis functions. The monomial basis functions chosen here are a particularly bad choice, in that as the order of the polynomials increases, the functions begin to resemble one another. Because of this, the condition number of the matrix **A** grows rapidly with increasing *N*. Indeed, the only reason that this is not obvious in the example presented is that the exact solution was obtained before the condition number increased too much. If the right-hand side of the differential equation were a higher-order polynomial, or some other arbitrary function, accurate results might require the inclusion of more monomials. Given the chosen basis, however, the inclusion of more monomial terms would vastly increase the condition number of the matrix, and thus potentially decrease the accuracy of the solutions. Figure 3, which plots the condition number of the matrix **A** versus the order of approximation *N*, shows just how serious the problem can become. With only 20 monomials, the condition number is

Figure 3. Condition number of the Rayleigh–Ritz matrix **A** in terms of approximation order for a monomial basis.

greater than 10^{12} , so the solution **x** loses 12 digits of accuracy relative to the accuracy with which **b** is computed.

3.4. The Rayleigh–Ritz Method for Eigenvalue Problems

As a final example of the Rayleigh–Ritz method, the fundamentally different eigenvalue problem is studied. We will see in this section, however, that the procedure for eigenvalue problems differs little from that for boundary value problems.

Consider the differential equation

$$\frac{d}{dt} \left(t \frac{du}{dt} \right) + k^2 t u = 0 \tag{62}$$

subject to the boundary conditions

$$u'(0) = u(1) = 0 \tag{63}$$

This equation will have solutions only for particular values of *k* called *eigenvalues*, and associated with each such *k* will be an *eigenfunction*. For Eq. (62), the eigenfunctions and eigenvalues are well known; in particular, the eigenfunctions of the equation are

$$u^m(t) = J_0(k_m t) \tag{64}$$

where J_0 denotes the zeroth-order Bessel function and k_m is its *m*th zero. [The superscript on *u* in Eq. (64) is used only to differentiate the *m*th eigenfunction, which will be denoted by a superscript, and the *m*th basis function, which is denoted by a subscript. The superscript is therefore not an exponent, but no confusion should arise as we will never have a need to exponentiate eigenfunctions.]

Using the recipe of Eqs. (25)–(29) leads to the functional for this problem, which may be written as

$$I(v) = \int_0^1 \left[t \left(\frac{dv}{dt} \right)^2 + k^2 t v^2 \right] dt \tag{65}$$

(The extraneous leading factor of $\frac{1}{2}$ has been dropped.) The trial function employed in this example will be

$$\tilde{u}_N = \sum_{n=1}^N x_n \cos(\kappa_n t) \tag{66}$$

where

$$\kappa_n = \frac{2n - 1}{2} \pi \tag{67}$$

These functions satisfy the essential boundary condition at $t = 1$, and even the natural boundary condition at $t = 0$. Of course, satisfaction of the natural boundary condition is not necessary, but since the problem statement implies that the solution will be an even function of *t*, the chosen basis functions seem a reasonable choice for the representation of the solution. (They are indeed the basis for even function Fourier series.)

Substituting the trial solution into the functional yields the function

$$I(\tilde{u}_N) = \mathbf{x}^T \mathbf{A} \mathbf{x} - k^2 \mathbf{x}^T \mathbf{B} \mathbf{x} \tag{68}$$

where, as usual, the vector \mathbf{x} contains the unknown coefficients x_n , $n = 1, \dots, N$, and \mathbf{A} and \mathbf{B} are $N \times N$ matrices. Defining the Krönercker delta symbol $\delta_{mn} = 0$ for $m \neq n$, and $\delta_{mm} = 1$, the elements of the matrices \mathbf{A} and \mathbf{B} are given by the expressions

$$[\mathbf{A}]_{mn} = \begin{cases} \frac{\kappa_m \kappa_n}{(\kappa_m + \kappa_n)^2} + \delta_{mn} \frac{\kappa_m^2}{4} & \text{for } m + n \text{ even} \\ -\frac{\kappa_m \kappa_n}{(\kappa_m - \kappa_n)^2} & \text{for } m + n \text{ odd} \end{cases} \quad (69)$$

$$[\mathbf{B}]_{mn} = \begin{cases} \frac{\delta_{mn}}{4} - \frac{1}{(\kappa_m + \kappa_n)^2} & \text{for } m + n \text{ even} \\ -\frac{1}{(\kappa_m - \kappa_n)^2} & \text{for } m + n \text{ odd} \end{cases} \quad (70)$$

The extremum of the functional of Eq. (68) occurs when

$$\mathbf{A}\mathbf{x} = k^2 \mathbf{B}\mathbf{x} \quad (71)$$

so the original problem has been reduced to a generalized algebraic eigenvalue problem. The eigenvalues of this problem (which we will denote by $K_{m,N}$) are approximations to the true eigenvalues, which in this case are the roots of the zeroth-order Bessel function. The eigenvectors, on the other hand, represent the weighting coefficients to be substituted into Eq. (66) to approximate the eigenfunctions. Since eigenvectors and eigenfunctions are unique only up to a multiplicative constant, all solutions related here have been scaled so that $\tilde{u}_N(0) = J_0(0) = 1$.

Figure 4 shows the first two approximations to the eigenfunction associated with the smallest eigenvalue returned by the Rayleigh–Ritz method. The true eigenvalue is given (to double precision) by $k_1 = 2.40482555769577$;

Figure 4. Approximations to $J_0(k_1 x)$: \tilde{u}_1 is shown as a dotted line, \tilde{u}_2 is shown as a dashed line, and $J_0(k_1 x)$ is shown as a solid line.

Figure 5. Convergence of the smallest eigenvalue as a function of the order of approximation.

the approximations associated with the two approximations shown in the figure are $K_{1,1} = 2.414$ and $K_{1,2} = 2.406$. These numbers represent relative errors of 0.41% and 0.056%, respectively. In contrast to the previous examples, this example illustrates how quickly the Rayleigh–Ritz method can converge with a good choice of trial function. Figure 5 shows the convergence of the eigenvalue approximation itself as a function of approximation. The order of convergence is nearly cubic.

This example also highlights some of the advantages of the Ritz method relative to Rayleigh’s original method. While Rayleigh’s method provides only an approximation to the smallest eigenvalue, the Ritz method actually provides estimates of all the lowest eigenvalues. For instance, taking the fifth smallest eigenvalue of the algebraic eigenvalue problem results in an approximation of the fifth smallest eigenvalue of the analytic problem. The true value of the fifth eigenvalue is given by $k_5 = 14.93091770848779$, and the first two estimates provided by the Rayleigh–Ritz method are $K_{5,5} = 14.9399$ and $K_{5,6} = 14.9325$, values that contain far less than one-tenth of one percent error.

4. GALERKIN’S METHOD

In this section, Galerkin’s method is described. The method itself is described in Section 4.1, and Section 4.2 discusses its relationship with the Rayleigh–Ritz method. Finally, Section 4.3 describes the weighted-residual method, which is a generalization of the Galerkin method.

4.1. Description of the Method

Galerkin’s method is used to solve equations involving linear operators. The operators may be integral operators, differential operators, or even integrodifferential operators.

For differential operators, the method is strongly related to the Rayleigh–Ritz method (as will be demonstrated in the next section), but it is much simpler to apply. (Indeed, this is the main reason why the Rayleigh–Ritz method takes up more space in this article than the Galerkin method, which is ostensibly the main topic.)

An operator \mathcal{L} is called *linear* if given two functions v and w , and two scalars a and b

$$\mathcal{L}(av + bw) = a\mathcal{L}v + b\mathcal{L}w \tag{72}$$

Galerkin’s method works by projecting the original operator equation, defined on a function space, onto a finite-dimensional vector space. This is accomplished with the help of an inner product. An *inner product* defined on a complex vector space (such as the space of all complex functions of N variables) is a complex scalar function of two vectors (functions) that satisfies certain criteria. If v , w , and s denote functions, and a and b are scalars, the inner product $\langle v, w \rangle$ must be

1. Linear, that is

$$\langle s, av + bw \rangle = a\langle s, v \rangle + b\langle s, w \rangle \tag{73}$$

2. Hermitian, that is

$$\langle v, w \rangle = \langle w, v \rangle^* \tag{74}$$

where the asterisk denotes complex conjugation.

3. Positive-definite, that is

$$\langle v, v \rangle \geq 0 \tag{75}$$

with equality only if $v = 0$ [22].

While this is the commonly accepted mathematical definition of inner products, in practical applications, products that are not positive definite are often used. Most often, such products are not Hermitian, but instead are symmetric:

$$\langle v, w \rangle = \langle w, v \rangle \tag{76}$$

(Generally, such products are also not positive definite.) In this article, we will not distinguish between the two, and refer to any linear and symmetric or Hermitian scalar functional of two functions as an inner product. In particular, over a three-dimensional domain Ω , the most common inner product definitions are

$$\langle v, w \rangle = \iiint_{\Omega} vwd\Omega \tag{77}$$

for scalar functions v and w , and

$$\langle \mathbf{v}, \mathbf{w} \rangle = \iiint_{\Omega} \mathbf{v} \cdot \mathbf{w}d\Omega \tag{78}$$

for vector functions \mathbf{v} and \mathbf{w} . If these products are defined over a real vector space, then the mathematical definition

of inner product is met by these functions. On the other hand, if these products are used over a complex vector space, they are not Hermitian or positive definite. Finally, note that these definitions extend trivially to an arbitrary number of dimensions.

Armed with this definition of inner product, Galerkin’s method is simple to describe. Consider the equation

$$\mathcal{L}u = f \tag{79}$$

where \mathcal{L} is a linear operator, u is an unknown function, and f is a known function. As in the Rayleigh–Ritz method, u is approximated by a series of basis functions of the form

$$u \approx \tilde{u}_N = u_0 + \sum_{i=1}^N x_i u_i \tag{80}$$

where the u_i are called basis functions, and the x_i are unknown basis function coefficients. As in the case of the Rayleigh–Ritz method, the extra function u_0 is included to satisfy inhomogeneous essential boundary conditions; we will ignore it for the time being and discuss it in the next section where boundary conditions are described.

Thus, assuming that there are no inhomogeneous essential boundary conditions, the approximation of Eq. (80) is substituted into Eq. (79). In view of the linearity of the operator, the resulting equation may be written as

$$\sum_{i=1}^N x_i \mathcal{L}u_i = f \tag{81}$$

Unfortunately, this equation is ill-posed; it is one equation in N unknowns. To create a set of N equations that can be solved for the x_i , the inner product of Eq. (81) can be taken with each basis function in turn. This procedure yields

$$\sum_{i=1}^N x_i \langle u_m, \mathcal{L}u_i \rangle = \langle u_m, \mathcal{L}f \rangle \tag{82}$$

for $m = 1, \dots, N$; a set of N equations in N unknowns.

The advantage of this method relative to the Rayleigh–Ritz approach should be obvious—the Galerkin approach does not require the creation of a functional, which may be difficult to find in some circumstances. The disadvantage of the Galerkin approach is that boundary condition application is not as elegant, and the difference between essential and natural boundary conditions is not as clear. Nonetheless, Galerkin’s method and the Rayleigh–Ritz method are closely related, as the discussion in the next section will demonstrate. (As was mentioned in the introduction, the genesis of Galerkin’s method can be found in I. G. Bubnov’s comment that the Rayleigh–Ritz equations could be derived more simply.)

4.2. Boundary Conditions and Relation to Rayleigh–Ritz

To demonstrate the application of boundary conditions in Galerkin’s method, and to elucidate its relation to the Rayleigh–Ritz method, we once again consider the model

problem defined by Eqs. (25)–(28). The first step in the Galerkin method is the creation of a trial function and its substitution into the equation. In this discussion, the trial function will be that given by Eq. (80), where, as usual, we assume that u_0 satisfies the inhomogeneous essential boundary condition on S_E , and that the remaining u_i satisfy the homogeneous version of the same essential boundary condition on S_E . Substituting the basis function series into the differential equation results in the specific equivalent of Eq. (81), a single equation in N unknowns given by

$$\sum_{i=1}^N x_i [\nabla \cdot (p \nabla u_i) + k^2 q u_i] = f - \nabla \cdot (p \nabla u_0) - k^2 q u_0 \quad (83)$$

To derive a set of N equations, this equation is multiplied by each of the functions u_m , $m = 1, \dots, N$, in turn, and integrated over the domain [i.e., the inner product of Eq. (83) is taken with each of the basis functions in turn.] This procedure yields a set of N equations that may be written as

$$\sum_{i=1}^N x_i \iiint_{\Omega} [u_m \nabla \cdot (p \nabla u_i) + k^2 q u_m u_i] d\Omega \quad (84)$$

$$= \iiint_{\Omega} [u_m f + u_m \nabla \cdot (p \nabla u_0) - k^2 q u_m u_0] d\Omega$$

This equation can be simplified using Eq. (31) (with $h = u_m$ and $u = u_i$) and the divergence theorem, resulting in

$$\begin{aligned} & \sum_{i=1}^N x_i \left\{ \iiint_{\Omega} [-p \nabla u_m \cdot \nabla u_i + k^2 q u_m u_i] d\Omega \right. \\ & \left. + \iint_S p u_m \frac{\partial u_i}{\partial n} dS \right\} \\ & = \iiint_{\Omega} [u_m f + p \nabla u_m \cdot \nabla u_0 - k^2 q u_m u_0] d\Omega \\ & - \iint_S p u_m \frac{\partial u_0}{\partial n} dS \end{aligned} \quad (85)$$

Now, the surface integrals in Eq. (85) vanish over S_E since the functions u_m satisfy homogeneous essential boundary conditions there by construction. On the other hand, on S_N , \tilde{u}_N must satisfy the natural boundary condition of Eq. (28). Substituting this equation into Eq. (85) yields

$$\begin{aligned} & \sum_{i=1}^N x_i \left\{ \iiint_{\Omega} [-p \nabla u_m \cdot \nabla u_i + k^2 q u_m u_i] d\Omega \right. \\ & \left. - \iint_{S_N} p a u_m u_i dS \right\} \\ & = \iiint_{\Omega} [u_m f + p \nabla u_m \cdot \nabla u_0 - k^2 q u_m u_0] d\Omega \\ & + \iint_{S_N} p u_m (a u_0 - U') dS \end{aligned} \quad (86)$$

for $m = 1, \dots, N$. This is the final form of the Galerkin equations.

Equation (86) may be related to the Rayleigh–Ritz approach for this problem very simply. Direct substitution of the trial function into the functional of Eq. (29) gives

$$\begin{aligned} I(\tilde{u}_N) = & \frac{1}{2} \sum_{i=1}^N \sum_{m=1}^N x_i x_m \left\{ \iiint_{\Omega} [p \nabla u_i \cdot \nabla u_m - k^2 q u_i u_m] d\Omega \right. \\ & \left. + \iint_{S_N} a p u_i u_m dS \right\} \\ & + \sum_{m=1}^N x_m \left\{ \iiint_{\Omega} [u_m f + p \nabla u_0 \cdot \nabla u_m - k^2 q u_0 u_m] d\Omega \right. \\ & \left. + \iint_{S_N} p u_m (a u_0 - U') dS \right\} \end{aligned} \quad (87)$$

if constant terms involving u_0 alone are ignored. (Such terms will be annihilated by differentiation in the Rayleigh–Ritz procedure.) Differentiating this equation with respect to each unknown and setting the result equal to zero clearly yields the same set of equations as the Galerkin method. Thus, all the examples of Section 2 apply equally well to Galerkin’s method. In particular, all the same integrals will be computed, and the equations derived will be identical (except for possibly a meaningless shared factor that multiplies all of the equations).

The close relationship between the Rayleigh–Ritz and Galerkin methods can be clarified by studying the methods from a geometric/linear algebraic point of view. For this discussion, we will assume that the inner product employed actually satisfies conditions 1–3 listed at the beginning of Section 4.1, and that we are dealing with real functions and operators. In this case, the norm (i.e., length) of a function (vector) can be defined by

$$\|v\|^2 = \langle v, v \rangle \quad (88)$$

Assume further that we are trying to solve Eq. (79), where \mathcal{L} is a *positive definite* operator, that is

$$\langle v, \mathcal{L}v \rangle \geq 0 \quad (89)$$

for all functions v , and equality holds only if $v = 0$. (Many physical problems in which the Rayleigh–Ritz method is applied involve positive definite operators. In particular, many variational principles are derived from energy considerations.)

Given that \mathcal{L} is positive definite, an alternative inner product (called the \mathcal{L} *inner product*) can be defined by the equation

$$\langle u, v \rangle_{\mathcal{L}} = \langle u, \mathcal{L}v \rangle \quad (90)$$

This inner product gives rise to its own norm (the \mathcal{L} norm)

$$\|v\|_{\mathcal{L}}^2 = \langle v, v \rangle_{\mathcal{L}} \quad (91)$$

much as the original inner product induced a norm. Assuming that \tilde{u}_N is a trial function defined in the usual way, we may seek to approximate the solution of Eq. (79) by demanding that the coefficients of \tilde{u}_N be chosen to minimize (half the square of) the \mathcal{L} norm of error given by

$$\begin{aligned} I(\tilde{u}_N) &= \frac{1}{2} \langle (u - \tilde{u}_N), \mathcal{L}(u - \tilde{u}_N) \rangle \\ &= \frac{1}{2} \langle \tilde{u}_N, \mathcal{L}\tilde{u}_N \rangle - \langle \tilde{u}_N, f \rangle + \frac{1}{2} \langle u, \mathcal{L}u \rangle \end{aligned} \quad (92)$$

This is the Rayleigh–Ritz approach.

Actually performing the minimization gives rise to N equations for the x_i , which may be written as

$$\sum_{i=1}^N x_i \langle u_m, \mathcal{L}u_i - f \rangle = 0 \quad (93)$$

for $m = 1, \dots, N$. These are the Galerkin equations. Moreover, Eqs. (93) can be written in the form

$$\langle u_m, (\tilde{u}_N - u) \rangle_{\mathcal{L}} = 0 \quad (94)$$

which shows that the Galerkin method imposes the condition that the error be \mathcal{L} orthogonal to the space spanned by the basis functions. Thus, in short, the equivalence of the Rayleigh–Ritz and Galerkin methods in many situations can be traced to the observation that the shortest distance between a point and a line is given by the orthogonal projection of the point onto the line. In fact, these observations are critical not only to the numerical formulation of electromagnetic problems but also to the creation of iterative solvers (like the conjugate-gradient method) that can be used to solve the equations once they are created [23].

4.3. Weighted-Residual Methods

The Galerkin method is actually a special case of a more general set of numerical techniques called *weighted-residual methods*. Weighted residual methods begin the solution of Eq. (79) in the same way as the Galerkin method—by inserting an appropriate combination of basis functions into the equation and arriving at Eq. (81). Instead of taking the inner product of Eq. (81) with the basis functions, however, weighted-residual methods take the inner product with a set of N testing functions v_m , $m = 1, \dots, N$, resulting in the set of equations

$$\sum_{i=1}^N x_i \langle v_m, \mathcal{L}u_i \rangle = \langle v_m, f \rangle \quad (95)$$

If $v_m = u_m$, Galerkin’s method is recovered.

Two other choices of testing function are worth mentioning. First, if the testing functions are taken to be Dirac delta functions shifted to testing points t_m , that is

$$v_m(t) = \delta(t - t_m) \quad (96)$$

the point collocation method is derived. Specifically, substituting Eq. (96) into Eq. (95) yields a set of equations of the form

$$\sum_{i=1}^N x_i (\mathcal{L}u_i)(t_m) = f(t_m) \quad (97)$$

The point collocation method thus enforces the original operator equation exactly over a finite set of points.

Second, in the least-squares method, the testing functions are chosen to be

$$v_m = \mathcal{L}u_m \quad (98)$$

Using these testing functions leads to a method that minimizes the (usual) norm of the residual. These alternative methods can be useful when the Galerkin method is difficult to apply for one reason or another. In particular, point collocation is often very simple to apply. On the other hand, the least-squares method has the advantage that it always leads to symmetric, positive definite systems of equations.

5. THE FINITE-ELEMENT METHOD AND THE METHOD OF MOMENTS

In this final section, we briefly describe FEM and MoM, the two most widespread applications of Galerkin’s method and the Rayleigh–Ritz method in electromagnetics. No attempt is made to make this discussion in any way complete; other articles in this encyclopedia cover these methods in detail.

The finite-element method is simply the application of the Rayleigh–Ritz or Galerkin method to differential equation problems using subsectional basis functions, that is, basis functions that do not span the entire problem domain. The FEM has a rather long history, as it was first suggested by Richard Courant during World War II [15].

As an example of the finite-element method, we will demonstrate how it can be used to determine the bandgap of a two-dimensional photonic bandgap (PBG) structure. The unit cell of the PBG lies in the x - y plane and is shown in Fig. 6. Unshaded areas correspond to free space, and shaded areas correspond to a material of relative permittivity $\epsilon_r = 13$ and relative permeability $\mu_r = 1$. The differential equation associated with this problem is Eq. (25), with $u = E_z$, the z component of the electric field, $p = 1/\mu_r$, $q = \epsilon_r$, $f = 0$, and $k = \omega/c$, where c is the speed of light in vacuum and ω is the angular frequency of the wave. Because the structure is periodic, the wave must satisfy the Floquet boundary condition, that is

$$\begin{aligned} u(S_R) &= u(S_L) \exp(-jk_x d - jk_y d) \\ u(S_T) &= u(S_B) \exp(-jk_x d - jk_y d) \end{aligned} \quad (99)$$

where d is the length of a side of the unit cell (which will be taken as unity in this example) and k_x and k_y are real numbers. This is an essential boundary condition.

Figure 6. A meshed PBG structure. Circles indicate node locations.

The goal in the solution of this eigenvalue problem is to find the frequencies of propagation allowed for each combination of k_x and k_y , and in particular to determine whether there are any frequency ranges in which propagation is disallowed. (The eigenvalues of such a problem are actually periodic in k_x and k_y , so the search can be accomplished in a finite amount of time.) *Bandgaps* are those ranges of the frequency axis over which propagation is not allowed.

To apply the FEM to this problem, the structure is first meshed with triangles as shown in Fig. 6. A basis function is associated with each node in the mesh that is one at its node and falls off linearly to zero at each node connected to it. In particular, these basis functions are subsectional; they vanish identically on triangles not connected to the associated node.

A set of equations can be created by applying either Galerkin's method or the Rayleigh-Ritz method using these subsectional bases. The essential boundary condition can be enforced by ensuring that nodes on the boundary are related by Eq. (99); this eliminates the unknowns associated with two edges of the mesh. Specifically, the unknowns associated with the white circles in Fig. 6 can be eliminated by expressing their values in terms of the values of the unknowns located at the black circle nodes. In the end, the result of this procedure is a generalized eigenvalue problem for the eigenvalues ω^2 and the associated eigenvectors that represent the electric field of the mode in question. Figure 7 shows the band structure of the lowest two bands for this PBG structure computed by the FEM with 400 unknowns. (The band structure diagram shows the allowed values of ω for each k_x, k_y pair.) A large bandgap is evident.

As a final example of Galerkin's method, we present an example of the method of moments. In computational electromagnetics circles, MoM refers to the use of the weighted-residual method for the solution of integral equations. Here, we will provide an example of Galerkin's method

Figure 7. Band structure of the PBG structure of Fig. 6 computed by FEM.

(i.e., the method where the testing functions are chosen to be the basis functions) specifically. In particular, we demonstrate an application of the MoM to scattering from conducting objects.

Thus, let the surface of a perfect conductor situated in free space be denoted by S , and imagine that the conductor is illuminated by an electric field $\mathbf{E}^{\text{inc}}(\mathbf{r})$. (Since the formulation of this problem is standard in the literature, we drop the usual notation of using u as the problem solution, u_i as the basis functions, and so on, in favor of a more standard MoM notation.) This incident field will induce a current $\mathbf{J}(\mathbf{r})$ on the surface of the scatterer, which radiates a scattered field in such a way to exactly cancel the incident electric field tangential to the scatterer. Mathematically, the current must satisfy the electric field integral equation

$$\begin{aligned} \mathbf{E}^{\text{inc}}(\mathbf{r}) = & jk\eta \iint_S \mathbf{J}(\mathbf{r}') \frac{e^{-jk|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} dS' \\ & - \frac{\eta}{jk} \nabla \iint_S [\nabla' \cdot \mathbf{J}(\mathbf{r}')] \frac{e^{-jk|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} dS' \end{aligned} \quad (100)$$

tangential to the surface of the scatter, where η is the impedance of free space, and $k = \omega/c$, where c is the speed of light in vacuum and ω is the angular frequency of the wave. The integral over dS' indicates that \mathbf{r}' is the integration variable, and the prime over the nabla symbol indicated differentiation with respect to \mathbf{r}' .

Assuming that the set of basis functions is denoted by $\mathbf{B}_i(\mathbf{r})$, $i = 1, \dots, N$, and that the inner product used in the formulation of the problem is that of Eq. (78), an application of Galerkin's method gives rise to a matrix equation of the form

$$\mathbf{A}\mathbf{x} = \mathbf{b} \quad (101)$$

where \mathbf{x} is a vector of unknown weighting function coefficients. The elements of \mathbf{b} are given by

$$[\mathbf{b}]_m = \iint_S \mathbf{E}^{\text{inc}}(\mathbf{r}) \cdot \mathbf{B}_m(\mathbf{r}) dS \quad (102)$$

and (if the chosen basis is divergence-conforming [24,25]) the elements of the matrix \mathbf{A} are given by

$$[\mathbf{A}]_{mi} = jk\eta \iint_S \iint_S \mathbf{B}_i(\mathbf{r}') \cdot \mathbf{B}_m(\mathbf{r}') \frac{e^{-jk|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} dS dS' + \frac{\eta}{jk} \iint_S \iint_S [\nabla \cdot \mathbf{B}_i(\mathbf{r}')] [\nabla \cdot \mathbf{B}_m(\mathbf{r})] \times \frac{e^{-jk|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} dS dS' \quad (103)$$

Solving Eq. (101) yields an approximation of the current, which can then be used to compute (for instance) the radar cross section of the object.

This technique was applied to the computation of the radar cross section of a 1-m-diameter sphere at 100 MHz. The sphere was meshed with 32 spherical triangle patches, and the current was discretized into 160 quadratic basis functions on these patches. The geometry model was exact; that is, the sphere was not approximated as a union of flat triangles. The details of the basis functions themselves may be found in Ref. 24; they are generalizations of the well-known linear Rao–Wilton–Glisson basis functions [25]. The radar cross section computed by the MoM technique is shown in Fig. 8, where it is compared to the result returned by the exact analytic solution (Mie series). The two results compare well. While the computation of the matrix elements in this case is far more complicated in this case than in all of the previous cases, in principle this example is a straightforward application of the Galerkin method. Thus, although the integrals in Eqs. (100) and (103) require numerical integration of functions that are often singular, no essential complication is introduced into Galerkin's method.

Figure 8. Radar cross section of a 1-m-diameter sphere as computed by the MoM (tickmarked, crossed line) versus Mie series (solid line) at 100 MHz.

GALLIUM ARSENIDE TECHNOLOGY AND APPLICATIONS

G. F. MANES
University of Florence
Italy

1. INTRODUCTION

Starting from the early 1970s, the increasing request for solid-state devices operating at microwave frequencies lead to investigations of semiconductor structures as alternatives to silicon. The properties of III-V compound materials exhibited favorable characteristics for that purpose, despite inherent limitations in wafer reproducibility and yield. Among various solutions, gallium arsenide generated interest and eventually emerged as the favorite material for high-frequency applications due to the high carrier mobility compared with silicon devices. To produce high-quality gallium arsenide crystals, scientists needed to solve a number of problems, including the need to understand the process in which chemical impurities, introduced either intentionally or unintentionally, are distributed during crystal growth. Operating at higher speed and using less power, electronic devices made from gallium arsenide crystals have several theoretical advantages over silicon.

The advantages in speed and high-frequency performance of GaAs are slightly offset by the manufacturing process limitations of GaAs, in terms of both complexity and reproducibility as opposed to Si. A relevant limitation, for instance, is the maximum wafer dimension (today only 4–6 in. in diameter, compared to the present 12 in. for silicon). This limitation reduces the number of devices per wafer, and thus the final monetary value of each wafer. The size limitation is due to the limited robustness of the bulk material. In addition, the device reliability is much lower than in Si; therefore GaAs is not suitable for very complex circuits. GaAs devices find application at RF and microwave frequencies for both linear and high-speed logic applications. RF devices and ICs are used in consumer electronics to meet specifications beyond Si device capabilities. GaAs microwave devices find extensive use in consumer applications as well in sophisticated warfare electronics. GaAs devices are used in the form of discrete components or microwave monolithic integrated circuits (MMICs). GaAs also exhibits relevant optical properties and finds extensive applications in optoelectronics, including LEDs, laser diodes, and solar cells; this issue, however, will not be addressed in this article.

2. MATERIAL PROPERTIES

Like many other III-V compounds, gallium arsenide crystallizes in the zincblende structure, whose name derives from the ZnS mineral. The primitive cell ($Z=1$) of the zincblende crystal structure is shown in Fig. 1. It can be described as the result of two face-centered cubic (fcc) lattices of gallium (Ga) and arsenic (As) reciprocally pene-

Figure 1. The zincblende primitive cell.

trating and shifted relative to each other by a quarter of the cube diagonal.

Unlike the tetrahedral atomic configuration of silicon and germanium, in the zincblende structure the midpoint between two nearest atoms is no longer a center of inversion. Because of this lack of inversion symmetry, in a gallium arsenide lattice, the directions $[111]$ and $[1\bar{1}\bar{1}]$ are not equivalent. The bonds between nearest Ga and As atoms are in the $[111]$ direction, while the closest equivalent atoms (Ga-Ga or As-As) are in the $[110]$ direction. The $[111]$ plane, which is perpendicular to the $[111]$ direction, is usually known as the *gallium plane*, while the $(\bar{1}\bar{1}\bar{1})$ plane is known as the *arsenic plane*. If the GaAs crystal is cleaved on the (111) plane, the wafer surface is made up of either gallium atoms with one free bond and three bonds with the layer below, or arsenic atoms with three free bonds and only one bond with the layer below. The opposite situation is obtained on the $(\bar{1}\bar{1}\bar{1})$ plane.

Unlike silicon or germanium crystals, which are cleaved on the (111) plane, GaAs crystals are usually cleaved along the (011) or $(01\bar{1})$ plane since, because of the partially heteropolar bonds between gallium and arsenic, the zincblende structure does not easily break along the (111) plane. At $T=300\text{ K}$ the lattice constant of the GaAs crystal is 5.653 \AA and its thermal conductivity is $0.55\text{ W cm}^{-1}\text{ }^{\circ}\text{C}^{-1}$.

The energy band diagram of gallium arsenide at $T=300\text{ K}$ is shown in Fig. 2. Like many other III-V compounds, GaAs is a direct-bandgap material; this means that the top of the valence band (light and heavy holes) and the bottom of the main conduction band valley (the \square valley) are located in the same point in the wavevector space. The conduction band also has two more valleys, one in the $\langle 111 \rangle$ direction and one in the $\langle 100 \rangle$ direction, respectively known as the L valley and the X valley. At room temperature the energy gap E_g between the \square valley and the top of the valence band is 1.42 eV ; in the same conditions the gaps between the top of the valence band and the bottoms of the two secondary valleys of the conduction band are 1.71 eV for the L valley and 1.90 eV for the X valley. The top of the splitoff subband is 0.34 eV below the top of the light- and heavy-hole bands.

All energy values reported are temperature-dependent; in the range $0\text{--}1000\text{ K}$ E_g can be calculated using the

Figure 2. The zincblende primitive cell.

following relation:

$$E_g(T) = 1.519 - 5.405 \times 10^{-4} \cdot \frac{T^2}{T + 204} \text{ (eV)} \quad (1)$$

The intrinsic carrier concentration is given by

$$n_i = (N_C \cdot N_V)^{1/2} \exp\left(-\frac{E_g}{2k_b T}\right) \text{ (cm}^{-3}\text{)} \quad (2)$$

Taking into account the nonparabolic behavior of the Γ valley and the contributions from the X and L valleys, the effective densities of states N_C and N_V can be calculated from the following relations:

$$\begin{aligned} N_C &= 8.63 \times 10^{13} \cdot T^{3/2} [1 - 1.93 \times 10^4 \cdot T \\ &\quad - 4.19 \times 10^8 \cdot T^2 + F_{LX}(T)] \text{ (cm}^{-3}\text{)} \\ F_{LX}(T) &= 21 \cdot \exp\left(-\frac{E_{\Gamma L}}{2k_b T}\right) 44 \cdot \exp\left(-\frac{E_{\Gamma X}}{2k_b T}\right) \\ N_V &= 1.83 \times 10^{15} \cdot T^{3/2} \text{ (cm}^{-3}\text{)} \end{aligned} \quad (3)$$

where $E_{\Gamma L}$ and $E_{\Gamma X}$ are the energy gaps between the main and the two secondary valleys.

The effective masses of carriers are reported in Table 1 ($m_0 = 9.11 \times 10^{-31}$ kg is the electron inertial mass).

Table 1. Effective Masses of Carriers

Conduction band	(Γ valley)	$m_\Gamma = 0.063 m_0$
	(L valley)	$m_L = 0.085 m_0$
	(X valley)	$m_X = 0.085 m_0$
Valence Band	Light holes	$m_{lh} = 0.082 m_0$
	Heavy holes	$m_{hh} = 0.51 m_0$
	Splitoff	$m_{so} = 0.15 m_0$

Figure 3. Electric field dependence of the electron drift velocity.

The field dependence of the electron drift velocity is depicted in Fig. 3; the negative differential mobility behavior is due to the increase of the carrier concentration in the L and X valleys for high electric fields. The solid curve was calculated by Pozhela and Reklaitis [*Solid State Electron.* 23(9):927–933 (1980)], dashed and dotted curves are measured data at room temperature.

Modern monolithic devices such as HBTs and HEMTs are based on the properties of wide-bandgap heterojunctions. Figure 4 illustrates the relationship between bandgap and lattice constant for various alloys in the InGaAsP and AlGaAsSb systems.

As can be seen in Fig. 4, gallium arsenide has nearly the same lattice constant of aluminum arsenide (AlAs); at the same time the bandgap difference between the two alloys is quite high (0.8 eV). This implies that the $Al_xGa_{1-x}As$ ternary compound has in any case a lattice

Figure 4. Relationship between bandgap and lattice constant for alloys in the InGaAsP and AlGaAsSb systems. (Figure taken from B. G. Streetman and S. Banerjee, *Solid State Electronic Devices*, Prentice-Hall, 2000.)

constant very close to that of gallium arsenide with a bandgap energy that can be modulated by correctly choosing the alloy composition x .

The properties of the GaAs/AlAs system can be applied to build a wide range of nearly lattice-matched heterojunctions starting from a binary GaAs substrate. The bandgap difference can be further increased by growing a series of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ and $\text{In}_y\text{Ga}_{1-y}\text{As}$ layers on a gallium arsenide substrate, as is done in a GaAs pseudomorphic HEMT. In this case, anyway, the lattice mismatch between GaAs and the $\text{In}_y\text{Ga}_{1-y}\text{As}$ compound quickly rises as the indium alloy composition y is increased.

3. GaAs MMIC FABRICATION

GaAs MMICs are manufactured starting with a wafer of semiconductor material. These wafers are sliced from a large single crystal, known as a *boule*. Boules are grown by the well-known Czochralski crystal growth method, which is substantially the same as the technique used for silicon and other semiconductors. Basically, a small seed crystal is lowered to the surface of the melting material, and then slowly lifted up. In this manner, it draws with it layer by layer of molten material, which cools gradually, resulting in a single crystal with the same crystalline structure as the seed crystal. Actually, growing compound semiconductors is slightly complicated because the vapor pressures of the constituent materials are different. A suitable encapsulate, together with a high pressure of inert gas within the growth chamber, is employed in order to prevent this problem.

After slicing the boules to thin wafers, their surface is smoothed by mechanical and chemical treatments, so that its roughness is reduced to an atomic layer level. The obtained product is the basic material for MMIC microfabrication.

GaAs-based devices need a mesastructure compound by several layers of different material alloys. Their thickness and molar fraction must be known quite accurately. So, process requirements are intrinsically dissimilar from what can be obtained by diffusion doping techniques, which are typically applied in traditional Si-based microcircuit fabrication. Consequently, epitaxial deposition is the most popular and perhaps the only method employed in fabricating GaAs MMICs. In the following sections two main techniques, molecular-beam epitaxy and metallorganic chemical vapor deposition, will be described.

These techniques allow the production of high-quality layers with very abrupt interfaces and good control of thickness, doping, and composition. In fact, they are also compatible with accurate growth measurement systems, such as the reflection high-energy electron diffraction method.

Photolithography and etching are then performed in order to selectively remove material from the sample, resulting in the effective transfer of the design layout to the chip. This kind of technology is not limited to GaAs processing, and its description is beyond the purpose of this section. Multiple metallization layers can be added by

thin-film vacuum evaporation, sputtering, or electroplating; additional sacrificial layers can be grown to allow air-bridge construction. Again, masks are used to control the geometry of the metal film on the device.

4. MOLECULAR-BEAM EPITAXY

Molecular-beam epitaxy (MBE) was developed in the early 1970s as a means of growing high-purity epitaxial layers of compound semiconductors.

The working principle of MBE is shown in Fig. 5. A sample wafer is heated in a chamber, and eventually it is kept in rotation; then, solid sources materials are placed in evaporation cells to provide an angular distribution of atoms or molecules in a beam. Every source is connected to the chamber via a shutter, so that the flux of material can be externally controlled with accuracy. Atoms and molecules combine onto the wafer surface, and epitaxial layers of the desired compound material grow on the sample.

However, some practical issues drastically complicate the construction of a real MBE system. First, the chamber is kept in ultra-high-vacuum (UHV) environment. Actually, the molecular-beam condition that the mean-free path of the particles should exceed the geometric size of the chamber is easily fulfilled if the total pressure does not exceed 10^{-5} torr. Nevertheless, the condition for growing a sufficiently clean epitaxial layer typically requires the partial pressure of the background residual vapor to be less than 10^{-11} torr. Thus, the total pressure is kept as low as reasonably possible—around 10^{-7} torr—and liquid N_2 cryopanel, together with cryopumps, act as a screening around the substrate, minimizing spurious fluxes of atoms and molecules from the chamber walls while reaching the desired level of residual vapor and undesired gas partial pressure. Moreover, the materials of the chamber are chosen so that they minimize the rate of gas evolution (e.g., pyrolytic boron nitride, molybdenum, tantalum) and a special maintenance is applied: a 24-h bakeout of the whole chamber at 200°C after each vent, and heating of the windows at 300°C for a couple of hours to prevent them from being coated.

Figure 5. MBE process setup.

Then, a proper temperature has to be chosen for the substrate. Consider one of the key points of MBE, namely, that when particles from the molecular beam reach the sample surface, they are not immediately included in the crystalline structure; instead, they should be able to migrate on the wafer for a relatively long path. In this manner, atoms are allowed to “search” for a minimum energy site, which is always at the edge that rises on a layer when a isle of atoms is forming a new layer because there are forces attracting the atom from both the bottom and the lateral side. This is important since the crystal does not grow randomly, and then grows roughly, but some initial atoms form isles that gradually expand until they coalesce to cover the whole surface. Consequently, the growth proceeds spontaneously layer by layer, resulting in an extremely homogeneous and controllable epitaxial deposition. Now, it is straightforward that the higher the wafer temperature, the longer the migration path of the atoms on its surface. However, looking at the phase diagram of a binary compound, one can conclude that there is a temperature over which the pressure of the more volatile component (in the GaAs case it is arsenic) increases more rapidly, a minimum for a suitable stoichiometry of the solid phase no longer exists, and a liquid gallium phase is created. Hence, a temperature below 630°C is required for GaAs substrates.

The effusion cells are independently heated at accurately controlled temperatures, so that the contained atomic species are able to escape by thermoionic emission. Since the typical rate of growth with MBE is as slow as that around a single monolayer per second, shutters posed in between the sources and the wafer can easily control the composition of the global flux of particles reaching the semiconductor surface, with up to 1% accuracy.

5. METALLORGANIC CHEMICAL VAPOR DEPOSITION

MOCVD (metallorganic chemical vapor deposition) or MOVPE (metallorganic vapor-phase epitaxy) is another widely used method of creating controllable epitaxial layered structures by atomic deposition over a substrate material.

This method involves passing metal oxides in an inert gas across a workpiece to deposit a layer of metal oxide on the surface. MOCVD is utilized largely by the semiconductor industry. As shown in Fig. 6, the substrate wafer is placed on the graphite susceptor inside a reaction vessel and heated by an RF induction heater.

The temperature depends on the type of compounds grown, but it is usually between 500 and 700°C. Growth occurs in an atmosphere of hydrogen at a pressure between 100 and 700 torr. The growth precursors decompose on contact with the hot substrate to form epitaxial layers. Group V precursors are AsH₃ (arsine); while group III are Ga(CH₃)₃ trimethylgallium (TMG). The MOCVD process offers good material distribution capabilities and reproduces fine details with reliable quality. The materials to be coated must be able to withstand the extreme temperatures associated with this process.

Figure 6. MOCVD process setup.

6. REFLECTION HIGH-ENERGY ELECTRON DIFFRACTION

One of the most useful tools for in situ monitoring of the growth is reflection high-energy electron diffraction (RHEED). It can be used to calibrate growth rates, observe removal of oxides from the surface, calibrate the substrate temperature, monitor the arrangement of the surface atoms, determine the proper arsenic overpressure, give feedback on surface morphology, and provide information about growth kinetics. The layout of the RHEED system, shown in Fig. 7, can be summarized as follows. The RHEED gun emits ~10-keV electrons, which strike the surface at a shallow angle (~0.5–2°), making it a sensitive probe of the semiconductor surface. Electrons reflect from the surface and strike a phosphor screen, forming a pattern consisting of a specular reflection and a diffraction pattern that is indicative of the surface crystallography. A camera monitors the screen and can record instantaneous pictures or measure the intensity of a given pixel as a function of time.

Starting from a flat substrate, the electrons are not scattered greatly and are recorded as an intense beam. As material is deposited on the surface, the atoms create islands of epitaxial growth with a concomitant decrease in the reflectivity of the surface of the material as the electrons are scattered. As the deposition process continues, material builds up on the surface and the islands join together and create new flat surfaces, while the original substrate forms as voids in the newly created material. As yet more material forms, the voids begin to fill up and the reflectivity increases once again, although in reality, the reflectivity does not reach as high a value, since the deposition process is random and the surface never regains the completely flat profile of the initial polished substrate. By monitoring the oscillations in the reflectivity one can estimate the thickness and growth rate of the epitaxial material.

The appearance of the RHEED diffraction pattern can be used to provide qualitative feedback on surface morphology. If the surface is smooth, then the RHEED diffraction patterns appear streaky. If the samples are rough, then the horizontal streaks are more “spotty” and the diffraction pattern is not as clear. An amorphous surface,

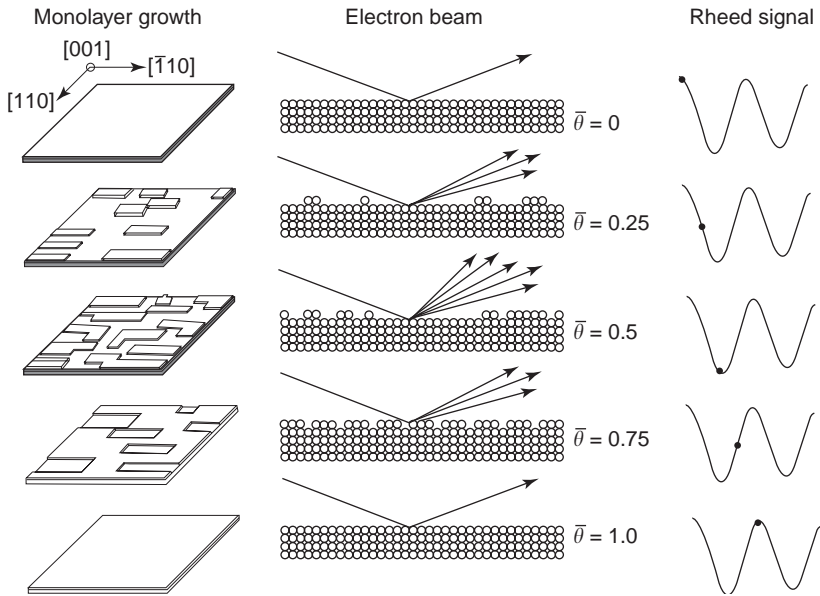

Figure 7. REED in situ growth monitoring technique.

such as an oxide layer, shows a haze instead of a diffraction pattern, and polycrystalline surfaces result in rings circling the straight-through beam. Such information, although only qualitative, can be a useful check of the surface condition.

7. GaAs HIGH-SPEED DEVICES

Gallium arsenide integrated circuit technology has been historically described as the “technology of the future.” Although initially it did not achieve the wide applicability originally predicted, it is now considered a relevant technology for microwave and millimeter-wave applications, and it is a fully accepted and commercially available source for high-speed integrated circuits. The main advantage of GaAs in high-frequency applications is its high electron mobility value. GaAs devices typically show a unity current gain frequency f_T that is 30–70% higher than that of an equivalent silicon transistor, for a given gate length or base width. Similar gainful can be achieved for the unity power gain frequency f_{max} . In addition, AlGaAs, which provides the ability to build lattice-matched and wide-bandgap heterojunctions, allows the device designer to have more freedom for performance optimization.

This feature of the AlGaAs/GaAs system is extremely important for a GaAs heterojunction bipolar transistor (HBT), where a higher emitter bandgap, with respect to the base bandgap material, is used to prevent holes from diffusing from base to emitter. As a result, a higher base doping can be reached, decreasing the base resistance, without degrading current gain. Besides, since undoped GaAs is a semiinsulating material, the parasitic capacitance due to wire interconnects is lower than in silicon technology.

The main GaAs technology drawback is related to the nonoptimal thermal behavior, which makes it more difficult to dissolve the heat generated by dissipated power.

Electrically speaking, the heat generation produces a drain current degradation for FET devices; this phenomenon is usually known as “self-heating”.

The three dominant GaAs high-speed device types are metal Schottky FET (MESFET), modulation doped FET or high-electron-mobility transistor (MODFET, HFET, HEMT), and the bipolar transistor type, known as the *heterojunction bipolar transistor* (HBT).

Besides thermodynamic problems, other drawbacks are observed, related principally to practical aspects, such as the low level of achievable integration, backdating, hysteresis, high $1/f$ noise, and parameter dispersion for MESFET and HEMT devices.

8. GaAs MESFET

The principle of GaAs MESFET transistor operation is similar to that of the simple and well-known silicon JFET, in particular concerning the current control mechanism by means of the voltage applied to the gate. The main difference between a silicon JFET and a GaAs MESFET is that in the former the drain current saturation is achieved at channel pinchoff, while in the latter saturation is induced by the electron velocity saturation. Even if GaAs HEMTs exhibit higher performance levels, GaAs MESFETs, are still commonly used in wireless applications.

GaAs MESFET technology is currently capable of realizing enhancement/depletion-mode integrated circuits of LSI complexity. The cross section of a typical GaAs MESFET is shown in Fig. 8. The maximum f_T of commercially available MESFET for integrated circuits applications is around 15 GHz, and the maximum f_T achieved by the best GaAs MESFET in a research laboratory environment is approximately 80 GHz. Commercially available devices have gate lengths of approximately $0.5\mu\text{m}$ down to $0.1\mu\text{m}$. The typical threshold voltage spread across a 3-in. wafer is 30–40 mV, and local threshold voltage spread,

Figure 8. Cross section of a MESFET.

which is important for comparator applications, is 15–20 mV. Because of the Schottky barrier gate, the maximum gate source voltage of GaAs MESFET is typically limited to approximately 0.7 V.

Most commercially available GaAs MESFETs suffer from low-frequency hysteresis effects, which make the design of high-accuracy comparators more difficult. This phenomenon is due to a drop in the high-frequency FET’s drain-to-source resistance, which is also associated with a phase shift, when the device is biased in the saturation region. This behavior produces a time-varying offset voltage or hysteresis, in the I - V relationship of the device, which is added to the DC offset of the comparator, thus reducing its achievable resolution. The hysteresis effect can be reduced by improving the circuit’s design procedures. More recent results obtained by means of improved processing techniques have demonstrated that it can be eliminated.

9. GaAs HEMT

Greater efficiency, along with a lower noise figure and a higher cutoff frequency, can be obtained by using the high-electron-mobility transistor (HEMT; see HEMT cross section in Fig. 9). The principle of operation is based on the concept of modulation doping.

In order to obtain a high-electron-mobility value, which means a high cutoff frequency and a lower noise figure, it is possible to use either a high-electron-mobility semiconductor material such as gallium arsenide or an undoped semiconductor material in which ionized impurity scattering is reduced. A more efficient method is to grow the FET channel using an undoped high-mobility semiconductor material and then increase the concentration of free carriers (which is extremely low at room temperature in an undoped material) by transferring them from an adjacent heavily doped layer, known as the “supply layer”. In this manner it is possible to obtain a high mobility of carriers, since electrons travel in an undoped material, and, at the same time, it is also possible to achieve high carrier concentrations and correspondingly high current densities.

The situation described above can be achieved by means of a heterojunction between two semiconductors with significantly different energy gaps. The wider-band-gap semiconductor is used to grow the heavily doped

Figure 9. Cross section of a HEMT.

supply layer, while the other alloy, which is intentionally not doped, is used for the FET channel. The electrostatic equilibrium of the heterojunction results in a triangular well at the interface, which confines the electrons in a two-dimensional (2D) electron gas known as 2DEG. The band diagram of this particular type of heterojunction is illustrated in Fig. 10.

At high frequencies, the HEMT structure, using the 2DEG as the current conducting channel, exhibits performance levels higher than those achievable with a conventional MESFET; therefore it is the most suitable transistor structure for microwave and millimeter-wave analog circuits as well as in high-speed digital applications. The first HEMT prototype was demonstrated in 1981 in the AlGaAs/GaAs material system.

The current control mechanism in the HEMT is obtained by tuning the density of electrons in the triangular well. When the gate voltage is modified, both the shape of triangular well and the position of the Fermi level are modified; therefore the number of electrons into the 2DEG is increased or decreased according to the sign of the V_G variation.

The sheet charge density n_s can be expressed as a function of the gate voltage V_G in the following way

$$n_s = \frac{\epsilon}{qd}(V_G - V_{TH}) \tag{4}$$

Figure 10. Band diagram of a HEMT.

where ε is the GaAs permittivity, d is the distance between the metal–semiconductor interface (where gate voltage is applied), and V_{TH} is the threshold voltage or pinchoff voltage.

As can be easily understood, n_s is related to the drain current, so that varying the sheet charge density allows the drain current to be controlled. The relationship between the drain current I_D and the gate voltage V_G can be calculated analytically, resulting in the following equation:

$$I_D = \begin{cases} \frac{WC_{OX}\mu_n}{L_G} \left[(V_{GS} - V_T)V_{DS} - \frac{V_{DS}^2}{2} \right] & \text{for } V_{DS} < V_{DS,sat} \\ \frac{WC_{OX}\mu_n}{L_G} \frac{(V_{GS} - V_T)^2}{2} = I_{D,sat} & \text{for } V_{DS} \geq V_{DS,sat} \end{cases} \quad (5)$$

In order to calculate the cutoff frequency, the equivalent circuit of the transistor, shown in Fig. 11, is needed.

Some circuitual components such as capacitances (both intrinsic and extrinsic or parasitic), as well as source and drain input resistances can be calculated. The other elements of the equivalent circuit, such as the transconductance g_m and the drain conductance g_d , can be deduced either from theoretical equations, or from small-signal measurements.

The aim of the analysis is to obtain the h_{21} hybrid parameter expression, which is frequency-dependent; by setting h_{21} to 1, one can calculate the cutoff frequency f_T (i.e., the frequency corresponding to a unit-gain current). Once the proper equivalent circuit has been defined, the same procedure can be used for HBT GaAs-based transistors, because the h_{21} parameter is related to the equivalent circuit and not to the physics behavior of the transistor. The full expression of f_T is

$$f_T = \frac{1}{2\pi \left(\frac{C_{GG,t}}{g_m} + \frac{C_{GG,t}}{g_m} (R_S + R_D)g_d + (R_S + R_D)C_{GD,t} \right)} \quad (6)$$

where $C_{GG,t}$ is related to the charge stored under the gate.

A similar approach can be followed to calculate the maximum oscillation frequency. In this case, however, we

Figure 11. Equivalent circuit of a HEMT.

are interested in deriving the unilateral power gain. Once the unilateral power gain is calculated, we set its value to 1, thus determining the maximum oscillation frequency f_{max} . With reference to the circuit in Fig. 11, the following expression can be derived for f_{max} :

$$f_{max} = \sqrt{\frac{f_T}{8\pi R_G C_{GD,t} \left[1 + \left(\frac{2\pi f_T}{C_{GD,t}} \right) \Psi \right]}} \quad (7)$$

$$\Psi = (R_S + R_D) \frac{C_{GG,t}^2 g_d^2}{g_m^2} + (R_S + R_D) \frac{C_{GG,t} C_{GD,t} g_d}{g_m} + \frac{C_{GG,t}^2 g_d}{g_m^2}$$

$$NF_{min} = 1 + \omega \frac{C_{GS}}{g_m} \left(\frac{R_S + R_G}{R_{IN}} \right)^{1/2} \quad (8)$$

9.1. Output Power

The power performance of a FET, as also of HBT, is determined by the maximum output power P_{out} defined as

$$P_{out} = \frac{1}{8} (I_{max} - I_{min}) (BV_{DS} - V_{knee}) \quad (9)$$

where

$$V_{knee} = V_{DS,sat} \quad (10)$$

$$I_{max} = I_{D,sat}(V_{GS} = 0, V_{DS} = V_{DS,sat}) \quad (11)$$

$$I_{min} = 0$$

The quantities used in these formulas are depicted in Fig. 12.

Figure 12. Static I/V characteristic of a HEMT.

The breakdown voltage is given by a semiempirical formula:

$$BV_{DS} = \frac{4.4 \times 10^{13}}{aN_d} \tag{12}$$

where a is the thickness of the channel layer, while N_d is the doping of the supply layer.

10. GaAs HETEROJUNCTION BIPOLAR TRANSISTOR (HBT)

Bipolar transistors, in spite of the advent of field-effect devices (which in Si technology dominate the memory market), continue to play a significant role still at microwave frequencies. The levels of current that can be handled, in fact, is greater than in field-effect devices, leading to both high speed and high power devices.

In field-effect devices, a way to achieve a high cutoff frequency and a low noise figure is to reduce the gate width. This goal, obviously, leads to a more critical lithographic process. For bipolar devices this step is replaced by the precise preparation of the thin base region; appropriate technologies for uniform growth of wafers have been defined to keep bipolar technology competitive.

However, the full fabrication process for bipolar transistors is more complex than for field-effect devices, and this factor has been relevant in making field-effect devices more popular. According to the standard transistor theory, the DC current gain (the ratio between the collector current and the hole current flowing from the base to the emitter) is given by

$$\beta = \left(\frac{n_e v_e}{p_b v_p} \right) \exp\left(\frac{\Delta E_G}{KT} \right) \tag{13}$$

where n_e and p_b are respectively the electron and hole densities in emitter and base, v_e and v_p are the electron and hole effective velocities, and ΔE_G is the difference in bandgap between emitter and base. As can be seen from this relationship, a higher level of gain current can be achieved by increasing the bandgap difference between emitter and base of the transistor. An AlGaAs/GaAs heterojunction, for instance, allows significant improve-

ments in performance; these improvements are summarized below:

- The difference in bandgap is 10 kT, and the exponential factor increases the value of β at room temperature up to 1000 (10–100 is sufficient in practice).
- The doping in the base can be increased significantly; thus the reverse flow in the holes is stopped by the heterojunction, and the lower base resistance provides a higher-speed device.
- The doping in the emitter can be increased without compromising the effect of bandgap narrowing; in turn, this leads to a higher current-handling ability.
- The notch in the conduction band edge can be eliminated by grading down the Al composition in the last few nanometers; this improves the emitter efficiency (see Fig. 13b).

In the transistor design tradeoff, the heterojunction can be used as a further design tool. A thin base, for example, increases the DC current gain (since there is a lower probability of electron–hole recombination in the base), but unfortunately it slows down the device (because of the increased lateral base resistance). A way to avoid this effect, allowed by heterojunctions, is to increase the p doping in order to offset any rise in lateral base resistance. A further advantage of heterojunctions is that the bipolar transistor can operate over a significantly enhanced temperature range, since the heterojunction prevents runaway thermal-based currents (higher temperature range) and because all the doping densities are above the levels at which carriers freeze out at low temperatures (lower temperature range).

If the composition of the base is graded (see Fig. 13b) from 10% Al content at the emitter–base heterojunction up to 100% at the base–collector interface, the electric field at the falling conduction band edge can be used to maintain acceleration of the injected hot electrons. A wider-gap collector can also be used to reduce hole injection from the base to collector when forward-biased (i.e., turned off) and to allow higher voltages to be applied to the collector junction without breakdown or leakage. The main drawback is related to the complex structures associated with the heterojunction bipolar transistor, which leads to a low yield.

Figure 13. (a) HBT band diagram; (b) Al-graded HBT band diagram.

In digital circuits, the low values of the base resistance and the short electron transit time from emitter to collector enable fast device operation (ON/OFF switching speeds of < 10 ps). The larger bandgap in AlGaAs compared with Si means that larger drive voltages are required for III-V HBTs. In a number of analog circuit configurations, such as amplifiers and high-speed digital-to-analog converters, some of the HBT features are highly desirable to systems designers, particularly the uniformity of the turnon voltage of the emitter-base junction, the absence of trapping effects typical of field-effect devices (where hot electrons are injected into the substrate or into the AlGaAs layer of a heterojunction device), and a low $1/f$ noise. Furthermore, the lower base resistance in the III-V HBTs leads to lower power consumption, when compared with the Si bipolar transistor.

Useful complementary materials for both HEMT and HBT devices are $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ and $\text{In}_{0.52}\text{Al}_{0.48}\text{As}$, as they are both lattice-matched to InP. The main advantages offered are

- Reliable technique for the growth of these materials
- Electron mobility 1.6 times higher than in GaAs, resulting in faster devices
- Smaller bandgap (0.75 eV) compared with 1.42 eV for GaAs, leading to a lower turnon voltage, reduced power consumption, and lower voltage supply

A further advantage of the InP substrate is its higher thermal conductivity.

11. APPLICATIONS

High-speed transistors based on gallium arsenide, such as MESFET, HEMT, and HBT, have found wide applications in microwave monolithic integrated circuits (MMICs).

At the early stage of development of GaAs technology, high-speed transistors based on GaAs were used only for defense and space applications because of high-performance system demand; more recently, the huge growth of commercial wireless and fiberoptic communication systems has opened up new application areas for those devices. GaAs MESFET was the first developed high-speed transistor, used for consumer wireless products; a few years later, HEMT and HBT, succeeded it. Mainly III-V based devices are currently used for amplifiers in consumer wireless communications. Initially, when the analog cellular phone market was developing, silicon-based transistors, such as BJT, were exclusively used for power amplifier applications because of their low cost and high-volume production capability. At that time GaAs technology had not yet emerged, so cost and volume requirements could not be met.

By the early 1990s, the GaAs MESFET, which was more efficient, was quickly replacing the Si-based transistor (BJT). The GaAs MESFET manufacturing technology has matured rapidly; cost and manufacturability have become competitive with those of silicon BJTs. In the full-duplex analog cellular phone, output power amplifier noise figures provided by GaAs MESFET has led to

relaxed filtering requirements, enabling a consistent cost reduction, greater integration capability, and improvement efficiency.

In the mid-1990s, cellular phone systems generally ran on digitally modulated schemes such as GSM and CDMA. In a short time the analog cellular phone was replaced by a digital one. Consequently, greater efficiency, lower power consumption, better noise figure, and higher linearity were required; unfortunately the classical MESFET was not able to provide such characteristics. For these reasons a more efficient GaAs-based transistor belonging to the field-effect transistor family, the high-electron-mobility transistor (HEMT), came out. HEMTs, and subsequently pseudomorphic HEMTs, replaced GaAs MESFETs in many application. At the same time, a new bipolar GaAs-based transistor, known as the *heterojunction bipolar transistor* (HBT), was developed. It exhibits greater efficiency than does the common silicon-based bipolar transistor; in many applications GaAs MESFETs were replaced by GaAs HBTs, which shows greater efficiency and smaller size, while providing adequate linearity and low noise figure.

One of the main advantages of HBTs in digital cellular phones, as well as all mobile applications, is that they require only a single polarity power supply, which is an important factor for size and weight reduction.

The most recent research efforts at TRW (Redondo Beach, CA) have shown a new commercially viable technology that monolithically integrates both HEMTs and HBTs in the same MMIC. This technology has potential applications in many applications, including single-chip transmit-receiver circuits, which combine HEMT low-noise front ends with HBT high-linearity output stages along with PIN diode variable gain control.

University of Illinois at Urbana-
Champaign

1. INTRODUCTION

The advent of blue light-emitting diodes (LEDs) and short-wavelength blue-violet laser diodes using the III-nitride alloys (AlN, GaN, and InN) have opened up an era of new optical devices that was not possible with the established

III-V material systems based on GaAs, AlAs, GaP, InAs, and related alloys. The direct bandgap and a wide spectrum of bandgap energies (0.7 eV for InN, 3.4 eV for GaN, and 6.2 eV for AlN) of III-nitride semiconductors make them suitable for a wide range of optoelectronic applications. Fundamental breakthroughs in the late 1980s in growth technologies such as improved epitaxial quality using AlN buffers [1,2] and the development of p-type conductivity [3,4] led to the realization of blue light-emitting diodes (LEDs) in 1993 [5,6].

Following the tremendous progress in material quality and device processing, a worldwide market for nitride-based devices has developed. One of the highest profile markets for nitride-based LEDs is in mobile phones, particularly blue LEDs for keypads and white LEDs for the liquid crystal display (LCD) backlight. Nitride-based LEDs also offer great promise for solid-state lighting applications such as architectural lighting, machine vision, illumination for signage, flashlights, and decorative lights. The market for high-brightness LEDs (HB-LEDs) in lighting applications has grown rapidly with an overall market in the billions of dollars [7,8]. Based on continuing positive trends in this dynamic industry, the market for HB-LEDs is projected to grow to ~\$5.0 billion by 2007 [9]. In terms of materials, the market was dominated by InGaN-based devices, which accounted for 68% of total HB-LED sales in 2002. White LEDs are considered very promising for commercial market for general illumination due to progress in lumen output, with higher efficiencies than that of incandescent lamps. With the introduction of blue-violet laser diodes [10], the development of next generation optical storage systems (e.g., DVD drives and recorders), is also underway [11]. Currently, the semiconductor industry is undergoing massive changes which is partly driven by III-nitride semiconductors and associated products.

2. APPLICATIONS OF GALLIUM NITRIDE ELECTRONICS

In addition to their usefulness in optoelectronic applications, GaN-based devices also have excellent electronic properties such as high critical breakdown fields, high saturation velocity, and good thermal conductivity. Many laboratories around the world have demonstrated microwave power performance for GaN devices that are far superior to the performance of other solid-state device technologies. The GaN-based high-electron-mobility transistor (HEMT) is considered an ideal candidate for high-power and high-temperature RF/microwave applications. GaN HEMTs can operate at high speeds, at high power levels, at high temperatures (~500°C), and also in very harsh (i.e., corrosive or high radiation) environments. Electronic systems that can reliably operate under these conditions are currently being sought in industries such as wireless communications, aerospace, automotive, petroleum, and power generation.

Commercial and military applications of GaN-based electronics are numerous and diverse. Power amplifiers (PAs) in the transmitters of 2.5G and 3G cellular base stations are promising and highly competitive market for GaN HEMTs. High-power devices based on GaN clearly

have many advantages in this market over Si and GaAs with the capability of delivering continuous high power levels without stringent cooling requirements. Currently, silicon LDMOS (laterally diffused metal-oxide-semiconductor) is the primary technology in use. However, the LDMOS technology is expected to reach its fundamental limit due to high power and high linearity requirements of next-generation PAs. GaN HEMTs are expected to enter the cellular base-station PA market sooner rather than later. In fact, high-performance wideband UMTS GaN PAs have already been demonstrated [12]. Reliability issues required for widespread commercial usage are yet to be fully addressed.

The automotive and aerospace industry represents another large potential market, where heat-tolerant GaN electronics incorporated in control systems would improve performance and reliability of the overall system. Wide bandgap GaN-based devices would allow bulky hydraulics (e.g., control actuators) and mechanical control systems (e.g., engine-gearbox-driven fuel pumps) to be replaced with solid-state power electronics. Replacement of these systems would reduce the weight and complexity of the overall system.

Radar and satellite-communications links, which operate at microwave frequencies, would benefit from GaN-based electronics as well. GaN electronics can deliver higher power levels per chip area than either Si or GaAs, and thus smaller system components can be realized. In addition, high power (dissipated handling capability allows for smaller cooling systems, so size reductions would significantly lower the overall payload weight and translate into cost savings in delivering satellites into orbit. The petroleum industry seeks to use GaN-based sensors to monitor environmental conditions within an oil well (well logging) where temperatures can be as high as 300°C. Radiation-hardened electronic instrumentation systems based on widegap GaN could also be implemented to directly monitor reactor conditions in nuclear power plants.

Although, GaN-based electronic devices are considered primarily for high-power and high-temperature applications, preliminary results also suggest that they are suitable for microwave low-noise applications. Further improvements in minimum noise figures are expected with optimization of GaN HEMTs. The low noise performance coupled with excellent high voltage capability make GaN HEMTs ideal candidates for robust low-noise amplifiers (LNAs). These properties of GaN HEMTs would eliminate the need for additional protection circuits, thus improving the system noise figure while simplifying overall system design. The excellent microwave power capabilities and the development of low-noise GaN HEMTs provide a path to the realization of highly linear, broadband, and robust transceiver systems.

3. MATERIAL PROPERTIES

The crystal structure of GaN is a hexagonal or wurtzite structure, as shown in Fig. 1, where the bilayers consist of two closely spaced hexagonal layers, one formed by Ga atoms and the other formed by N atoms. The compound

Figure 1. Schematic of (a) Ga-face and (b) N-face wurtzite GaN crystal structures [13].

structure exhibits two different sequences (Ga face and N face) in the atomic layers. The lack of inversion symmetry with the strong ionicity of the covalent bonds leads to the polarization vectors, and these polarization vectors are additive along the *c*-axis of the wurtzite crystal, resulting in macroscopic polarization fields. In AlGaN/GaN hetero-structures, there are two different polarizations: strain-induced (piezoelectric) polarization and zero-strain (spontaneous) polarization. The magnitude and direction of the electric fields associated with these polarization effects depend on the substrate, growth orientation, and nature of the surface (Ga-face or N-face). The most common nitride structures are grown along the [0001] direction with Ga-terminated surface. The high-polarization electric fields in the AlGaN layer induce a high two-dimensional electron gas (2DEG) with very high sheet carrier density at the AlGaN/GaN interface without intentional doping [13]. Due to large piezoelectric constants, the piezoelectric effect is important in determining the charge control model of AlGaN/GaN HEMTs.

As discussed earlier, GaN-based transistors are promising candidates for high-power and high-temperature applications due to the materials' superior electronic properties. Table 1 shows the material parameters for wide-bandgap semiconductors (GaN and 4H-SiC) as well as for Si and GaAs [14–17]. The obvious difference between GaN and conventional semiconductors is the wide bandgap, which results in significantly lower intrinsic carrier density for GaN. This allows GaN-based devices

Table 1. Material Properties of Various Semiconductors

Physical Property/Material	Si	GaAs	4H-SiC	GaN
Bandgap (eV)	1.12	1.43	3.2	3.4
Electron mobility (cm ² /Vs)	1350	8500	800	1500
Peak electron saturation velocity (cm/s) × 10 ⁷	1	1	2	1.5
Breakdown field (V/cm) × 10 ⁵	3	4	32	34
Thermal conductivity (300 K) (W/cmK)	1.5	0.5	3.3	1.3
Dielectric constant	11.8	12.8	9.7	9.5

to operate at much higher temperatures. Also, the material system has high breakdown fields (≥ 3 MV/cm) and high saturation velocity (1.5×10^7 cm/s). Breakdown field is a very important criterion for high-power electronics, since the maximum output power for a class A amplifier can be estimated from the following expression

$$P_{\max} = \frac{(V_{\text{BK}} - V_{\text{knee}})^2}{8R_L},$$

where R_L is the load resistance, V_{BK} is a transistor's breakdown voltage, and V_{knee} is the knee voltage, defined as the voltage at which the transistor current saturates. It is obvious that a high-power output requires high breakdown voltage, which in most cases is directly related to the critical breakdown field. From Table 1, it can be seen that the breakdown field for GaN is much higher than that for GaAs and Si. It means that GaN-based devices can withstand higher bias voltages, thus producing higher total power output.

The current drive capability of AlGaIn/GaN heterostructure is also excellent due to very high sheet carrier density and high saturation velocity. The high conduction band offsets at AlGaIn/GaN interfaces results in high electron mobilities (≥ 2000 cm²/Vs [18]). Because of the strong spontaneous and piezoelectric polarization effects, AlGaIn/GaN heterostructure typically has 2DEG with sheet density values of about 1×10^{13} /cm² with no intentional doping [19]. These values are higher than those seen in AlGaAs/InGaAs and InAlAs/InGaAs heterostructures. In the form of AlGaIn/GaN HEMTs, these transport properties translate to both high current drive capability and high breakdown voltage. High power operation is further facilitated by the use of semiinsulating SiC substrates that are characterized by high thermal conductivity (3.3 W/cmK).

By combining various materials' parameters, the overall potential of any semiconductor material system for high-power, high-frequency performance can be predicted using well-known figures of merit (FoMs). For example, Johnson's figure of merit, $\text{JFoM} = (E_C v_{\text{sat}}/2\pi)^2$ (where E_C is the critical breakdown field and v_{sat} is the saturation velocity) [20], defines the power \times frequency² product for the transistor and determines its output power capability at given frequencies. In addition, Shenai's figure of merit, $Q_{\text{F1}} = \lambda \sigma_A$ (where λ is the thermal conductivity and σ_A is the conductance of the channel) [21], measures the power-handling capability in terms of the dissipated power. Alekseev et al. [22] proposed an extended definition of Shenai's figure of merit, $Q_{\text{FS}} = \lambda_{\text{sub}} \sigma_A$, which takes into account thermal conductivity of the substrate material (sapphire or SiC). Table 2 compares the FoMs calculated for GaN- and GaAs-based devices. It can be seen that GaN is a far more superior material to GaAs for high-power and high-frequency applications.

4. AlGaIn/GaN HEMT OPERATION AND FABRICATION

The basic principle of HEMT operation involves the transfer of electrons from ionized donor impurities in the wider-

Table 2. Comparison of GaN- and GaAs-Based Devices for High-Power and High-Frequency Performance^a

Figures of Merit (FoMs)	GaAs	GaN on Sapphire	GaN on SiC
$\text{JFoM} = (E_C v_{\text{sat}}/2\pi)^2$	1	100	100
$Q_{\text{F1}} = \lambda \sigma_A$	1	22	22
$Q_{\text{FS}} = \lambda_{\text{sub}} \sigma_A$	1	5	76

^aResults are normalized to GaAs.

bandgap semiconductor (e.g., AlGaIn) to form a 2DEG in a potential well at the AlGaIn/GaN hetero-interface. The term "high electron mobility transistor" is used because the structure takes advantage of the superior transport properties (high mobility and velocity) of electrons in the lightly doped semiconductor material (e.g., GaN).

A typical AlGaIn/GaN HEMT structure is shown in Fig. 2; it consists of an AlGaIn barrier layer grown on GaN channel layer. The device structures are mainly grown on sapphire or semiinsulating SiC substrates. Since neither of these substrates is lattice-matched to GaN, an AlN buffer layer is generally used to isolate the channel layer from the substrate. Defects and dislocations occur in the epitaxial layers due to lattice mismatch, with typical dislocation densities on the order of 10^8 – 10^9 /cm². The lattice mismatches of GaN on sapphire and SiC substrates are 13% and 3.1%, respectively; therefore, the GaN crystal quality is better on SiC. As the thermal conductivity of SiC is about 10 times that of sapphire, it is evident that SiC is better suited for high-power and high-temperature applications.

We delineate a typical device fabrication procedure here. The first step for the device fabrication is mesaisolation, which can be etched down to the undoped GaN using Cl₂/Ar plasma in an inductively coupled-plasma reactive-ion etch (ICP-RIE) system. Next, ohmic contacts are formed by rapid thermal annealing of either evaporated Ti/Al/Ti/Au [23] or Ti/Al/Mo/Au [24] in N₂ ambient. A pre-treatment of the ohmic contact area using SiCl₄ plasma in a RIE is performed prior to Ti/Al/Ti/Au (Ti/Al/Mo/Au) metallization. In the case of Ti/Al/Mo/Au ohmic metallization, the surface morphology of the annealed contact is very smooth as well as having low specific contact resistivity. No degradation in contact resistance was observed when the contact was subjected to long-term annealing at

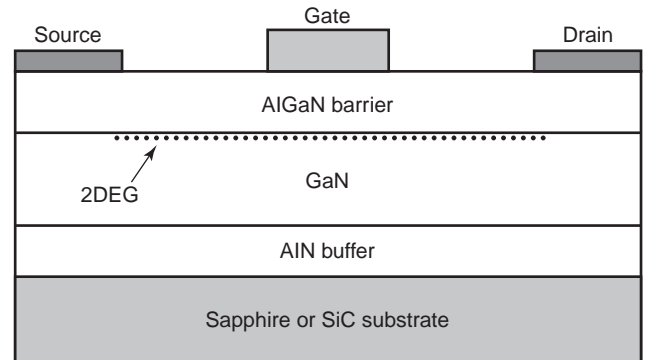

Figure 2. Basic AlGaIn/GaN HEMT structure.

Figure 3. Micrograph of a GaN HEMT.

500°C for 360 h, demonstrating excellent thermal stability. T-shaped gates are defined using a trilayer PMMA/P(MMAMAA)/PMMA and electron-beam lithography. Ni/Au metals are then evaporated for gate metallization. Overlay metallization on ohmic contacts and measurement pads are also deposited during gate formation. Silicon nitride passivation is then deposited. Fig. 3 shows the micrograph of a GaN HEMT.

5. STATE-OF-THE-ART AlGaIn/GaN HEMTs

The first AlGaIn/GaN HEMTs were demonstrated by Khan et al. in 1994 [25]. Transistors with 0.25 μm gate length produced a current density of 60 mA/mm and a transconductance of 27 mS/mm. Since then, dramatic progress has been made in material growth and process technology for AlGaIn/GaN HEMTs. A breakdown voltage as high as 570 V in an AlGaIn/GaN HEMT with a source–drain spacing of 13 μm and a gate length of 0.5 μm using an overlapping gate structure was reported [26]. AlGaIn/GaN HEMTs with current density of 2.1 A/mm have also been reported [27]. A power density as high as 10.7 W/mm at 10 GHz has been achieved on GaN HEMTs [28]; however, their suitability for power applications at frequencies ≥ 30 GHz is currently being limited by the speed of these devices.

5.1. High-Speed Performance

AlGaIn/GaN HEMTs with a unity current gain cutoff frequency (f_T) of 110 GHz and a maximum frequency of oscillation (f_{max}) of > 140 GHz have been demonstrated by reducing the gate length down to 50 nm [29]. However, this reduction of gate length leads to a decrease in breakdown voltage.

To achieve higher performance, indium has been utilized as a surfactant during the growth of AlGaIn/GaN HEMTs [30]. A demonstration of the concept used a MOCVD-grown epilayer which consists of a 100 nm AlN buffer, 2 μm undoped GaN, a 5-nm undoped Al_{0.25}Ga_{0.75}N spacer, a 10-nm Si-doped ($\sim 5 \times 10^{18}/\text{cm}^3$) Al_{0.25}Ga_{0.75}N

Figure 4. Short-circuit current gain ($|h_{21}|$) and maximum stable/maximum available gain (MSG/MAG) of a 0.12 μm × 100 μm AlGaIn/GaN HEMT on SiC substrates. The device was biased at $V_{DS} = 8$ V and $V_{GS} = -3.95$ V [31].

charge supply layer, and a 10-nm undoped Al_{0.25}Ga_{0.75}N barrier layer. The layer was grown on 4H-SiC. A low-level flux of trimethylindium (TMI) during the growth of the structure helped in improving the surface and interface roughness through the incorporation of trace amounts of indium. Hall measurements showed a sheet carrier concentration of $1.1 \times 10^{13}/\text{cm}^2$ and an electron mobility of 1300 cm²/Vs at room temperature on as-grown wafers.

A device fabricated from this layer demonstrated a typical drain current density of 1.23 A/mm, peak transconductance of 314 mS/mm, and a gate drain breakdown voltage of over 60 V. Figure 4 shows the short-circuit current gain ($|h_{21}|$) and maximum stable gain/maximum available gain (MSG/MAG) derived from on-wafer *S*-parameter measurements as a function of frequency for the 0.12-μm-gate-length device. The effect of pad parasitics was deembedded by conventional *Y*-parameter subtraction. The values of unity current gain cutoff frequency (f_T) and maximum frequency of oscillation (f_{max}) were determined by extrapolation of the $|h_{21}|$ and MSG data at 20 dB/decade. At a drain bias of 8 V and a gate bias of −3.95 V, an f_T of 121 GHz, and an f_{max} of 162 GHz were obtained, which to the best of the authors' knowledge are the highest data ever reported for GaN-based HEMTs [31]. This excellent RF performance is attributed to the high quality of material and also to the optimized device processing.

5.2. High-Power Performance

In terms of power, wide-bandgap AlGaIn/GaN HEMTs on semi-insulating SiC substrates have yielded a continuous-wave (CW) power density of 32 W/mm at 4 GHz and 16.5 W/mm at 10 GHz, and a pulsed power output of 113 W at 1.95 GHz, making them promising candidates for next-generation commercial power amplifier systems [32–34]. Also, more recent millimeter-wave power performance of GaN HEMTs suggests that operation of GaN HEMTs can be extended to K/Ka band. At 20 GHz, 3 W/mm CW power density with 22.5% power-added efficiency

(PAE) has been attained for 0.3- μm -gate-length devices [35] and 6.6 W/mm CW power density with 35% PAE for 0.15- μm -gate-length devices [36]. At 35 GHz, an output power density of 4.13 W/mm with 23% of PAE and 7.54 dB of linear gain were achieved at a drain bias of 30 V [37]. The combined results of power density, PAE, and gain that have been achieved using GaN HEMT technology are impressive. For comparison, silicon-based transistors can efficiently amplify signals up to only 2–3 GHz. GaAs transistors can handle 10 GHz but deliver a power density of less than 1 W/mm at that frequency.

At relatively low frequencies, the field-plated technique have achieved impressive power results [32,33]. Figure 5 shows the measured CW power, gain, and PAE of a modified field-plated device at 10 GHz, where the AlGaIn/GaN HEMTs with an optimized gate structure enabled the device to operate at higher drain biases than did conventional gate structure, yielding improved power levels. Details of the device structure are reported elsewhere by Thompson et al. [33]. Power data were taken on wafer using an automatic load-pull system at room temperature. The large signal performance of a 0.35- μm -gate-length device was measured when the device was biased at a drain-source voltage of 60 V. The device had a saturated output power density of 16.5 W/mm and PAE of 47% as shown in Fig. 5.

State-of-the-art CW power performances at 20 GHz were obtained from a 0.25 $\mu\text{m} \times 100 \mu\text{m}$ AlGaIn/GaN HEMT on 4H-SiC substrates [38]. The devices exhibited high current density, transconductance, and millimeter-wave output power density. The large-signal performance of the device at 20 GHz is shown in Fig. 6. The device was biased with a drain-source voltage of 30 V at a DC drain current of 620 mA/mm. The device had a saturated output power of 6.4 W/mm with an associated gain of 2.9 dB and PAE of 16%. The peak efficiency was 22% with an output power of 5.8 W/mm and gain of 6.1 dB.

Figure 5. CW power sweep of a 0.35 \times 150- μm field-plated gate device at 10 GHz, demonstrating output power of 16.5 W/mm and PAE of 47% when operated at 60 V drain bias [33].

Figure 6. Large-signal performance of a 0.25 \times 100- μm AlGaIn/GaN HEMT on 4H-SiC at 20 GHz when biased with $V_{DS} = 30$ V and $V_{GS} = -1.87$ V, saturated output power was 6.4 W/mm with 2.9 dB gain and 16% PAE [38].

Figure 7 shows the large signal performance of a 0.25 \times 200- μm AlGaIn/GaN HEMT at 30 and 35 GHz [37]. With a drain voltage of 30 V and a drain current of 325 mA/mm, the device had a saturated output power density of 5.43 W/mm at 30 GHz with 9.17 dB gain and PAE of 33%. When the device was tested at the same bias conditions at 35 GHz, the device delivered a remarkable output power of 4.13 W/mm with a peak PAE of 23% and a linear gain of 7.54 dB. This performance vividly demonstrates the potential for very-high-power solid-state amplifiers employing 0.25- μm -gate-length GaN-based HEMTs to replace TWT amplifiers in space-based millimeter-wave communication systems.

The combined results of power density, PAE, and gain that have been achieved to date using GaN HEMT technology are impressive. No other solid-state device technologies have demonstrated these capabilities. Figure 8 shows the various reported power densities over a fre-

Figure 7. Output power, PAE, and gain as a function of input power of a 0.25 $\mu\text{m} \times 4 \times 50 \mu\text{m}$ AlGaIn/GaN HEMT at 30 and 35 GHz [37].

Figure 8. Reported power densities over a frequency range of 4–40 GHz are shown with symbols. The solid line represents a best fit to the points.

quency range of 4–40 GHz. With these results, GaN HEMTs have demonstrated at least an order of magnitude higher power density over the existing Si- and GaAs-based RF and microwave transistor technologies. The excellent material properties of AlGaIn/GaN material system have indeed delivered a new level of microwave power and frequency operation.

5.3. Low-Noise Performance

In parallel with the improvement in power density results, microwave noise performance has also shown rapid improvement. From the first report [39] on the noise characteristics of GaN HEMTs to more recent results [40–42], it has been shown that these devices exhibit promising microwave noise properties. The minimum noise figure of 0.25- μm -gate-length AlGaIn/GaN HEMTs [43] is comparable to the results reported previously for a pseudomorphic GaAs HEMT with similar gate length [44]. The investigation of GaN-based devices for microwave noise applications is of interest because wide-bandgap GaN with its relatively low intrinsic carrier generation and the high breakdown fields provides an enabling technology that can sustain a higher input power and breakdown voltages at higher temperatures than GaAs- and Si-based devices.

Figure 9 shows the measured microwave noise performance of 0.12- μm -gate-length GaN HEMTs on SiC substrate [40]. The minimum noise figure (NF_{min}) and associated gain (G_a) of the devices were measured on wafer using an ATN NP5 noise parameter test set over the 4–18 GHz frequency range. For these measurements, devices were biased at $V_{\text{DS}} = 10\text{ V}$ and $V_{\text{GS}} = -4.8\text{ V}$. The devices exhibited an NF_{min} of 0.77 dB and 0.99 dB at 12 and 18 GHz, respectively. This excellent noise performance is attributed to the higher gains engendered by the smaller gate length and the excellent low leakage Schottky gate characteristics. The current results show significant improvement compared to previously reported 0.25- μm AlGaIn/GaN HEMTs that had minimum noise figures of 1.8 dB [39] and 2.0 dB [42] at 18 GHz, respectively.

Figure 9. Minimum noise figure (NF_{min}) and associated power gain (G_a) versus frequency for a 0.12 μm AlGaIn/GaN HEMT; the solid line is the modeled minimum noise figure for the extrinsic device; the bias condition was $V_{\text{DS}} = 10\text{ V}$ and $V_{\text{GS}} = -4.8\text{ V}$ [40].

6. GALLIUM NITRIDE RF AND MICROWAVE POWER AMPLIFIERS

6.1. Advantages of GaN-Based Power Amplifiers

High-power-density GaN HEMTs provide many advantages for the realization of power amplifiers: (1) higher output power per unit area needs smaller device size and translates to broader bandwidth for given output power, (2) small device size reduces matching circuit complexity, and (3) efficient heat dissipation through high thermal conductivity of SiC substrates relieves cooling requirement. For high-power amplifiers where multimillimeter-to-centimeter gate peripheries are needed, large impedance transformation ratio limits useful bandwidth for given output power requirement. With higher power density per picofarad of input/output capacitance of GaN HEMTs than devices based on Si and GaAs, multioctave broadband GaN HEMT amplifiers are realizable. Also, small device size for the same output power rating drastically reduces both the input and output impedance transformation ratios, thus simplifying overall matching circuits. For example, let us consider how high-power-density GaN HEMTs can simplify overall amplifier system. Figure 10 shows a conventional amplifier based on InGaAs pHEMTs, which produce a total output power of 4 W at 20 GHz. With the minimum impedance transformation requirement, the output power of an InGaAs-based HEMT MMIC amplifier is limited to about 1 W at 20 GHz. To deliver a total output power of 4 W, external power combining of multiple MMICs is necessary. The external power combining not only adds to assembly cost but also makes the overall system complicated and large. If GaN HEMTs are utilized for the amplifier, a single GaN MMIC can directly produce 4 W at 20 GHz without bulky external power combiners. Thus, using GaN HEMTs provides simple and compact design, which enhances overall system reliability. These advantages are valuable for applications requiring broad bandwidth, high temperature, and high power operation such as in commercial wireless base stations,

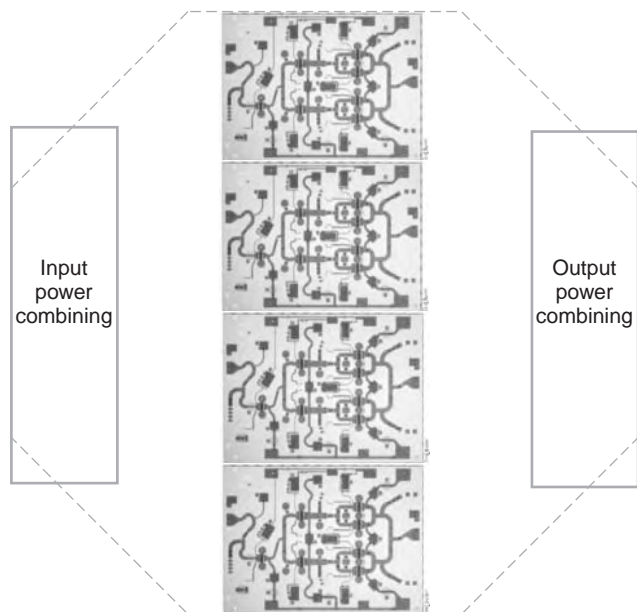

Figure 10. A 20-GHz InGaAs pHEMTs power amplifier system. To deliver overall output power of 4 W, external power combining is required. (From the 6th Widegap III-Nitride Workshop at UCSB; figures of MMIC amplifiers are from Triquint Inc.).

satellite communications, local multipoint distribution system (LMDS), and assorted defense systems.

More recent applications of GaN HEMTs in broadband power amplifiers have included a monolithic nonuniform distributed amplifier with a cascode-connected gain cell [45], an amplifier with *LCR* matching having an input power splitter and an output combiner [46], and a two-stage, reactively matched MMIC amplifier with backside via holes through the SiC substrate [47]. In addition to linear class A operation or nonlinear class AB operation, GaN-based class B amplifiers also have been demonstrated at microwave frequencies. A single-ended class B amplifier employing bandpass filtering at the output resulted in a 36 dBm output with good linearity [48]. In an amplifier with two devices for push-pull operation, a maximum output power of 35 dBm and a PAE of 42% were obtained at 5 GHz [49]. These GaN-based microwave power amplifiers have demonstrated great potential for achieving both high power and broadband performance at microwave frequencies.

6.2. 50-W C-Band GaN HEMT Power Amplifier

A C-band power amplifier is described as an example to show the advantages of using the AlGaN/GaN HEMT for high-power amplifiers [50]. The devices used in the amplifier were 0.6- μm -gate-length GaN HEMTs with maximum drain current of ~ 1 A/mm and a breakdown voltage of 80 V. The power density of a unit device was more than 6 W/mm and a total gate periphery of 8 mm was chosen for the amplifier to achieve 50 W total output power at 6 GHz. The AlGaN/GaN HEMTs typically had an input capacitance of 2.7 pF/mm, similar to that of a GaAs-based HEMT, while the optimum output load was 75 Ω ·mm,

Figure 11. Chip microphotograph of a 50-W GaN-based flip-chip integrated power amplifier incorporating a 8-mm AlGaN/GaN HEMT; die size is about 10×7 mm² [50].

about 2 times that of a GaAs HEMT. Since the GaN HEMT offers 10 times the power density for the same output power, the input transformation ratio is 10 times less, while the transformation ratio is 20 times less than a GaAs HEMT at the output. To achieve 50 W output power using the conventional GaAs-based FET technology (either HEMT or MESFET) the device gate periphery would have to be 80 mm, requiring a challenging input/output impedance transformation ratio.

With the reduced impedance transformation ratio for GaN-based amplifier, an *LCR*-matching network was used to convert the capacitive gate impedance to a real value of $\sim 1.5 \Omega$ within the bandwidth. This was then transformed to the 50 Ω input impedance by an output matching network. At the output, the power load for the 8-mm-wide device was transformed to the 50 W circuit output. The fabricated amplifier is shown in Fig. 11. The circuit was laid out in a coplanar-wave transmission-line system and constructed using a flip-chip integrated-circuit scheme for thermal management and electrical connection. The amplifier exhibited a midband small-signal gain of 14.5 dB when biased at 25 V. Pulsed-power measurement was performed using 0.5 ms pulsewidth and 5% duty cycle. The output power at 6 GHz was 51 W when biased at 39 V with a corresponding power density of 6.4 W/mm. This represents a remarkable power output obtained from a small periphery solid-state FET and simple input/output matching network design.

6.3. Broadband High-Power Cascode GaN HEMT MMICs on SiC Substrates

GaN HEMTs have higher output power per device input/output capacitance ratio than do conventional devices. On the basis of this idea, a broadband high-power cascode GaN HEMT MMIC amplifier with high gain and PAE was fabricated on SiC substrates [45]. Traditionally, distributed amplifiers (DAs) have been used for applications requiring broad bandwidths. DAs offer broadband operation by incorporating gain elements in synthetic lumped-element approximate transmission lines, realized by the transistor capacitances and intervening inductances [51]. This topology allows the addition of transconductance

Figure 12. Chip microphotograph of the nonuniform distributed amplifier with cascode-connected GaN HEMTs as gain elements; die size is about $2.5 \times 1.4 \text{ mm}^2$ [45].

without adding device capacitance, thus resulting in excellent gain–bandwidth products.

Figure 12 shows a multioctave broadband GaN HEMT MMIC amplifier fabricated on SiC substrates. It contains three cascode-connected GaN HEMTs as gain elements. Each device has 1 mm of total gate periphery for both the common-source and common-gate devices. The two devices are separated by a 125- μm section of a high-impedance transmission line to further facilitate heat dissipation. Cascode topology reduces the Miller effect, resulting in reduced feedback capacitance. A cascode gain cell exhibited 5 W output power at 8 GHz with a small-signal gain of 19 dB, thus providing high gain and broad bandwidth for the amplifier. All gate CPW line impedances are 80Ω , and the drain-line impedances, from the left- to right-hand sides, are 60Ω , 50Ω , and 30Ω . The drain-line dummy load was removed to prevent power consumption by the synthetic drain-line termination dummy load, thus improving PAE of the amplifier. The gate- and drain-line sections were carefully optimized for optimum power and efficiency using the genetic algorithm method. The resulting amplifier has nonuniform drain-line lengths and impedance to effectively combine output power from three gain elements. The amplifier based on this process yielded a saturated output power of 3–6 W over a DC-to-8 GHz bandwidth with an associated PAE of 13–31%.

6.4. Broadband GaN-Based Flip-Chip Integrated Power Amplifier

With excellent gain–bandwidth product, distributed amplifiers (DAs) are preferred for broadband operation. However, conventional DAs usually exhibit poor output power because nonuniform device loading along the drain line limits effective combining of devices, and also because frequency-dependent attenuation along the gate line supplies limits drive power for the active devices in the later stages.

A new circuit topology employed novel LCR-matching networks in a four-way Wilkinson combiner structure to divide and combine power uniformly from each device. Figure 13 shows a high-power broad band microwave amplifier that used multiple-stage quarter-wavelength transformers for the power combiner to realize the desired bandwidth and impedance transformation ratios [46].

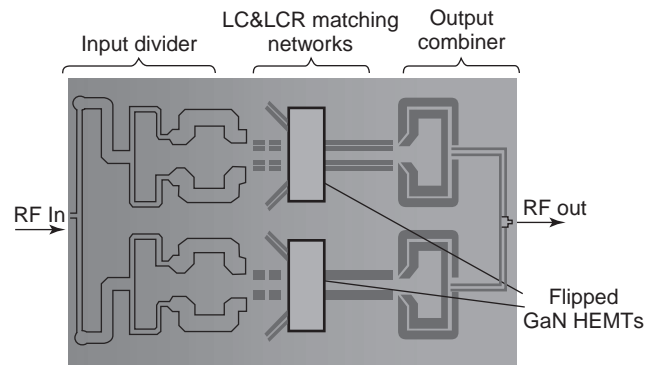

Figure 13. Chip microphotograph of the broadband GaN-HEMT flip-chip integrated power amplifier; die size is about $12 \times 8 \text{ mm}^2$ [46].

Additional LC matching networks were then utilized to reactively compensate for input and output capacitance and provide additional impedance transformation. GaN epitaxial layers grown on sapphire substrates have the advantage of lower cost and availability in larger wafer size than does SiC, but it has poor thermal conductivity. Adequate thermal management was achieved through flip-chip bonding of the device onto a thermally conductive, electrically insulating AlN substrate, which also hosts the matching and combiner networks.

Using devices with $0.7 \mu\text{m}$ gate length and 4 mm gate width, a small-signal gain of 7 dB was obtained over 3–10 GHz bandwidth. A CW output power of 8 W at 9.5 GHz with about 20% PAE was achieved when biased at 24 V, which is a significantly higher output power over the entire bandwidth compared to the results obtained using GaAs-based FET technology.

7. CONCLUSION

This article described the high-speed, high-power, and low-noise performance of GaN HEMTs. Further improvement of device speed, power, and noise figure will be possible with optimization of the GaN HEMT design, growth, and fabrication. In combination with the excellent microwave power capabilities, GaN HEMTs have great potential for other applications such as low noise and high power switching, and will be very attractive for delivering highly linear, broadband, and robust transceiver in future commercial and military communication systems.

1. INTRODUCTION

Many complex microwave devices can usually be decomposed into a set of elementary waveguide junctions (canonical step discontinuities) that are located at specific transverse reference planes where the waveguide cross section changes abruptly, and are connected through longitudinally uniform waveguide sections. In this context, the mode-matching (MM) technique is capable of providing very accurate results, provided that adequate numbers of higher-order modes—including the evanescent ones—are employed for representation of the field within each elementary waveguiding structure [3,5]. In this approach, the electromagnetic fields within the individual longitudinally uniform waveguide sections are represented as a weighted summation of elementary solutions to Maxwell's equations, and the weight coefficients are obtained by matching the tangential fields at the interfaces of the sections where the structure is discontinuous. A microwave device can be accurately analyzed by using this method, once the equivalent circuits of each of the constituent discontinuities have been obtained [4]. However, a simple characterization of the discontinuities in terms of their conventional fundamental mode scattering parameters (S parameters) cannot recover the full-wave behavior of the device when the interactions between the discontinuities are not negligible—which is a common occurrence. In this event, it becomes essential to include the higher-order modes, generalize the concept of scattering parameters [1], and develop a generalized scattering matrix, which is the subject of discussion in this article.

The article is organized as follows. In Section 2, we review the basic concepts of guided-wave propagation in order to derive a modal representation of the fields. This expansion is represented by an equivalent circuit, which leads to the definition of the generalized admittance matrix (GAM) and the generalized impedance matrix. The modal representation is then rearranged in terms of the incident and reflected waves in order to derive the definition of the generalized scattering matrix (GSM). The next step is to consider the canonical problem of a step discontinuity between two waveguides with dissimilar cross sections, and use this simple canonical problem as the building block for the analysis of more complex geometries constituting multiple cascaded discontinuities, such as filters, matching networks, and directional

couplers. Finally, we present some numerical examples to illustrate the potentials of the GSM technique.

2. MODAL EXPANSION

We begin our discussion of modal expansion by considering the geometry of the problem shown in Fig. 1, specifically, a hollow, lossless, metallic waveguide, with a uniform cross-section and perfectly electric conductor (PEC) type of walls. The structure is uniform along z , which is the direction of propagation in the waveguide. We assume that the guide is filled with a homogeneous and lossless dielectric material, with dielectric permittivity ϵ and magnetic permeability μ .

The solution of the propagation problem is obtained by referring to the source-free Maxwell's equations:

$$\begin{aligned} \nabla \times \underline{E} &= -j\omega\mu\underline{H} \\ \nabla \times \underline{H} &= j\omega\epsilon\underline{E} \end{aligned} \tag{1}$$

The differential equations (1) are a system of six scalar equations with six unknowns. Since the cross section of the waveguide is uniform along the z axis, it is advantageous to split the field solution into two parts—the longitudinal components (E_z, H_z) and the transverse components (\underline{E}_t and \underline{H}_t), as follows:

$$\begin{aligned} \underline{E} &= \underline{E}_t + E_z \underline{i}_z \\ \underline{H} &= \underline{H}_t + H_z \underline{i}_z \end{aligned} \tag{2}$$

The longitudinal and transverse components are interrelated, of course, through Maxwell's equations, and they can be easily derived from each other. This assumption results in a simplification, since we can derive the solution for the only transverse components of the fields, and take advantage of the fact that the longitudinal components are dependent on the latter and vice versa [2].

It can be shown that for the problem at hand, Maxwell's equations can be cast in the form of an eigenvalue problem whose solutions (eigenfunctions) represent a set of elementary configurations (modes) supported by the structure. They constitute a complete set of basis functions for representing the fields in the waveguide. Therefore, we can express the transverse field components as

Figure 1. Geometry of a waveguide problem.

summations of modes with complex amplitudes as

$$\underline{E}_t(t_1, t_2; z) = \sum_{m=1}^{\infty} \underline{E}_{t,m}(t_1, t_2; z) \tag{3}$$

$$\underline{H}_t(t_1, t_2; z) = \sum_{m=1}^{\infty} \underline{H}_{t,m}(t_1, t_2; z)$$

where (t_1, t_2) represent the coordinates in the transverse plane as shown in Fig. 1 (in rectangular coordinates $t_1 = x, t_2 = y$).

The separation into longitudinal and transverse components enables us to define three types of modes: (i) transverse electric (TE), for which we have $E_z = 0$ (in this case the electric field is totally transverse: $\underline{E} = \underline{E}_t$); (ii) transverse magnetic (TM), for which we have $H_z = 0$, (i.e., the magnetic field is totally transverse: $\underline{H} = \underline{H}_t$); and (iii) transverse electric and magnetic (TEM), for which we have both E_z and $H_z = 0$.

By invoking the principle of separation of variables, we can represent the electric and the magnetic field components of each mode as a product of a scalar function of z and a vector function of the transverse coordinates that read

$$\underline{E}_{t,m}(t_1, t_2; z) = V_m(z) \underline{e}_m(t_1, t_2) \tag{4}$$

$$\underline{H}_{t,m}(t_1, t_2; z) = I_m(z) \underline{h}_m(t_1, t_2)$$

Following the well-established terminology for waveguiding structures, we refer to the functions \underline{e}_m and \underline{h}_m as the modal vector functions, and to $V_m(z)$ and $I_m(z)$ as the modal scalar functions. The latter satisfy the transmission-line equations (telegraphist's equations), with the standard solution:

$$V_m(z) = V_m^+ e^{-j\beta_m z} + V_m^- e^{+j\beta_m z} \tag{5a}$$

$$I_m(z) = I_m^+ e^{-j\beta_m z} + I_m^- e^{+j\beta_m z} \tag{5b}$$

The modal scalar functions can be interpreted as the equivalent voltages and currents associated with the m th mode of the multimode line—the waveguide. The corresponding modal characteristic impedance for the m th mode is given by

$$Z_{0,m} = \frac{V_m^+}{I_m^+} = -\frac{V_m^-}{I_m^-} \tag{6}$$

and these impedances can be chosen such that they normalize the corresponding modal vector functions. In particular, if we choose:

$$Z_{0,m} = \zeta_{0,m} = \begin{cases} \omega\mu/\beta_m & \text{for TE modes} \\ \beta_m/\omega\epsilon & \text{for TM modes} \end{cases} \tag{7}$$

the modal vector functions are related as follows:

$$\underline{e}_m = \underline{h}_m \times \underline{i}_z \tag{8}$$

The modal vector functions are the solutions of an eigenvalue problem; in particular, we can introduce a potential function φ_m , which satisfies the two-dimensional eigenvalue equation

$$\nabla_t^2 \varphi_m(t_1, t_2) + k_{c,m}^2 \varphi_m(t_1, t_2) = 0 \quad (9)$$

with the following boundary conditions on the contour C of S

$$\varphi_m|_C = 0, \text{ for TE modes} \quad (10a)$$

$$\left. \frac{\partial \varphi_m}{\partial n} \right|_C = 0, \text{ for TM modes} \quad (10b)$$

where $\partial/\partial n$ is the derivative along the outward normal to the contour C . In (9), $k_{c,m}$ is the transverse eigenvalue of the m th mode. The value of the transverse eigenvalue (and, consequently, the final form of the solution φ_m) depends on the geometric shape of the waveguide cross section. Once we have obtained the solution for φ_m , the corresponding vector functions can be evaluated from

$$\underline{e}_m = \begin{cases} \hat{z} \times \nabla_t \varphi_m & \text{for TE modes} \\ -\nabla_t \varphi_m & \text{for TM modes} \end{cases} \quad (11)$$

The wavenumber along the z axis for the m th mode is given by

$$k_z = k_{z\text{TE}} = \sqrt{\omega^2 \epsilon \mu - k_{c,m}^2} \quad (12)$$

An examination of this equation leads to some useful interpretations of the propagation properties of the waveguide. Specifically, we note that the propagation constant β_m in (12) goes to zero at the cutoff frequencies given by

$$\omega_{c,m} = \frac{k_{c,m}}{\sqrt{\mu \epsilon}} \quad (13)$$

For frequencies below the cutoff, the wavenumber is purely imaginary and the corresponding mode is evanescent, with an attenuation constant given by

$$j\beta_m = \alpha_m = \sqrt{k_{c,m}^2 - \omega^2 \epsilon \mu} \quad (14)$$

A TEM mode can be interpreted as a limiting case of a TE or TM mode, with a null transverse eigenvalue k_c . It exists only if the guiding structure consists of at least two parallel electric conductors (i.e., two separated metallic regions on the guiding structure transverse plane). This mode has no cutoff and its propagation constant is identical to that relevant to a uniform plane wave propagating in an unbounded homogeneous medium, with the same electrical characteristics as those of the TEM mode:

$$k_z = k_0 = \omega \sqrt{\epsilon \mu} \quad (15)$$

In contrast to this, the characteristic impedance of the TEM mode depends on both the electric properties of the

medium surrounding the guiding structure and the geometric parameters of the transverse plane.

3. CIRCUIT REPRESENTATIONS OF THE DISCONTINUITIES

In this section, we introduce a formalism that leads to an N -port circuit representation of a waveguiding system [4].

We start by considering a generic discontinuity, with respect to which we define two reference transverse planes T_1 and T_2 (see Fig. 2), where the electric and magnetic fields can be expressed in terms of the modal expansions we have previously introduced. Although, in principle, the modal expansion contains an infinite number of terms, from a practical point of view it is sufficient to truncate it to a finite value. For convenience, we will refer to each of the reference planes as “physical” ports. If we retain N_i modes at the i th “physical” port ($i = 1, 2$) that are sufficient to describe the discontinuity, then we need to know $N_1 + N_2$ modal voltages and currents, implying that an equal number of equations relating the voltages and currents are required, which can be obtained from the Maxwell’s equations. Furthermore, by virtue of the uniqueness theorem, it is sufficient to consider only the tangential components at the interfaces (fields transverse to z) at both the “physical” ports. The discontinuity can therefore be represented by using its multiport equivalent circuit, shown in Fig. 3, where each port is associated with a different mode (“modal” port). Such a network formalism enables us to deal with the voltages and currents—in the same manner as in circuit analysis—instead of working with the electric and magnetic fields.

For the multiport circuit introduced previously, the set of equations relating the voltages and currents can be cast in a more convenient form by expressing all the modal currents as functions of the corresponding voltages. More specifically, we can obtain the following matrix form:

$$\underline{I} = \underline{Y} \underline{V} \quad (16)$$

$$\begin{bmatrix} I_1^{(1)} \\ \vdots \\ I_{N_1}^{(1)} \\ I_1^{(2)} \\ \vdots \\ I_{N_2}^{(2)} \end{bmatrix} = \begin{bmatrix} \underline{Y}_{11} & \underline{Y}_{12} \\ \underline{Y}_{21} & \underline{Y}_{22} \end{bmatrix} \begin{bmatrix} V_1^{(1)} \\ \vdots \\ V_{N_1}^{(1)} \\ V_1^{(2)} \\ \vdots \\ V_{N_2}^{(2)} \end{bmatrix} \quad (17)$$

Figure 2. Geometry for representing a waveguide discontinuity.

Figure 3. Multiport equivalent circuit to the discontinuity depicted in Fig. 2.

It is important to note that the voltages and currents in these equations are related by the admittance matrix \underline{Y} , which now includes both the evanescent and propagating modes. Consequently, the admittance matrix (17) is more general than the conventional one, which relates only the currents and voltages of the propagating modes. Such a generalization leads to the concept and the definition of a generalized admittance matrix (GAM). In addition, we can divide the modes into two classes: accessible (propagating) and localized (evanescent). If we are interested only in the propagating modes (typically the fundamental modes) at the input and output “physical” ports, then the corresponding admittance matrix has the dimensions of (2×2) , and it can be extracted from the corresponding GAM whose dimensions are $(N_1 + N_2) \times (N_1 + N_2)$. To this end, we consider the equivalent circuit shown in Fig. 4, where all the “modal” ports corresponding to the evanescent modes are matched to their respective characteristic impedances, so that

$$I_m^{(i)} = -Y_{0,m}^{(i)} V_m^{(i)} \quad m = 2, \dots, N_i \quad (18)$$

with

$$Y_{0,m}^{(i)} = 1/Z_{0,m}^{(i)} \quad (19)$$

We can now rearrange and partition the admittance matrix with the objective of separating the entries pertaining to the two fundamental modes (subscript “f”) from to the higher-order evanescent modes (subscript “h”) as follows:

$$\underline{Y} = \begin{bmatrix} \underline{Y}_{ff} & \underline{Y}_{fh} \\ \underline{Y}_{hf} & \underline{Y}_{hh} \end{bmatrix} \quad (20)$$

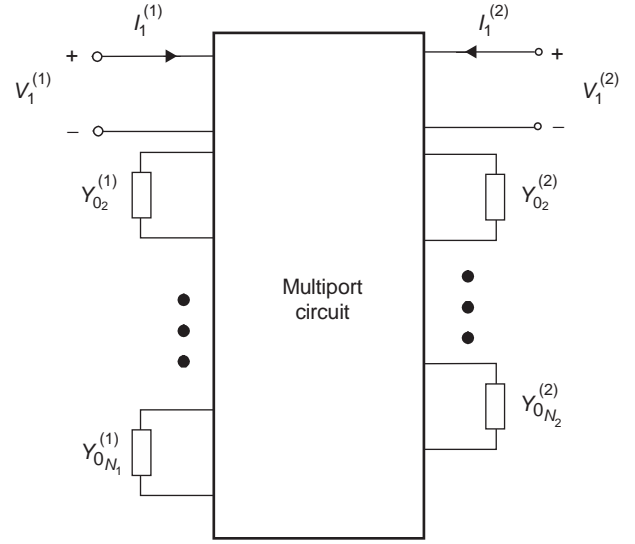

Figure 4. Multiport circuit representation of a waveguide discontinuity for deriving the standard admittance matrix.

The admittance matrix \underline{Y}' of the discontinuity can be expressed as

$$\underline{Y}' = \underline{Y}_{ff} - \underline{Y}_{fh}(\underline{Y}_{hh} + \underline{Y}_{=0})^{-1}\underline{Y}_{hf} \quad (21)$$

where $\underline{Y}_{=0}$ is a diagonal matrix containing the characteristic modal admittances:

$$\underline{Y}_{=0} = \text{diag} [Y_{0,2}^{(1)}, \dots, Y_{0,N_1}^{(1)}, Y_{0,2}^{(2)}, \dots, Y_{0,N_2}^{(2)}] \quad (22)$$

It is important to realize that the higher-order modes, although inaccessible, nevertheless influence the behavior (and the final value of the complex amplitude) of the fundamental modes. We will touch on this aspect again in Section 9 and present some examples to validate the preceding statement.

An alternative description can be obtained by expressing the modal voltages as functions of the modal currents, so that we can obtain an impedance matrix description as follows

$$\underline{V} = \underline{Z}\underline{I} \quad (23)$$

where \underline{Z} is defined as the generalized impedance matrix. In microwave applications, a more useful representation of the electromagnetic field is obtained by working with the incident and reflected wavevectors of the discontinuity, and it is convenient to derive a description that is not tied to the particular type of transmission line feeding the network. Toward this end, we define a normalized modal voltage of the m th mode at the i th port as follows:

$$\hat{V}_m^{(i)} = \frac{V_m^{(i)}}{\sqrt{Z_{0,m}^{(i)}}} \quad (24)$$

Similarly, we can define a normalized modal current of the m th mode at the i th port as

$$\hat{\mathbf{I}}_m^{(i)} = I_m^{(i)} \sqrt{Z_{0,m}^{(i)}} \quad (25)$$

The corresponding voltage and current modal vectors (normalized) are

$$\hat{\mathbf{V}} = [\hat{\mathbf{V}}_m^{(i)}] \quad (26a)$$

$$\hat{\mathbf{I}} = [\hat{\mathbf{I}}_m^{(i)}] \quad (26b)$$

These vectors are related by the normalized impedance matrix $\hat{\underline{\underline{Z}}}$ as

$$\hat{\mathbf{V}} = \hat{\underline{\underline{Z}}} \hat{\mathbf{I}} \quad (27)$$

where the entries of the impedance matrix given above are defined as follows:

$$\hat{Z}_{mn}^{(i,j)} = \frac{Z_{mn}^{(i,j)}}{\sqrt{Z_{0,m}^{(i)}} \sqrt{Z_{0,n}^{(j)}}} \quad (28)$$

The expression in (28) can be interpreted as the normalized mutual impedance between the m th “modal” port at the “physical” port i and the n th “modal” port at the “physical port” j .

A similar normalization can also be applied to the GAM, which can be written as

$$\hat{\mathbf{I}} = \hat{\underline{\underline{Y}}} \hat{\mathbf{V}} \quad (29)$$

The entries of the matrix above are given by

$$\hat{Y}_{mn}^{(i,j)} = \frac{Y_{m,n}^{(i,j)}}{\sqrt{Y_{0,m}^{(i)}} \sqrt{Y_{0,n}^{(j)}}} \quad (30)$$

and they can also be interpreted in a procedure similar to that followed for the impedance matrix elements.

We can now define, at each port, the incident wave amplitude of the m th mode at i th terminal as

$$a_m^{(i)} = \frac{V_m^{+(i)}}{\sqrt{Z_{0,m}^{(i)}}} = I_m^{+(i)} \sqrt{Z} = \frac{V_m^{(i)} + Z_{0,m}^{(i)} I_m^{(i)}}{2\sqrt{Z_{0,m}^{(i)}}} \quad (31)$$

Similarly, the corresponding reflected wave amplitude can also be defined as

$$b_m^{(i)} = \frac{V_m^{-(i)}}{\sqrt{Z_{0,m}^{(i)}}} = -I_m^{-(i)} \sqrt{Z_{0,m}^{(i)}} = \frac{V_m^{(i)} - Z_{0,m}^{(i)} I_m^{(i)}}{2\sqrt{Z_{0,m}^{(i)}}} \quad (32)$$

Finally, using these definitions, we can fully characterize the device in terms of its generalized scattering matrix (GSM) $\underline{\underline{S}}$, which relates the vectors representing the reflected wave and the incident wave amplitudes. The

matrix is defined as

$$\underline{\underline{b}} = \underline{\underline{S}} \underline{\underline{a}} \quad (33)$$

This description in terms of the GSM is equivalent to that in terms of the impedance or admittance matrices. In fact, starting from the following equations

$$\hat{\mathbf{V}} = \underline{\underline{a}} + \underline{\underline{b}} \quad (34a)$$

$$\hat{\mathbf{I}} = \underline{\underline{a}} - \underline{\underline{b}} \quad (34b)$$

we can also write

$$(\underline{\underline{a}} + \underline{\underline{b}}) = \hat{\underline{\underline{Z}}}(\underline{\underline{a}} - \underline{\underline{b}}) \quad (35)$$

Using (33), we obtain the final result

$$\underline{\underline{S}} = (\hat{\underline{\underline{Z}}} + \underline{\underline{1}})^{-1}(\hat{\underline{\underline{Z}}} - \underline{\underline{1}}) = (\underline{\underline{1}} + \hat{\underline{\underline{Y}}})^{-1}(\underline{\underline{1}} - \hat{\underline{\underline{Y}}}) \quad (36)$$

where $\underline{\underline{1}}$ is the unit matrix with dimensions $(N_1 + N_2) \times (N_1 + N_2)$. From knowledge of the GSM of a discontinuity, we can obtain the corresponding admittance and impedance matrices as follows:

$$\hat{\underline{\underline{Y}}} = \hat{\underline{\underline{Z}}}^{-1} = (\underline{\underline{S}} + \underline{\underline{1}})^{-1}(\underline{\underline{1}} - \underline{\underline{S}}) \quad (37)$$

$$\hat{\underline{\underline{Z}}} = \hat{\underline{\underline{Y}}}^{-1} = (\underline{\underline{S}} + \underline{\underline{1}})(\underline{\underline{1}} - \underline{\underline{S}})^{-1} \quad (38)$$

It is important to recognize that, for linear networks, the matrix $\underline{\underline{S}}$ can always be defined, while in some particular situations the matrices $\underline{\underline{Z}}$ and $\underline{\underline{Y}}$ cannot. Moreover, a GSM can always be defined, even if the value of the characteristic impedance of the port is not available.

4. STEP JUNCTION

In this section, we consider the discontinuity problem of a junction between two waveguides with different cross sections S_1 and S_2 . The junction is located at the plane $z = 0$. Let S_C be the common interface, shared by the two waveguides ($S_C = S_1 \cap S_2$) and let S_P be the metallic surface at the interface (for the case shown in Fig. 5, associated with the *boundary enlargement*).

The electromagnetic fields in both the waveguides can be expressed in terms of their respective modes. In particular, by using (4) and (5), we can express the transverse components of the electromagnetic field in the first waveguides (on the left) as a finite summation

Figure 5. Boundary enlargement problem.

of modes as follows:

$$\left\{ \begin{array}{l} \underline{E}_t^{(1)} = \sum_{m=1}^{N_1} \left(\sqrt{Z_{0,m}^{(1)}} a_m^{(1)} e^{-j\beta_m z} \right. \\ \quad \left. + \sqrt{Z_{0,m}^{(1)}} b_m^{(1)} e^{+j\beta_m z} \right) \underline{e}_m^{(1)}(\underline{t}) \\ \underline{H}_t^{(1)} = \sum_{m=1}^{N_1} \left(\frac{a_m^{(1)}}{\sqrt{Z_{0,m}^{(1)}}} e^{-j\beta_m z} \right. \\ \quad \left. - \frac{b_m^{(1)}}{\sqrt{Z_{0,m}^{(1)}}} e^{+j\beta_m z} \right) \underline{h}_m^{(1)}(\underline{t}) \end{array} \right. \quad (39)$$

Similarly, in the second waveguide (on the right) we have

$$\left\{ \begin{array}{l} \underline{E}_t^{(2)} = \sum_{n=1}^{N_2} \left(\sqrt{Z_{0,n}^{(2)}} a_n^{(2)} e^{+j\beta_n z} \right. \\ \quad \left. + \sqrt{Z_{0,n}^{(2)}} b_n^{(2)} e^{-j\beta_n z} \right) \underline{e}_n^{(2)}(\underline{t}) \\ \underline{H}_t^{(2)} = \sum_{n=1}^{N_2} \left(\frac{a_n^{(2)}}{\sqrt{Z_{0,n}^{(2)}}} e^{+j\beta_n z} \right. \\ \quad \left. - \frac{b_n^{(2)}}{\sqrt{Z_{0,n}^{(2)}}} e^{-j\beta_n z} \right) \underline{h}_n^{(2)}(\underline{t}) \end{array} \right. \quad (40)$$

In these expressions, the wave amplitudes of the modes are the unknowns in this problem that are yet to be determined. As explained in the previous section, a complete characterization of the discontinuity can be obtained if we can relate the $(N_1 + N_2)$ amplitudes of the $a^{(i)}$ incident waves to the corresponding amplitudes of the reflected waves, $b^{(i)}$ ($i = 1, 2$). We can derive these equations by imposing the boundary conditions at the junction, specifically, the continuity of the transverse components of

both the electric and magnetic fields as follows:

$$\left\{ \begin{array}{l} \underline{E}_t^{(2)} = \underline{E}_t^{(1)} \quad \text{at } S_C \\ \underline{E}_t^{(2)} = 0 \quad \text{at } S_P = S_2 \setminus S_1 \\ \underline{H}_t^{(2)} = \underline{H}_t^{(1)} \quad \text{at } S_C \end{array} \right. \quad (41)$$

The simplest way to derive the desired $(N_1 + N_2)$ equations is to impose the continuity condition at $(N_1 + N_2)$ different points. However, such a point-matching technique, although simple from a conceptual point of view, is not very accurate since it imposes the continuity condition only at a finite set of points, and it is better to impose the condition stated above in an integral sense instead. With this in mind, we introduce a definition of the inner product, which must be computed in the process.

5. GSM OF A STEP JUNCTION

In this section, we derive a GSM representation of the step junction, shown in Fig. 5, by using the formulation based on the conservation of complex power [6,7]. However, it can be shown that any relation originating from this formulation is equivalent to the ones derived by matching the transverse electric fields or the transverse magnetic fields at the junction plane. We begin by expressing the transverse electric and magnetic fields at $z = 0$ as

$$\left\{ \begin{array}{l} \underline{E}_t^{(1)}(z=0) = \sum_{m=1}^{N_1} \sqrt{Z_{0,m}^{(1)}} (a_m^{(1)} + b_m^{(1)}) \underline{e}_m^{(1)}(\underline{t}) \\ \underline{H}_t^{(1)}(z=0) = \sum_{m=1}^{N_1} \frac{1}{\sqrt{Z_{0,m}^{(1)}}} (a_m^{(1)} - b_m^{(1)}) \underline{h}_m^{(1)}(\underline{t}) \end{array} \right. \quad (42)$$

$$\left\{ \begin{array}{l} \underline{E}_t^{(2)}(z=0) = \sum_{n=1}^{N_2} \sqrt{Z_{0,n}^{(2)}} (a_n^{(2)} + b_n^{(2)}) \underline{e}_n^{(2)}(\underline{t}) \\ \underline{H}_t^{(2)}(z=0) = \sum_{n=1}^{N_2} \frac{1}{\sqrt{Z_{0,n}^{(2)}}} (a_n^{(2)} - b_n^{(2)}) \underline{h}_n^{(2)}(\underline{t}) \end{array} \right. \quad (43)$$

From the continuity conditions, we have

$$\begin{aligned} \underline{E}_t^{(1)}(z=0) &= \underline{E}_t^{(2)}(z=0) \\ &\Rightarrow \sum_{m=1}^{N_1} \sqrt{Z_{0,m}^{(1)}} (a_m^{(1)} + b_m^{(1)}) \underline{e}_m^{(1)}(\underline{t}) \\ &= \sum_{n=1}^{N_2} \sqrt{Z_{0,n}^{(2)}} (a_n^{(2)} + b_n^{(2)}) \underline{e}_n^{(2)}(\underline{t}) \end{aligned} \quad (44)$$

$$\begin{aligned} \underline{H}_t^{(1)}(z=0) &= \underline{H}_t^{(2)}(z=0) \\ &\Rightarrow \sum_{m=1}^{N_1} \frac{1}{\sqrt{Z_{0,m}^{(1)}}} (a_m^{(1)} - b_m^{(1)}) \underline{h}_m^{(1)}(\underline{t}) \\ &= \sum_{n=1}^{N_2} \frac{1}{\sqrt{Z_{0,n}^{(2)}}} (a_n^{(2)} - b_n^{(2)}) \underline{h}_n^{(2)}(\underline{t}) \end{aligned} \quad (45)$$

Next, we define an inner product between the two functions f_1 and f_2 as

$$\langle f_1, f_2 \rangle = \int_{S_C} f_1(t) \times f_2^*(t) \cdot \hat{z} dS \quad (46)$$

and use this definition to project the continuity equation of the electric (magnetic) field onto each magnetic (electric) modal vector function and the continuity equation. Such a projection guarantees that the continuity is ensured not only at a discrete set of points but also across the junction in an integral sense. In particular, by projecting the first equation onto the eigenfunctions $h_m^{(1)*}$, we have

$$\begin{aligned} & \sum_{m=1}^{N_1} \sqrt{Z_{0,m}^{(1)}} (a_m^{(1)} + b_m^{(1)}) \int_{S_1} (e_m^{(1)} \times h_m^{(1)*}) \cdot d\underline{S} \\ &= \sum_{n=1}^{N_2} \sqrt{Z_{0,n}^{(2)}} (a_n^{(2)} + b_n^{(2)}) \int_{S_1} (e_n^{(2)} \times h_m^{(1)*}) \cdot d\underline{S} \end{aligned} \quad (47)$$

Similarly, by projecting the second equation onto the eigenfunctions $e_n^{(2)*}$, we obtain

$$\begin{aligned} & \sum_{m=1}^{N_1} \frac{1}{\sqrt{Z_{0,m}^{(1)}}} (a_m^{(1)} - b_m^{(1)}) \int_{S_2} (h_m^{(1)} \times e_n^{(2)*}) \cdot d\underline{S} \\ &= \sum_{n=1}^{N_2} \frac{1}{\sqrt{Z_{0,n}^{(2)}}} (a_n^{(2)} - b_n^{(2)}) \int_{S_1} (h_n^{(2)} \times e_n^{(2)*}) \cdot d\underline{S} \end{aligned} \quad (48)$$

By exploiting the orthogonality of the modes at each of the waveguide sections, we can express (47) and (48) in matrix forms as

$$\begin{aligned} & \text{diag} \left\{ \sqrt{Z_{0,m}^{(1)}} \int_{S_1} (e_m^{(1)} \times h_m^{(1)*}) \cdot d\underline{S} \right\} \\ & \times (\underline{a}^{(1)} + \underline{b}^{(1)}) = \underline{A} (\underline{a}^{(2)} + \underline{b}^{(2)}) \end{aligned} \quad (49)$$

$$\begin{aligned} & \underline{B} (\underline{a}^{(1)} - \underline{b}^{(1)}) = \text{diag} \left\{ \frac{1}{\sqrt{Z_{0,n}^{(2)}}} \int_{S_2} (h_n^{(2)} \times e_n^{(2)*}) \cdot d\underline{S} \right\} \\ & \times (\underline{a}^{(2)} - \underline{b}^{(2)}) \end{aligned} \quad (50)$$

The elements of the matrices $\underline{A} (N_1 \times N_2)$ and $\underline{B} (N_2 \times N_1)$ can be written as

$$a_{mn} = \sqrt{Z_{0,n}^{(2)}} \int_{S_1} (e_n^{(2)} \times h_m^{(1)*}) \cdot d\underline{S} \quad (51)$$

$$b_{mn} = \frac{1}{\sqrt{Z_{0,m}^{(1)}}} \int_{S_2} (h_m^{(1)} \times e_n^{(2)*}) \cdot d\underline{S} \quad (52)$$

These matrices have some special properties, and, in order to understand them, we resort to the normalization procedure outlined in Section 2, for which the characteristic impedance of the equivalent transmission line assumes a

unit value:

$$Z_{0,m} \equiv 1 \quad (53)$$

As a consequence, for the corresponding vector functions of each mode, we can write

$$e_m = \zeta_m h_m \times \hat{i}_z, \quad h_m = \frac{1}{\zeta_m} \hat{i}_z \times e_m \quad (54)$$

so that

$$a_{mn} = \frac{1}{\zeta_{0,m}^{(1)*}} \int_{S_C} (e_n^{(2)} \cdot e_m^{(1)*}) \cdot d\underline{S} \quad (55)$$

$$b_{mn} = \frac{1}{\zeta_{0,m}^{(1)}} \int_{S_C} (e_m^{(1)} \cdot e_n^{(2)*}) \cdot d\underline{S} = a_{nm}^* \quad (56)$$

This implies that the following relationship holds:

$$\underline{B} = (\underline{A}^T)^* \quad (57)$$

Thus the matrix B is the conjugate transpose of A . It is worth noting that with a correct choice of the normalization impedance, some interesting and important properties regarding the final form of the GSM can be observed [11].

By defining the following diagonal matrices (power matrices)

$$\begin{aligned} \underline{P} &= \text{diag} \left\{ \frac{1}{\zeta_{0,m}^{(1)*}} \int_{S_1} |e_m^{(1)}|^2 \cdot d\underline{S} \right\} \\ &= \text{diag} \left\{ \zeta_{0,m}^{(1)} \int_{S_1} |h_m^{(1)}|^2 \cdot d\underline{S} \right\} (N_1 \times N_1) \end{aligned} \quad (58)$$

$$\begin{aligned} \underline{Q} &= \text{diag} \left\{ \frac{1}{\zeta_{0,n}^{(2)}} \int_{S_2} |e_n^{(2)}|^2 \cdot d\underline{S} \right\} \\ &= \text{diag} \left\{ \zeta_{0,n}^{(2)*} \int_{S_1} |h_n^{(2)}|^2 \cdot d\underline{S} \right\} (N_2 \times N_2) \end{aligned} \quad (59)$$

Eqs. (49) and (50) can be recast in the following form:

$$\underline{P} (\underline{a}^{(1)} + \underline{b}^{(1)}) = \underline{A} (\underline{a}^{(2)} + \underline{b}^{(2)}) \quad (60)$$

$$(\underline{A}^T)^* (\underline{a}^{(1)} - \underline{b}^{(1)}) = \underline{Q} (\underline{a}^{(2)} - \underline{b}^{(2)}) \quad (61)$$

We can now define the matrices below

$$\begin{aligned} \underline{M}_E &= \underline{P}^{-1} \underline{A} \text{ whose dimensions are} \\ & (N_1 \times N_2) \end{aligned} \quad (62)$$

$$\begin{aligned} \underline{M}_H &= \underline{Q}^{-1} (\underline{A}^T)^* \text{ whose dimensions are} \\ & (N_2 \times N_1) \end{aligned} \quad (63)$$

to derive the final matrix representations:

$$(\underline{a}^{(1)} + \underline{b}^{(1)}) = \underline{M}_E(\underline{a}^{(2)} + \underline{b}^{(2)}) \tag{64}$$

$$\underline{M}_H(\underline{a}^{(1)} - \underline{b}^{(1)}) = (\underline{a}^{(2)} - \underline{b}^{(2)})$$

From (64) we can derive the generalized scattering matrix that relates the vectors \underline{b} and \underline{a}

$$\begin{bmatrix} \underline{b}^{(1)} \\ \underline{b}^{(2)} \end{bmatrix} = \underline{S} \begin{bmatrix} \underline{a}^{(1)} \\ \underline{a}^{(2)} \end{bmatrix} = \begin{bmatrix} \underline{S}_{11} & \underline{S}_{12} \\ \underline{S}_{21} & \underline{S}_{22} \end{bmatrix} \begin{bmatrix} \underline{a}^{(1)} \\ \underline{a}^{(2)} \end{bmatrix} \tag{65}$$

where

$$\begin{cases} \underline{S}_{11} = (\underline{1} + \underline{M}_H \cdot \underline{M}_E)^{-1} \cdot (\underline{1} - \underline{M}_H \cdot \underline{M}_E) \\ \underline{S}_{21} = \underline{M}_E \cdot (\underline{1} + \underline{S}_{11}) \\ \underline{S}_{12} = 2(\underline{1} + \underline{M}_H \cdot \underline{M}_E)^{-1} \cdot \underline{M}_H \\ \underline{S}_{22} = (\underline{M}_E \cdot \underline{S}_{12} - \underline{1}) \end{cases} \tag{66}$$

are the self- and mutual blocks of the GSM.

It should be realized that the computation of the scattering matrix carried out in this manner requires the inversion of an $(N_1 \times N_1)$ matrix for each frequency. Finally, the scattering parameters of the discontinuity can be finally obtained by identifying the first element of each of the submatrices (see Fig. 6) that are

$$\begin{aligned} s_{11} &= \underline{S}_{11}(1, 1), \quad s_{12} = \underline{S}_{12}(1, 1), \\ s_{21} &= \underline{S}_{21}(1, 1), \quad s_{22} = \underline{S}_{22}(1, 1) \end{aligned} \tag{67}$$

For a discussion of the properties of the GSM, the reader is referred to Refs. 8–10.

Figure 6. Identification of the scattering parameters of the step discontinuity as entries of the GSM.

6. CASCADING DISCONTINUITIES

A step discontinuity can be viewed as a basic building block for describing more complex configurations. We now consider, as a simple example, the geometry sketched in Fig. 7, where two such discontinuities are separated by a distance L .

The GSM of the uniform waveguide section spanning from $z = 0$ and $z = L$ simply accounts for the phase shift (and/or attenuation) of each mode, as it traverses this section of the guide. This GSM can be written as

$$\underline{S} = \begin{bmatrix} 0 & \underline{D} \\ \underline{D} & 0 \end{bmatrix} \tag{68}$$

where

$$\underline{D} = \text{diag}\{e^{-j\beta_n L}\} \tag{69}$$

The propagating modes only suffer a phase shift, while the evanescent ones are attenuated, since β_n is purely imaginary for the latter. If the distance L is sufficiently large, the evanescent modes originating from the first discontinuity are completely attenuated and do not interact with the second discontinuity; hence they can be neglected.

It is possible to express the wave amplitudes at the second interface in terms of the \underline{S} matrix defined in (8)

$$\begin{bmatrix} \underline{a}^{(2)} \\ \underline{a}_L^{(2)} \end{bmatrix} = \underline{S} \begin{bmatrix} \underline{b}^{(2)} \\ \underline{b}_L^{(2)} \end{bmatrix} = \begin{bmatrix} 0 & \underline{D} \\ \underline{D} & 0 \end{bmatrix} \begin{bmatrix} \underline{b}^{(2)} \\ \underline{b}_L^{(2)} \end{bmatrix} \tag{70}$$

and

$$\begin{aligned} \underline{a}_L^{(2)} &= \underline{D} \underline{b}^{(2)}; \quad \underline{a}^{(2)} \\ &= \underline{D} \underline{b}_L^{(2)} \Rightarrow \underline{b}_L^{(2)} = \underline{D}^{-1} \underline{a}^{(2)} \end{aligned} \tag{71}$$

It is important to note that, in deriving (71), the outgoing waves, transmitted to the right of the first discontinuity, are interpreted as waves incident on the waveguide section located between $z = 0$ and $z = L$. By inserting (71) into (70), we obtain the GSM of the entire configuration, formed by the two discontinuities flanking the waveguide

Figure 7. Geometry for analysis of a double-step discontinuity.

Figure 8. Reference systems at a step discontinuity analyzed through the transmission matrix.

section in between. We can generalize the analysis a bit further and derive the expression for the GSM matrix when we extend the lengths of the waveguide sections at both ends of the discontinuity (see Fig. 8). For this case, the GSM can be expressed as

$$\underline{\underline{S}}' = \underline{\underline{\phi}} \underline{\underline{S}} \underline{\underline{\phi}} = \begin{bmatrix} \underline{\underline{D}}_1 & 0 \\ 0 & \underline{\underline{D}}_2 \end{bmatrix} \underline{\underline{S}} \begin{bmatrix} \underline{\underline{D}}_1 & 0 \\ 0 & \underline{\underline{D}}_2 \end{bmatrix} \quad (72)$$

where

$$\begin{aligned} \underline{\underline{D}}_1 &= \text{diag} \left\{ e^{-j\beta_m^{(1)} l_1} \right\} \\ \underline{\underline{D}}_2 &= \text{diag} \left\{ e^{-j\beta_n^{(2)} l_2} \right\} \end{aligned} \quad (73)$$

To derive the composite solution of this extended geometry case, we need certain connection formulas, which we provide below [11,12]. Given two structures, each of which is characterized by its own GSM $\underline{\underline{S}}^{(1)}$ and $\underline{\underline{S}}^{(2)}$, respectively, we can construct a composite GSM by using the following submatrix blocks [3]

$$\begin{cases} \underline{\underline{S}}_{-11}^{(\text{tot})} = \underline{\underline{S}}_{-11}^{(1)} + \underline{\underline{S}}_{-12}^{(1)} \underline{\underline{S}}_{-11}^{(2)} \underline{\underline{E}} \underline{\underline{S}}_{-21}^{(1)} \\ \underline{\underline{S}}_{-12}^{(\text{tot})} = \underline{\underline{S}}_{-12}^{(1)} \cdot \left(\underline{\underline{1}} + \underline{\underline{S}}_{-12}^{(2)} \underline{\underline{E}} \underline{\underline{S}}_{-22}^{(1)} \right) \underline{\underline{S}}_{-12}^{(2)} \\ \underline{\underline{S}}_{-21}^{(\text{tot})} = \underline{\underline{S}}_{-21}^{(2)} \underline{\underline{E}} \underline{\underline{S}}_{-21}^{(1)} \\ \underline{\underline{S}}_{-22}^{(\text{tot})} = \underline{\underline{S}}_{-22}^{(2)} + \underline{\underline{S}}_{-21}^{(2)} \underline{\underline{E}} \underline{\underline{S}}_{-22}^{(1)} \underline{\underline{S}}_{-22}^{(2)} \end{cases} \quad (74)$$

where

$$\underline{\underline{E}} = \left(\underline{\underline{1}} - \underline{\underline{S}}_{-22}^{(1)} \underline{\underline{S}}_{-11}^{(2)} \right)^{-1} \quad (75)$$

Once again, an inversion is needed to construct the matrix $\underline{\underline{E}}$ in (75), which appears in the expressions given in (74) for the various blocks.

It is important to observe that the expressions in Eqs. (74) and (75) originate from an iterative process that accounts for multiple reflections at both discontinuities. In particular, the modes inside the central section go through a multiple scattering phenomenon that can be

mathematically expressed as a Neumann series with final value given by (74). For an in-depth discussion of this phenomenon, the reader is referred to Ref. 1, where a proof of convergence has been provided.

A more intuitive approach might have been followed, which makes use of an alternative representation in terms of the transmission matrix. It relates the wave amplitudes (both incoming and outgoing) at the first port with those at the second port as follows:

$$\begin{bmatrix} \underline{\underline{a}}^{(1)} \\ \underline{\underline{b}}^{(1)} \end{bmatrix} = \underline{\underline{T}} \begin{bmatrix} \underline{\underline{b}}^{(2)} \\ \underline{\underline{a}}^{(2)} \end{bmatrix} = \begin{bmatrix} \underline{\underline{T}}_{11} & \underline{\underline{T}}_{12} \\ \underline{\underline{T}}_{21} & \underline{\underline{T}}_{22} \end{bmatrix} \begin{bmatrix} \underline{\underline{b}}^{(2)} \\ \underline{\underline{a}}^{(2)} \end{bmatrix} \quad (76)$$

For the cascaded junction, the total transmission matrix can be simply expressed as a product of the single transmission matrices:

$$\underline{\underline{T}}^{\text{tot}} = \underline{\underline{T}}^{(1)} \underline{\underline{T}}^{(2)} \quad (77)$$

However, there are two significant disadvantages when using this approach that we can easily identify. The first one arises from the fact that the wavenumber in the uniform waveguide section between the two step discontinuities exhibits a negative sign with respect to the previous representation, implying that the cutoff modes are mapped into the constituent block matrices with real and positive exponentials. This renders the entries of the final matrix unstable, especially for large n and L . The second difficulty stems from the requirement that we must use an identical number of modes at both ends of the junction, since the use of a different number of modes results in an ill-conditioned matrix. This condition, in turn, suffers from the problem of relative convergence, which will be discussed in the following section.

7. CONVERGENCE CRITERIA

The accuracy of the final results is strongly affected by the truncation of the series used for the modal expansion. Convergence tests are usually performed in order to determine the minimum number of modes required to obtain a certain degree of accuracy; specifically, the number of modes is increased until the final result does not change significantly.

However, an interesting phenomenon can occur when following this procedure; namely, the final results may converge to a value that is strongly dependent on the ratio N_1/N_2 of the total numbers of modes used in the two longitudinally uniform waveguide sections directly connected to the discontinuity. This phenomenon, known as “relative convergence,” may affect the validity of the final results [13,14].

Several different criteria have been presented in the literature to cope with this problem. If we consider the step discontinuity problem reported in Fig. 9, where two rectangular waveguides of the same width and different heights are connected, it is possible to show that a correct result is guaranteed by increasing the number of modes and maintaining the ratio N_1/N_2 approximately equal to

Figure 9. Step discontinuity between two rectangular waveguides of different heights.

the ratio h_1/h_2 . Intuitively, this result can be explained by considering the fact that both modal expansions should be able to follow the same variability of the field at both sides of discontinuity; since the basis functions used in the modal expansions have different periodicities on each side of the junction, the choice of the ratio $N_1/N_2 = h_1/h_2$ leads to the correct behavior of the two final expressions.

For a double step discontinuity (along both height and width), accurate results have been obtained by using the area criterion $N_1/N_2 = A_1/A_2$, where A_1 and A_2 are the cross-sectional areas of the waveguides 1 and 2, respectively. However, this criterion is not as general as a more useful one based on the condition that the maximum values of the transverse eigenvalues for modes at both sides of the discontinuity be the same. This is known as the *spectral criterion*, and it requires that once that the maximum value of the transverse eigenvalue $k_{c,max}$ is fixed, only the modes with $k_c < k_{c,max}$ are to be retained.

8. NUMERICAL EXAMPLES

Numerical results are presented in this section with the objective of demonstrating that the accuracy can be improved by including higher-order modes. As a first example, we consider a single-step discontinuity problem at the junction between a rectangular waveguide (waveguide 1) with dimensions of 10×5 mm, and a smaller rectangular

Figure 10. Amplitudes of the S_{11} scattering parameters for the boundary enlargement problem at the junction between two rectangular waveguides with dimensions 7×3.5 mm and 10×5 mm, respectively. The dashed curve is based on the exclusion of the higher order modes.

Figure 11. Amplitude of the S_{11} scattering parameter relevant to a thick iris in a rectangular waveguide. The waveguide has dimensions 10×5 mm, whereas the iris has dimensions 7×3.5 mm and a thickness of 2 mm. The dashed line corresponds to the case where the higher-order modes are not included.

waveguide (waveguide 2) whose dimensions are 7×3.5 mm. The single-mode bandwidth of the first waveguide spans from 15 to 30 GHz, whereas the second waveguide exhibits a single-mode bandwidth between 21.42 and 42.84 GHz. The scattering parameter S_{11} of this discontinuity has been calculated by using only the fundamental mode in both the waveguides. These results have been compared with those obtained by calculating the whole GSM of the discontinuity with 71 and 33 modes in the waveguides, respectively. The results are shown in Fig. 10, where the net discrepancy between the two curves clearly demonstrates the importance of including the higher-order modes.

The effects of higher-order modes become even more apparent if we refer to the following problem, where a rectangular iris of finite thickness is considered. This

Figure 12. Amplitude of the S_{11} scattering parameter relevant to a thick iris in a rectangular waveguide. The waveguide has dimensions 10×5 mm, whereas the iris has dimensions 7×3.5 mm and a thickness of 5 mm. The dashed line corresponds to the case where the higher-order modes are not included.

problem can be analyzed by following the methodology presented in Section 6, where we cascade the two discontinuity problems and shift the GSM of the first discontinuity toward the second by a length equal to the thickness of the iris. In particular, the results obtained by using only the fundamental modes in the three waveguide sections are shown in Figs. 11 and 12 for two different lengths of the iris, and they are compared with those derived for the same configuration by accounting for the presence of higher-order modes (more precisely, 71 modes are included in the first and third waveguide sections, while 33 modes are retained in the central waveguide section).

GEOMETRICAL OPTICS

University of Illinois at Chicago
Chicago, Illinois

1. INTRODUCTION

Geometric optics is the simplest theory to explain the formation of images. It represents a useful approximation of more complex theories and, in practical situations, such as the design of optical systems, it provides a useful way to make preliminary assessments. Geometric optics is also important because of the influence it has had on other disciplines, for example, in electrical engineering, on the design of antennas, which is discussed in Section 13. Geometric optics is attractive because it is a simple theory based on rays. However, it also is limited in its applications because it does not include diffraction, which is important to explain more precisely the formation of images and usually requires complex mathematical formulations. Many efforts have been devoted to extend geometric optics to include diffraction while keeping the advantages of a simpler ray theory, which are discussed in Section 14.

Let us consider the location of geometric optics within the realm of optical phenomena. Light is an electromagnetic phenomenon [1], and its propagation may be described in terms of two mutually coupled vectors: the electric and magnetic fields. In practice, many phenomena may be described by simply using only one of these two vector quantities. Hence, this simplification leads to a scalar theory where light is treated as a scalar function and the resulting theory is called *wave optics*. When light propagates around objects that are much larger than its wavelength, the wave nature of light may not be revealed and its propagation may simply be described using rays, and the corresponding theory is called *ray optics* or *geometric optics*. Ray optics is an approximation of wave optics, which, in turn, is a simplification of the electromagnetic theory of optics. All these theories are classical, but there are other light phenomena that are quantum-mechanical, which cannot be explained in terms of the classical electromagnetic theory. The most complete theory that combines quantum-mechanical phenomena with the classical electromagnetic theory is called *quantum electrodynamics* and, in the realm of optics, is referred to as *quantum optics*. The level of complexity of these theories follows their historical development: (1) geometric optics, (2) wave optics, (3) electromagnetic optics, and (4) quantum optics.

Historically, geometric optics was devised to explain the behavior of light. The basic principles of geometric optics that are discussed in this article were all formulated before the year 1900. Some relevant steps in the development of theories related to light follow and are based on Ref. 2; a more complete overview is provided in Ref. 3. The law of reflection was given by the Greek Euclid (ca. 300 B.C.). Refraction was observed by Alexandrian Greeks, but they could not explain it. Abu Ali al-Hasan Ibn al-Haytham (ca. 965–1039), latinized as Alhazen, in

his book on optics [4] gave a detailed description of refraction and investigated reflection from plane and curved surfaces, also known as “Alhazens’ problem.” Optics was put on solid foundation only after the introduction of the experimental method by the Italian Galileo Galilei (1564–1642). We have to wait until the seventeenth century to obtain a mathematical formulation of the law of refraction by the French René Descartes (1596–1650) and the Dutch Willebrod Snell (1580–1626). During the same century, two physical theories of light appeared. One theory was developed by the Dutch physicist Christiaan Huygens (1629–1695) and consisted in a geometric wave theory of light [5]. The other theory was created by the British Sir Isaac Newton (1643–1727), who developed a mechanical theory of propagation of particles [6]. Newton’s theory was accepted for nearly another century only because of his reputation, while Huygens’ theory was ignored.

The seventeenth century gave also birth to experimental discoveries such as interference by the British Robert Boyle (1627–1691) and the British Robert Hooke (1635–1703); the finiteness of the speed of light by the Danish Olaf Römer (1644–1710) and diffraction by the Italian Francesco Maria Grimaldi (1618–1663) and Hooke. After the experimental discoveries, geometric optics appeared as a limited theory of light that was based on four principles: (1) light travels along straight lines in a homogeneous medium, (2) light rays travel out of a source independently, (3) light rays obey the law of reflection, and (4) light rays obey the law of refraction. It is interesting to observe that all these laws follow from a mathematical principle that says nothing about the nature of light. This is principle of least time by the French Pierre de Fermat (1601–1665).

The mathematical theory of geometric optics received its definitive formulation with the work of the Irish Sir William Rowan Hamilton (1805–1865). Hamilton was aware of the works of the French Augustin Jean Fresnel (1788–1827), Huygens, and Newton, but he ignored their works because his goal was to build a mathematical science of optics from which all properties could be deduced. Hamilton’s main idea was the characteristic function. In fact, he showed that from the knowledge of the characteristic function all optical problems involving, for instance, lenses, mirrors, crystals, and propagation in the atmosphere could be solved.

Many scientists pointed out that in order to explain properties of light such as interference, diffraction, and polarization, a wave theory was necessary. Most of the early works on the wave theory of light were driven by an equivalence with waves inside elastic media. Before the work of the British James Clerk Maxwell (1831–1879), it is worth mentioning the results of the Irish James MacCullagh (1809–1847), who introduced differential equations that are closely related to the ones of Maxwell [7]. As of today, the best theory available to explain the behavior of light (with the exception of some problems that are investigated by quantum electrodynamics) is the one that subjects light to an electromagnetic wave that obeys Maxwell’s laws.

As mentioned earlier, geometric optics is an approximate representation. Wavelengths do not come into account, so interference and dispersion cannot be deduced.

Additionally, the vector character of light (i.e., polarization) and diffraction are not incorporated.

2. THE POSTULATES OF GEOMETRIC OPTICS

Geometric optics can be explained using four postulates:

- Light rays travel out of a source independently.
- Inside a homogeneous medium, light rays travel along straight lines.
- Light rays obey the law of reflection.
- Light rays obey the law of refraction.

When light rays propagate inside a homogeneous medium, they travel at a speed $v \leq c_0$, where c_0 is the speed of light in vacuum, and the medium is characterized by the index of refraction

$$n = \frac{c_0}{v} \quad (1)$$

The time taken by a ray of light to travel the geometric distance ℓ is proportional to the product $n\ell$, which is called the *optical path length*.

Let us now consider the simplest kind of optical source, a point source inside a homogeneous medium. Rays emitted from a point source are associated with spherical surfaces, centered at the source, called *wavefronts*. Each wavefront has the property that all its points have the same optical pathlength from the source. Equivalently, all the points that belong to the same wavefront have the same phase. Since there is an equivalence between rays and the associated wavefronts, in what follows we will refer to either rays or wavefronts depending on what is more convenient.

3. THE LAW OF REFLECTION

3.1. Reflection from a Plane Surface

The law of reflection considers a ray that, after interacting with a surface, bounces back to the same medium where it came from. Let us examine a ray with unit vector $\hat{\mathbf{r}}_1$ that is incident on a plane reflecting surface whose unit normal vector is $\hat{\mathbf{v}}$, as shown in Fig. 1. The incident ray $\hat{\mathbf{r}}_1$ and the normal $\hat{\mathbf{v}}$ define the *plane of incidence* that contains the reflected ray unit vector $\hat{\mathbf{r}}_2$. The angle of incidence θ_i and the reflection angle θ_r are related to each other by

$$\theta_i = \theta_r \quad (2)$$

which is the mathematical statement of the law of reflection.

3.2. The Method of Images

The reflected ray $\hat{\mathbf{r}}_2$ appears to an observer O as if it had originated from S' , which is symmetric to S with respect to the plane reflecting surface. The point S' is called the *image of S* and suggests an equivalent method to determine the direction of reflection of a ray incident at P . According to this method, the location P of the reflection point is

Figure 1. Geometry for the reflection from a plane surface. The plane of incidence defined by the unit vectors $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{v}}$ contains the unit vector $\hat{\mathbf{r}}_2$.

determined by tracing the straight line from S' toward O . The formation of the image of an extended source due to the reflection from a plane surface is easily explained with the method of images. In fact, an observer O will receive rays that appear to have originated from points symmetric to the source, with respect to the plane reflecting source. Hence, in particular, the spherical wavefront originated by a point source will maintain its spherical shape on reflection from a plane interface because all rays associated with the reflected wavefront appear to have originated from the image of the original point source.

3.3. Reflection from a Curved Surface

When the reflecting surface is curved, one can still apply the law of reflection using the formulation (2) provided that the geometry is made locally plane by considering the plane tangent to the curved surface Σ at P , as shown in Fig. 4. In such a case, the plane of incidence contains the normal $\hat{\mathbf{v}}$ to the tangent plane and the angles of incidence and reflection are measured between the normal and the direction of incidence or reflection, respectively. When reflection occurs at a smooth curved surface, it is convenient to present the law of reflection in a compact vector notation. For this purpose, let $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{r}}_2$ be the unit vectors along the directions of the incident and reflected rays and $\hat{\mathbf{v}}$ the unit vector of the normal to the surface at the point of reflection. The law of reflection may be written

$$\hat{\mathbf{r}}_2 = \hat{\mathbf{r}}_1 + \alpha \hat{\mathbf{v}} \quad (3)$$

where the constant α is determined from

$$\alpha = -2\hat{\mathbf{r}}_1 \cdot \hat{\mathbf{v}} \quad (4)$$

Since, according to (3), the unit vector $\hat{\mathbf{r}}_2$ is a linear combination of $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{v}}$, the reflected ray is contained in the plane of incidence. In addition $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{r}}_2$ have the same length, therefore they intersect $\hat{\mathbf{r}}_1 - \hat{\mathbf{r}}_2$ and, hence, $\hat{\mathbf{v}}$ at the same angle. Thus the angle of incidence equals the angle of reflection and

$$\theta_1 = \arccos(\hat{\mathbf{r}}_1 \cdot \hat{\mathbf{v}}) = \arccos(\hat{\mathbf{r}}_2 \cdot \hat{\mathbf{v}}) = \theta_r \quad (5)$$

For practical applications, such as in ray tracing, one is usually given $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{v}}$. Hence, after obtaining α from (4), the direction of the reflected ray is obtained from (3). Further details for reflection from general curved surfaces are given in Refs. 8 and 9.

For a generic curved surface there is no method of images. In fact, for an observer O all rays incident on the curved surface at P will appear to have originated from the images of their sources with respect to the tangent plane at P . However, rays that are reflected at other points will, in general, appear to have originated from images that are different from the previous ones. In particular, a spherical wavefront will not appear to be originated from a single image source on reflection from a curved surface. The reflected wavefront will be, in general, astigmatic.

3.4. Cartesian Reflecting Surfaces

Some conic sections represent *Cartesian reflecting surfaces*; that is, the surfaces form perfect images of point objects upon reflection. These surfaces are the ellipsoid; the paraboloid and the hyperboloid and their cross sections are shown in Fig. 2. The ellipsoid has the property that all rays passing through one focus are reflected at the surface so that the reflected ray passes through the other focus. The paraboloid has the property that rays parallel to its axis are reflected so that they all pass through the focus. For the hyperboloid, rays emitted from one focus are reflected so that they appear to have originated from the other focus. Unfortunately, the relationship that leads to perfect images is valid only for certain points.

Figure 2. Cross sections of Cartesian reflecting surfaces: (a) ellipsoid; (b) paraboloid; (c) hyperboloid.

4. THE LAW OF REFRACTION

4.1. Refraction from a Plane Surface

The law of refraction considers the passage of a ray from one medium to another. Figure 3 shows the geometry for a ray with unit vector $\hat{\mathbf{r}}_1$ that is incident at P on a plane interface between two media with indices of refraction n_1 and n_2 . As in the case of reflection, one can define a plane of incidence that contains $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{v}}$. The incident ray $\hat{\mathbf{r}}_1$ generates one reflected ray $\hat{\mathbf{r}}$ and a refracted or transmitted ray $\hat{\mathbf{r}}_2$. Both $\hat{\mathbf{r}}$ and $\hat{\mathbf{r}}_2$ are contained in the plane of incidence. The angles of incidence and refraction (or transmission) depend on the properties of the media through their indices of refraction according to

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \tag{6}$$

which is known as *Snell's law*. Because of Snell's law, the direction of the refracted ray

$$\theta_2 = \arcsin\left(\frac{n_1}{n_2} \sin \theta_1\right) \tag{7}$$

is closer to the normal to the interface when $n_2 > n_1$ and farther away from the normal when $n_2 < n_1$. In particular, when $n_2 < n_1$, the value of the incidence angle θ_1 that causes $\theta_2 = \pi/2$ is called *critical angle* because for $\theta_1 > \theta_c$ there is no refracted ray, a phenomenon known as *total internal reflection*.

4.2. Refraction from a Curved Surface

Refraction from a smooth curved surface is more conveniently expressed using a compact vector notation. Referring to Fig. 4, let $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{r}}_2$ be the unit vectors along the directions of the incident and refracted rays, respectively, and $\hat{\mathbf{v}}$ the unit vector of the normal to the surface at the point of refraction. The law of refraction may then be written as

$$n_2 \hat{\mathbf{r}}_2 = n_1 \hat{\mathbf{r}}_1 - \beta \hat{\mathbf{v}} \tag{8}$$

Figure 3. Geometry for the refraction of a ray. The plane of incidence defined by the unit vectors $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{v}}$ contains the unit vector $\hat{\mathbf{r}}_2$ and $\hat{\mathbf{r}}$.

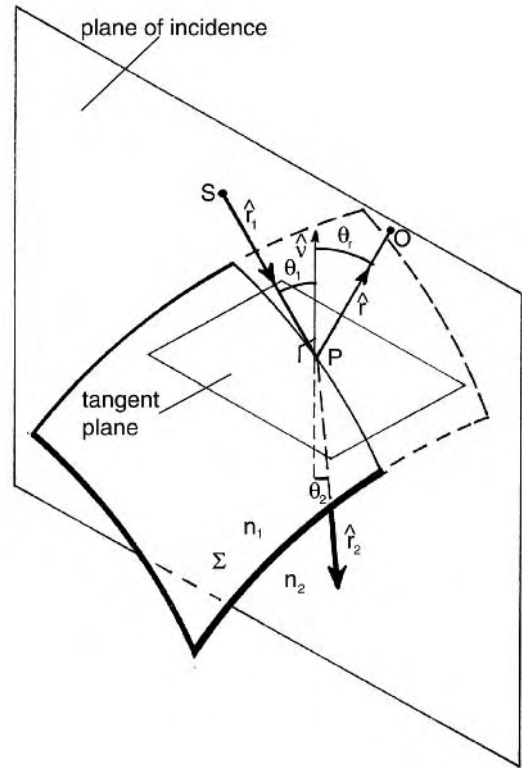

Figure 4. Geometry for the reflection and refraction of a ray from a curved surface.

where the constant β is determined from

$$\beta = n_2 \cos \theta_2 - n_1 \cos \theta_1 \tag{9}$$

and

$$\begin{aligned} \cos \theta_1 &= \hat{\mathbf{r}}_1 \cdot \hat{\mathbf{v}} \\ n_2 \cos \theta_2 &= \sqrt{n_2^2 - n_1^2 + n_1^2 \cos^2 \theta_1} \end{aligned} \tag{10}$$

Equation (8) defines $\hat{\mathbf{r}}_2$ as a linear combination of $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{v}}$ so that the refracted ray is located in the plane of incidence. By taking the cross-product of (8) with $\hat{\mathbf{v}}$, one obtains the usual form of Snell's law

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \tag{11}$$

(since $|\sin \hat{\mathbf{r}}_1 \times \hat{\mathbf{v}}| = \sin \theta_1$, $|\sin \hat{\mathbf{r}}_2 \times \hat{\mathbf{v}}| = \sin \theta_2$, and $|\sin \hat{\mathbf{v}} \times \hat{\mathbf{v}}| = 0$). In a ray-tracing application, one usually knows $\hat{\mathbf{r}}_1$ and $\hat{\mathbf{v}}$. Then, after evaluating (10), the constant β is obtained from (9) and the direction of the refracted ray is derived from (8). Further details for refraction from general curved surfaces are given in Refs. 8 and 9.

Contrary to the law of reflection, there is no equivalent to the method of images for refraction, even in the case of a

plane interface. In fact, let us consider, for example, rays from a point source S located in a medium 1. Rays from S incident at the interface are refracted into medium 2 along different directions that, when extended back into medium 1, will not intersect all at the same point. Each ray refracted into medium 2 appears to be coming from a different source inside medium 1. Hence this could lead to the formation of multiple images, but the problem is avoided if one observes only a narrow bundle of rays so that they will appear to be coming from the same source. This is the case of a human eye that observes an object under water. Since the pupil captures only a narrow bundle of rays, no multiple images are observed. However, it is possible to find only one image by limiting the consideration to rays that make small angles with the normal $\hat{\nu}$. In fact, when the angles are small, the sine function can be approximated with its argument. Accordingly, the refraction law (6) takes the form

$$n_1\theta_1 = n_2\theta_2 \quad (12)$$

Therefore, referring to Fig. 5, rays that make small angles with the normal appear to an observer O as if they had originated by S' at an apparent depth

$$d' = \frac{n_1}{n_2}d \quad (13)$$

Most optical systems contain spherical surfaces. Similar to the case of refraction at a plane interface, rays in medium 2, originated by a point source in medium 1 and refracted by a spherical surface, do not intersect all at the same point. This is a statement of the fact that spherical surfaces do not produce perfect images. This difficulty of spherical surfaces is overcome, again, by limiting the rays to make small angles with a preferred axis. This results

Figure 5. Geometry for the refraction at a plane interface when angles are small.

into the *paraxial approximation*, which is explained in Section 8. Further details of the limitations of spherical surfaces are explained in Section 11. A different approach to the laws of geometric optics is considered next.

5. FERMAT'S PRINCIPLE

The laws of geometric optics may be derived from the purely mathematical Fermat principle. In order to introduce this principle, let us recall that the optical path length of a ray that propagates from point A to point B inside a medium with index of refraction $n(x, y, z)$ is expressed by

$$\int_A^B n(x, y, z) ds \quad (14)$$

According to Fermat's principle, the actual path followed by the ray of light is such that the optical pathlength (14) is stationary in the sense of variational calculus

$$\delta \int_A^B n(x, y, z) ds = 0 \quad (15)$$

where the symbol δ represents the variation. Without going into the formal definition of what a variation is according to variational calculus, the condition (15) may be understood by making a parallelism with ordinary differential calculus and looking at (15) as being a derivative of (14). In particular, if p_0 is the trajectory that satisfies (15), trajectories that are in the neighborhood of p_0 will not change the value of (14) to a first-order approximation. Hence, the trajectory p_0 behaves similarly to a stationary point that may represent either a maximum, a minimum, or an inflection point for the quantity represented by (14). Usually, the trajectory p_0 corresponds to a minimum and, since (14) is proportional to the travel time, the Fermat principle is formulated by saying that light rays travel along paths of least time.

Using Fermat's principle, one can derive the laws of reflection and refraction. For the law of reflection, referring to Fig. 6a, it is easy to prove that the path SPO that satisfies Fermat's principle (15) is shorter than any other path such as SAO . Only for the path SPO , the angles θ_i and θ_r satisfy the law of reflection (2). For the law of refraction, Fig. 6b shows that when the location of a variable point P is chosen so that the path SPO satisfies (15), then the angles θ_1 and θ_2 satisfy the law of refraction (6).

5.1. Principle of Reversibility

The principle of reversibility states that if a ray of light propagating from A to B is reversed in direction, it will follow the same path backward. This property follows from Fermat's principle that does not account for the actual direction of propagation of light.

5.2. Ray Equation

Another consequence of Fermat's principle is the ray equation. If the trajectory of a ray \mathbf{r} is described by the

Figure 6. Fermat’s principle: (a) geometry for the reflection of a ray at a plane surface; (b) geometry for the refraction of a ray at a plane interface between two media with different indices of refraction.

coordinates $(x(s), y(s), z(s))$, where s is the length of the trajectory measured from an arbitrary point along the trajectory, it can be shown that the ray equation is

$$\frac{d}{ds} \left(n \frac{dr}{ds} \right) = \nabla n \tag{16}$$

or, equivalently, that the functions $x(s), y(s), z(s)$ must satisfy the partial-differential equations:

$$\frac{d}{ds} \left(n \frac{dx}{ds} \right) = \frac{\partial n}{\partial x}, \frac{d}{ds} \left(n \frac{dy}{ds} \right) = \frac{\partial n}{\partial y}, \frac{d}{ds} \left(n \frac{dz}{ds} \right) = \frac{\partial n}{\partial z} \tag{17}$$

One of the postulates of geometric optics, the rectilinear propagation of rays of light inside a homogeneous medium, follows directly from the ray equation (16). In fact, for a homogeneous medium, $\nabla n = 0$ so that after two integrations, one obtains

$$\mathbf{r} = \mathbf{a}s + \mathbf{b} \tag{18}$$

which is the equation for a straight line where \mathbf{a} and \mathbf{b} are constant vectors. When the medium is not homogeneous, the analytical derivation of the solution of (16) is usually not trivial, but mathematical solutions are possible when the paraxial approximation is made. Accordingly, one assumes that the trajectory is almost parallel to the z axis so that the following two equations are obtained

$$\frac{d}{dz} \left(n \frac{dx}{dz} \right) = \frac{\partial n}{\partial x}, \frac{d}{dz} \left(n \frac{dy}{dz} \right) = \frac{\partial n}{\partial y} \tag{19}$$

5.3. Graded-Index Fiber

Consider a glass fiber cylinder with an index of refraction that depends on the distance from the axis, such as

$$n^2 = n_0^2 [1 - \alpha^2(x^2 + y^2)] \tag{20}$$

When this expression for n is substituted into (19) and the approximation $\alpha^2(x^2 + y^2) \ll 1$ is made, one finds that the components $x(s), y(s)$ of the ray follow the equations

$$\frac{d^2x}{dz^2} = -\alpha^2x, \frac{d^2y}{dz^2} = -\alpha^2y \tag{21}$$

which represent harmonic motions with period $2\pi/\alpha$. Assume that the initial position of a ray is (x_0, y_0) and the initial angle is $(\theta_{x_0}, \theta_{y_0})$. Since this problem has circular symmetry, one may set $x_0 = 0$ without loss of generality. Then the solutions of (21) may be written as follows:

$$x(z) = \frac{\theta_{x_0}}{\alpha} \sin(\alpha z), y(z) = \frac{\theta_{y_0}}{\alpha} \sin(\alpha z) + y_0 \cos(\alpha z) \tag{22}$$

In the particular case of a *meridional ray*, a ray inside a plane that contains the z axis, $\theta_{x_0} = 0$ and the solution (22) shows that the ray will continue to lie in the same plane and will propagate along a sinusoidal trajectory. When $\theta_{y_0} = 0$ and $\theta_{x_0} = \alpha y_0$, then (22) reduces to a helical trajectory on the surface of a cylinder of radius y_0 . In both these cases, the trajectory remains confined within the glass fiber cylinder, which, therefore, operates as a light guide. By changing the initial conditions, other helical trajectories are obtained.

5.4. Spherical Symmetric Media and Lenses

An optical medium with index of refraction that is only a function of the radial distance from the origin is of considerable interest because it makes it possible to determine conditions to obtain perfect images. In fact, if $n = n(r)$, the light ray trajectories are plane curves (similarly to the trajectories of a particle in the field of a central force) and, without loss of generality, one may limit the investigation to trajectories that lie in a plane [11]. Referring to Fig. 7, assume that a unit radius sphere, a spherical lens, is made with material of index of refraction $n = n(r)$ and that the material outside the lens is homogeneous with $n = 1$. The problem consists in finding the functional dependence $n = n(r)$ so that all rays originating

Figure 7. Geometry for the problem of a spherical lens made of a material with index of refraction that is axially nonhomogeneous.

at O and passing through the spherical lens are focused at I . This problem was solved by Luneburg when $n(r)$ is continuous and monotonic in $0 \leq r \leq 1$. Two explicit solutions are *Maxwell's fisheye* and the *standard Luneburg lens*. Maxwell's fisheye images points on the surface of the spherical lens into points that are diametrically opposite on the lens surface, hence $r_O = r_I = 1$ and $n(r) = 2/(1 + r^2)$. The standard Luneburg lens images a point on the surface of the spherical lens at infinity, hence $r_O = 1, r_I = \infty$ and $n(r) = \sqrt{2 - r^2}$. The Luneburg lens and its generalizations find many applications in other disciplines, as mentioned in Section 13.

Now that the laws of geometric optics have been introduced, we will examine what an optical system is and how perfect images are created.

6. DEFINITION OF AN OPTICAL SYSTEM

A source point O inside a medium with index of refraction n generates an infinite number of rays, only a finite number of which, in general, will reach any other point in the medium. If it is possible to find a point I through which an infinite number of rays pass, this point is said to be a stigmatic (or sharp) image of O . An ideal optical system transforms every point O of a three-dimensional region called the *object space* into a stigmatic image I . The collection of all image points is called *image space* [12]. An optical system is composed of a number of refracting and reflecting surfaces and is usually described by neglecting its internal structure and referring to the transformation that it operates, as indicated in Fig. 8. Points that correspond to each other through this transformation are called *conjugate points*. Figure 8 shows a *real* object because rays propagate out of an actual source. Similarly, the image I of the point O is real because it is formed by rays converging at one location. An image may also be *virtual*. This occurs when the rays forming the image appear to have originated from a point even though no actual source of light is located at that point. The relationship between the object and the image may be equivalently described using wavefronts. For example, the optical system of Fig. 8, transforms a wavefront diverging out of O into a wavefront converging at I . In the case of a virtual image, its wavefront appears to be diverging out of a point where no

actual source of light is located [13]. When O describes a curve C_O in the object space, I will describe a conjugate curve C_I in the image space. In general, the conjugate curves are not similar to each other. However, if every curve C_O is geometrically similar to its conjugate curve C_I , the imaging between the two spaces is perfect and so is the optical system.

To determine the transformation operated by an optical system, a sufficient knowledge of its internal structure is required. The numerical analysis of a given optical system is carried out by considering a point $O \equiv (x_O, y_O)$ of a certain plane $z = z_O$, the *object plane*. An appropriate number of rays, which originate at O , are traced through the system with the goal of finding the intersections (x_I, y_I) in another plane $z = z_I$, the *image plane*. The ray tracing operations are carried out using the laws of reflection and refraction described earlier. If the optical system is perfect, these rays intersect the image plane at the ideal image point

$$x_I = Mx_O, y_I = My_O \tag{23}$$

where M is a constant of the optical system that depends only on the choice of the object plane and is called *magnification*. Hence, a perfect image is a scaled replica of the object.
